Sections 3 and 4 are the densest in terms of new vocabulary. The `ioctl` macros and the `sysctl` callback signatures are the only truly new APIs in the chapter; the rest is composition. If the macros feel opaque on a first pass, that is normal. Stop, run the matching exercise on the driver, and come back when the shape has settled.

24.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 23 Stage 3 (1.6-debug). The starting point assumes every Chapter 23 primitive: the `DPRINTF` macro, the SDT probes, the debug mask `sysctl`, and the `my-first_debug.c/myfirst_debug.h` file pair. Chapter 24 builds new integration code that uses each of those at appropriate moments.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF` is built, installed, and booting cleanly.
- `bhyve(8)` or `qemu-system-x86_64` is available, and you have a usable VM snapshot at the 1.6-debug state. Chapter 24's labs include intentional failure scenarios for the cleanup-discipline section, and a snapshot makes recovery cheap.
- The following user-space commands are in your path: `dmesg`, `sysctl`, `kldstat`, `kldload`, `kldunload`, `devctl`, `cc`, `make`, `dtrace`, `dd`, `head`, `cat`, `chown`, `chmod`, and `truss`. Chapter 24's labs make light use of `truss`, the FreeBSD equivalent of Linux `strace`, to verify that user-space programs really do reach the driver through the new `ioctl`s.
- You are comfortable writing a short C program against the FreeBSD `libc` headers. The chapter introduces the user-space side of the new `ioctl`s through a small program named `myfirstctl`.
- A working knowledge of `git` is helpful but not required. The chapter recommends you commit between stages so each version of the driver has a recoverable point.

If any item above is shaky, fix it now. Integration code is, on balance, less dangerous than the kernel-mode work of earlier chapters because most of the failure modes are caught at module load or at user-space invocation rather than producing kernel panics. But the lessons compound: a clone-aware `make_dev` mistake in this chapter will produce ugly diagnostics in Chapter 28 when the network driver also wants its own nodes, and a `sysctl` OID leak in this chapter will produce confusing module-load failures in Chapter 27 when the storage driver tries to register names that already exist.

24.1.7 How to Get the Most Out of This Chapter

Five habits pay off in this chapter more than in any of the previous Part 5 chapters.

First, keep `/usr/src/sys/dev/null/null.c`, `/usr/src/sys/sys/conf.h`, `/usr/src/sys/sys/ioccom.h`, and `/usr/src/sys/sys/sysctl.h` bookmarked. The first is the shortest non-trivial character driver in the FreeBSD source tree and is the canonical example of the `cdevsw/make_dev/destroy_dev` pattern. The second declares the `cdevsw` structure, the `make_dev` family, and the `MAKEDEV_*` flag bits the chapter uses repeatedly. The third defines the `ioctl` encoding macros (`_IO`, `_IOR`, `_IOW`, `_IOWR`) and contains the `IOC_VOID`, `IOC_IN`, `IOC_OUT`, and `IOC_INOUT` constants the kernel uses to decide whether to copy data automatically. The fourth defines the `sysctl` OID macros, the `SYSTCL_HANDLER_ARGS` calling convention, and the static and dynamic OID interfaces. None of these files are long; the longest is a few thousand lines and most of that is comments. Reading each once at the start of the corresponding section is the single most effective thing you can do for fluency.

Second, keep three real driver examples close to hand: `/usr/src/sys/dev/null/null.c`, `/usr/src/sys/net/if_tuntap.c`, and `/usr/src/sys/dev/virtio/block/virtio_blk.c`. The first is the minimal

cdevsw example. The second is the canonical clone-aware `dev_clone` example used by Section 5 to introduce `ifnet`. The third illustrates a full `device_get_sysctl_ctx` based dynamic `sysctl` tree and a `SYSCTL_ADD_PROC` callback that toggles a runtime knob. Chapter 24 points back to each at the right moment. Reading them once now, without trying to memorise, gives the rest of the chapter concrete anchors to hang its ideas on.

A note on line numbers. Pointers into `null.c`, `if_tuntap.c`, and `virtio_blk.c` later in the chapter are anchored on named symbols: a specific `make_dev` call, a `SYSCTL_ADD_PROC` handler, a particular `cdevsw`. Those names carry across future FreeBSD 14.x releases. The specific line each name sits on does not. When the prose quotes a location, open the file and search for the symbol rather than scrolling to the number.

Third, type every code change into the `myfirst` driver by hand. Integration code is the kind of code that is easy to copy and very hard to remember later. Typing out the `cdevsw` table, the `ioctl` command definitions, the `sysctl` tree construction, and the user-space `myfirstctl` program builds the kind of familiarity that copy-paste cannot. The goal is not to have the code; the goal is to be the person who could write it again, from scratch, in twenty minutes when a future bug demands it.

Fourth, build the user-space program at every stage. Many of the chapter's lessons are visible only on the user side. Whether the kernel has copied an `ioctl` payload correctly, whether a `sysctl` is readable but not writable, whether a `/dev` node has the permissions you set, whether a clone produces a usable device node, all of those questions are answered with `cat`, `dd`, `chmod`, `sysctl`, `truss`, and the small `myfirstctl` companion program. A driver tested only by its kernel-side counters has been only half tested.

Fifth, after finishing Section 4 re-read Chapter 23's debug discipline. Each integration surface in Chapter 24 is wrapped in a `DPRINTF` from Chapter 23. Each `ioctl` path fires `MYF_DBG_IOCTL` log lines. Each `sysctl` path can be observed through the SDT machinery. Seeing how Chapter 23's tools serve Chapter 24's interfaces reinforces both chapters and prepares the reader for Chapter 25, where the same pattern continues.

24.1.8 Roadmap Through the Chapter

The sections in order are:

1. **Why Integration Matters.** The conceptual story. From standalone module to system component; the price of leaving integration as an afterthought; the four user-visible interfaces every integrated driver eventually needs; the optional subsystem hooks the chapter introduces but does not finish.
2. **Working With devfs and the Device Tree.** The kernel's view of `/dev`. What `devfs` is and how it differs from the static device tables of older systems; the lifecycle of a `cdev`; `make_dev` and friends in detail; the `cdevsw` structure and its callbacks; the `si_drv1/si_drv2` fields; permissions and ownership; clonable nodes through the `dev_clone` event handler. Stage 1 of the Chapter 24 driver replaces the original ad-hoc node creation with a clean clone-aware pattern.
3. **Implementing ioctl() Support.** The user-driven control interface. What `ioctls` are; the `_IO/_IOR/_IOW/_IOWR` encoding; the kernel's automatic copyin/copyout layer; how to choose a magic letter and number; how to lay out a public `ioctl` header; how to write a `d_ioctl` callback that dispatches on the command word; common pitfalls (variable-length data, embedded pointers, version evolution). Stage 2 adds `myfirst_ioctl.c` and `myfirst_ioctl.h` and a small `myfirstctl` user-space program.

4. **Exposing Metrics Through `sysctl()`.** The monitoring and tuning interface. What `sysctls` are; static versus dynamic OIDs; the `device_get_sysctl_ctx/device_get_sysctl_tree` pattern; counters, knobs, and procedural callbacks; the `SYSCTL_ADD_*` family; tunables in `/boot/loader.conf`; access control and units. Stage 3 adds `myfirst_sysctl.c` and a per-instance metrics subtree.
5. **Integration With the Networking Subsystem (Optional).** A brief, conceptual look at `ifnet`. What `if_t` is; the `if_alloc/if_initname/if_attach/bpfattach/if_detach/if_free` outline; how `tun(4)` and `tap(4)` are structured around it; what role the driver plays inside the larger network stack. The section is short on purpose; Chapter 28 is the network driver chapter.
6. **Integration With the CAM Storage Subsystem (Optional).** A brief, conceptual look at CAM. What CAM is; what a SIM and a CCB are; the `cam_sim_alloc/xpt_bus_register/xpt_action/xpt_done` outline; how a small read-only memory disk could be exposed through it. The section is short on purpose; Chapter 27 is the storage driver chapter.
7. **Registration, Teardown, and Cleanup Discipline.** The cross-cutting topic. Module event handlers (`MOD_LOAD`, `MOD_UNLOAD`, `MOD_SHUTDOWN`); attach failure with partial cleanup; detach failure when users still hold open handles; the cleanup-on-failure pattern; ordering between integration surfaces; what `bus_generic_attach`, `bus_generic_detach`, and `device_delete_children` do for you; `SYSINIT` and `EVENTHANDLER` for cross-cutting registrations.
8. **Refactoring and Versioning an Integrated Driver.** The clean house. The final split into `myfirst.c`, `myfirst_debug.c/.h`, `myfirst_ioctl.c/.h`, and `myfirst_sysctl.c/.h`; the public `myfirst.h` header for user-space callers; the `INTEGRATION.md` document; the version bump to 1.7-integration; the regression test additions; the commit and tag.

After the eight sections come a set of hands-on labs that exercise each integration surface end to end, a set of challenge exercises that stretch the reader without introducing new foundations, a troubleshooting reference for the symptoms most readers will hit, a Wrapping Up that closes Chapter 24's story and opens Chapter 25's, a bridge to the next chapter, and the usual quick-reference card and glossary.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 2 and 3 stand alone and make good single-sitting reads. Section 5 and Section 6 are short and conceptual and can be skipped on a first pass without losing the chapter's main thread, then returned to before starting Chapter 26 or Chapter 27.

A small note before the technical work begins. The chapter often asks the reader to compile a tiny user-space program, run it against the driver, observe the result, and then return to the kernel side to read what happened. That rhythm is deliberate. Integration is not a property of the driver alone; it is a property of the relationship between the driver and the rest of the system. The user-space programs are short, but they are how the chapter measures whether each integration surface really works.

24.2 Section 1: Why Integration Matters

Before the code, the framing. Section 1 spells out what changes when a driver becomes integrated. The reader who has followed Part 4 and the first chapters of Part 5 has built a working driver. What does it mean to say that this driver is not yet *integrated*, and what specific qualities does integration add?

This section answers that question carefully and at length, because the rest of the chapter is the implementation of these qualities. A reader who knows clearly *why* each integration surface exists will find the implementation work in Sections 2 through 8 much easier. A reader who skips the framing will spend the chapter wondering

why the driver needs an `ioctl` at all when an internal `sysctl` could do the same job; that question has a real answer, and Section 1 is where the answer lives.

24.2.1 From Standalone Module to System Component

A standalone driver is a kernel module that does its job correctly when called by the kernel and stays out of the way otherwise. The current `myfirst` driver, at version 1.6-debug, is exactly that kind of module. It has a single `cdev` node, no public `ioctls`, no published `sysctls` beyond a handful of internal debug knobs, no relationship to any kernel subsystem outside its own little corner, and no expectation that any user-space program will reach in and tell it what to do. It works, and it works in isolation.

A system component, by contrast, is a kernel module whose value depends on its relationships with the rest of the system. The same `myfirst` driver, integrated, presents a `/dev/myfirst0` node with the right permissions for the role of its hardware, exposes a small `ioctl` interface that user programs can use to reset the device or query its status, publishes a per-instance `sysctl` tree that monitoring software can scrape, registers itself with the appropriate kernel subsystem if the hardware is a network or storage device, and cleans up cleanly when unloaded. Each of those interfaces is small. Together they are the difference between a driver that runs on one developer's lab machine and a driver that ships with FreeBSD.

The shift from standalone to integrated is not a one-line change to the driver. It is a series of conscious decisions, each of which expands the driver's public surface and each of which incurs a maintenance cost. Decisions that look small in the moment, like the choice of a magic letter for an `ioctl` or the name of a `sysctl` OID, become long-lived contracts. A driver that picked the letter `M` for its `ioctls` in 2010 still has those numbers in its public header today, because changing them would break every user-space program that ever called them.

A useful way to picture the shift is to imagine two readers approaching the driver. The first reader is the developer who wrote the driver: they know everything about it, they can change anything in it, and they can rebuild it whenever they like. The second reader is the system administrator who installs the module from a package and never reads its source: they only ever see the driver through its `/dev` nodes, its `sysctls`, its `ioctls`, and its log messages. A standalone driver is one designed for the first reader; an integrated driver is one designed for both.

Chapter 24 teaches the reader how to design for the second reader. That is the conceptual work the chapter does, and the code work in Sections 2 through 8 is the practical realisation of it.

24.2.2 Common Integration Targets

A FreeBSD driver typically integrates with four kernel-side surfaces and, depending on the hardware, with one of two subsystems. Naming the targets clearly at the outset helps the reader hold the chapter's structure in mind.

The first target is **devfs**. Every character driver creates one or more `/dev` nodes through `make_dev` (or one of its variants) and removes them through `destroy_dev`. The shape and naming of those nodes is how the rest of the system addresses the driver. A node named `/dev/myfirst0` lets the administrator open it with `cat /dev/myfirst0`, lets a script include it in a `find /dev -name 'myfirst*'`, and lets the kernel itself dispatch open, read, write, and `ioctl` calls into the driver. Section 2 is dedicated to devfs.

The second target is **ioctl(2)**. The `read(2)` and `write(2)` syscalls move bytes; they do not control the driver. Any control operation that does not fit the read/write data-flow model lives in `ioctl(2)`. A user-space program

calls `ioctl(fd, MYF_RESET)` to ask the driver to reset its hardware, or `ioctl(fd, MYF_GET_STATS, &stats)` to read out a counter snapshot. Each `ioctl` is a small, well-typed entry point with a number, a direction, and a payload. Section 3 is dedicated to `ioctls`.

The third target is **`sysctl(8)`**. Counters, statistics, and tunable parameters live in the system-wide `sysctl` tree, accessible from user space with `sysctl(8)` and from C with `sysctlbyname(3)`. A driver places its OIDs under `dev.<driver>.<unit>.<name>` so that `sysctl dev.myfirst.0` lists every metric and knob the device exposes. The `sysctl` interface is the right home for read-only counters and for slow-changing knobs; `ioctl` is the right home for fast actions and for typed data. Section 4 is dedicated to `sysctls`.

The fourth target is **the kernel's lifecycle hooks**. The module event handler (`MOD_LOAD`, `MOD_UNLOAD`, `MOD_SHUTDOWN`), the device tree's attach and detach methods, and the cross-cutting registrations through `EVENTHANDLER(9)` and `SYSINIT(9)` together define what happens when the driver enters and leaves the kernel. A driver that gets the integration interfaces right but the lifecycle wrong leaks resources, deadlocks at unload, or panics on the third `kldload`/`kldunload` cycle. Section 7 is dedicated to lifecycle discipline.

In addition, drivers whose hardware is a network device integrate with the **`ifnet`** subsystem, and drivers whose hardware is a storage device integrate with the **`CAM`** subsystem. Both are conceptually large enough that a deep treatment requires its own chapter (Chapter 28 for `ifnet`, Chapter 27 for `CAM` and `GEOM`). Section 5 and Section 6 of this chapter introduce them at the level needed to recognise their shape and to know what kind of work they involve.

Each target deserves naming for a specific reason. `devfs` is the name a casual user types into a shell. `ioctl` is the entry point for typed actions a program needs to issue against a device. `sysctl` is the place a monitoring tool looks for numbers. The lifecycle hooks are the place a packager and a system administrator hit when they `kldload` and `kldunload`. The four together cover the four faces of the driver that matter to anyone other than its author.

24.2.3 Benefits of Proper Integration

Integration is not an end in itself. It is a means to a small set of practical outcomes that the chapter will keep returning to.

The first outcome is **monitoring**. A driver whose counters are visible through `sysctl` can be scraped by `prometheus-fbsd-exporter`, by Nagios checks, by a small shell script that runs every minute. A driver whose counters are only visible through `device_printf` to `dmesg` can only be inspected by reading the log file by hand. The two operational realities are very different, and the difference is determined entirely by the integration choice the developer made when the driver was written.

The second outcome is **management**. A driver that exposes an `ioctl` named `MYF_RESET` lets the administrator script a reset cycle into a maintenance window. A driver without that interface forces the administrator to `kldunload` and `kldload` the module, which is a much heavier operation that drops every open file descriptor and may not be acceptable while production traffic is flowing through the device.

The third outcome is **automation**. A driver that emits well-formed `/dev` nodes with predictable names lets `devd(8)` react to attach and detach events, run scripts on hotplug, and integrate the driver into the larger system's startup, shutdown, and recovery flows. A driver that emits an opaque single node and never tells anyone about its lifecycle cannot be automated without resorting to `dmesg` log scraping, which is brittle.

The fourth outcome is **reusability**. A driver whose ioctl interface is well documented can be the foundation of higher-level libraries. The `bsnmp` daemon, for example, uses well-defined kernel interfaces to expose driver counters through SNMP without touching the driver source. A driver that designed its interfaces correctly the first time gains those benefits without further work.

These four outcomes (monitoring, management, automation, reusability) are the practical reason for everything that follows. Each section in the chapter delivers a piece of one of these outcomes, and the closing refactor in Section 8 is what makes the whole package presentable to the rest of the system.

24.2.4 A Small Tour of System Tools That Depend on Integration

A useful exercise before the technical work is to look at the user-space tools that exist precisely because drivers integrate with the kernel subsystems above. None of these tools work for a standalone driver. All of them work, automatically, for an integrated one.

`devinfo(8)` walks the kernel's device tree and prints what it finds. It works because every device in the tree was registered through the newbus interface and every device has a name, a unit number, and a parent. The administrator runs `devinfo -v` and sees the entire device hierarchy, including the `myfirst0` instance.

`sysctl(8)` reads from and writes to the kernel `sysctl` tree. It works because every counter and knob in the kernel is reachable through the OID hierarchy, including the OIDs the driver registered through `device_get_sysctl_tree`.

`devctl(8)` lets the administrator manipulate individual devices: `devctl detach`, `devctl attach`, `devctl suspend`, `devctl resume`, `devctl rescan`. It works because every device implements the `kobj` methods the kernel's device tree machinery expects. Chapter 22 already used `devctl suspend myfirst0` and `devctl resume myfirst0`.

`devd(8)` watches the kernel's device-event channel and runs scripts in response to `attach`, `detach`, `hotplug`, and similar events. It works because the kernel emits structured events for each newbus operation. A driver that follows the standard newbus pattern is automatically visible to `devd`.

`ifconfig(8)` configures network interfaces. It works because every network driver registers with the `ifnet` subsystem and accepts a standard set of ioctls (Section 5 introduces this).

`camcontrol(8)` controls SCSI and SATA devices through CAM. It works because every storage driver registers a SIM and processes CCBs (Section 6 introduces this).

`gstat(8)` shows real-time GEOM statistics, `geom(8)` lists the GEOM tree, `top -H` shows per-thread CPU usage. Each of these tools relies on a specific integration surface that drivers register with. The driver that ignores those surfaces gets none of the benefit.

A simple way to confirm the point is to run, on your lab machine, the following exercises:

```
# Tour the device tree
```

```
devinfo -v | head -40
```

```
# Tour the sysctl tree, just the dev branch
```

```
sysctl dev | head -40
```

```
# See what the live network interfaces look like
ifconfig -a

# See what storage looks like through CAM
camcontrol devlist

# See what GEOM sees
geom -t

# Watch the device event channel for a few seconds
sudo devd -d -f /dev/null &
DEVDPID=$!
sleep 5
kill $DEVDPID
```

Each command exists because drivers integrate. Read the output and notice how much of what is visible came from drivers that did the integration work. The `myfirst` driver, at the start of Chapter 24, contributes almost nothing to that output. By the end of Chapter 24, it will contribute its `dev.myfirst.0` subtree to `sysctl`, its `myfirst0` device to `devinfo -v`, and its `/dev/myfirst*` nodes to the file system. Each step is small. The aggregate is the difference between a one-off lab driver and a real piece of FreeBSD.

24.2.5 What “Optional” Means in This Chapter

Section 5 (networking) and Section 6 (storage) are labelled optional. The label deserves a careful definition.

Optional does not mean unimportant. Both sections will become essential reading later in the book, the networking material before Chapter 27 and the storage material before Chapter 26 and Chapter 28. Optional means that for a reader who is following the `myfirst` PCI driver as the running example, the network and storage hooks would not be exercised in this chapter, because `myfirst` is not a network device and is not a storage device. The chapter introduces the conceptual shape of those hooks so that the reader recognises them when they appear, and so that the structural decisions in Section 7 and Section 8 take them into account.

A reader on a first pass who is short on time can skip Sections 5 and 6. The other sections do not depend on them. A reader who plans to follow Chapter 26 or Chapter 27 should read them, because they introduce the vocabulary those chapters will assume.

The chapter is honest about the depth of what it teaches in those sections. The networking subsystem is several thousand lines of source code in `/usr/src/sys/net`. The CAM subsystem is several thousand lines of source code in `/usr/src/sys/cam`. Each took years to design and is still evolving. Chapter 24 introduces them at the level of *here is the shape, here are the calls a driver typically makes, here is one real driver that uses each*. The full mechanics belong elsewhere.

24.2.6 Pitfalls on the Way to Integration

Three pitfalls trip up most first-time integrators.

The first pitfall is **adding integration surfaces ad hoc**. A driver that grew an `ioctl` one Tuesday because the developer needed a quick way to test the device, and a `sysctl` the following week because the developer wanted to see a counter, and another `ioctl` the following month because of a reported bug, ends up with a public surface that is inconsistent in style, inconsistent in naming, inconsistent in error handling, and inconsistent in documentation. The right pattern is to design the public surface deliberately, to use consistent naming, and to document each entry point in a header file before writing the implementation. Section 3 and Section 8 return to this discipline.

The second pitfall is **mixing concerns inside the device methods**. A driver whose `device_attach` does the `kobj` work, the resource allocation, the `devfs` node creation, the `sysctl` tree construction, and the user-space-facing setup in one long function quickly becomes unreadable. The chapter recommends separating these concerns into helper functions at first, and into separate source files in Section 8. The `myfirst_debug.c` and `myfirst_debug.h` pair from Chapter 23 was the first step in that direction; the new `myfirst_ioctl.c` and `myfirst_sysctl.c` files from this chapter continue the pattern.

The third pitfall is **not testing the public surface from user space**. A driver that the developer tested only by exercising it from the kernel side will pass every kernel-side test and still fail the moment a real user-space program calls it, because the developer assumed something about the calling convention that does not hold in practice. The chapter therefore insists on building the small `myfirstctl` companion program as soon as the driver has any `ioctls`, and on testing every `sysctl` through `sysctl(8)` rather than only by reading the in-driver counter directly. The user-space tests are the only ones that confirm integration actually works.

These pitfalls are not unique to FreeBSD. They show up in every operating system that has a kernel-user boundary. FreeBSD's tooling makes it easier than most systems to do the right thing, because the conventions are well documented in the manual pages (`devfs(5)`, `ioctl(2)`, `sysctl(9)`, `style(9)`) and because the kernel itself ships with hundreds of integrated drivers the reader can study. The chapter relies on those conventions and points back to the matching real drivers as it goes.

24.2.7 A Mental Model for the Chapter

Before moving into Section 2, it helps to fix a single picture in mind. The driver, by the end of Chapter 24, will look like this from the outside:

Userland tools		Kernel
+-----+		+-----+
myfirstctl	ioctl(2)	d_ioctl callback
sysctl(8)	+----->	sysctl OID tree
cat /dev/myfirst0	read/write	d_read, d_write
chmod, chown	fileops	devfs node lifecycle
devinfo -v	newbus query	device_t myfirst0
dtrace -n 'myfirst:::'	SDT probes	sc_debug, DPRINTF
+-----+		+-----+

Every entry on the left is a tool a real FreeBSD user already knows. Every entry on the right is a piece of integration the chapter teaches you to write. The arrows in between are what each section of the chapter implements.

Hold that picture in mind as the technical work begins. The point of every section that follows is to add one of those arrows to the driver, with the discipline that lets the arrow stay reliable as the driver grows.

24.2.8 Wrapping Up Section 1

Integration is the discipline of making a driver visible, controllable, and observable from outside its own source code. The four primary integration surfaces in FreeBSD are `devfs`, `ioctl`, `sysctl`, and the kernel lifecycle hooks. Two optional subsystem hooks are `ifnet` for network devices and `CAM` for storage devices. Together, these are how a driver stops being a one-developer project and becomes a piece of FreeBSD. The remaining sections of this chapter implement each surface, with the `myfirst` driver as the running example and the version bumping from 1.6-debug to 1.7-integration as the visible milestone.

In the next section, we turn to the first and most foundational integration surface: `devfs` and the device file system that gives every character driver its `/dev` presence.

24.3 Section 2: Working With `devfs` and the Device Tree

The first integration surface every character driver crosses is `devfs`, the device file system. The reader has been creating `/dev/myfirst0` since the earliest chapters, but the call to `make_dev` was always presented as a single line of boilerplate without much explanation. Section 2 fills that gap. It explains what `devfs` actually is, walks through the lifecycle of a `cdev`, surveys the variants of `make_dev` and the `cdevsw` callback table in detail, shows how to attach per-node state through `si_drv1` and `si_drv2`, teaches the modern clone-aware pattern for drivers that want one node per instance on demand, and ends by showing how an administrator can adjust permissions and ownership without rebuilding the driver.

24.3.1 What `devfs` Is

`devfs` is a virtual file system that exposes the kernel's set of registered character devices as a tree of files under `/dev`. It is virtual in the same sense `procfs` and `tmpfs` are virtual: there is no on-disk storage backing it. Every file under `/dev` is the kernel's projection of a `cdev` structure into the file system namespace. When a user-space program calls `open("/dev/null", O_RDWR)`, the kernel looks up the path in `devfs`, finds the matching `cdev`, follows the pointer to the `cdevsw` table, and dispatches the open through it.

Older UNIX systems used a static device tree. An administrator ran a program like `MAKEDEV` or edited `/dev` directly, and the file system contained device nodes whether the corresponding hardware was present or not. The static approach had two well-known problems. First, the administrator had to know in advance which devices were possible and create the matching nodes by hand, with the right major and minor numbers. Second, the file system contained orphan nodes for hardware the system did not actually have, which was confusing.

FreeBSD's `devfs`, introduced as the default in the early 5.x release series, replaced the static scheme with a dynamic one. The kernel itself decides which device nodes exist, based on which drivers have called `make_dev`. When the driver calls `make_dev`, the node appears under `/dev`. When the driver calls `destroy_dev`, the node disappears. The administrator does not maintain device entries by hand any more, and there are no orphan nodes for hardware that is not present.

The trade-off `devfs` introduces is that the lifecycle of a `/dev` node is now controlled by the kernel rather than by the file system. A driver that fails to remove its node on detach leaves it visible until the kernel itself removes it (which it eventually will, but not as immediately as the driver). A driver that accidentally creates the same node twice gets a panic from the duplicate-name check. A driver that creates a node from the wrong context can deadlock the kernel. The chapter teaches the patterns that avoid each of these.

A useful detail for understanding devfs is that the kernel keeps a single global namespace of device nodes, and `make_dev` registers into that namespace. The administrator can mount additional devfs instances inside jails or chroots; each instance projects a filtered view of the global namespace, controlled through `devfs.rules(8)`. The driver itself does not need to know about these projections. It simply registers its `cdev` once, and the kernel and the rule system together decide which views can see it.

24.3.2 The Lifecycle of a `cdev`

Every `cdev` goes through five stages. Knowing these stages by name makes the rest of the section easier to follow.

The first stage is **registration**. The driver calls `make_dev` (or one of its variants) from `device_attach` (or from a module event handler, depending on whether the device is bus-attached or pseudo-device). The call returns a `struct cdev *` that the driver stores in its `softc`. From this moment on, the node is visible under `/dev`.

The second stage is **use**. User-space programs can open the node and call `read`, `write`, `ioctl`, `mmap`, `poll`, or `kqueue` against it. Each call goes through the matching `cdevsw` callback the driver installed at registration time. A `cdev` may have many open file handles against it at any moment, and the driver's callbacks must be safe to call concurrently with each other and with the driver's own internal work (interrupts, callouts, taskqueues).

The third stage is **destruction request**. The driver calls `destroy_dev` (or `destroy_dev_sched` for the asynchronous variant). The node is unlinked from `/dev` immediately, so no new opens can succeed. Existing opens are not closed at this moment.

The fourth stage is **drain**. `destroy_dev` blocks until every open file handle for the `cdev` has gone through `d_close` and every in-flight call into the driver has returned. The driver's callbacks are guaranteed not to be called any more once `destroy_dev` returns.

The fifth stage is **release**. Once `destroy_dev` returns, the driver can free the `softc`, release any resources the `cdev` callbacks were using, and unload the module. The `struct cdev *` itself is owned by the kernel and is freed by the kernel when its last reference goes away; the driver does not free it.

The drain step is the one that catches first-time drivers most often. A naive driver does the equivalent of “`destroy_dev; free(sc);`” and then a held open file handle calls into the `cdevsw` and dereferences the freed `softc`, which panics. The chapter teaches how to handle this correctly: put the `destroy_dev` call before any state-freeing in the detach path, and trust the kernel to drain the in-flight calls before the destroy returns.

24.3.3 The `make_dev` Family

FreeBSD provides several variants of `make_dev`, each with a different combination of options. They live in `/usr/src/sys/sys/conf.h` and `/usr/src/sys/fs/devfs/devfs_devs.c`. The chapter introduces the most useful four.

The simplest form is **`make_dev`** itself:

```
struct cdev *
make_dev(struct cdevsw *devsw, int unit, uid_t uid, gid_t gid,
         int perms, const char *fmt, ...);
```

This call creates a node owned by `uid:gid` with permissions `perms`, named according to the `printf`-style format. It uses `M_WAITOK` internally and may sleep, so it must be called from a context that can sleep (typically `device_attach` or a module load handler, never an interrupt handler). It cannot fail: if it cannot allocate memory, it sleeps until it can. The reader has been using this form since the early chapters.

The richer form is `make_dev_credf`:

```
struct cdev *
make_dev_credf(int flags, struct cdevsw *devsw, int unit,
               struct ucred *cr, uid_t uid, gid_t gid, int mode,
               const char *fmt, ...);
```

This variant takes an explicit `flags` argument and an explicit credential. The credential is used by the MAC framework when checking whether the device may be created with the given owner. The flags select features such as `MAKEDEV_ETERNAL` (the kernel never destroys this node automatically) and `MAKEDEV_ETERNAL_KLD` (the same, but allowed only inside a loadable module). The `null(4)` driver uses this form, as the chapter quoted in Section 1's reference list.

The form recommended for new drivers is `make_dev_s`:

```
int
make_dev_s(struct make_dev_args *args, struct cdev **cdev,
           const char *fmt, ...);
```

This variant takes a structure of arguments rather than a long argument list. The structure is initialised with `make_dev_args_init(&args)` before its fields are filled in. The advantage of `make_dev_s` is that it can fail rather than sleep, and the failure is reported through a return value rather than through a sleep. It also has an output parameter for the `cdev *`, which means the caller does not need to remember which positional return represents what. New code should prefer `make_dev_s` because the failure path is cleaner.

The argument structure looks like this:

```
struct make_dev_args {
    size_t      mda_size;
    int         mda_flags;
    struct cdevsw *mda_devsw;
    struct ucred *mda_cr;
    uid_t       mda_uid;
    gid_t       mda_gid;
    int         mda_mode;
    int         mda_unit;
    void        *mda_si_drv1;
    void        *mda_si_drv2;
};
```

The `mda_size` field is used by the kernel to detect ABI mismatches; `make_dev_args_init` sets it correctly. The `mda_si_drv1` and `mda_si_drv2` fields let the driver attach two pointers of its own to the `cdev` at creation time; the chapter uses `mda_si_drv1` to attach a pointer to the `softc`.

The `MAKEDEV_*` flag bits relevant to most drivers are:

Flag	Meaning
<code>MAKEDEV_REF</code>	The returned <code>cdev</code> is referenced; balance with <code>dev_rel</code> .
<code>MAKEDEV_NOWAIT</code>	Do not sleep; return failure if the call would have to sleep.
<code>MAKEDEV_WAITOK</code>	The call may sleep (default for <code>make_dev</code>).
<code>MAKEDEV_ETERNAL</code>	The kernel does not destroy this node automatically.
<code>MAKEDEV_ETERNAL_KLD</code>	Same as <code>ETERNAL</code> but allowed inside a loadable module.
<code>MAKEDEV_CHECKNAME</code>	Validate the name against the devfs character set.

The `make_dev_p` variant is similar to `make_dev_s` but takes a positional argument list. It is older, still supported, and used by some drivers in the tree; new drivers can ignore it in favour of `make_dev_s`.

24.3.4 The `cdevsw` Structure

The `cdevsw` table is the dispatch table for character device callbacks. The reader has installed one in earlier chapters, but Section 2 examines it field by field.

A minimal modern `cdevsw` looks like:

```
static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_flags   = D_TRACKCLOSE,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
    .d_ioctl   = myfirst_ioctl,
};
```

`d_version` must be set to `D_VERSION`. The kernel uses this field to detect drivers built against an older `cdevsw` layout. A missing or wrong `d_version` is a common source of confusing module-load failures; always set it explicitly.

`d_flags` controls a small set of optional behaviours. The most common flags are:

Flag	Meaning
D_TRACKCLOSE	Call <code>d_close</code> on the last close of each fd, not on every close.
D_NEEDGIANT	Take the kernel-wide Giant lock around dispatch (rare in modern code).
D_NEEDMINOR	Allocate a minor number (legacy; rarely needed today).
D_MMAP_ANON	The driver supports anonymous mmap through <code>dev_pager</code> .
D_DISK	The cdev is the entry point for a disk-like device.
D_TTY	The cdev is a terminal device; affects line-discipline routing.

For the `myfirst` driver, `D_TRACKCLOSE` is the only flag worth setting. It causes the kernel to call `d_close` exactly once per file descriptor, on the last close of that descriptor, rather than on every close. Without `D_TRACKCLOSE`, a driver that wants to count open file handles has to handle the same `d_close` being called many times, which is awkward.

`d_name` is the name the kernel uses in some diagnostic messages. It is conventionally the same as the driver's name.

The callback fields are pointers to the functions that implement each operation. A driver only needs to install the callbacks it actually supports; missing callbacks default to safe stubs that return `ENODEV` or `EOPNOTSUPP`. The most common combination for a character driver is `d_open`, `d_close`, `d_read`, `d_write`, and `d_ioctl`. Drivers that support polling add `d_poll`. Drivers that support `kqueue` add `d_kqfilter`. Drivers that map memory into user space add `d_mmap` or `d_mmap_single`. Drivers that emulate a disk add `d_strategy`.

The `d_purge` callback is rare but worth knowing. The kernel calls it when the cdev is being destroyed and the driver should release any pending I/O. Most drivers do not need it because their `d_close` already handles release.

The `d_open` callback signature is:

```
int myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td);
```

`dev` is the cdev being opened. `oflags` is the union of the `open(2)` flags (`O_RDWR`, `O_NONBLOCK`, etc.). `devtype` carries the device type and is rarely useful for a character driver. `td` is the thread doing the open. The callback returns 0 on success or an `errno` on failure. A typical pattern stores the softc pointer found through `dev->si_drv1` into a per-open private structure that subsequent calls can recover.

The `d_close` signature is parallel:

```
int myfirst_close(struct cdev *dev, int fflags, int devtype, struct thread *td);
```

The `d_read` and `d_write` signatures use the `uio` machinery the reader met in Chapter 8:

```
int myfirst_read(struct cdev *dev, struct uio *uio, int ioflag);
int myfirst_write(struct cdev *dev, struct uio *uio, int ioflag);
```

The `d_ioctl` signature is:

```
int myfirst_ioctl(struct cdev *dev, u_long cmd, caddr_t data,
                 int fflag, struct thread *td);
```

`cmd` is the `ioctl` command word. `data` points to the `ioctl` data buffer (which the kernel has already copied in for `IOC_IN` commands and will copy out for `IOC_OUT` commands, as Section 3 will discuss in detail). `fflag` is the file flags from the open call. `td` is the calling thread.

24.3.5 Per-Cdev State Through `si_drv1`

The `cdev` is the kernel's handle to the device, and the driver almost always needs a way to find its own `softc` from a `cdev` pointer. The standard mechanism is `cdev->si_drv1`. The driver sets this field when it creates the `cdev` (either at the call to `make_dev` or by writing to the field afterward) and reads it in every `cdevsw` callback.

The pattern looks like this in attach:

```
sc->sc_cdev = make_dev(&myfirst_cdevsw, device_get_unit(dev),
                     UID_ROOT, GID_WHEEL, 0660, "myfirst%d", device_get_unit(dev));
sc->sc_cdev->si_drv1 = sc;
```

And like this in each callback:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;

    DPRINTF(sc, MYF_DBG_OPEN, "open: pid=%d flags=%#x\n",
            td->td_proc->p_pid, oflags);
    /* ... rest of open ... */
    return (0);
}
```

`si_drv2` is a second pointer the driver can use however it likes. Some drivers use it for a per-instance cookie; others use it for nothing and leave it `NULL`. The `myfirst` driver uses only `si_drv1`.

The `make_dev_s` variant is cleaner because it sets `si_drv1` at creation time:

```
struct make_dev_args args;
make_dev_args_init(&args);
args.mda_devsw = &myfirst_cdevsw;
args.mda_uid = UID_ROOT;
args.mda_gid = GID_WHEEL;
```

```

args.mda_mode = 0660;
args.mda_si_drv1 = sc;
args.mda_unit = device_get_unit(dev);
error = make_dev_s(&args, &sc->sc_cdev, "myfirst%d", device_get_unit(dev));
if (error != 0) {
    device_printf(dev, "make_dev_s failed: %d\n", error);
    goto fail;
}

```

The `make_dev_s` form has the additional advantage that `si_drv1` is set before the `cdev` is visible in `/dev`, which closes a small but real race window in which a quick-to-open program could call into a `cdevsw` whose `si_drv1` was still `NULL`. New drivers should prefer this form.

24.3.6 The `null(4)` Reference

The cleanest small example of `cdevsw` and `make_dev_credf` in the tree is `/usr/src/sys/dev/null/null.c`. The relevant excerpts are short enough to read in one pass. The `cdevsw` declarations (a separate one for `/dev/null` and `/dev/zero`):

```

static struct cdevsw null_cdevsw = {
    .d_version = D_VERSION,
    .d_read    = (d_read_t *)nullop,
    .d_write   = null_write,
    .d_ioctl   = null_ioctl,
    .d_name    = "null",
};

```

The module event handler that creates and destroys the nodes:

```

static int
null_modevent(module_t mod, int type, void *data)
{
    switch (type) {
    case MOD_LOAD:
        full_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &full_cdevsw, 0,
            NULL, UID_ROOT, GID_WHEEL, 0666, "full");
        null_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &null_cdevsw, 0,
            NULL, UID_ROOT, GID_WHEEL, 0666, "null");
        zero_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &zero_cdevsw, 0,
            NULL, UID_ROOT, GID_WHEEL, 0666, "zero");
        break;
    case MOD_UNLOAD:
        destroy_dev(full_dev);
    }
}

```

```

        destroy_dev(null_dev);
        destroy_dev(zero_dev);
        break;
    case MOD_SHUTDOWN:
        break;
    default:
        return (EOPNOTSUPP);
    }
    return (0);
}

DEV_MODULE(null, null_modevent, NULL);
MODULE_VERSION(null, 1);

```

A few details are worth pausing on. The `MAKEDEV_ETERNAL_KLD` flag tells the kernel that even if the module is unloaded under unusual circumstances, the `cdev` should not be silently invalidated. The `0666` mode means everyone can read and write; that is correct for `/dev/null`. The unit number is `0` because there is only ever one of each. The `MOD_LOAD` arm runs at module load and creates the nodes; the `MOD_UNLOAD` arm runs at module unload and destroys them; `MOD_SHUTDOWN` runs during the system shutdown sequence and does nothing here, because no shutdown work is needed for these pseudo-devices.

This is the canonical shape of a pseudo-device that lives at module scope rather than at device-tree scope. The `myfirst` driver, by contrast, creates its `cdev` in `device_attach` because the `cdev`'s lifetime is tied to a specific PCI device's lifetime, not to the module's lifetime. The two patterns are different but coexist comfortably.

24.3.7 Multiple Nodes and Clonable Nodes

A single driver can create more than one node. Three patterns are common.

The first is **fixed-name nodes**. The driver knows in advance how many nodes it needs and creates them with fixed names: `/dev/myfirst0`, `/dev/myfirst-status`, `/dev/myfirst-config`. This is the right pattern when each node has a different role and the count is known.

The second is **indexed nodes**. The driver creates one node per unit, named `/dev/myfirstN` where `N` is the unit number. This is the right pattern when each node represents a separate instance of the same kind of object, such as one per attached PCI card.

The third is **clonable nodes**. The driver registers a clone handler that creates a new node on demand whenever a user opens a name matching a pattern. The reader of `tun(4)` opens `/dev/tun` and gets `/dev/tun0`; opening `/dev/tun` again yields `/dev/tun1`; the kernel allocates the next free unit on each open. This is the right pattern for pseudo-devices that the user wants to “create” by simply opening them.

The clone mechanism is the `dev_clone` event handler. It lives in `/usr/src/sys/sys/conf.h`:

```

typedef void (*dev_clone_fn)(void *arg, struct ucred *cred, char *name,
    int namelen, struct cdev **result);

```

```
EVENTHANDLER_DECLARE(dev_clone, dev_clone_fn);
```

The driver registers a handler with `EVENTHANDLER_REGISTER`, and the kernel calls the handler whenever an open path under `/dev` does not match an existing node. The handler decides whether the name belongs to its driver, allocates a new unit if so, calls `make_dev` to create the node with that name, and stores the resulting `cdev` pointer through the `result` argument. The kernel then re-opens the freshly created node and continues with the user's open call.

The `tun(4)` driver shows this pattern. From `/usr/src/sys/net/if_tuntap.c`:

```
static eventhandler_tag clone_tag;

static int
tuntapmodevent(module_t mod, int type, void *data)
{
    switch (type) {
        case MOD_LOAD:
            clone_tag = EVENTHANDLER_REGISTER(dev_clone, tuncclone, 0, 1000);
            if (clone_tag == NULL)
                return (ENOMEM);
            ...
            break;
        case MOD_UNLOAD:
            EVENTHANDLER_DEREGISTER(dev_clone, clone_tag);
            ...
    }
}

static void
tuncclone(void *arg, struct ucred *cred, char *name, int namelen,
          struct cdev **dev)
{
    /* If *dev != NULL, another handler already created the cdev. */
    if (*dev != NULL)
        return;

    /* Examine name; if it matches our pattern, allocate a unit */
    /* and call make_dev to populate *dev. */
    ...
}
```

A few rules apply to clone handlers. The handler must not assume it is the only handler registered; multiple subsystems can register against `dev_clone`, and each handler must check whether `*dev` is already non-NULL

before doing any work. The handler runs in a context that can sleep, so it can call `make_dev` directly. The handler should validate the name carefully because it is supplied by user space.

The `myfirst` driver uses an indexed-node pattern at first (one node per attached PCI device, `/dev/myfirst0`, `/dev/myfirst1`, etc.), and Section 2's lab walks through adding a clone handler so the user can open `/dev/myfirst-clone` and get a new unit on demand. The clone pattern is most useful for pseudo-devices that have no underlying hardware; for hardware-backed drivers it is rarely needed.

24.3.8 Permissions, Ownership, and `devfs.rules`

`make_dev` takes the initial owner UID, group GID, and permissions for the node. These values are baked in at creation time. They are visible from user space through `ls -l /dev/myfirst0` and they determine which user-space programs can open the node.

For a hardware-backed driver, the right defaults depend on the role. A device that should only be accessible to root uses `UID_ROOT`, `GID_WHEEL`, `0600`. A device that any administrative user should be able to access uses `UID_ROOT`, `GID_OPERATOR`, `0660`. A device that any user can read but only root can write uses `UID_ROOT`, `GID_WHEEL`, `0644`. The `myfirst` driver uses `UID_ROOT`, `GID_WHEEL`, `0660` by default; the user is expected to be root or to be given access through `devfs.rules` if they need it.

The administrator can override these defaults at runtime through `devfs.rules(8)`. A typical rule file looks like:

```
[localrules=10]
add path 'myfirst*' mode 0660
add path 'myfirst*' group operator
```

The administrator activates the rules by adding to `/etc/rc.conf`:

```
devfs_system_ruleset="localrules"
```

After service `devfs restart` (or a reboot), the rules apply to new device nodes that appear. This mechanism lets the administrator grant access to the driver without rebuilding the module, which is the right division of responsibility: the developer chooses safe defaults, and the administrator widens them when needed.

A common mistake is to make a device world-writable by default because “it makes testing easier”. A driver that ships with `0666` permissions to a device that controls hardware is a security problem. The chapter's recommendation is `0660` with `GID_WHEEL` as the default, and to instruct readers in `INTEGRATION.md` how to use `devfs.rules` to change it if they need to.

24.3.9 Putting It All Together: The Stage 1 Driver

The Chapter 24 Stage 1 driver replaces the original ad-hoc node creation with the modern `make_dev_s` pattern, sets `si_drv1` at creation time, uses the `D_TRACKCLOSE` flag, and prepares the way for the `ioctl` callbacks to be added in Section 3. Here is the relevant excerpt of the new attach function. Type this in by hand; the whole point of the chapter is the careful change from the old ad-hoc form to the new disciplined form.

```

static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc;
    struct make_dev_args args;
    int error;

    sc = device_get_softc(dev);
    sc->sc_dev = dev;

    /* ... earlier attach work: PCI resources, MSI-X, DMA, sysctl tree
       * stub, debug subtree. See Chapters 18-23 for these. ... */

    /* Build the cdev for /dev/myfirstN. */
    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_WHEEL;
    args.mda_mode = 0660;
    args.mda_si_drv1 = sc;
    args.mda_unit = device_get_unit(dev);
    error = make_dev_s(&args, &sc->sc_cdev, "myfirst%d",
        device_get_unit(dev));
    if (error != 0) {
        device_printf(dev, "make_dev_s failed: %d\n", error);
        DPRINTF(sc, MYF_DBG_INIT, "cdev creation failed (%d)\n", error);
        goto fail;
    }
    DPRINTF(sc, MYF_DBG_INIT, "cdev created at /dev/myfirst%d\n",
        device_get_unit(dev));

    /* ... rest of attach: register callouts, finalise sysctl OIDs, etc. */

    return (0);

fail:
    /* Unwind earlier resources in reverse order. */
    /* See Section 7 for the discipline that goes here. */
    return (error);
}

```

The corresponding cdevsw with D_TRACKCLOSE:

```

static d_open_t myfirst_open;
static d_close_t myfirst_close;
static d_read_t myfirst_read;
static d_write_t myfirst_write;
static d_ioctl_t myfirst_ioctl;

static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_flags   = D_TRACKCLOSE,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
    .d_ioctl   = myfirst_ioctl,
};

```

The corresponding open and close, with `si_drv1` lookups and per-open counter updates:

```

static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;

    SDT_PROBE2(myfirst, , , open, sc, oflags);

    mtx_lock(&sc->sc_mtx);
    sc->sc_open_count++;
    mtx_unlock(&sc->sc_mtx);

    DPRINTF(sc, MYF_DBG_OPEN,
        "open: pid=%d flags=%#x open_count=%u\n",
        td->td_proc->p_pid, oflags, sc->sc_open_count);
    return (0);
}

static int
myfirst_close(struct cdev *dev, int fflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;

    SDT_PROBE2(myfirst, , , close, sc, fflags);

    mtx_lock(&sc->sc_mtx);

```

```

KASSERT(sc->sc_open_count > 0,
    ("myfirst_close: open_count underflow"));
sc->sc_open_count--;
mtx_unlock(&sc->sc_mtx);

DPRINTF(sc, MYF_DBG_OPEN,
    "close: pid=%d flags=0x%x open_count=%u\n",
    td->td_proc->p_pid, fflags, sc->sc_open_count);
return (0);
}

```

And the matching detach update, with `destroy_dev` before any softc state release:

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Refuse detach while users still hold the device open. */
    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count > 0) {
        mtx_unlock(&sc->sc_mtx);
        device_printf(dev, "detach refused: %u open(s) outstanding\n",
            sc->sc_open_count);
        return (EBUSY);
    }
    mtx_unlock(&sc->sc_mtx);

    /* Destroy the cdev first. The kernel drains any in-flight
     * callbacks before destroy_dev returns. */
    if (sc->sc_cdev != NULL) {
        destroy_dev(sc->sc_cdev);
        sc->sc_cdev = NULL;
        DPRINTF(sc, MYF_DBG_INIT, "cdev destroyed\n");
    }

    /* ... rest of detach: tear down DMA, MSI-X, callouts, sysctl ctx,
     * etc., in reverse order of attach. See Section 7. */

    return (0);
}

```

This is the Stage 1 milestone. The driver now has a clean, modern, beginner-friendly devfs entry. The next stages will add ioctls and sysctls on top of this foundation.

24.3.10 A Concrete Walkthrough: Loading and Inspecting the Stage 1 Driver

Build, load, and inspect the Stage 1 driver:

```
cd ~/myfirst-1.7-integration/stage1-devfs
make
sudo kldload ./myfirst.ko

# Confirm the device exists and has the expected attributes.
ls -l /dev/myfirst0

# Read its sysctl debug subtree (still from Chapter 23).
sysctl dev.myfirst.0

# Open it with cat to confirm the cdevsw read and close paths fire.
sudo cat /dev/myfirst0 > /dev/null
dmesg | tail -20
```

The expected output for `ls -l /dev/myfirst0`:

```
crw-rw----  1 root  wheel  0x71 Apr 19 16:30 /dev/myfirst0
```

The `crw-rw----` says character device, owner read+write, group read+write, no permission for others. The owner is root. The group is wheel. The minor number is `0x71` (the kernel's allocation; the value will differ between systems). The size is the unit number that `make_dev_s` was called with.

The expected output for the `dmesg` snippet:

```
myfirst0: cdev created at /dev/myfirst0
myfirst0: open: pid=4321 flags=0x1 open_count=1
myfirst0: close: pid=4321 flags=0x1 open_count=0
```

(Assuming the debug mask has `MYF_DBG_INIT` and `MYF_DBG_OPEN` set. If the mask is zero, the lines are silent; turn them on with `sysctl dev.myfirst.0.debug.mask=0xFFFFFFFF` from Chapter 23's debug discipline.)

If the open and close lines do not appear, check the debug mask. If the open line appears but not the close, you forgot `D_TRACKCLOSE` and the kernel is calling close on every fd close rather than only the last; either turn `D_TRACKCLOSE` on or expect multiple close lines per open. If the open count goes negative, you have a real bug: a close was called without a matching open.

24.3.11 Common Mistakes With devfs

Five mistakes account for most of the devfs problems first-time integrators encounter. Naming them up front saves a debugging session later.

The first mistake is **calling `make_dev` from an unsleepable context**. `make_dev` may sleep. If it is called from an interrupt handler, from a callout, from inside a spin lock, or from inside any context where sleeping is forbidden, the kernel will panic with `WITNESS` or with `INVARIANTS` complaining about a sleepable function in a non-sleepable context. The fix is either to call `make_dev` from `device_attach` or from a module event handler (both safe contexts), or to use `make_dev_s` with `MAKEDEV_NOWAIT` (which then can fail and the caller must handle the failure).

The second mistake is **forgetting to set `si_drv1`**. The `cdevsw` callbacks then dereference a `NULL` pointer and panic the kernel. The fix is to set `si_drv1` immediately after `make_dev` (or, better, to use `make_dev_s` and set `mda_si_drv1` in the args, which closes the race window between creation and assignment).

The third mistake is **calling `destroy_dev` after freeing the `softc`**. The `cdevsw` callbacks may still be in flight when `destroy_dev` is called; the kernel drains them before `destroy_dev` returns. If the `softc` is already freed, the callbacks dereference garbage. The fix is to call `destroy_dev` first, then free the `softc`, in that strict order.

The fourth mistake is **creating two `cdevs` with the same name**. The kernel checks for duplicate names and the second `make_dev` call panics or returns an error depending on the variant. The fix is to compose the name from the unit number, or to use a clone handler.

The fifth mistake is **not handling the case where the device is open at detach**. A naive driver simply calls `destroy_dev` and frees the `softc`, which works only if no user has the device open. The user holding `/dev/my-first0` open with `cat` defeats this. The fix is to refuse detach when `open_count > 0`, or to use the kernel's `dev_ref/dev_rel` machinery to coordinate. The chapter's pattern is the simple refusal (`return (EBUSY)`) because it gives the cleanest user-visible error.

24.3.12 Pitfalls Unique to Multi-Instance Drivers

Drivers that create more than one `cdev` per attached device, or one `cdev` per channel inside a multi-channel device, hit a few additional pitfalls.

The first is **leaking nodes on partial failure**. If the driver creates three `cdevs` and the third call fails, it must destroy the first two before returning. Section 7's cleanup-on-failure pattern is the canonical solution. The chapter's lab in this section walks through the pattern with a deliberate failure injection.

The second is **forgetting that each `cdev` needs its own `si_drv1`**. A driver that creates per-channel nodes typically wants `si_drv1` to point to the channel rather than to the `softc`. The `cdevsw` callbacks then walk back from the channel to the `softc` as needed. Mixing the two leads to channels stomping on each other's state.

The third is **race-free node visibility**. Between `make_dev` (or `make_dev_s`) returning and the driver finishing the rest of attach, a fast user can already open the node. The driver must be ready to handle opens that arrive before attach is fully done. The simplest pattern is to defer `make_dev` to the very end of attach, so the node is only visible after every other piece of state is ready. The `myfirst` driver follows this pattern.

These pitfalls do not arise often for single-`cdev` drivers like `myfirst`, but recognising them now means the reader will not be surprised when they show up in Chapter 27 (storage drivers can have many `cdevs`, one per LUN) or Chapter 28 (network drivers can have many `cdevs`, one per command channel)

24.3.13 Wrapping Up Section 2

Section 2 made the driver's `/dev` presence first-class. The `cdev` is now created with the modern `make_dev_s` pattern, the `cdevsw` is fully populated with `D_TRACKCLOSE` and a debug-friendly callback set, the per-`cdev` state is wired through `si_drv1`, and the detach path drains and destroys the `cdev` cleanly. The driver still does the same work as 1.6-`debug`, but it now exposes that work through a properly-constructed `/dev` node that an administrator can `chmod`, `chown`, monitor through `ls`, and reason about from outside the kernel.

In the next section, we turn to the second integration surface: the user-driven control interface that lets a program tell the driver what to do. The vocabulary is `ioctl(2)`, `_IO`, `_IOR`, `_IOW`, `_IOWR`, and a small public header that user-space programs include.

24.4 Section 3: Implementing `ioctl()` Support

24.4.1 What `ioctl(2)` Is, and Why Drivers Need It

The `read(2)` and `write(2)` system calls are excellent for moving streams of bytes between a user program and a driver. They are not, however, well suited to control. A `read` cannot ask the driver “what is your current state?” without overloading the meaning of the bytes returned. A `write` cannot ask the driver “please reset your statistics” without inventing a private command vocabulary inside the byte stream. The system call that fills this gap is `ioctl(2)`, the input/output control call.

`ioctl` is a side channel for commands. The signature in user space is straightforward: `int ioctl(int fd, unsigned long request, ...)`; The first argument is a file descriptor (in our case, an open `/dev/myfirst0`). The second is a numeric request code that tells the driver what to do. The third is an optional pointer to a structure that carries the parameters of the request, either inbound, outbound, or both. The kernel routes the call into the `cdevsw` of the `cdev` backing that file descriptor, into the function pointed at by `d_ioctl`. The driver looks at the request code, performs the corresponding action, and returns 0 on success or a positive `errno` on failure.

Almost every driver that exposes a control interface to user space uses `ioctl` for it. Disk drivers use `ioctl` to report sector size, partition tables, and dump targets. Tape drivers use `ioctl` for rewind, eject, and tension commands. Network drivers use `ioctl` for media changes (`SIOCIFLAGS`), MAC address updates, and bus probe commands. Sound drivers use `ioctl` for sample rate, channel count, and buffer size negotiation. The vocabulary is so universal that learning it once unlocks every category of driver in the tree.

For the `myfirst` driver, `ioctl` lets us add commands that have no clean expression as bytes. We can let the operator query the in-memory message length without having to read it. We can let the operator reset the message and the open counters without having to write a special sentinel. We can expose the driver's version number so user-space tools can detect the API they are talking to. Each of these is a one-line change for the operator and a half-page change for the driver, and each is a textbook fit for `ioctl`.

This section walks through the entire `ioctl` pipeline: the encoding of request codes, the kernel's automatic copyin and copyout, the design of a public header, the implementation of the dispatcher, the construction of a small user-space companion program, and the most common pitfalls. By the end of the section the driver will be at version 1.7-integration-stage-2 and will support four `ioctl` commands: `MYFIRSTIOC_GETVER`, `MYFIRSTIOC_GETMSG`, `MYFIRSTIOC_SETMSG`, and `MYFIRSTIOC_RESET`.

24.4.2 How `ioctl` Numbers Are Encoded

An `ioctl` request code is not an arbitrary integer. It is a packed 32-bit value that encodes four pieces of information in fixed bit fields, defined in `/usr/src/sys/sys/ioccom.h`. The header begins with a comment showing the layout, which is worth reading before going further.

```
/*
 * Ioctl's have the command encoded in the lower word, and the size of
 * any in or out parameters in the upper word. The high 3 bits of the
 * upper word are used to encode the in/out status of the parameter.
 *
 *      31 29 28                16 15                8 7                0
 *      +-----+-----+-----+-----+
 *      | I/O | Parameter Length | Command Group | Command |
 *      +-----+-----+-----+-----+
 */
```

The four fields are:

The **direction bits** (bits 29 to 31) tell the kernel whether the third argument to `ioctl` is purely outbound (`IOC_OUT`, the kernel will copy the result back to user space), purely inbound (`IOC_IN`, the kernel will copy the user data into the kernel before the dispatcher runs), bidirectional (`IOC_INOUT`, both directions), or absent (`IOC_VOID`, the request takes no data argument). The kernel uses these bits to decide what `copyin` and `copyout` to perform automatically. The driver itself never has to call `copyin` or `copyout` for a properly encoded `ioctl`.

The **parameter length** (bits 16 to 28) encodes the size in bytes of the structure passed as the third argument, capped at `IOCPARM_MAX` = 8192. The kernel uses this size to allocate a temporary kernel buffer, perform the appropriate `copyin` or `copyout`, and present the buffer to the dispatcher as the `caddr_t` data argument. A driver that needs to pass more than 8192 bytes through a single `ioctl` must either embed a pointer in a smaller structure (with the cost of doing its own `copyin`), or use a different mechanism such as `mmap` or `read`.

The **command group** (bits 8 to 15) is a single character that names the family of related `ioctls`. It is conventionally one of the printable ASCII letters and identifies the subsystem. 'd' is used by GEOM disk `ioctls` (`DIOCGMEDIASIZE`, `DIOCGSECTORSIZE`). 'i' is used by `if_ioctl` (`SIOCIFFLAGS`). 't' is used by terminal `ioctls` (`TIOCGPTN`). The reader should choose a letter that is not already taken by something the driver might coexist with. For the `myfirst` driver we will use 'M'.

The **command number** (bits 0 to 7) is a small integer that identifies the specific `ioctl` within the group. Numbering usually starts at 1 and increases monotonically as commands are added. Reusing a number is a backward-compatibility hazard, so a driver that retires a command should leave the number reserved rather than recycle it.

The macros in `ioccom.h` build these encodings for you. They are the only way to construct `ioctl` numbers correctly:

```
#define _IO(g,n)      _IOC(IOC_VOID, (g), (n), 0)
#define _IOR(g,n,t)   _IOC(IOC_OUT,  (g), (n), sizeof(t))
```

```
#define _IOW(g,n,t)      _IOC(IOC_IN,  (g), (n), sizeof(t))
#define _IOWR(g,n,t)     _IOC(IOC_INOUT,(g), (n), sizeof(t))
```

`_IO` declares a command that takes no argument. `_IOR` declares a command that returns a `t`-sized result to user space. `_IOW` declares a command that accepts a `t`-sized argument from user space. `_IOWR` declares a command that accepts a `t`-sized argument and writes a `t`-sized result back through the same buffer. The `t` is a type, not a pointer; the macros use `sizeof(t)` to compute the length field.

A few real-world examples make the pattern concrete. From `/usr/src/sys/sys/disk.h`:

```
#define DIOCGSECTORSIZE _IOR('d', 128, u_int)
#define DIOCGMEDIASIZE _IOR('d', 129, off_t)
```

These commands are read-only requests for the sector size (returned as `u_int`) and the media size (returned as `off_t`). The group letter `'d'` and the numbers 128 and 129 are reserved for the disk subsystem.

The driver itself never has to decode the bit layout. The command code is opaque to the dispatcher, which compares it to named constants:

```
switch (cmd) {
case MYFIRSTIOC_GETVER:
    ...
    break;
case MYFIRSTIOC_RESET:
    ...
    break;
default:
    return (ENOIOCTL);
}
```

The kernel uses the bit layout when it sets up the call (to allocate the buffer and perform copyin/copyout), and user space uses it implicitly through the macros. Between those two points, the request code is simply a label.

24.4.3 Choosing a Group Letter

The choice of a group letter matters because conflicts are silent. Two drivers that pick the same group letter and the same command number will see ioctl requests intended for the other driver if the operator confuses the two. The kernel does not enforce uniqueness across drivers, partly because no central authority assigns letters and partly because most letters are de facto reserved by tradition rather than registration.

A defensive approach is to follow these conventions:

Use **lowercase letters** (`'d'`, `'t'`, `'i'`) only when extending a well-known subsystem whose letter you already know. The lowercase letters are heavily used by base drivers and are easy to collide with.

Use **uppercase letters** (`'M'`, `'X'`, `'Q'`) for fresh drivers that need their own ioctl namespace. There are 26 uppercase letters and far fewer collisions in tree.

Avoid **digits** entirely. They are reserved by historical convention for early subsystems and a new driver that uses one will look out of place to a reviewer.

For the `myfirst` driver we use 'M'. It is the first letter of the driver name, it is uppercase (so it does not collide with any base subsystem), and it makes the request codes self-documenting in stack traces and in `kt race` output: a hex dump of an `ioctl` number with `0x4d` (the ASCII value of 'M') in the group field is unambiguously a `myfirst` command.

24.4.4 The `d_ioctl` Callback Signature

The dispatcher function pointed at by `cdevsw->d_ioctl` has the type `d_ioctl_t`, defined in `/usr/src/sys/sys/conf.h`. The signature is:

```
typedef int d_ioctl_t(struct cdev *dev, u_long cmd, caddr_t data,
                     int fflag, struct thread *td);
```

The five arguments deserve a slow read.

`dev` is the `cdev` that backs the file descriptor on which the user called `ioctl`. The driver uses `dev->si_drv1` to recover its softc. This is the same pattern used by every `cdevsw` callback we have already seen.

`cmd` is the request code, the value the user passed as the second argument to `ioctl`. The driver compares it to the named constants in its public header.

`data` is the kernel's local copy of the third argument. Because the kernel did the copyin and will do the copyout (for `_IOR`, `_IOW`, and `_IOWR` requests), `data` is always a kernel pointer. The driver dereferences it directly without calling `copyin`. For `_IO` requests, `data` is undefined and must not be dereferenced.

`fflag` is the file flags from the open call: `FREAD`, `FWRITE`, or both. The driver can use `fflag` to enforce read-only or write-only access for specific commands. A command that resets state, for example, might require `FWRITE` and return `EBADF` otherwise.

`td` is the calling thread. The driver can use `td` to extract the caller's credentials (`td->td_ucred`), to perform privilege checks (`priv_check_cred(td->td_ucred, PRIV_DRIVER, 0)`), or simply to log the caller's pid. For most commands, `td` is unused.

The return value is 0 on success, or a positive `errno` value on failure. The special value `ENOIOCTL` (defined in `/usr/src/sys/sys/errno.h`) tells the kernel that the driver does not recognise the command, and the kernel will then route the command through the file-system layer's generic `ioctl` handler. Returning `EINVAL` instead of `ENOIOCTL` for an unknown command is a subtle bug: it tells the kernel "I recognised the command but the arguments are wrong", which suppresses the generic fallback. Always use `ENOIOCTL` for the default case.

24.4.5 How the Kernel Performs Copyin and Copyout

Before the dispatcher runs, the kernel inspects the direction bits and parameter length encoded in `cmd`. If `IOC_IN` is set, the kernel reads the parameter length, allocates a temporary kernel buffer of that size, copies the user-space argument into it (`copyin`), and passes the kernel buffer as `data`. If `IOC_OUT` is set, the kernel allocates a buffer, calls the dispatcher with the (uninitialised) buffer as `data`, and on a 0 return, copies the buffer back

to user space (copyout). If both bits are set (IOC_INOUT), the kernel does both copyin and copyout around the dispatcher call. If neither is set (IOC_VOID), no buffer is allocated and data is undefined.

This automation has two consequences worth remembering.

First, the dispatcher writes to and reads from data using normal C dereference. The driver never calls copyin or copyout for a correctly encoded ioctl. This is one of the reasons a properly designed ioctl interface is so much simpler to implement than, say, a write-and-read protocol that fakes a control channel.

Second, the parameter type encoded in _IOW or _IOR must match what the dispatcher actually reads or writes. If the user-space header declares _IOR('M', 1, uint32_t) but the dispatcher writes a uint64_t into *(uint64_t *)data, the dispatcher will overrun the kernel's 4-byte buffer and corrupt adjacent stack memory, panicking the kernel under a WITNESS-enabled build and silently corrupting state under a production build. The header is the contract; the dispatcher must honour it byte for byte.

For ioctls with embedded pointers (a struct that contains a char *buf pointing at a separate buffer), the kernel cannot copyin or copyout the buffer because it is not part of the structure. The driver must do its own copyin and copyout for the buffer contents, while the kernel handles the wrapping struct. This pattern is needed for variable-length data and is covered in the pitfalls subsection below.

24.4.6 Designing a Public Header

A driver that exposes ioctls must publish a header that declares the request codes and the data structures. User-space programs include this header to construct correct calls. The header lives outside the kernel module: it is part of the driver's contract with user space and must be installable on the system (for example, into /usr/local/include/myfirst/myfirst_ioctl.h).

The convention is to place the header in the driver's source directory with a .h suffix that matches the public name. For the myfirst driver the header is myfirst_ioctl.h. Its responsibilities are narrow: declare the ioctl numbers, declare the structures used as ioctl arguments, declare any related constants (such as the maximum length of the message field), and nothing else. It must not include kernel-only headers, must not declare kernel-only types, and must compile cleanly when included by a user-space program.

Here is the full header for the chapter's stage 2 driver:

```
/*
 * myfirst_ioctl.h - public ioctl interface for the myfirst driver.
 *
 * This header is included by both the kernel module and any user-space
 * program that talks to the driver. Keep it self-contained: no kernel
 * headers, no kernel types, no inline functions that pull kernel state.
 */

#ifndef _MYFIRST_IOCTL_H_
#define _MYFIRST_IOCTL_H_

#include <sys/ioccom.h>
#include <sys/types.h>
```

```
/*
 * Maximum length of the in-driver message, including the trailing NUL.
 * The driver enforces this on SETMSG; user-space programs that build
 * larger buffers will see EINVAL.
 */
#define MYFIRST_MSG_MAX 256

/*
 * The interface version. Bumped when this header changes in a way that
 * is not backward-compatible. User-space programs should call
 * MYFIRSTIOC_GETVER first and refuse to operate on an unexpected
 * version.
 */
#define MYFIRST_IOCTL_VERSION 1

/*
 * MYFIRSTIOC_GETVER - return the driver's interface version.
 *
 *   ioctl(fd, MYFIRSTIOC_GETVER, &ver);    // ver = 1, 2, ...
 *
 * No FREAD or FWRITE flag is required.
 */
#define MYFIRSTIOC_GETVER _IOR('M', 1, uint32_t)

/*
 * MYFIRSTIOC_GETMSG - copy the current in-driver message into the
 * caller's buffer. The buffer must be MYFIRST_MSG_MAX bytes; the
 * message is NUL-terminated.
 */
#define MYFIRSTIOC_GETMSG _IOR('M', 2, char[MYFIRST_MSG_MAX])

/*
 * MYFIRSTIOC_SETMSG - replace the in-driver message. The buffer must
 * be MYFIRST_MSG_MAX bytes; the kernel takes the prefix up to the
 * first NUL or to MYFIRST_MSG_MAX - 1 bytes.
 *
 * Requires FWRITE on the file descriptor.
 */
#define MYFIRSTIOC_SETMSG _IOW('M', 3, char[MYFIRST_MSG_MAX])

/*
 * MYFIRSTIOC_RESET - reset all per-instance counters and clear the
 * message. Returns 0 on success.
 */
```

```

*
* Requires FWRITE on the file descriptor.
*/
#define MYFIRSTIOC_RESET    _IO('M', 4)

#endif /* _MYFIRST_IOCTL_H_ */

```

A few details in this header are worth pausing on.

The use of `uint32_t` and `sys/types.h` (rather than `u_int32_t` and `sys/cdefs.h`) keeps the header portable across the FreeBSD base and any program that follows POSIX. The kernel and user-space agree on the size of `uint32_t`, so the encoded length in the request code matches the dispatcher's view of the data.

The maximum message length, `MYFIRST_MSG_MAX = 256`, is well under `IOCPARM_MAX = 8192`, so the kernel will copyin and copyout the message without complaint. A driver that needed to move larger messages would either raise the limit (up to 8192) or switch to the embedded-pointer pattern.

The `MYFIRST_IOCTL_VERSION` constant gives user-space a way to detect API changes. The first ioctl that any program should issue is `MYFIRSTIOC_GETVER`; if the returned version is not what the program was compiled against, the program should refuse to issue further ioctls and print a clear error. This is standard practice for drivers that expect to evolve.

The argument type `char[MYFIRST_MSG_MAX]` is unusual but legal in `_IOR` and `_IOW`. The macro takes `sizeof(t)`, and `sizeof(char[256]) == 256`, so the encoded length is exactly the array size. This is the cleanest way to express a fixed-size buffer in a public ioctl header.

24.4.7 Implementing the Dispatcher

With the header in hand, the dispatcher is a switch statement that reads the command code, performs the action, and either returns 0 (success) or a positive `errno` (failure). The dispatcher lives in `myfirst_ioctl.c`, a new source file added to the driver in stage 2.

The complete dispatcher:

```

/*
 * myfirst_ioctl.c - ioctl dispatcher for the myfirst driver.
 *
 * The d_ioctl callback in myfirst_cdevsw points at myfirst_ioctl.
 * Per-command argument layout is documented in myfirst_ioctl.h, which
 * is shared with user space.
 */

#include <sys/param.h>
#include <sys/systm.h>
#include <sys/conf.h>
#include <sys/file.h>
#include <sys/lock.h>

```

```
#include <sys/mutex.h>
#include <sys/malloc.h>
#include <sys/proc.h>

#include "myfirst.h"
#include "myfirst_debug.h"
#include "myfirst_ioctl.h"

SDT_PROBE_DEFINE3(myfirst, , , ioctl,
    "struct myfirst_softc *", "u_long", "int");

int
myfirst_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
    struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error = 0;

    SDT_PROBE3(myfirst, , , ioctl, sc, cmd, fflag);
    DPRINTF(sc, MYF_DBG_IOCTL, "ioctl: cmd=0x%08lx fflag=0x%x\n",
        cmd, fflag);

    mtx_lock(&sc->sc_mtx);

    switch (cmd) {
    case MYFIRSTIOC_GETVER:
        *(uint32_t *)data = MYFIRST_IOCTL_VERSION;
        break;

    case MYFIRSTIOC_GETMSG:
        /*
         * Copy the current message into the caller's buffer.
         * The buffer is MYFIRST_MSG_MAX bytes; we always emit
         * a NUL-terminated string.
         */
        strncpy((char *)data, sc->sc_msg, MYFIRST_MSG_MAX);
        break;

    case MYFIRSTIOC_SETMSG:
        if ((fflag & FWRITE) == 0) {
            error = EBADF;
            break;
        }
        /*
```

```

        * The kernel has copied MYFIRST_MSG_MAX bytes into
        * data. Take the prefix up to the first NUL.
        */
        strncpy(sc->sc_msg, (const char *)data, MYFIRST_MSG_MAX);
        sc->sc_msglen = strlen(sc->sc_msg);
        DPRINTF(sc, MYF_DBG_IOCTL,
            "SETMSG: new message is %zu bytes\n", sc->sc_msglen);
        break;

case MYFIRSTIOC_RESET:
    if ((fflag & FWRITE) == 0) {
        error = EBADF;
        break;
    }
    sc->sc_open_count = 0;
    sc->sc_total_reads = 0;
    sc->sc_total_writes = 0;
    bzero(sc->sc_msg, sizeof(sc->sc_msg));
    sc->sc_msglen = 0;
    DPRINTF(sc, MYF_DBG_IOCTL,
        "RESET: counters and message cleared\n");
    break;

default:
    error = ENOIOCTL;
    break;
}

mtx_unlock(&sc->sc_mtx);
return (error);
}

```

Several disciplined choices are baked into this dispatcher and they are worth pointing out before the reader writes their own.

The dispatcher takes the softc mutex once at the top and releases it once at the bottom. Every command runs under the mutex. This prevents a read from racing a SETMSG (the read would otherwise see a half-replaced message buffer) and prevents two simultaneous RESET calls from corrupting the counters. The mutex is the same `sc->sc_mtx` introduced earlier in Part IV; we are simply extending its scope to cover ioctl serialisation.

The dispatcher's first action after taking the mutex is a single SDT probe and a single DPRINTF. Both report the command and the file flags. The SDT probe lets a DTrace script trace every ioctl in real time; the DPRINTF lets an operator turn on `MYF_DBG_IOCTL` and watch the same flow through `dmesg`. Both use the debug infrastructure introduced in Chapter 23 with no new machinery.

The `MYFIRSTIOC_SETMSG` and `MYFIRSTIOC_RESET` paths check `fflag & FWRITE` before they mutate state.

Without this check, a program that opened the device read-only could change the driver's state, which is a privilege-escalation pattern in some drivers. The check returns `EBADF` (bad file descriptor for the operation) rather than `EPERM` (no permission), because the failure is about the file's open flags rather than about the user's identity.

The default branch returns `ENOIOCTL`, never `EINVAL`. This is the rule from the previous subsection, repeated here because it is the single most common bug in homemade dispatchers.

The `strncpy` calls in `GETMSG` and `SETMSG` are the safe string copy primitive in the FreeBSD kernel. They guarantee NUL termination and never overrun the destination. The same calls would be `strncpy` in older code; `strncpy` is the modern preferred form and is what `style(9)` recommends.

24.4.8 The Softc Additions

Stage 2 extends the `softc` with two fields and confirms that the existing fields are still in use:

```
struct myfirst_softc {
    device_t      sc_dev;
    struct cdev    *sc_cdev;
    struct mtx     sc_mtx;

    /* From earlier chapters. */
    uint32_t      sc_debug;
    u_int         sc_open_count;
    u_int         sc_total_reads;
    u_int         sc_total_writes;

    /* New for stage 2. */
    char          sc_msg[MYFIRST_MSG_MAX];
    size_t        sc_msglen;
};
```

The message buffer is a fixed-size array sized to match the public header. Storing it inline (rather than as a pointer to a separately allocated buffer) keeps the lifetime simple: the buffer lives exactly as long as the `softc`. There is no `malloc` to track and no `free` to forget.

The initialisation in `myfirst_attach` becomes:

```
strncpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
sc->sc_msglen = strlen(sc->sc_msg);
```

The driver now has a default greeting that survives until the operator changes it through `SETMSG`, and survives unload/load cycles only by virtue of the new value being re-set on each load. (This is the same lifetime as every other `softc` field; persistence across reboots would require a `sysctl` tunable, which is the subject of Section 4.)

24.4.9 Wiring the Dispatcher Into cdevsw

The cdevsw declared in stage 1 already had a `.d_ioctl` slot waiting to be filled. Stage 2 fills it:

```
static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_flags   = D_TRACKCLOSE,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
    .d_ioctl   = myfirst_ioctl,    /* new */
};
```

The kernel reads this table once, when the module loads. There is no runtime registration step; the cdevsw is part of the driver's static state.

24.4.10 Building the Stage 2 Driver

The Makefile for stage 2 must include the new source file:

```
KMOD=    myfirst
SRCS=    myfirst.c myfirst_debug.c myfirst_ioctl.c

CFLAGS+= -I${.CURDIR}

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

The build commands are unchanged from stage 1:

```
$ make
$ sudo kldload ./myfirst.ko
$ ls -l /dev/myfirst0
crw-rw----  1 root wheel 0x... <date> /dev/myfirst0
```

If the build fails because `myfirst_ioctl.h` is not found, check that the `CFLAGS` line includes `-I${.CURDIR}`. If the load fails because of an unresolved symbol such as `myfirst_ioctl`, check that `myfirst_ioctl.c` is listed in `SRCS` and that the function name matches the cdevsw entry.

24.4.11 The myfirstctl User-Space Companion

A driver with an ioctl interface needs a small companion program that exercises it. Without one, the operator has no way to call the ioctls except through a hand-written test or through `devctl(8)`'s ioctl pass-through, which is awkward for routine use.

The companion is `myfirstctl`, a single-file C program that takes a subcommand on the command line and calls the corresponding ioctl. It is intentionally small (under 200 lines) and depends only on the public header.

```
/*
 * myfirstctl.c - command-line front end to the myfirst driver's ioctls.
 *
 * Build:  cc -o myfirstctl myfirstctl.c
 * Usage:  myfirstctl get-version
 *         myfirstctl get-message
 *         myfirstctl set-message "<text>"
 *         myfirstctl reset
 */

#include <sys/types.h>
#include <sys/ioctl.h>

#include <err.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#include "myfirst_ioctl.h"

#define DEVPATH "/dev/myfirst0"

static void
usage(void)
{
    fprintf(stderr,
        "usage: myfirstctl get-version\n"
        "       myfirstctl get-message\n"
        "       myfirstctl set-message <text>\n"
        "       myfirstctl reset\n");
    exit(EX_USAGE);
}

int
main(int argc, char **argv)
```

```
{

    int fd, flags;
    const char *cmd;

    if (argc < 2)
        usage();
    cmd = argv[1];

    /*
     * SETMSG and RESET need write access; the others only need
     * read. Open the device with the right flags so the dispatcher
     * does not return EBADF.
     */
    if (strcmp(cmd, "set-message") == 0 ||
        strcmp(cmd, "reset") == 0)
        flags = O_RDWR;
    else
        flags = O_RDONLY;

    fd = open(DEVPATH, flags);
    if (fd < 0)
        err(EX_OSERR, "open %s", DEVPATH);

    if (strcmp(cmd, "get-version") == 0) {
        uint32_t ver;
        if (ioctl(fd, MYFIRSTIOC_GETVER, &ver) < 0)
            err(EX_OSERR, "MYFIRSTIOC_GETVER");
        printf("driver ioctl version: %u\n", ver);
    } else if (strcmp(cmd, "get-message") == 0) {
        char buf[MYFIRST_MSG_MAX];
        if (ioctl(fd, MYFIRSTIOC_GETMSG, buf) < 0)
            err(EX_OSERR, "MYFIRSTIOC_GETMSG");
        printf("%s\n", buf);
    } else if (strcmp(cmd, "set-message") == 0) {
        char buf[MYFIRST_MSG_MAX];
        if (argc < 3)
            usage();
        strlcpy(buf, argv[2], sizeof(buf));
        if (ioctl(fd, MYFIRSTIOC_SETMSG, buf) < 0)
            err(EX_OSERR, "MYFIRSTIOC_SETMSG");
    } else if (strcmp(cmd, "reset") == 0) {
        if (ioctl(fd, MYFIRSTIOC_RESET) < 0)
            err(EX_OSERR, "MYFIRSTIOC_RESET");
    } else {
```

```
        usage();  
    }  
  
    close(fd);  
    return (0);  
}
```

Two details deserve note.

The program opens the device with the minimum flags required for the requested operation. `MYFIRSTIOC_GETVER` and `MYFIRSTIOC_GETMSG` work fine with `O_RDONLY`, but `MYFIRSTIOC_SETMSG` and `MYFIRSTIOC_RESET` require `O_RDWR` because the dispatcher checks `fflag & FWRITE`. A user who runs `myfirstctl set-message foo` without the appropriate group membership will see `Permission denied` from `open`; one who has the membership but the dispatcher still rejects them would see `Bad file descriptor` from `ioctl`. Both errors are intelligible.

The `MYFIRSTIOC_RESET` call passes no third argument because the macro `_IO` (with no `R` or `W`) declares a void-data `ioctl`. The library's `ioctl(2)` is variadic, so calling it with two arguments is legal, but care is needed because an extra argument would be passed but ignored. The convention in this book is to call `_IO` `ioctls` with exactly two arguments to make the void-data nature clear in the source.

A typical session looks like this:

```
$ myfirstctl get-version  
driver ioctl version: 1  
$ myfirstctl get-message  
Hello from myfirst  
$ myfirstctl set-message "drivers are fun"  
$ myfirstctl get-message  
drivers are fun  
$ myfirstctl reset  
$ myfirstctl get-message  
  
$
```

After the reset, the message buffer is empty and `myfirstctl get-message` prints a blank line. The counters are also reset, which the next section's `sysctl` interface will let us verify directly.

24.4.12 Common Pitfalls With `ioctl`

The first pitfall is **type-size mismatch between header and dispatcher**. If the header declares `_IOR('M', 1, uint32_t)` but the dispatcher writes a `uint64_t` into `*(uint64_t *)data`, the kernel allocated a 4-byte buffer and the dispatcher writes 8 bytes into it. The 4 extra bytes corrupt whatever sat next to the buffer (often other `ioctl` arguments or the dispatcher's local stack frame). Under `WITNESS` and `INVARIANTS`, the kernel may catch the overrun and panic; under a production build, the result is silent corruption. The fix is to keep the header

and the dispatcher in lockstep, ideally by including the same header in both places (which the chapter's pattern does).

The second pitfall is **embedded pointers**. A struct that contains `char *buf; size_t len;` cannot be safely transferred through a single `_IOW`. The kernel will copy in the struct (the pointer and the length), but the buffer that the pointer points at is in user space and the dispatcher cannot dereference it directly. The dispatcher must call `copyin(uap->buf, kbuf, uap->len)` to transfer the buffer contents itself. Forgetting this step causes the dispatcher to read user-space memory through a kernel pointer, which the kernel's address-space protection will trap as a fault. The fix is either to inline the buffer in the struct (the pattern this chapter uses for the message field) or to add explicit `copyin/copyout` calls inside the dispatcher.

The third pitfall is **forgetting to handle `ENOIOCTL` correctly**. A driver that returns `EINVAL` for an unknown command suppresses the kernel's generic `ioctl` fallback. The user might see `Invalid argument` from a command that should have been silently passed up to the file system layer (such as `FIONBIO` for non-blocking I/O hint). The fix is to use `ENOIOCTL` as the default return.

The fourth pitfall is **changing the wire format of an existing `ioctl`**. Once a program is compiled against `MYFIRSTIOC_SETMSG` declared with a 256-byte buffer, recompiling the driver with a 512-byte buffer breaks the program: the encoded length in the request code changes, the kernel detects the mismatch (because the user passed a 256-byte buffer with the new 512-byte command), and the `ioctl` call returns `ENOTTY` ("Inappropriate `ioctl` for device"). The fix is to leave existing `ioctls` alone and to define new commands with new numbers when the format must change. The `MYFIRST_IOCTL_VERSION` constant lets user-space programs detect such evolution before they issue the affected calls.

The fifth pitfall is **doing slow work in the dispatcher while holding a mutex**. The dispatcher in this section holds `sc->sc_mtx` for the entire switch statement, which is fine because every command is fast (a `memcpy`, a counter reset, a `strncpy`). A real driver that needs to perform a hardware operation that may take milliseconds must drop the mutex first and re-acquire it after, or use a sleepable lock. Holding a non-sleepable mutex across a `tsleep` or `msleep` would panic the kernel.

24.4.13 Wrapping Up Section 3

Section 3 completed the second integration surface: a properly designed `ioctl` interface. The driver now exposes four commands through `MYFIRSTIOC_GETVER`, `MYFIRSTIOC_GETMSG`, `MYFIRSTIOC_SETMSG`, and `MYFIRSTIOC_RESET`. The interface is self-describing (any user-space program can call `MYFIRSTIOC_GETVER` to detect the API version), the encoding is explicit (the `_IOR/_IOW/_IO` macros from `/usr/src/sys/sys/ioc-com.h`), and the kernel handles the `copyin` and `copyout` automatically based on the bit layout. The companion `myfirstctl` program demonstrates how a user-space tool exercises the interface without ever touching the bytes of the request code itself.

The driver milestone for stage 2 is the addition of `myfirst_ioctl.c` and `myfirst_ioctl.h`, both of which integrate cleanly with the debug infrastructure from Chapter 23 (the `MYF_DBG_IOCTL` mask bit and the `myfirst:::ioctl` SDT probe). The `Makefile` grew one entry in `SRCS` and the `cdevsw` grew one filled-in callback. Everything else in the driver is unchanged.

In Section 4 we turn to the third integration surface: read-only and read-write knobs that an administrator can query and tune from the shell using `sysctl(8)`. Where `ioctl` is the right channel for a program that already has the device open, `sysctl` is the right channel for a script or an operator who wants to inspect or adjust driver state without opening anything. The two interfaces complement each other; most production drivers offer both.

24.5 Section 4: Exposing Metrics Through `sysctl()`

24.5.1 What `sysctl` Is, and Why Drivers Use It

`sysctl(8)` is the FreeBSD kernel's hierarchical name service. Every name in the tree maps to a piece of kernel state: a constant, a counter, a tunable variable, or a function pointer that produces a value on demand. The tree is rooted at `kern.`, `vm.`, `hw.`, `net.`, `dev.`, and a handful of other top-level prefixes. Any program with the appropriate privileges can read and (for writable nodes) modify these values through the `sysctl(3)` library, the `sysctl(8)` command-line tool, or the `sysctlbyname(3)` convenience interface.

For drivers, the relevant subtree is `dev.<driver_name>.<unit>.*`. The Newbus subsystem creates this prefix automatically for every attached device. A driver named `myfirst` with unit 0 attached gets the prefix `dev.myfirst.0` for free, with no driver code required. The driver's only job is to populate the prefix with named OIDs (object identifiers) for the values it wants to expose.

Why expose state through `sysctl` rather than `ioctl`? The two mechanisms answer different questions. `ioctl` is the right channel for a program that has already opened the device and wants to issue a command. `Sysctl` is the right channel for an operator at a shell prompt who wants to inspect or adjust state without opening anything. Most production drivers offer both: the `ioctl` interface for programs, and the `sysctl` interface for humans, scripts, and monitoring tools.

The common pattern is that `sysctl` exposes:

- **counters** that summarise the driver's activity since attach
- **read-only state** such as version numbers, hardware identifiers, and link state
- **read-write tunables** such as debug masks, queue depths, and timeout values
- **boot-time tunables** that are read from `/boot/loader.conf` before the driver attaches

By the end of this section, the `myfirst` driver will expose all four categories under `dev.myfirst.0` and will read its initial debug mask from `/boot/loader.conf`. The driver milestone for stage 3 is the addition of `myfirst_sysctl.c` and a small tree of OIDs.

24.5.2 The `Sysctl` Namespace

A complete `sysctl` name looks like a dotted path. The default Newbus prefix for our driver is:

```
dev.myfirst.0
```

Underneath this prefix the driver may add anything it likes. The `myfirst` driver in stage 3 will add:

```
dev.myfirst.0.%desc      "myfirst pseudo-device, integration version 1.7"
dev.myfirst.0.%driver    "myfirst"
dev.myfirst.0.%location  ""
dev.myfirst.0.%pnpinfo   ""
dev.myfirst.0.%parent    "nexus0"
dev.myfirst.0.version    "1.7-integration"
dev.myfirst.0.open_count 0
```

```

dev.myfirst.0.total_reads      0
dev.myfirst.0.total_writes    0
dev.myfirst.0.message         "Hello from myfirst"
dev.myfirst.0.debug.mask      0
dev.myfirst.0.debug.classes    "INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) ..."

```

The first five names (the ones starting with %) are added by Newbus automatically and describe the device-tree relationship. The remaining names are the driver's contribution. Of these, `version`, `open_count`, `total_reads`, `total_writes`, and `debug.classes` are read-only; `message` and `debug.mask` are read-write. The `debug` subtree is itself a node, which means it can hold further OIDs as the driver grows.

The reader can already see the result on a system with `myfirst` loaded:

```

$ sysctl dev.myfirst.0
dev.myfirst.0.debug.classes: INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) INTR(0x10)
↪ DMA(0x20) PWR(0x40) MEM(0x80)
dev.myfirst.0.debug.mask: 0
dev.myfirst.0.message: Hello from myfirst
dev.myfirst.0.total_writes: 0
dev.myfirst.0.total_reads: 0
dev.myfirst.0.open_count: 0
dev.myfirst.0.version: 1.7-integration
dev.myfirst.0.%parent: nexus0
dev.myfirst.0.%pnpinfo:
dev.myfirst.0.%location:
dev.myfirst.0.%driver: myfirst
dev.myfirst.0.%desc: myfirst pseudo-device, integration version 1.7

```

The order of the lines is the order of OID creation, reversed. (Newbus adds the %-prefixed names last, so they print first when `sysctl` walks the list backward. This is cosmetic and has no semantic meaning.)

24.5.3 Static OIDs Versus Dynamic OIDs

`Sysctl` OIDs come in two flavours.

A **static OID** is declared at compile time with one of the `SYSCTL_*` macros (`SYSCTL_INT`, `SYSCTL_STRING`, `SYSCTL_ULONG`, and so on). The macro generates a constant data structure that the linker glues into a special section, and the kernel assembles the section into the global tree at boot. Static OIDs are appropriate for system-wide values that exist for the lifetime of the kernel: timer ticks, scheduler statistics, and similar.

A **dynamic OID** is created at runtime with one of the `SYSCTL_ADD_*` functions (`SYSCTL_ADD_INT`, `SYSCTL_ADD_STRING`, `SYSCTL_ADD_PROC`, and so on). The function takes a context, a parent, a name, and a pointer to the underlying data, and inserts a new node into the tree. Dynamic OIDs are appropriate for per-instance values that come and go with a device: a driver creates them in `attach` and tears them down in `detach`.

Driver code uses dynamic OIDs almost exclusively. A driver does not exist at compile time of the kernel; it appears when the module loads, and any sysctl subtree it owns must be built up at attach time and disposed of at detach. The Newbus framework gives every driver a per-device sysctl context and a parent OID specifically for this purpose:

```
struct sysctl_ctx_list *ctx;
struct sysctl_oid *tree;
struct sysctl_oid_list *child;

ctx = device_get_sysctl_ctx(dev);
tree = device_get_sysctl_tree(dev);
child = SYSCTL_CHILDREN(tree);
```

`device_get_sysctl_ctx` returns the per-device context. The context tracks every OID the driver creates so the framework can free them all in one call when the driver detaches. The driver does not have to track them itself.

`device_get_sysctl_tree` returns the per-device tree node, which is the OID corresponding to `dev.<driver>.<unit>`. The tree was created by Newbus when the device was added.

`SYSCTL_CHILDREN(tree)` extracts the child list from the tree node. This is what the driver passes as the parent argument to subsequent `SYSCTL_ADD_*` calls.

With these three handles in hand, the driver can add any number of OIDs to its subtree:

```
SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "open_count",
    CTLFLAG_RD, &sc->sc_open_count, 0,
    "Number of times the device has been opened");
```

The `SYSCTL_ADD_UINT` call adds an unsigned-int OID under the parent named `open_count`, with `CTLFLAG_RD` (read-only), backed by `&sc->sc_open_count`, with no special initial value, and with a description. The description is what `sysctl -d dev.myfirst.0.open_count` will print. Always write a useful description; an empty one is a documentation hole.

The matching call for a read-write integer is identical except for the flag:

```
SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "debug_mask_simple",
    CTLFLAG_RW, &sc->sc_debug, 0,
    "Simple writable debug mask");
```

The `CTLFLAG_RW` flag tells the kernel to allow writes from privileged users (root, or processes with `PRIV_DRIVER`).

For a string, the macro is `SYSCTL_ADD_STRING`:

```
SYSCALL_ADD_STRING(ctx, child, OID_AUTO, "version",
    CTLFLAG_RD, sc->sc_version, 0,
    "Driver version string");
```

The third-from-last argument is a pointer to the buffer that holds the string, and the second-from-last is the buffer's size (zero means unbounded for read-only strings).

24.5.4 Handler-Backed OIDs

Some OIDs need more logic than a plain memory access. Reading the OID may need to compute the value from several softc fields; writing the OID may need to validate the new value and update related state. These OIDs use a handler function and the macro `SYSCALL_ADD_PROC`.

A handler has the signature:

```
static int handler(SYSCALL_HANDLER_ARGS);
```

`SYSCALL_HANDLER_ARGS` is a macro that expands to:

```
struct sysctl_oid *oidp, void *arg1, intptr_t arg2,
struct sysctl_req *req
```

`oidp` identifies the OID being accessed. `arg1` and `arg2` are the user-supplied arguments registered when the OID was created (typically `arg1` points at the softc and `arg2` is unused or holds a small constant). `req` carries the read/write context: `req->newptr` is non-NULL for a write (and points at the new value the user is supplying), and the handler must call `SYSCALL_OUT(req, value, sizeof(value))` to return a value on a read.

A typical handler that exposes a computed value:

```
static int
myfirst_sysctl_message_len(SYSCALL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    u_int len;

    mtx_lock(&sc->sc_mtx);
    len = (u_int)sc->sc_msglen;
    mtx_unlock(&sc->sc_mtx);

    return (sysctl_handle_int(oidp, &len, 0, req));
}
```

The handler computes the value (here, by copying the message length under the mutex), then defers to `sysctl_handle_int`, which does the bookkeeping for the read or write and (for a write) calls back into the

handler with the new value already in `*ptr`. The handler-of-handlers pattern is idiomatic; using it correctly avoids reimplementing copyin and copyout for every typed handler.

The handler is registered with `SYSCTL_ADD_PROC`:

```
SYSCTL_ADD_PROC(ctx, child, OID_AUTO, "message_len",
    CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE,
    sc, 0, myfirst_sysctl_message_len, "IU",
    "Current length of the in-driver message");
```

Three arguments deserve attention. `CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE` is the type-and-flag word. `CTLTYPE_UINT` declares the OID's external type (unsigned int); `CTLFLAG_RD` declares it read-only; `CTLFLAG_MPSAFE` declares that the handler is safe to call without the giant lock. The `CTLFLAG_MPSAFE` flag is mandatory for new code; without it, the kernel still works but takes the giant lock around every read, which serialises the entire system on any sysctl access.

The seventh argument is the format string. "IU" declares an unsigned int (I for integer, U for unsigned). The full set is documented in `/usr/src/sys/sys/sysctl.h`: "I" for int, "IU" for uint, "L" for long, "LU" for ulong, "Q" for int64, "QU" for uint64, "A" for string, "S, structname" for an opaque struct. The `sysctl(8)` command uses the format string to decide how to print the value when invoked without `-x` (the raw hex flag).

24.5.5 The myfirst Sysctl Tree

The full sysctl tree for stage 3 is built in a single function, `myfirst_sysctl_attach`, called from `myfirst_attach` after the cdev has been created. The function is short enough to read end to end:

```
/*
 * myfirst_sysctl.c - sysctl tree for the myfirst driver.
 *
 * Builds dev.myfirst.<unit>.* with version, counters, message, and a
 * debug subtree (debug.mask, debug.classes).
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/conf.h>
#include <sys/kernel.h>
#include <sys/lock.h>
#include <sys/malloc.h>
#include <sys/mutex.h>
#include <sys/sysctl.h>

#include "myfirst.h"
#include "myfirst_debug.h"
```

```
#define MYFIRST_VERSION "1.7-integration"

static int
myfirst_sysctl_message_len(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    u_int len;

    mtx_lock(&sc->sc_mtx);
    len = (u_int)sc->sc_msglen;
    mtx_unlock(&sc->sc_mtx);

    return (sysctl_handle_int(oidp, &len, 0, req));
}

void
myfirst_sysctl_attach(struct myfirst_softc *sc)
{
    device_t dev = sc->sc_dev;
    struct sysctl_ctx_list *ctx;
    struct sysctl_oid *tree;
    struct sysctl_oid_list *child;
    struct sysctl_oid *debug_node;
    struct sysctl_oid_list *debug_child;

    ctx = device_get_sysctl_ctx(dev);
    tree = device_get_sysctl_tree(dev);
    child = SYSCTL_CHILDREN(tree);

    /* Read-only: driver version. */
    SYSCTL_ADD_STRING(ctx, child, OID_AUTO, "version",
        CTLFLAG_RD, MYFIRST_VERSION, 0,
        "Driver version string");

    /* Read-only: counters. */
    SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "open_count",
        CTLFLAG_RD, &sc->sc_open_count, 0,
        "Number of currently open file descriptors");

    SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "total_reads",
        CTLFLAG_RD, &sc->sc_total_reads, 0,
        "Total read() calls since attach");

    SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "total_writes",
```

```

        CTLFLAG_RD, &sc->sc_total_writes, 0,
        "Total write() calls since attach");

/* Read-only: message buffer (no copy through user) */
SYSCTL_ADD_STRING(ctx, child, OID_AUTO, "message",
        CTLFLAG_RD, sc->sc_msg, sizeof(sc->sc_msg),
        "Current in-driver message");

/* Read-only handler: message length, computed. */
SYSCTL_ADD_PROC(ctx, child, OID_AUTO, "message_len",
        CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE,
        sc, 0, myfirst_sysctl_message_len, "IU",
        "Current length of the in-driver message in bytes");

/* Subtree: debug. */
debug_node = SYSCTL_ADD_NODE(ctx, child, OID_AUTO, "debug",
        CTLFLAG_RD | CTLFLAG_MPSAFE, NULL,
        "Debug controls and class enumeration");
debug_child = SYSCTL_CHILDREN(debug_node);

SYSCTL_ADD_UINT(ctx, debug_child, OID_AUTO, "mask",
        CTLFLAG_RW | CTLFLAG_TUN, &sc->sc_debug, 0,
        "Bitmask of enabled debug classes");

SYSCTL_ADD_STRING(ctx, debug_child, OID_AUTO, "classes",
        CTLFLAG_RD,
        "INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) "
        "INTR(0x10) DMA(0x20) PWR(0x40) MEM(0x80)",
        0, "Names and bit values of debug classes");
}

```

Three details are worth a closer look.

The version OID is backed by a string constant (MYFIRST_VERSION), not a softc field. A read-only string OID can point at any stable buffer; the kernel never writes through the pointer. This is safer and simpler than carrying a per-softc copy of the version, and it lets the version be visible through `sysctl` even if the driver fails attach partway through.

The message OID points directly into the softc's `sc_msg` field with `CTLFLAG_RD`. A reader that calls `sysctl dev.myfirst.0.message` will get the current value. Because the OID is read-only, `sysctl` will not write to the buffer, so we do not need a write handler. (A read-write version of this OID would need a handler to validate the input; the read-write path runs through the `ioctl` interface in stage 2.)

The `debug.mask` OID has `CTLFLAG_RW | CTLFLAG_TUN`. The `RW` flag allows writes from a privileged user. The `TUN` flag tells the kernel to look for a matching tunable in `/boot/loader.conf` and apply it before the OID becomes accessible. (We will set up the `loader.conf` hook in the next subsection.)

24.5.6 Wiring Sysctl Into Attach and Detach

The attach path now calls the sysctl builder after the cdev is created:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
    int error;

    sc->sc_dev = dev;
    mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);
    strncpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
    sc->sc_msglen = strlen(sc->sc_msg);

    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_WHEEL;
    args.mda_mode = 0660;
    args.mda_si_drv1 = sc;
    args.mda_unit = device_get_unit(dev);

    error = make_dev_s(&args, &sc->sc_cdev,
        "myfirst%d", device_get_unit(dev));
    if (error != 0) {
        mtx_destroy(&sc->sc_mtx);
        return (error);
    }

    myfirst_sysctl_attach(sc);

    DPRINTF(sc, MYF_DBG_INIT, "attach: cdev created and sysctl tree built\n");
    return (0);
}
```

The detach path is unchanged: it does not have to call `myfirst_sysctl_detach`. The Newbus framework owns the per-device sysctl context and tears it down automatically when the device detaches. The driver only needs to clean up resources that it allocated outside the framework (the cdev and the mutex). This is one of the small but real reasons to prefer the per-device context over a private context.

24.5.7 Boot-Time Tunables Through `/boot/loader.conf`

A driver can let the operator configure its initial behaviour at boot time by reading values from the loader environment. The loader (`/boot/loader.efi` or `/boot/loader`) parses `/boot/loader.conf` before the kernel starts and exports the variables into a small environment that the kernel can query.

The simplest way to read a loader variable is `TUNABLE_INT_FETCH`:

```
TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default", &sc->sc_debug);
```

The first argument is the loader variable name. The second is a pointer to the destination, which is also the default if the variable is absent. The call is silent if the variable is absent and writes the parsed value otherwise.

The call goes in `myfirst_attach` before `myfirst_sysctl_attach`. By the time the `sysctl` tree is built, `sc->sc_debug` already has the loader-supplied value (or the compile-time default), and the `dev.myfirst.0.debug.mask` OID reflects it.

A representative `/boot/loader.conf` entry for the driver looks like:

```
myfirst_load="YES"  
hw.myfirst.debug_mask_default="0x06"
```

The first line tells the loader to load `myfirst.ko` automatically. The second sets the default debug mask to `MYF_DBG_OPEN | MYF_DBG_IO`. After boot, `sysctl dev.myfirst.0.debug.mask` reports 6 and the operator can modify it at runtime without rebooting.

The naming convention is loose but follows a few practices. Keep loader variables under `hw.<driver>.<knob>` because the `hw.` namespace is conventionally read-only at runtime and is not subject to surprise renames. Use `default` in the variable name when the value is the initial value of a runtime-modifiable OID, to make the relationship clear. Document every loader variable in the driver's man page or in the chapter's reference card (the chapter has one at the end).

24.5.8 Combining Sysctl With the Debug Mask

The reader will recall from Chapter 23 that the driver already has a `sc->sc_debug` field and a `DPRINTF` macro that consults it. With stage 3 in place, the operator can now manipulate the mask from the shell:

```
$ sysctl dev.myfirst.0.debug.mask  
dev.myfirst.0.debug.mask: 0  
$ sysctl dev.myfirst.0.debug.classes  
dev.myfirst.0.debug.classes: INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) ...  
$ sudo sysctl dev.myfirst.0.debug.mask=0xff  
dev.myfirst.0.debug.mask: 0 -> 255  
$ # now every DPRINTF call inside the driver will print
```

The `classes` OID exists precisely to spare the operator from having to memorise the bit values. `sysctl` prints both names together and the operator can copy a hex value off the screen and paste it into the next command.

The same mechanism extends to any other knob the driver may want to expose. A driver that has a tunable timeout would add:

```
SYSCTL_ADD_UINT(ctx, child, OID_AUTO, "timeout_ms",
    CTLFLAG_RW | CTLFLAG_TUN, &sc->sc_timeout_ms, 0,
    "Operation timeout in milliseconds");
```

A driver that wants per-instance enable/disable of a feature would add a `bool` (declared with `SYSCTL_ADD_BOOL`, which is the modern preferred type for boolean flags) or an `int` with two valid values (0 and 1).

24.5.9 Building the Stage 3 Driver

The Makefile for stage 3 lists the new source file:

```
KMOD=    myfirst
SRCS=    myfirst.c myfirst_debug.c myfirst_ioctl.c myfirst_sysctl.c

CFLAGS+= -I${.CURDIR}

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

After make and `kldload`, the operator can immediately walk the tree:

```
$ sudo kldload ./myfirst.ko
$ sysctl -a dev.myfirst.0
dev.myfirst.0.debug.classes: INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) ...
dev.myfirst.0.debug.mask: 0
dev.myfirst.0.message_len: 18
dev.myfirst.0.message: Hello from myfirst
dev.myfirst.0.total_writes: 0
dev.myfirst.0.total_reads: 0
dev.myfirst.0.open_count: 0
dev.myfirst.0.version: 1.7-integration
dev.myfirst.0.%parent: nexus0
dev.myfirst.0.%pnpinfo:
dev.myfirst.0.%location:
dev.myfirst.0.%driver: myfirst
dev.myfirst.0.%desc: myfirst pseudo-device, integration version 1.7
```

Opening and reading the device should immediately bump the counters:

```
$ cat /dev/myfirst0
Hello from myfirst
$ sysctl dev.myfirst.0.total_reads
dev.myfirst.0.total_reads: 1
$ sysctl dev.myfirst.0.open_count
dev.myfirst.0.open_count: 0
```

The `open_count` shows zero because `cat` opens the device, reads, and immediately closes; by the time `sysctl` runs, the count has returned to zero. To see a non-zero value, hold the device open in another terminal:

```
# terminal 1
$ exec 3< /dev/myfirst0

# terminal 2
$ sysctl dev.myfirst.0.open_count
dev.myfirst.0.open_count: 1

# terminal 1
$ exec 3<&-

# terminal 2
$ sysctl dev.myfirst.0.open_count
dev.myfirst.0.open_count: 0
```

The shell's `exec 3< /dev/myfirst0` opens the device on file descriptor 3 and leaves it open until `exec 3<&-` closes it. This is a useful technique for inspecting any driver's open-count metric without writing a program.

24.5.10 Common Pitfalls With Sysctl

The first pitfall is **forgetting `CTLFLAG_MPSAFE`**. Without the flag, the kernel takes the giant lock around the OID's handler. For a read-only integer this is harmless; for a heavily accessed OID it serialises the entire kernel and is a latency disaster. Modern kernel code uses `CTLFLAG_MPSAFE` everywhere; the absence of the flag is a sign that the code predates the move to fine-grained locking and should be reviewed for correctness anyway.

The second pitfall is **using a static OID in driver code**. The `SYSCTL_INT` and `SYSCTL_STRING` macros (without the `_ADD_` prefix) declare static OIDs and place them in a special linker section that is processed at kernel boot. A loadable module that uses these macros will install the OIDs when the module loads, but the OIDs will reference per-instance fields that did not exist at compile time, leading to crashes the moment the operator reads them. The fix is to use the `SYSCTL_ADD_*` family for all driver OIDs.

The third pitfall is **leaking the per-driver context**. A driver that uses its own `sysctl_ctx_init` and `sysctl_ctx_free` (rather than the per-device context returned by `device_get_sysctl_ctx`) must remember to call `sysctl_ctx_free` in detach. Forgetting this leaks every OID the driver created and panics the kernel the next time the operator reads one. The fix is to use the per-device context (which the framework cleans up automatically) wherever possible.

The fourth pitfall is **putting per-instance state in a process-shared OID**. A driver that wants a tunable shared across all its instances might be tempted to put it under `kern.myfirst.foo` or under `dev.myfirst.foo`. The latter looks innocent but breaks: when the second instance attaches, Newbus tries to create `dev.myfirst.0.foo` and `dev.myfirst.1.foo`, and the existing `dev.myfirst.foo` (without the unit) is no longer in scope. The fix is to use either `hw.myfirst.<knob>` for shared tunables or per-instance OIDs for per-instance state, but not both with the same name.

The fifth pitfall is **changing the type of an OID**. An OID declared as `CTLTYPE_UINT` cannot have its type changed without invalidating any user-space program that called `sysctlbyname` against it. The kernel returns `EINVAL` if the user passes a buffer of the wrong size. The fix is to keep the type stable across releases; if a different type is needed, define a new OID name and deprecate the old one.

24.5.11 Wrapping Up Section 4

Section 4 added the third integration surface: the `sysctl` tree under `dev.myfirst.0`. The driver now exposes its version, counters, current message, debug mask, and class enumeration, all with descriptive help text and all built with the per-device `sysctl` context provided by Newbus. The debug mask can be set at boot time through `/boot/loader.conf` and tuned at runtime through `sysctl(8)`. A short stanza in `attach` builds the entire tree; `detach` does nothing because the framework cleans up automatically.

The driver milestone for stage 3 is the addition of `myfirst_sysctl.c` and a small extension to `myfirst_attach`. The `cdevsw`, the `ioctl` dispatcher, the debug infrastructure, and the rest of the driver are unchanged. The `sysctl` tree is purely additive.

In Section 5 we look at an optional but illustrative integration target: the network stack. Most drivers will never become network drivers, but understanding how a driver registers an `ifnet` and participates in the `if_*` API gives the reader an example of the pattern the kernel uses for every “subsystem with a registration interface.” If the driver is not a network driver, the reader can read Section 5 for context and skip directly to Section 7.

24.6 Section 5: Networking Integration (Optional)

24.6.1 Why This Section Is Optional

The `myfirst` driver is not a network driver and will not become one in this chapter. The `cdevsw`, `ioctl`, and `sysctl` interfaces we have built are sufficient for it. The reader who is following the chapter to integrate a non-network driver may safely skip ahead to Section 7 and lose nothing essential.

However, networking integration is a perfect illustration of a more general principle: many FreeBSD subsystems offer a registration interface that turns a driver into a participant in a larger framework. The pattern is the same whether the framework is networking, storage, USB, or sound: the driver allocates a framework-defined object, fills in callbacks, calls a registration function, and from that moment forward receives callbacks from the framework. Reading this section, even without writing a network driver, builds the intuition for every other framework integration in the book.

The chapter uses the network stack as its example for two reasons. First, it is the most widely understood framework, so the vocabulary (`ifnet`, `if_attach`, `bpf`) connects to user-visible commands such as `ifconfig(8)` and `tcpdump(8)`. Second, the network registration interface is small enough to walk through end to end without losing the reader. Section 6 then shows the same pattern applied to the CAM storage stack.

24.6.2 What an ifnet Is

ifnet is the network stack's per-interface object. It is the network counterpart to the cdev we worked with in Section 2. Just as a cdev represents one device node under /dev, an ifnet represents one network interface under ifconfig. Every line of ifconfig -a corresponds to one ifnet.

The ifnet is opaque from outside the network stack. Drivers see it through the if_t typedef and manipulate it through accessor functions (if_setflags, if_getmtu, if_settransmitfn). The opacity is deliberate: it lets the network stack evolve the ifnet internals without breaking every driver every release. New drivers should use the if_t API exclusively.

The lifecycle of an ifnet in a driver is:

1. **allocate** with if_alloc(IFT_<type>)
2. **name** with if_initname(ifp, "myif", unit)
3. **fill in callbacks** for ioctl, transmit, init, and similar
4. **attach** with if_attach(ifp), which makes the interface visible
5. **attach to BPF** with bpfattach(ifp, ...) so tcpdump can see traffic
6. ... interface lives, sees traffic, runs ioctls ...
7. **detach from BPF** with bpfdetach(ifp)
8. **detach** with if_detach(ifp), which removes it from the visible list
9. **free** with if_free(ifp)

The lifecycle mirrors the cdev lifecycle (allocate, name, attach, detach, free) almost exactly, which is not a coincidence; both the network stack and devfs evolved from the same registration-interface pattern.

24.6.3 A Walkthrough Using disc(4)

The simplest in-tree example of an ifnet driver is disc(4), the discard interface. disc(4) accepts packets and silently drops them; its driver code is therefore mostly the integration scaffolding, with no protocol logic to distract the reader. The full driver lives in /usr/src/sys/net/if_disc.c.

The relevant function is disc_clone_create, which is called whenever the operator runs ifconfig disc create:

```
static int
disc_clone_create(struct if_clone *ifc, int unit, caddr_t params)
{
    struct ifnet      *ifp;
    struct disc_softc *sc;

    sc = malloc(sizeof(struct disc_softc), M_DISC, M_WAITOK | M_ZERO);
    ifp = sc->sc_ifp = if_alloc(IFT_LOOP);
    ifp->if_softc = sc;
    if_initname(ifp, discname, unit);
    ifp->if_mtu = DSMTU;
    ifp->if_flags = IFF_LOOPBACK | IFF_MULTICAST;
```

```

    ifp->if_drv_flags = IFF_DRV_RUNNING;
    ifp->if_ioctl = discioctl;
    ifp->if_output = discoutput;
    ifp->if_hdrlen = 0;
    ifp->if_addrlen = 0;
    ifp->if_snd.ifq_maxlen = 20;
    if_attach(ifp);
    bpfattach(ifp, DLT_NULL, sizeof(u_int32_t));

    return (0);
}

```

Step by step:

`malloc` allocates the driver's softc with `M_WAITOK | M_ZERO`. The `waitok` flag is allowed because `clone-create` runs in a sleepable context. The zero flag initialises the structure to zero, which lets the driver assume any field it does not explicitly set is zero or `NULL`.

`if_alloc(IFT_LOOP)` allocates the `ifnet` from the network stack's pool. The `IFT_LOOP` argument identifies the interface type, which the stack uses for SNMP-style reporting and for some default behaviours. Other common types are `IFT_ETHER` (for Ethernet drivers) and `IFT_TUNNEL` (for tunnel pseudo-devices).

`if_initname` sets the user-visible name. `discname` is the string "disc", and `unit` is the unit number passed in by the cloning framework. Together they form `disc0`, `disc1`, and so on.

The next several lines fill in callbacks and per-interface data: the MTU, the flags, the `ioctl` handler (`discioctl`), the output function (`discoutput`), the maximum send queue length, and so on. This is the network equivalent of the `cdevsw` table from Section 2; the difference is that it is filled into a per-interface object rather than into a static table.

`if_attach(ifp)` makes the interface visible to user space. After this call returns, `ifconfig disc0` works, the interface shows up in `netstat -i`, and protocols can bind to it.

`bpfattach(ifp, DLT_NULL, ...)` attaches the interface to the BPF (Berkeley Packet Filter) machinery, which is what `tcpdump` reads. `DLT_NULL` declares the link-layer type as "no link layer", appropriate for a loopback. An Ethernet driver would call `bpfattach(ifp, DLT_EN10MB, ETHER_HDR_LEN)`. Without `bpfattach`, `tcpdump` cannot see the interface's traffic, even though the interface itself works.

The destruction path mirrors the creation path, in reverse:

```

static void
disc_clone_destroy(struct ifnet *ifp)
{
    struct disc_softc *sc;

    sc = ifp->if_softc;

    bpfdetach(ifp);
}

```

```
    if_detach(ifp);
    if_free(ifp);

    free(sc, M_DISC);
}
```

bpfdetach first, because tcpdump may have a reference. if_detach next, because the network stack may still be queuing traffic to the interface; if_detach drains the queue and removes the interface from the visible list. if_free last, because the ifnet may still be referenced by sockets that the upper layers have not yet finished cleaning up; if_free defers the actual free until the last reference goes away.

The disc(4) driver is roughly 200 lines. A real Ethernet driver is closer to 5000, but the integration boilerplate (allocate, initname, attach, bpfattach, detach, bpfdetach, free) is identical. The 4800 extra lines are protocol-specific details: descriptor rings, interrupt handlers, MAC address management, multicast filters, statistics, link-state polling, and so on. Each is its own pattern, and Chapter 28 covers them in detail. The integration framing covered here is the foundation under all of them.

24.6.4 How an Operator Sees the Result

Once disc_clone_create returns successfully, the operator can manipulate the interface from the shell:

```
$ sudo ifconfig disc create
$ ifconfig disc0
disc0: flags=8049<UP,LOOPBACK,RUNNING,MULTICAST> metric 0 mtu 1500
$ sudo ifconfig disc0 inet 169.254.99.99/32
$ sudo tcpdump -i disc0 &
$ ping -c1 169.254.99.99
... ping output ...
$ sudo ifconfig disc destroy
```

Each of these commands hits a different part of the integration:

- ifconfig disc create calls disc_clone_create, which builds the ifnet and attaches it.
- ifconfig disc0 reads the ifnet's flags and MTU through the if_t accessors.
- ifconfig disc0 inet 169.254.99.99/32 calls into discioctl with SIOCAIFADDR, the ioctl that adds an address.
- tcpdump -i disc0 opens the BPF tap that bpfattach created.
- ping -c1 sends a packet, which routes through discoutput, gets dropped, and never returns.
- ifconfig disc destroy calls disc_clone_destroy, which detaches and frees.

The whole integration is visible at the user-space level. None of the underlying protocol machinery had to change to accommodate the new driver; the network stack's framework already had a slot for it.

24.6.5 What This Pattern Generalises To

The same registration pattern applies to many other subsystems:

- The **sound stack** (`sys/dev/sound`) uses `pcm_register` and `pcm_unregister` to make a sound device visible. The driver fills in callbacks for buffer playback, mixer access, and channel configuration.
- The **USB stack** (`sys/dev/usb`) uses `usb_attach` and `usb_detach` to register USB device drivers. The driver fills in callbacks for transfer setup, control requests, and disconnection.
- The **GEOM I/O framework** (`sys/geom`) uses `g_attach` and `g_detach` to register storage providers and consumers. The driver fills in callbacks for I/O start, completion, and orphaning.
- The **CAM SIM framework** (`sys/cam`) uses `cam_sim_alloc` and `xpt_bus_register` to register storage adapters. Section 6 walks through this in more detail.
- The **kobj method dispatch system** (which we have already seen behind `device_method_t`) is itself a registration framework: the driver declares a methods table and the kobj subsystem dispatches calls through it.

In every case the steps are the same: allocate the framework's object, fill in callbacks, call the registration function, take traffic, and unregister cleanly. The vocabulary changes, but the rhythm does not.

24.6.6 Wrapping Up Section 5

Section 5 used the network stack to illustrate a registration-style integration. The driver allocates an `ifnet`, names it, fills in callbacks, attaches it to the stack, attaches it to BPF, takes traffic, and tears down in reverse order at destroy time. The pattern is small and well bounded; the protocol machinery sits behind it and is the subject of Chapter 27.

The reader who is not writing a network driver gets a useful payoff from this section even without applying it to `myfirst`: every other registration-style integration in the FreeBSD kernel follows the same shape. Once the rhythm of allocate-name-fill-attach-trafficdetach-free is internalised, the storage stack in Section 6 will look familiar at a glance.

In Section 6 we apply the same lens to the CAM storage stack. The vocabulary changes (`cam_sim`, `xpt_bus_register`, `xpt_action`, CCBs), but the registration shape is the same.

24.7 Section 6: CAM Storage Integration (Optional)

24.7.1 Why This Section Is Optional

`myfirst` is not a storage adapter and will not become one. The reader integrating a non-storage driver should skim this section for vocabulary, take note of the registration shape that mirrors Section 5, and continue to Section 7.

The reader who is integrating a storage adapter (a SCSI host bus adapter, an NVMe controller, an emulated virtual storage controller) will find here the bare bones of how CAM expects a driver to talk to it. The complete protocol surface is large enough to fill a chapter on its own and is the topic of Chapter 27; what we cover here is just the integration framing, identical in spirit to the `if_alloc / if_attach` framing we used for networking.

24.7.2 What CAM Is

CAM (Common Access Method) is FreeBSD's storage subsystem above the device-driver layer. It owns the queue of pending I/O requests, the abstract notion of a target and a logical unit number (LUN), the path-routing

logic that sends a request to the right adapter, and the set of generic peripheral drivers (da(4) for disks, cd(4) for optical, sa(4) for tape) that turn block I/O into protocol-specific commands. The driver sits underneath CAM and is responsible only for the adapter-specific work of sending commands to the hardware and reporting completions.

The vocabulary CAM uses is small but specific:

- A **SIM** (SCSI Interface Module) is the framework's view of a storage adapter. The driver allocates one with `cam_sim_alloc`, fills in a callback (the action function), and registers it with `xpt_bus_register`. The SIM is the analogue of an `ifnet` for the storage stack.
- A **CCB** (CAM Control Block) is a single I/O request. CAM hands a CCB to the driver through the action callback; the driver inspects the CCB's `func_code`, performs the requested action, fills in the result, and returns the CCB to CAM with `xpt_done`. CCBs are the analogue of `mbufs` for the storage stack, with the difference that a CCB carries both the request and the response.
- A **path** identifies a destination as a (bus, target, LUN) triple. The driver calls `xpt_create_path` to build a path it can use for asynchronous events.
- The **XPT** (Transport Layer) is the central CAM dispatch mechanism. The driver calls `xpt_action` to send a CCB to CAM (or to itself, for self-targeted actions); CAM eventually calls back into the driver's action function for I/O CCBs targeted at the driver's bus.

24.7.3 The Registration Lifecycle

For a single-channel adapter the registration steps are:

1. Allocate a CAM device queue with `cam_simq_alloc(maxq)`.
2. Allocate a SIM with `cam_sim_alloc(action, poll, "name", softc, unit, mtx, max_tagged, max_dev_transactions, devq)`.
3. Lock the driver's mutex.
4. Register the SIM with `xpt_bus_register(sim, dev, 0)`.
5. Create a path that the driver can use for events: `xpt_create_path(&path, NULL, cam_sim_path(sim), CAM_TARGET_WILDCARD, CAM_LUN_WILDCARD)`.
6. Unlock the mutex.

The cleanup runs in reverse order:

1. Lock the driver's mutex.
2. Free the path with `xpt_free_path(path)`.
3. Deregister the SIM with `xpt_bus_deregister(cam_sim_path(sim))`.
4. Free the SIM with `cam_sim_free(sim, TRUE)`. The `TRUE` argument tells CAM to free the underlying `devq` as well; pass `FALSE` if the driver wants to retain the `devq` for reuse.
5. Unlock the mutex.

The `ahci(4)` driver in `/usr/src/sys/dev/ahci/ahci.c` is a good real-world example. Its channel attach path includes the canonical sequence:

```
ch->sim = cam_sim_alloc(ahciaction, ahcipoll, "ahcich", ch,
    device_get_unit(dev), (struct mtx *)&ch->mtx,
```

```

    (ch->quirks & AHCI_Q_NOCCS) ? 1 : min(2, ch->numslots),
    (ch->caps & AHCI_CAP_SNCQ) ? ch->numslots : 0,
    devq);
if (ch->sim == NULL) {
    cam_simq_free(devq);
    device_printf(dev, "unable to allocate sim\n");
    error = ENOMEM;
    goto err1;
}
if (xpt_bus_register(ch->sim, dev, 0) != CAM_SUCCESS) {
    device_printf(dev, "unable to register xpt bus\n");
    error = ENXIO;
    goto err2;
}
if (xpt_create_path(&ch->path, NULL, cam_sim_path(ch->sim),
    CAM_TARGET_WILDCARD, CAM_LUN_WILDCARD) != CAM_REQ_CMP) {
    device_printf(dev, "unable to create path\n");
    error = ENXIO;
    goto err3;
}

```

The goto labels (err1, err2, err3) feed into a single cleanup section that unwinds whatever has been allocated so far. This is the standard FreeBSD-driver pattern for failure handling and is exactly the discipline Section 7 will codify.

24.7.4 The Action Callback

The action callback is the heart of a CAM driver. Its signature is `void action(struct cam_sim *sim, union ccb *ccb)`. The driver inspects `ccb->ccb_h.func_code` and dispatches:

```

static void
mydriver_action(struct cam_sim *sim, union ccb *ccb)
{
    struct mydriver_softc *sc;

    sc = cam_sim_softc(sim);

    switch (ccb->ccb_h.func_code) {
    case XPT SCSI IO:
        mydriver_start_io(sc, ccb);
        /* completion is asynchronous; xpt_done called later */
        return;

    case XPT_RESET_BUS:

```

```

        mydriver_reset_bus(sc);
        ccb->ccb_h.status = CAM_REQ_CMP;
        break;

    case XPT_PATH_INQ: {
        struct ccb_pathinq *cpi = &ccb->cpi;

        cpi->version_num = 1;
        cpi->hba_inquiry = PI_SDTR_ABLE | PI_TAG_ABLE;
        cpi->target_sprt = 0;
        cpi->hba_misc = PIM_NOBUSRESET | PIM_SEQSCAN;
        cpi->hba_eng_cnt = 0;
        cpi->max_target = 0;
        cpi->max_lun = 7;
        cpi->initiator_id = 7;
        strncpy(cpi->sim_vid, "FreeBSD", SIM_IDLEN);
        strncpy(cpi->hba_vid, "MyDriver", HBA_IDLEN);
        strncpy(cpi->dev_name, cam_sim_name(sim), DEV_IDLEN);
        cpi->unit_number = cam_sim_unit(sim);
        cpi->bus_id = cam_sim_bus(sim);
        cpi->ccb_h.status = CAM_REQ_CMP;
        break;
    }

    default:
        ccb->ccb_h.status = CAM_REQ_INVALID;
        break;
}

xpt_done(ccb);
}

```

Three branches illustrate the patterns:

`XPT SCSI IO` is the data path. The driver kicks off an asynchronous I/O (writing descriptors to the hardware, programming DMA, and so on) and returns immediately without calling `xpt_done`. The hardware completes the I/O some milliseconds later, raises an interrupt, the interrupt handler computes the result, fills in the CCB's status, and only then calls `xpt_done`. CAM does not require synchronous completion; the driver may take as long as the hardware takes.

`XPT RESET BUS` is a synchronous control. The driver performs the reset, sets `CAM_REQ_CMP`, and falls through to `xpt_done`. There is no asynchronous component.

`XPT PATH INQ` is the SIM's self-description. The first time CAM probes the SIM it issues `XPT_PATH_INQ` and reads back the bus characteristics: maximum LUN, supported flags, vendor identifiers, and so on. The driver fills in the structure and returns. Without a correct `XPT_PATH_INQ` response, CAM cannot probe targets behind

the SIM and the driver appears registered but inert.

The default branch returns `CAM_REQ_INVALID` for any function code the driver does not implement. CAM is forgiving about this; it simply treats the request as unsupported and either falls back to a generic implementation or surfaces the error to the peripheral driver.

24.7.5 How an Operator Sees the Result

Once a CAM-bearing driver has called `xpt_bus_register`, CAM probes the bus and the user-visible result is one or more entries in `camcontrol devlist`:

```
$ camcontrol devlist
<MyDriver Volume 1.0>          at scbus0 target 0 lun 0 (pass0,da0)
$ ls /dev/da0
/dev/da0
$ diskinfo /dev/da0
/dev/da0    512 ... ..
```

The `da0` device under `/dev` is a CAM peripheral driver (`da(4)`) wrapping the LUN that CAM discovered behind the SIM. The operator never deals with the SIM directly; they see only the standard `/dev/daN` interface that every block device uses. This is what makes CAM such a productive integration target: write a SIM, get full disk-style I/O for free.

24.7.6 Pattern Recognition

By now the reader should see the same shape we saw in Section 5:

Step	Networking	CAM
Allocate object	<code>if_alloc</code>	<code>cam_sim_alloc</code>
Name and configure	<code>if_initname</code> , set callbacks	implicit in <code>cam_sim_alloc</code> arguments
Attach to framework	<code>if_attach</code>	<code>xpt_bus_register</code>
Make discoverable	<code>bpfattach</code>	<code>xpt_create_path</code>
Take traffic	<code>if_output</code> callback	action callback
Complete an op	(synchronous)	<code>xpt_done(ccb)</code>
Detach	<code>bpfdetach</code> , <code>if_detach</code>	<code>xpt_free_path</code> , <code>xpt_bus_deregister</code>
Free	<code>if_free</code>	<code>cam_sim_free</code>

Other registration interfaces (`pcm_register` for sound, `usb_attach` for USB, `g_attach` for GEOM) follow the same column structure with their own vocabulary. Once the reader sees this table once, every subsequent integration is a matter of looking up the names.

24.7.7 Wrapping Up Section 6

Section 6 sketched the registration interface for a CAM SIM. The driver allocates a SIM with `cam_sim_alloc`, registers it with `xpt_bus_register`, creates a path for events, takes I/O through the action callback, completes I/O with `xpt_done`, and unregisters in reverse order at detach. The same registration-style integration pattern that we saw with `ifnet` applies, with the obvious change of vocabulary.

The reader has now seen three integration surfaces (`devfs`, `ioctl`, `sysctl`) that almost every driver needs and two registration-style surfaces (network, CAM) that some drivers need. In Section 7 we step back and codify the lifecycle discipline that holds it all together: the order of registration in attach, the order of teardown in detach, and the small set of patterns that distinguish a driver that loads, runs, and unloads cleanly from one that leaks resources or panics on detach.

24.8 Section 7: Registration, Teardown, and Cleanup Discipline

24.8.1 The Cardinal Rule

A driver that integrates with the kernel through several frameworks (`devfs` for `/dev`, `sysctl` for tunables, `ifnet` for networking, CAM for storage, callouts for timers, taskqueues for deferred work, and so on) accumulates a small zoo of allocated objects and registered callbacks. Every one of these has the same property: it must be released in the reverse order in which it was created. Forgetting this turns clean detach into a kernel panic, leaks resources at module unload, and scatters dangling pointers through subsystems the driver no longer owns.

The cardinal rule of integration is therefore very simple to state, even if applying it cleanly requires care:

Every successful registration must be paired with a deregistration. The order of deregistration is the reverse of the order of registration. A failed registration must trigger the deregistration of every preceding successful one before the function returns the failure.

That single sentence describes the entire lifecycle discipline. The rest of this section is a guided tour of how to apply it.

24.8.2 Why Reverse Order

The reverse-order rule sounds arbitrary; it is not. Each registration is a promise to the framework that “from now until I call deregister, you may call back into me, depend on my state, or hand me work.” A framework that has a callback into the driver and that holds work for it cannot safely be torn down while another framework still has access to the same state.

For example, suppose the driver registers a callout, then a `cdev`, then a `sysctl` OID. The `cdev`’s read callback may consult a value that the callout updates; the callout, in turn, may read state that the `sysctl` OID exposes. If detach tears down the callout first, then while the `cdev` is being torn down, a read from user space could try to consult a value that the callout was supposed to keep refreshed; the value is now stale and the read returns nonsense. If detach tears down the `cdev` first, then there is no way for read to come in any more, and the callout can be safely cancelled. The order matters.

The general rule is: tear down whatever can call into you, before tearing down what it depends on.

For most drivers the dependency chain is the same as the creation order:

- The cdev depends on the softc (the cdev's callbacks dereference `si_drv1`).
- The sysctl OIDs depend on the softc (they point at softc fields).
- The callouts and taskqueues depend on the softc (they receive a softc pointer as their argument).
- The interrupt handlers depend on the softc, the locks, and any DMA tags.
- The DMA tags and bus resources depend on the device.

If the driver creates these in this order, it should destroy them in the exact reverse order: interrupts first (they can fire at any time), then callouts and taskqueues (they execute at any time), then cdevs (they take user-space calls), then sysctl OIDs (the framework cleans these up automatically), then DMA, then bus resources, then locks. The softc itself is the last thing to free.

24.8.3 The `goto err1` Pattern in Attach

The hardest place to apply the rule is in attach, when a partial failure can leave the driver halfway initialised. The canonical FreeBSD pattern is the chain of `goto` labels, each of which represents the cleanup needed up to that point:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
    int error;

    sc->sc_dev = dev;
    mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);
    strncpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
    sc->sc_msglen = strlen(sc->sc_msg);

    TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default", &sc->sc_debug);

    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_WHEEL;
    args.mda_mode = 0660;
    args.mda_si_drv1 = sc;
    args.mda_unit = device_get_unit(dev);

    error = make_dev_s(&args, &sc->sc_cdev,
        "myfirst%d", device_get_unit(dev));
    if (error != 0)
        goto fail_mtx;
```

```

    myfirst_sysctl_attach(sc);

    DPRINTF(sc, MYF_DBG_INIT, "attach: stage 3 complete\n");
    return (0);

fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}

```

The single error label here exists because there is only one point at which a real failure can occur (the `make_dev_s` call). A more elaborate driver would have one label per registration step. By convention each label is named for the step that failed (`fail_mtx`, `fail_cdev`, `fail_sysctl`), and each label runs the cleanup for every step **above** it in the function. The label that handles the last possible failure is the longest cleanup; the label that handles the first failure is the shortest.

A four-stage attach for a hypothetical hardware driver would look like:

```

static int
mydriver_attach(device_t dev)
{
    struct mydriver_softc *sc = device_get_softc(dev);
    int error;

    mtx_init(&sc->sc_mtx, "mydriver", NULL, MTX_DEF);

    error = bus_alloc_resource_any(...);
    if (error != 0)
        goto fail_mtx;

    error = bus_setup_intr(...);
    if (error != 0)
        goto fail_resource;

    error = make_dev_s(...);
    if (error != 0)
        goto fail_intr;

    return (0);

fail_intr:
    bus_teardown_intr(...);
fail_resource:
    bus_release_resource(...);
}

```

```
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}
```

The labels read top-to-bottom in the same order as the cleanup actions execute. A failure at any step jumps to the matching label and falls through the cleanup labels for every preceding successful step. The pattern is so common that reading driver code without it is jarring; reviewers expect to see it.

24.8.4 The Detach Mirror

Detach should be the exact mirror of a successful attach. Every registration done in attach must have a matching deregistration in detach, in reverse order:

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count > 0) {
        mtx_unlock(&sc->sc_mtx);
        return (EBUSY);
    }
    mtx_unlock(&sc->sc_mtx);

    DPRINTF(sc, MYF_DBG_INIT, "detach: tearing down\n");

    /*
     * destroy_dev drains any in-flight cdevsw callbacks. After
     * this call returns, no new open/close/read/write/ioctl can
     * arrive, and no in-flight callback is still running.
     */
    destroy_dev(sc->sc_cdev);

    /*
     * The per-device sysctl context is torn down automatically by
     * the framework after detach returns successfully. Nothing to
     * do here.
     */

    mtx_destroy(&sc->sc_mtx);
    return (0);
}
```

The detach starts by checking `open_count` under the mutex; if anyone holds the device open, detach refuses (returning `EBUSY`) so the operator gets a clear error rather than a panic. After the check, the function tears down whatever attach allocated, in reverse order: `cdev` first, then `sysctl` (automatic), then mutex.

The early `EBUSY` return is the “soft” detach pattern. It puts the responsibility for closing the device on the operator: `kldunload myfirst` will fail until the operator runs `kill cat` (or whatever else is holding the device open). The alternative is the “hard” pattern of refusing detach only if a critical resource is in use and accepting that ordinary file descriptors are a kernel responsibility to drain. The hard pattern is more involved (it usually requires `dev_ref` and `dev_rel`) and is left as a topic for Chapter 27’s CAM-driver section.

24.8.5 Module Event Handlers

Up to this point we have discussed attach and detach, the per-device lifecycle hooks Newbus calls when a driver instance is added or removed. There is also a per-module lifecycle, controlled by the function registered through `DRIVER_MODULE` (or `MODULE_VERSION` plus a `DECLARE_MODULE`). The kernel calls this function on `MOD_LOAD`, `MOD_UNLOAD`, and `MOD_SHUTDOWN`.

For most drivers the per-module hook is unused. `DRIVER_MODULE` takes a `NULL` event handler by default, and the kernel does the right thing: on `MOD_LOAD` it adds the driver to the bus’s driver list, and on `MOD_UNLOAD` it walks the bus and detaches every instance. The driver author writes only attach and detach.

Some drivers do need a module-level hook, however. The classic case is a driver that has to set up a global resource (a global hash table, a global mutex, a global event handler) that is shared across all instances. The hook for that is:

```
static int
myfirst_modevent(module_t mod, int what, void *arg)
{
    switch (what) {
        case MOD_LOAD:
            /* allocate global state */
            return (0);
        case MOD_UNLOAD:
            /* free global state */
            return (0);
        case MOD_SHUTDOWN:
            /* about to power off; flush anything important */
            return (0);
        default:
            return (EOPNOTSUPP);
    }
}

static moduledata_t myfirst_mod = {
    "myfirst", myfirst_modevent, NULL
};
```

```
DECLARE_MODULE(myfirst, myfirst_mod, SI_SUB_DRIVERS, SI_ORDER_ANY);  
MODULE_VERSION(myfirst, 1);
```

The `myfirst` driver in this chapter does not have global state and therefore does not need a `modevent`. The default `DRIVER_MODULE` machinery is sufficient. We mention the hook here so the reader can recognise it in larger drivers.

24.8.6 EVENTHANDLER for System Events

Some drivers care about events that happen elsewhere in the kernel: a process is forking, the system is shutting down, the network is changing state, and so on. The `EVENTHANDLER` mechanism lets a driver register a callback for a named event:

```
static eventhandler_tag myfirst_eh_tag;  
  
static void  
myfirst_shutdown_handler(void *arg, int howto)  
{  
    /* called when the system is shutting down */  
}  
  
/* In attach: */  
myfirst_eh_tag = EVENTHANDLER_REGISTER(shutdown_pre_sync,  
    myfirst_shutdown_handler, sc, EVENTHANDLER_PRI_ANY);  
  
/* In detach: */  
EVENTHANDLER_DEREGISTER(shutdown_pre_sync, myfirst_eh_tag);
```

The `shutdown_pre_sync`, `shutdown_post_sync`, `shutdown_final`, and `vm_lowmem` event names are the most commonly used in drivers. Each is a documented hook point and each has its own semantics about what the driver may do (sleep, allocate memory, take locks, talk to hardware) inside the callback.

The cardinal rule applies to event handlers exactly as it does to everything else: every successful `EVENTHANDLER_REGISTER` must be paired with an `EVENTHANDLER_DEREGISTER` in the reverse order. Forgetting the deregister leaves a dangling function pointer in the event-handler table; the next time the event fires after module unload, the kernel will jump into freed memory and panic.

24.8.7 SYSINIT for One-Shot Kernel Init

One last machinery worth knowing about is `SYSINIT(9)`, the kernel's compile-time-registered one-shot init mechanism. A `SYSINIT` declaration in driver code:

```
static void
myfirst_sysinit(void *arg __unused)
{
    /* runs once, very early at kernel boot */
}
SYSINIT(myfirst_init, SI_SUB_DRIVERS, SI_ORDER_FIRST,
        myfirst_sysinit, NULL);
```

declares a function that runs at a specific point during kernel init, before any user-space process exists. `SYSINIT` is rarely needed in driver code; the function does not get re-run when the module reloads, so it does not give the driver a chance to set up per-load state. Most drivers that think they want `SYSINIT` actually want a `MOD_LOAD` event handler instead.

The matching `SYSUNINIT(9)` declaration:

```
SYSUNINIT(myfirst_uninit, SI_SUB_DRIVERS, SI_ORDER_FIRST,
        myfirst_sysuninit, NULL);
```

declares a function that runs at the corresponding teardown point. The order of declaration matters: `SI_SUB_DRIVERS` runs after `SI_SUB_VFS` but before `SI_SUB_KICK_SCHEDULER`, so a `SYSINIT` at this level can already use the file system but cannot yet schedule processes.

24.8.8 bus_generic_detach and device_delete_children

Drivers that are themselves buses (a PCI-to-PCI bridge driver, a USB hub driver, a bus-style virtual driver) have child devices attached to them. Detaching the parent must first detach all the children, in the right order. The framework provides two helpers:

`bus_generic_detach(dev)` walks the device's children and calls `device_detach` on each one. It returns 0 if every child detached successfully, or the first non-zero return code if any child refused.

`device_delete_children(dev)` calls `bus_generic_detach` and then `device_delete_child` for every child, freeing the child device structures.

A bus-style driver's detach should always begin with one of these two:

```
static int
mybus_detach(device_t dev)
{
    int error;

    error = bus_generic_detach(dev);
    if (error != 0)
        return (error);

    /* now safe to tear down per-bus state */
```

```
...  
return (0);  
}
```

If the driver tears down its bus state before detaching the children, the children find their parent's resources freed out from under them and crash. The order is therefore: detach children first (`bus_generic_detach`), then tear down per-bus state.

24.8.9 Putting It All Together

The lifecycle discipline can be summarised in a small checklist that every driver should pass:

1. **Every allocation has a corresponding free.** Track this with a `goto err` chain in `attach` and a mirror order in `detach`.
2. **Every registration has a corresponding deregistration.** This applies equally to `cdevs`, `sysctls`, `callouts`, `taskqueues`, `event handlers`, `interrupt handlers`, `DMA tags`, and `bus resources`.
3. **The order of teardown is the reverse of the order of setup.** A driver that violates this will leak, panic, or both.
4. **The detach function refuses the operation if any externally-visible resource is still in use.** `EBUSY` is the right return code.
5. **The detach function never frees the softc; the framework does that automatically after detach returns successfully.**
6. **The cdev is destroyed (not freed) with `destroy_dev`, and `destroy_dev` blocks until in-flight callbacks return.**
7. **The per-device `sysctl` context is torn down automatically; the driver does not call `sysctl_ctx_free` for it.**
8. **Bus-style drivers detach their children first with `bus_generic_detach` or `device_delete_children`, then tear down per-bus state.**
9. **A failed attach unwinds every preceding step before returning the failure code.**
10. **The kernel never sees a half-attached driver: `attach` either succeeds completely or fails completely.**

The `myfirst` driver of stage 3 passes every item on this checklist; the lab in Section 9 has the reader inject a deliberate failure to see the unwinding in action.

24.8.10 Wrapping Up Section 7

Section 7 codified the lifecycle discipline that holds every previous section together. The `goto err` chain in `attach` and the reverse-order teardown in `detach` are the two patterns the reader will use in every driver they write from now on. Module-level hooks (`MOD_LOAD`, `MOD_UNLOAD`), event-handler registration (`EVENTHANDLER_REGISTER`), and bus-style detach (`bus_generic_detach`) are the variations that some drivers need; for a single-instance pseudo-driver such as `myfirst`, the basic `attach/detach` pair plus the `goto err` chain is sufficient.

In Section 8 we step back to the chapter's other meta-topic: how the driver evolved from version 1.0 in Part II through 1.5-`channels` in Part III, 1.6-`debug` in Chapter 23, and now 1.7-`integration` here, and how that

evolution should be visible in source comments, in the `MODULE_VERSION` declaration, and in user-visible places such as the `sysctl` version OID. The reader will leave Chapter 24 not just with a fully integrated driver but with a discipline for how a driver's version number tells a reader what to expect.

24.9 Section 8: Refactoring and Versioning

24.9.1 A Driver Has a History

The `myfirst` driver did not appear fully formed. It started in Part II as a single-file demonstration of how `DRIVER_MODULE` works, grew in Part III to support multiple instances and per-channel state, gained debug and tracing infrastructure in Chapter 23, and acquires its full integration surface in this chapter. Each step left the source larger and more capable.

Drivers in the FreeBSD tree have similarly long histories. `null(4)` dates back to 1982; its `cdevsw` has been refactored at least three times to accommodate kernel evolution, but its user-visible behaviour is unchanged. `if_ethersubr.c` predates IPv6 and its API has grown new functions every release while the legacy ones stayed in place. The art of driver maintenance is partly about knowing how to extend a driver without breaking what came before.

This section is a short pause to talk about three closely related disciplines: how to refactor a driver as it grows, how to express the version it is at, and how to decide what counts as a breaking change. The chapter's working example is the transition from 1.6-debug (the end of Chapter 23) to 1.7-integration (the end of this chapter), but the patterns generalise to any driver project.

24.9.2 From One File to Several

The `myfirst` driver in Chapter 23 was a small but real source tree:

```
myfirst.c      /* probe, attach, detach, cdevsw, read, write */
myfirst.h      /* softc, function declarations */
myfirst_debug.c /* SDT provider definition */
myfirst_debug.h /* DPRINTF, debug class bits */
Makefile
```

Stage 3 of this chapter adds two new source files:

```
myfirst_ioctl.c /* ioctl dispatcher */
myfirst_ioctl.h /* PUBLIC ioctl interface for user space */
myfirst_sysctl.c /* sysctl OID construction */
```

The decision to split each new concern into its own pair of files is deliberate. A single 2000-line `myfirst.c` would compile and load and work, but it would also be harder to read, harder to test, and harder for a co-maintainer to navigate. Splitting along concern lines (open/close vs ioctl vs sysctl vs debug) lets each file fit on a screen and lets the reader understand one concern at a time.

The pattern is roughly:

- `<driver>.c` holds probe, attach, detach, the `cdevsw` struct, and the small set of `cdevsw` callbacks (open, close, read, write).
- `<driver>.h` holds the `softc`, function declarations shared across files, and any private constants. **Not** included by user space.
- `<driver>_debug.c` and `<driver>_debug.h` hold the SDT provider, the `DPRINTF` macro, the debug class enumeration. **Not** included by user space.
- `<driver>_ioctl.c` holds the `ioctl` dispatcher. `<driver>_ioctl.h` is the **public** header, includes only `sys/types.h` and `sys/ioccom.h`, and is safe to include from user-space code.
- `<driver>_sysctl.c` holds the `sysctl` OID construction. **Not** included by user space.

The split between public and private headers matters for two reasons. First, public headers must compile cleanly without kernel context (`_KERNEL` is not defined when user space includes them); a header that pulls in `sys/lock.h` and `sys/mutex.h` will fail to compile from a user-space build. Second, public headers are part of the driver's contract with user space and must be installable into a system-wide location such as `/usr/local/include/myfirst/myfirst_ioctl.h`. A private header that accidentally becomes public is a maintenance trap: every user-space program that includes it pins the driver's internal layout, and any future refactor breaks them.

The `myfirst_ioctl.h` header in this chapter is the driver's only public header. It is small, self-contained, and uses only stable types.

24.9.3 Version Strings, Version Numbers, and the API Version

A driver carries three different versions, each meaning something different.

The **release version** is the human-readable string printed in `dmesg`, exposed through `dev.<driver>.0.version`, and used in conversation and documentation. The `myfirst` driver uses dotted strings such as `1.6-debug` and `1.7-integration`. The format is convention; what matters is that the string is short, descriptive, and unique per release.

The **module version** is an integer declared with `MODULE_VERSION(<name>, <integer>)`. It is used by the kernel to enforce dependencies between modules. A module that depends on `myfirst` declares `MODULE_DEPEND(other, myfirst, 1, 1, 1)`, where the three integers are the minimum, preferred, and maximum acceptable versions. Bumping the module version signals "I broke compatibility with previous versions; modules that depend on me must be rebuilt."

The **API version** is the integer exposed through `MYFIRSTIOC_GETVER` and stored in the `MYFIRST_IOCTL_VERSION` constant. It is used by user-space programs to detect API drift before they issue `ioctls` that might fail. Bumping the API version signals "the user-space-visible interface changed in a way that older programs will not handle."

The three versions are independent. The same release may bump only the API version (because a new `ioctl` was added) without bumping the module version (because in-kernel dependents are unaffected). Conversely, a refactor that changes the layout of an exported in-kernel data structure may bump the module version without bumping the API version, because user space sees no change.

For `myfirst`, the chapter uses these values:

```
/* myfirst_sysctl.c */
#define MYFIRST_VERSION "1.7-integration"

/* myfirst.c */
MODULE_VERSION(myfirst, 1);

/* myfirst_ioctl.h */
#define MYFIRST_IOCTL_VERSION 1
```

The release is 1.7-integration because we just landed the integration work. The module version remains 1 because no in-kernel dependents exist. The API version is 1 because this is the first chapter that exposes ioctls; the chapter's stage 2 introduced the interface, and any future change to the ioctl layout would have to bump it.

24.9.4 When to Bump Each

The rule for bumping the **release version** is “every time the driver changes in a way the operator might care about.” Adding a feature, changing default behaviour, fixing a notable bug all qualify. The release version is for humans; it should change often enough that the field is informative.

The rule for bumping the **module version** is “when in-kernel users of the driver would need a recompile to keep working.” Adding a new in-kernel function is not a bump (old dependents still work). Removing a function or changing its signature is a bump. Renaming a struct field that other modules read is a bump. A driver that exports nothing in-kernel may keep its module version at 1 forever.

The rule for bumping the **API version** is “when an existing user-space program would misinterpret the driver's responses or fail in a non-obvious way.” Adding a new ioctl is not a bump (old programs do not use it). Changing the layout of an existing ioctl's argument structure is a bump. Renumbering an existing ioctl is a bump. A driver that has not yet released to users may freely change the API version while the interface is still being designed; once the first user has shipped against it, every change is a public event.

24.9.5 Compatibility Shims

A driver that has shipped widely accumulates compatibility shims. The classic shape is a “version 1” ioctl that the driver supports forever next to a “version 2” ioctl that supersedes it. User-space programs that use the v1 interface keep working, programs that use v2 get the new behaviour, and the driver carries both code paths.

The cost of shims is real. Every shim is code that has to be tested, documented, and maintained. Every shim is also a covered API that constrains future refactors. A driver with five shims is harder to evolve than a driver with one.

The discipline is therefore to design carefully up front so that shims are rare. Three habits help:

- **Use named constants, not literal numbers.** A program that says MYFIRSTIOC_SETMSG rather than 0x802004d3 will keep working when the driver renumbers the ioctl, because both header and program rebuild against the new header.

- **Prefer additive change over mutating change.** When the driver needs to expose a new field, add a new `ioctl` rather than extending an existing structure. The old `ioctl` keeps its layout; the new one carries the extra information.
- **Version every public structure.** A struct `myfirst_v1_args` paired with `MYFIRSTIOC_SETMSG_V1` is a small annotation now and a large compatibility win later.

`myfirst` in this chapter is so small that it does not yet have any shims. The chapter's sole concession to versioning is the `MYFIRSTIOC_GETVER` `ioctl`, which gives a future maintainer a clean place to add shim logic when the time comes.

24.9.6 A Worked Refactor: Splitting `myfirst.c`

The transition from Chapter 23's stage 3 (debug) to this chapter's stage 3 (`sysctl`) is itself a small refactor. The starting source had a single 1000-line `myfirst.c` and a small `myfirst_debug.c`. The ending source has the same `myfirst.c` shrunk by about 100 lines, plus two new files (`myfirst_ioctl.c` and `myfirst_sysctl.c`) that absorb the new logic.

The refactor steps were:

1. Add the two new files with the new logic.
2. Add the new function declarations to `myfirst.h` so the `cdevsw` can reference `myfirst_ioctl`.
3. Update `myfirst.c` to call `myfirst_sysctl_attach(sc)` from `attach`.
4. Update the `Makefile` to list the new files in `SRCS`.
5. Build, load, exercise, and verify that the driver still passes every Chapter 23 lab.
6. Bump the release version to 1.7-integration.
7. Add the `MYFIRSTIOC_GETVER` test to the chapter's verification scripts.

Each step is small enough to review on its own. None of them touches the existing logic, which means the refactor is unlikely to introduce regressions in code that worked before. This is the discipline of additive refactoring: grow the driver outward by adding new files and new declarations, leave the existing code in place, and bump the version when the dust settles.

A more aggressive refactor (renaming a function, rearranging a structure, changing the `cdevsw`'s flag set) would need a different discipline: a single commit per change, regression tests run after each, and a clear note in the version bump about what was rearranged. Drivers that ship widely use this discipline for every release; the in-tree `if_em` driver, for example, has a multi-commit refactor in nearly every minor release of FreeBSD, each commit rolled out independently and tested in isolation.

24.9.7 Three In-Tree Drivers Compared

Three drivers in the FreeBSD source tree illustrate the source-layout discipline at three points along the complexity spectrum. Reading them as a triplet makes the patterns visible.

`/usr/src/sys/dev/null/null.c` is the smallest. It is a single 200-line source file with one `cdevsw` table, one set of callbacks, no separate header, and no debug or `sysctl` machinery. The whole driver fits on three printed pages. This is the layout for a driver whose entire job is to be present and to absorb (or generate) bytes; integration is only at the `cdev` layer.

`/usr/src/sys/net/if_disc.c` is a two-file network driver: `if_disc.c` for the driver code and the implicit `if.h` for the framework. The driver registers with the network stack but otherwise has no `sysctl` tree, no debug subtree, and no public `ioctl` header (it uses the standard `if_ioctl` set defined by the framework). This is the layout for a driver that is an instance of a framework rather than its own thing; the framework defines the surface, the driver fills in the slots.

`/usr/src/sys/dev/ahci/ahci.c` is a multi-file driver with separate files for the AHCI core, the PCI attach glue, the device-tree FDT attach glue, the enclosure-management code, and the bus-specific logic. Each file is dedicated to one concern; the central file is over 5000 lines but the per-file size is manageable. This is the layout that scales to a real production driver: split by concern, glue by header, and use the file boundary as the unit of refactoring.

The `myfirst` driver in this chapter sits in the middle. Stage 3 has five source files: `myfirst.c` (open/close/read/write and the `cdevsw`), `myfirst.h` (softc, declarations), `myfirst_debug.c` and `myfirst_debug.h` (debug and SDT), `myfirst_ioctl.c` and `myfirst_ioctl.h` (ioctl, with the latter being public), and `myfirst_sysctl.c` (`sysctl` tree). This is enough to demonstrate the split-by-concern pattern without the cognitive overhead of a fifty-file driver. A reader who needs to grow `myfirst` further has a clear template: add a new pair of files for the new concern, add the source file to `SRCS`, add the public header to the install set if user space needs it, and update `MYFIRST_VERSION`.

24.9.8 Wrapping Up Section 8

Section 8 closed the loop on the chapter's other theme: how a driver's source layout, version numbers, and refactor discipline track its evolution. The driver milestone for this chapter is 1.7-integration, expressed simultaneously as the release string in `MYFIRST_VERSION`, the module version 1 (unchanged because no in-kernel dependents exist), and the API version 1 (set for the first time because this is the first chapter that exposes a stable `ioctl` interface). Refactoring was kept additive, so no shim was needed.

The reader has now seen the full integration surface: Sections 2 through 4 covered the three universals (`devfs`, `ioctl`, `sysctl`), Sections 5 and 6 sketched the registration-style integrations (network, CAM), Section 7 codified the lifecycle discipline, and Section 8 framed the whole as an evolution that the driver's version numbers should track. The remaining sections of the chapter give the reader hands-on practice with the same material.

24.9.9 Putting It All Together: The Final Attach and Detach

Before the chapter moves to the labs, it is worth seeing the chapter's complete attach and detach functions in one place. They tie every previous section together: the `cdev` construction from Section 2, the `ioctl` wiring from Section 3, the `sysctl` tree from Section 4, the lifecycle discipline from Section 7, and the version handling from Section 8.

The complete attach for stage 3:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
```

```
int error;

/* 1. Stash the device pointer and initialise the lock. */
sc->sc_dev = dev;
mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

/* 2. Initialise the in-driver state to its defaults. */
strncpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
sc->sc_msglen = strlen(sc->sc_msg);
sc->sc_open_count = 0;
sc->sc_total_reads = 0;
sc->sc_total_writes = 0;
sc->sc_debug = 0;

/* 3. Read the boot-time tunable for the debug mask. If the
 * operator set hw.myfirst.debug_mask_default in
 * /boot/loader.conf, sc_debug now holds that value;
 * otherwise sc_debug remains zero.
 */
TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default", &sc->sc_debug);

/* 4. Construct the cdev. The args struct gives us a typed,
 * versionable interface; mda_si_drv1 wires the per-cdev
 * pointer to the softc atomically, closing the race window
 * between creation and assignment.
 */
make_dev_args_init(&args);
args.mda_devsw = &myfirst_cdevsw;
args.mda_uid = UID_ROOT;
args.mda_gid = GID_WHEEL;
args.mda_mode = 0660;
args.mda_si_drv1 = sc;
args.mda_unit = device_get_unit(dev);

error = make_dev_s(&args, &sc->sc_cdev,
    "myfirst%d", device_get_unit(dev));
if (error != 0)
    goto fail_mtx;

/* 5. Build the sysctl tree. The framework owns the per-device
 * context, so we do not need to track or destroy it
 * ourselves; detach below does not call sysctl_ctx_free.
 */
myfirst_sysctl_attach(sc);
```

```

DPRINTF(sc, MYF_DBG_INIT,
        "attach: stage 3 complete, version " MYFIRST_VERSION "\n");
return (0);

fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}

```

The complete detach for stage 3:

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* 1. Refuse detach if anyone holds the device open. The
     *    chapter's pattern is the simple soft refusal; Challenge 3
     *    walks through the more elaborate dev_ref/dev_rel pattern
     *    that drains in-flight references rather than refusing.
     */
    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count > 0) {
        mtx_unlock(&sc->sc_mtx);
        return (EBUSY);
    }
    mtx_unlock(&sc->sc_mtx);

    DPRINTF(sc, MYF_DBG_INIT, "detach: tearing down\n");

    /* 2. Destroy the cdev. destroy_dev blocks until every
     *    in-flight cdevsw callback returns; after this call,
     *    no new open/close/read/write/ioctl can arrive.
     */
    destroy_dev(sc->sc_cdev);

    /* 3. The per-device sysctl context is torn down automatically
     *    by the framework after detach returns successfully.
     *    Nothing to do here.
     */

    /* 4. Destroy the lock. Safe now because the cdev is gone and
     *    no other code path can take it.
     */
}

```

```
    */  
    mtx_destroy(&sc->sc_mtx);  
  
    return (0);  
}
```

Two things deserve a final note.

The order of operations is the strict reverse of attach: lock first in attach, lock destroyed last in detach; cdev created near the end of attach, cdev destroyed near the start of detach; sysctl tree created last in attach, sysctl tree torn down first (by the framework, automatically) in detach. This is the cardinal rule of Section 7 in concrete form.

The refusal pattern in detach (the `if (open_count > 0)` check) is the chapter's choice for simplicity. A real driver may need the more elaborate `dev_ref/dev_rel` machinery to implement a draining detach; Challenge 3 walks through that variant. For `myfirst`, the simple refusal gives the operator a clear error and is sufficient.

In Section 9 we move from explanation to practice. The labs walk the reader through building stage 1, stage 2, and stage 3 of the integration in turn, with verification commands and expected output for each. After the labs come the challenge exercises (Section 10), the troubleshooting catalogue (Section 11), and the wrap-up and bridge that close the chapter.

24.10 Hands-on Labs

The labs in this section take the reader from a freshly cloned working tree through every integration surface added in the chapter. Each lab is small enough to complete in one sitting and is paired with a verification command that confirms the change. Run the labs in order; later labs build on earlier ones.

The companion files under `examples/part-05/ch24-integration/` contain three staged reference drivers (`stage1-devfs/`, `stage2-ioctl/`, `stage3-sysctl/`) that match the milestones of this chapter. The labs assume the reader either starts from their own end-of-Chapter-23 driver (version 1.6-debug) or copies the appropriate stage directory into a working location, makes changes there, and consults the matching staged directory if they get stuck.

Each lab uses a real FreeBSD 14.3 system. A virtual machine is fine; do not run these labs on a production host because module load and unload can hang or panic the system if the driver has bugs.

24.10.1 Lab 1: Build and Load the Stage 1 Driver

Goal: bring the driver from the Chapter 23 baseline (1.6-debug) up to the stage 1 milestone of this chapter (a properly constructed cdev under `/dev/myfirst0`).

Setup:

Start from your own end-of-Chapter-23 working tree (the driver at version 1.6-debug) or copy the reference tree of Chapter 23's last stage into a lab directory:

```
$ cp -r ~/myfirst-1.6-debug ~/myfirst-lab1
$ cd ~/myfirst-lab1
$ ls
Makefile  myfirst.c  myfirst.h  myfirst_debug.c  myfirst_debug.h
```

If you want to compare against the already-migrated starting point for the chapter's stage 1 (with `make_dev_s` already applied), consult `examples/part-05/ch24-integration/stage1-devfs/` as a reference solution rather than as a starting directory.

Step 1: Open `myfirst.c` and find the existing call to `make_dev`. The Chapter 23 code uses the older single-call form. Replace it with the `make_dev_args` form from Section 2:

```
struct make_dev_args args;
int error;

make_dev_args_init(&args);
args.mda_devsw = &myfirst_cdevsw;
args.mda_uid = UID_ROOT;
args.mda_gid = GID_WHEEL;
args.mda_mode = 0660;
args.mda_si_drv1 = sc;
args.mda_unit = device_get_unit(dev);

error = make_dev_s(&args, &sc->sc_cdev,
    "myfirst%d", device_get_unit(dev));
if (error != 0) {
    mtx_destroy(&sc->sc_mtx);
    return (error);
}
```

Step 2: Add `D_TRACKCLOSE` to the `cdevsw` flags (it should already have `D_VERSION`):

```
static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_flags   = D_TRACKCLOSE,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
};
```

Step 3: Confirm `myfirst_open` and `myfirst_close` use `dev->si_drv1` to recover the softc:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    ...
}
```

Step 4: Build and load:

```
$ make
$ sudo kldload ./myfirst.ko
```

Verification:

```
$ ls -l /dev/myfirst0
crw-rw---- 1 root wheel 0x... <date> /dev/myfirst0
$ sudo cat /dev/myfirst0
Hello from myfirst
$ sudo kldstat | grep myfirst
N    1 0xffff... 1...    myfirst.ko
$ sudo dmesg | tail
... (debug messages from MYF_DBG_INIT)
```

If the `ls` shows the wrong owner, group, or mode, re-check the `mda_uid`, `mda_gid`, and `mda_mode` values. If `cat` returns an empty string, check that `myfirst_read` is filling the user buffer from `sc->sc_msg`. If the load succeeds but the device does not appear, check that the `cdevsw` is referenced from `make_dev_args`.

Cleanup:

```
$ sudo kldunload myfirst
$ ls -l /dev/myfirst0
ls: /dev/myfirst0: No such file or directory
```

A successful unload removes the device node. If the unload fails with `Device busy`, check that no shell or program has the device open (`fstat | grep myfirst0`).

24.10.2 Lab 2: Add the `ioctl` Interface

Goal: extend the driver to stage 2 by adding the four `ioctl` commands from Section 3.

Setup:

```
$ cp -r examples/part-05/ch24-integration/stage1-devfs ~/myfirst-lab2
$ cd ~/myfirst-lab2
```

Step 1: Create `myfirst_ioctl.h` from the template in Section 3. Place it in the same directory as the other source files. Include `sys/ioccom.h` and `sys/types.h`. Define `MYFIRST_MSG_MAX = 256` and the four `ioctl` numbers. Do not include any kernel-only header.

Step 2: Create `myfirst_ioctl.c` from the template in Section 3. The dispatcher is a single function `myfirst_ioctl` with the standard `d_ioctl_t` signature.

Step 3: Add `myfirst_ioctl.c` to `SRCS` in the `Makefile`:

```
SRCS=    myfirst.c myfirst_debug.c myfirst_ioctl.c
```

Step 4: Update the `cdevsw` to point `.d_ioctl` at the new dispatcher:

```
.d_ioctl = myfirst_ioctl,
```

Step 5: Add `sc_msg` and `sc_msglen` to the `softc` and initialise them in `attach`:

```
strcpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
sc->sc_msglen = strlen(sc->sc_msg);
```

Step 6: Build the user-space companion. Place `myfirstctl.c` in the same directory and create a small `Makefile.user`:

```
CC?= cc
CFLAGS+= -Wall -Werror -I.

myfirstctl: myfirstctl.c myfirst_ioctl.h
    ${CC} ${CFLAGS} -o myfirstctl myfirstctl.c
```

(Note that the indentation must be a tab, not spaces, for `make` to parse the rule.)

Build the kernel module and the companion:

```
$ make
$ make -f Makefile.user
$ sudo kldload ./myfirst.ko
```

Verification:

```
$ ./myfirstctl get-version
driver ioctl version: 1
$ ./myfirstctl get-message
Hello from myfirst
$ sudo ./myfirstctl set-message "drivers are fun"
$ ./myfirstctl get-message
drivers are fun
$ sudo ./myfirstctl reset
$ ./myfirstctl get-message

$
```

If set-message returns `Permission denied`, the issue is that the device is mode `0660` and the user is not in `wheel`. Either run with `sudo` (as the verification commands above do) or change the device group to one the user belongs to with `mda_gid` and reload the module.

If set-message returns `Bad file descriptor`, the issue is that `myfirstctl` opened the device read-only. Check that the program selects `O_RDWR` for set-message and reset.

If any ioctl returns `Inappropriate ioctl for device`, the issue is a mismatch between the encoded length in `myfirst_ioctl.h` and the dispatcher's view of the data. Re-check the `_IOR/_IOW` macros and the size of the structures they declare.

Cleanup:

```
$ sudo kldunload myfirst
```

24.10.3 Lab 3: Add the Sysctl Tree

Goal: extend the driver to stage 3 by adding the sysctl OIDs from Section 4 and reading a tunable from `/boot/loader.conf`.

Setup:

```
$ cp -r examples/part-05/ch24-integration/stage2-ioctl ~/myfirst-lab3
$ cd ~/myfirst-lab3
```

Step 1: Create `myfirst_sysctl.c` from the template in Section 4. The function `myfirst_sysctl_attach(sc)` builds the entire tree.

Step 2: Add `myfirst_sysctl.c` to `SRCS` in the Makefile.

Step 3: Update `myfirst_attach` to call `TUNABLE_INT_FETCH` and `myfirst_sysctl_attach`:

```
TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default", &sc->sc_debug);
```

```
/* ... after make_dev_s succeeds: */  
myfirst_sysctl_attach(sc);
```

Step 4: Build and load:

```
$ make  
$ sudo kldload ./myfirst.ko
```

Verification:

```
$ sysctl -a dev.myfirst.0  
dev.myfirst.0.debug.classes: INIT(0x1) OPEN(0x2) IO(0x4) IOCTL(0x8) ...  
dev.myfirst.0.debug.mask: 0  
dev.myfirst.0.message_len: 18  
dev.myfirst.0.message: Hello from myfirst  
dev.myfirst.0.total_writes: 0  
dev.myfirst.0.total_reads: 0  
dev.myfirst.0.open_count: 0  
dev.myfirst.0.version: 1.7-integration
```

Open the device once and re-check the counters:

```
$ cat /dev/myfirst0  
Hello from myfirst  
$ sysctl dev.myfirst.0.total_reads  
dev.myfirst.0.total_reads: 1
```

Test the loader-time tunable. Edit `/boot/loader.conf` (back it up first):

```
$ sudo cp /boot/loader.conf /boot/loader.conf.backup  
$ sudo sh -c 'echo hw.myfirst.debug_mask_default="\0x06\" >> /boot/loader.conf'
```

Note that this only takes effect on the next reboot, and only if the module is loaded by the loader (not by `kldload` after boot). For an interactive test without rebooting, set the value before loading:

```
$ sudo kenv hw.myfirst.debug_mask_default=0x06  
$ sudo kldload ./myfirst.ko  
$ sysctl dev.myfirst.0.debug.mask  
dev.myfirst.0.debug.mask: 6
```

If the value is 0 instead of 6, check that the `TUNABLE_INT_FETCH` call uses the same string as the `kenv` command. The call must run before `myfirst_sysctl_attach` so the value is in place when the OID is created.

Cleanup:

```
$ sudo kldunload myfirst
$ sudo cp /boot/loader.conf.backup /boot/loader.conf
```

24.10.4 Lab 4: Walk the Lifecycle by Injecting a Failure

Goal: see the goto err chain in attach actually unwind by deliberately failing one of the steps.

Setup:

```
$ cp -r examples/part-05/ch24-integration/stage3-sysctl ~/myfirst-lab4
$ cd ~/myfirst-lab4
```

Step 1: Open myfirst.c and find myfirst_attach. Insert a deliberate failure right after make_dev_s succeeds:

```
error = make_dev_s(&args, &sc->sc_cdev,
    "myfirst%d", device_get_unit(dev));
if (error != 0)
    goto fail_mtx;

/* DELIBERATE FAILURE for Lab 4 */
device_printf(dev, "Lab 4: injected failure after make_dev_s\n");
error = ENXIO;
goto fail_cdev;

myfirst_sysctl_attach(sc);
return (0);

fail_cdev:
    destroy_dev(sc->sc_cdev);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
```

Step 2: Build and try to load:

```
$ make
$ sudo kldload ./myfirst.ko
kldload: an error occurred while loading module myfirst. Please check dmesg(8) for more
↪ details.
$ sudo dmesg | tail
myfirst0: Lab 4: injected failure after make_dev_s
```

Verification:

```
$ ls /dev/myfirst0
ls: /dev/myfirst0: No such file or directory
$ kldstat | grep myfirst
$
```

The cdev is gone (the goto `fail_cdev` cleanup destroyed it), the module is not loaded, and no resources leaked. If the cdev remains after the failure, the cleanup is missing a `destroy_dev` call. If the kernel panics on the next module load attempt, the cleanup is freeing or destroying something twice.

Bonus: change the failure injection to occur **before** `make_dev_s`. The cleanup chain should now skip the `fail_cdev` label and only run `fail_mtx`. Verify that the cdev was never created and that the mutex is destroyed:

```
$ sudo kldload ./myfirst.ko
$ sudo dmesg | tail
... no Lab 4 message because it now runs before make_dev_s ...
```

Cleanup:

Remove the deliberate failure block before continuing.

24.10.5 Lab 5: Trace the Integration Surfaces with DTrace

Goal: use the SDT probes from Chapter 23 to trace `ioctl`, `open`, `close`, and read traffic in real time.

Setup: stage 3 driver loaded as in Lab 3.

Step 1: Verify the probes are visible to DTrace:

```
$ sudo dtrace -l -P myfirst
  ID PROVIDER  MODULE  FUNCTION  NAME
... id myfirst  kernel  -         open
... id myfirst  kernel  -         close
... id myfirst  kernel  -         io
... id myfirst  kernel  -         ioctl
```

If the list is empty, the SDT probes are not registered. Check that `myfirst_debug.c` is in `SRCS` and that `SDT_PROBE_DEFINE*` is called from there.

Step 2: Open a long-running trace in one terminal:

```
$ sudo dtrace -n 'myfirst:::ioctl { printf("ioctl cmd=0x%x flags=0x%x", arg1, arg2); }'
dtrace: description 'myfirst:::ioctl' matched 1 probe
```

Step 3: Exercise the driver in another terminal:

```
$ ./myfirstctl get-version
$ ./myfirstctl get-message
$ sudo ./myfirstctl set-message "Lab 5"
$ sudo ./myfirstctl reset
```

The DTrace terminal should show one line per ioctl with the command code and the file flags.

Step 4: Combine multiple probes into one script:

```
$ sudo dtrace -n '
    myfirst:::open { printf("open  pid=%d", pid); }
    myfirst:::close { printf("close pid=%d", pid); }
    myfirst:::io    { printf("io    pid=%d write=%d resid=%d", pid, arg1, arg2); }
    myfirst:::ioctl { printf("ioctl pid=%d cmd=0x%x", pid, arg1); }
'
```

In another terminal:

```
$ cat /dev/myfirst0
$ ./myfirstctl get-version
$ echo "hello" | sudo tee /dev/myfirst0
```

The DTrace output now shows the complete traffic pattern, with the open and close around each operation, the read or write inside, and any ioctls. This is the value of having SDT probes integrated with the cdevsw callbacks: every integration surface that the driver exposes is also a probe surface for DTrace.

Cleanup:

```
^C
$ sudo kldunload myfirst
```

24.10.6 Lab 6: Integration Smoke Test

Goal: build a single shell script that exercises every integration surface in one run and produces a green/red summary that the reader can paste into a bug report or a release-readiness checklist.

A smoke test is a small, fast, end-to-end check that the driver is alive and that every surface responds. It does not replace careful unit testing; it gives the reader a five-second confirmation that nothing is obviously broken before they invest more time. Real drivers have smoke tests; the chapter recommends adding one to every new driver from day one.

Setup: stage 3 driver loaded.

Step 1: Create `smoke.sh` in the working directory:

```
#!/bin/sh
# smoke.sh - end-to-end smoke test for the myfirst driver.

set -u
fail=0

check() {
    if eval "$1"; then
        printf "  PASS  %s\n" "$2"
    else
        printf "  FAIL  %s\n" "$2"
        fail=$((fail + 1))
    fi
}

echo "=== myfirst integration smoke test ==="

# 1. Module is loaded.
check "kldstat | grep -q myfirst" "module is loaded"

# 2. /dev node exists with the right mode.
check "test -c /dev/myfirst0" "/dev/myfirst0 exists as a character device"
check "test \"\$(stat -f %Lp /dev/myfirst0)\\" = \"660\" " "/dev/myfirst0 is mode 0660"

# 3. Sysctl tree is present.
check "sysctl -N dev.myfirst.0.version >/dev/null 2>&1" "version OID is present"
check "sysctl -N dev.myfirst.0.debug.mask >/dev/null 2>&1" "debug.mask OID is present"
check "sysctl -N dev.myfirst.0.open_count >/dev/null 2>&1" "open_count OID is present"

# 4. Ioctls work (requires myfirstctl built).
check "./myfirstctl get-version >/dev/null" "MYFIRSTIOC_GETVER returns success"
check "./myfirstctl get-message >/dev/null" "MYFIRSTIOC_GETMSG returns success"
check "sudo ./myfirstctl set-message smoke && [ \"\$(./myfirstctl get-message)\\" =
↪ smoke ]" "MYFIRSTIOC_SETMSG round-trip works"
check "sudo ./myfirstctl reset && [ -z \"\$(./myfirstctl get-message)\\" ]"
↪ "MYFIRSTIOC_RESET clears state"

# 5. Read/write basic path.
check "echo hello | sudo tee /dev/myfirst0 >/dev/null" "write to /dev/myfirst0
↪ succeeds"
check "[ \"\$(cat /dev/myfirst0)\\" = hello ]" "read returns the previously written
↪ message"

# 6. Counters update.
```

```

sudo ./myfirstctl reset >/dev/null
cat /dev/myfirst0 >/dev/null
check "[ \"\$(sysctl -n dev.myfirst.0.total_reads)\\" = 1 ]" "total_reads incremented
↳ after one read"

# 7. SDT probes are registered.
check "sudo dtrace -l -P myfirst | grep -q open" "myfirst:::open SDT probe is visible"

echo "=== summary ==="
if [ $fail -eq 0 ]; then
    echo "ALL PASS"
    exit 0
else
    printf "%d FAIL\n" "$fail"
    exit 1
fi

```

Step 2: Make it executable and run it:

```

$ chmod +x smoke.sh
$ ./smoke.sh
=== myfirst integration smoke test ===
PASS module is loaded
PASS /dev/myfirst0 exists as a character device
PASS /dev/myfirst0 is mode 0660
PASS version OID is present
PASS debug.mask OID is present
PASS open_count OID is present
PASS MYFIRSTIOC_GETVER returns success
PASS MYFIRSTIOC_GETMSG returns success
PASS MYFIRSTIOC_SETMSG round-trip works
PASS MYFIRSTIOC_RESET clears state
PASS write to /dev/myfirst0 succeeds
PASS read returns the previously written message
PASS total_reads incremented after one read
PASS myfirst:::open SDT probe is visible
=== summary ===
ALL PASS

```

If any check fails, the script's output points directly at the broken integration surface. A failed `version OID` is present means the `sysctl` construction did not run; a failed `MYFIRSTIOC_GETVER` means the `ioctl` dispatcher is not wired correctly; a failed `total_reads incremented` means the `read` callback is not bumping the counter under the mutex.

Verification: re-run after every change to the driver. A passing smoke test before a commit is the cheapest possible insurance against a regression that breaks the basic flow.

24.10.7 Lab 7: Reload Without Restarting User-Space Programs

Goal: confirm that the driver can be unloaded and reloaded while a user-space program holds an open file descriptor open in another terminal.

This test reveals lifecycle bugs that the chapter's "soft detach" pattern is supposed to prevent. A driver that returns `EBUSY` from `detach` when a user holds the device open is correctly defending itself; a driver that lets `detach` succeed and then panics when the user issues an `ioctl` is broken.

Setup: stage 3 driver loaded.

Step 1 (terminal 1): hold the device open with a long-running command:

```
$ sleep 3600 < /dev/myfirst0 &
$ jobs
[1]+  Running                  sleep 3600 < /dev/myfirst0 &
```

Step 2 (terminal 2): try to unload:

```
$ sudo kldunload myfirst
kldunload: can't unload file: Device busy
```

This is the expected behaviour. The chapter's `myfirst_detach` checks `open_count > 0` and returns `EBUSY` rather than tearing down the `cdev` under an open file descriptor.

Step 3 (terminal 2): verify that the device is still functional from a different shell:

```
$ ./myfirstctl get-version
driver ioctl version: 1
$ sysctl dev.myfirst.0.open_count
dev.myfirst.0.open_count: 1
```

The open count reflects the held file descriptor.

Step 4 (terminal 1): release the file descriptor:

```
$ kill %1
$ wait
```

Step 5 (terminal 2): unload now succeeds:

```
$ sudo kldunload myfirst
$ sysctl dev.myfirst.0
sysctl: unknown oid 'dev.myfirst.0'
```

The OID is gone because Newbus tore down the per-device sysctl context after detach returned successfully.

Verification: the unload should succeed every time without a panic. If the kernel panics during step 5, the cause is almost always that the cdev's callbacks are still in flight when `destroy_dev` returns; check that the cdevsw's `d_close` correctly releases anything it acquired in `d_open`, and check that no callout or taskqueue is still scheduled.

A bonus extension is to write a small program that opens the device, immediately calls `MYFIRSTIOC_RESET`, and then loops on `MYFIRSTIOC_GETVER` for several seconds. While the loop is running, try to unload from another terminal. The unload should still fail with `EBUSY`; the in-flight ioctls should not corrupt anything.

24.10.8 Wrapping Up the Labs

The seven labs walked the reader through the full integration surface, the lifecycle discipline, the smoke test, and the soft-detach contract. Stage 1 added the cdev; stage 2 added the ioctl interface; stage 3 added the sysctl tree; the lab on lifecycle (Lab 4) confirmed the unwind; the DTrace lab (Lab 5) confirmed integration with Chapter 23's debug infrastructure; the smoke test (Lab 6) gave the reader a reusable verification script; and the reload lab (Lab 7) confirmed the soft-detach contract.

A driver that passes all seven labs is at the chapter's milestone version, `1.7-integration`, and is ready for the next chapter's topic. The challenge exercises in Section 10 give the reader optional follow-on work that extends the driver beyond what the chapter covers.

24.11 Challenge Exercises

The challenges below are optional and are intended for the reader who wants to push the driver beyond the chapter's milestone. Each challenge has a stated goal, a few hints about the approach, and a note about which sections of the chapter contain the relevant material. None of the challenges has a single correct answer; readers are encouraged to compare their solution with a reviewer or with the in-tree drivers cited as references.

24.11.1 Challenge 1: Add a Variable-Length Ioctl

Goal: extend the ioctl interface so that a user-space program can transfer a buffer larger than the fixed 256 bytes used by `MYFIRSTIOC_SETMSG`.

The chapter's pattern is fixed-size: `MYFIRSTIOC_SETMSG` declares `_IOW('M', 3, char[256])` and the kernel handles the entire copyin. For larger buffers (say, up to 1 MB), the embedded-pointer pattern is needed:

```
struct myfirst_blob {
    size_t  len;
    char   *buf;    /* user-space pointer */
}
```

```
};
#define MYFIRSTIOC_SETBLOB _IOW('M', 5, struct myfirst_blob)
```

The dispatcher must call `copyin` to transfer the bytes the pointer references; the structure itself comes through automatic `copyin` as before. Hints: enforce a maximum length (1 MB is reasonable). Allocate a temporary kernel buffer with `malloc(M_TEMP, len, M_WAITOK)`; do not allocate it inside the softc mutex. Free it before returning. Reference: Section 3, “Common Pitfalls With `ioctl`”, second pitfall.

A bonus extension is to add `MYFIRSTIOC_GETBLOB` that copies the current message in the same variable-length format; pay attention to the case where the user-supplied buffer is shorter than the message and decide whether to truncate, return `ENOMEM`, or write back the required length. Real drivers (`SIOCGIFCAP`, `KIOCGRPC`) use the latter pattern.

24.11.2 Challenge 2: Add a Per-Open Counter

Goal: maintain a per-file-descriptor counter (one number for each open of `/dev/myfirst0`) instead of just the per-instance counter we have now.

The chapter’s `sc_open_count` aggregates across all opens. A per-open counter would let a program know how much it has read from its own descriptor. Hints: use `cdevsw->d_priv` to attach a per-fd structure (a `struct myfirst_fdpriv` containing a counter). Allocate the structure in `myfirst_open` and free it in `myfirst_close`. The framework gives each `cdev_priv` a unique pointer in the file’s `f_data` field; the read and write callbacks can then look up the per-fd structure through `devfs_get_cdevpriv()`.

Reference: `/usr/src/sys/kern/kern_conf.c` for `devfs_set_cdevpriv` and `devfs_get_cdevpriv`. The pattern is also used by `/usr/src/sys/dev/random/random_harvestq.c`.

A bonus extension is to add a `sysctl` OID that reports the sum of per-fd counters and verify that it equals the existing aggregate counter at all times. Discrepancies indicate a missing increment somewhere.

24.11.3 Challenge 3: Implement Soft Detach With `dev_ref`

Goal: replace the chapter’s “refuse detach if open” pattern with the cleaner “drain to last close, then detach” pattern.

The chapter’s `detach` returns `EBUSY` if any user holds the device open. A more elegant pattern uses `dev_ref/dev_rel` to count outstanding references and waits for the count to reach zero before completing detach. Hints: take a `dev_ref` in `myfirst_open` and release it in `myfirst_close`. In `detach`, set a “going-away” flag, then call `destroy_dev_drain` (or write a small loop that calls `tsleep` while `dev_refs > 0`) before calling `destroy_dev`. Once the count reaches zero and the `cdev` is destroyed, complete detach normally.

Reference: `/usr/src/sys/kern/kern_conf.c` for the `dev_ref` machinery; `/usr/src/sys/fs/cuse` is a real driver that uses the drain pattern for sleeping detach.

The bonus extension is to add a `sysctl` OID that reports the current reference count and verify that it matches the open count.

24.11.4 Challenge 4: Replace the Static Magic Letter

Goal: replace the hard-coded 'M' magic letter in `myfirst_ioctl.h` with a name that does not collide with anything else in the tree.

The chapter chose 'M' arbitrarily and warned about the risk of collisions. A more defensive driver uses a longer magic identifier and constructs the ioctl numbers from it. Hints: define `MYFIRST_IOC_GROUP = 0x83` (or any byte not used by another driver). The `_IOC` macro then takes that constant rather than a character literal. Document the choice with a comment in the header explaining how it was chosen.

A bonus is to `grep /usr/src/sys` for `_IO[RW]?\\(.\\? 'M'` and produce a list of every existing use of 'M'. (There are several, including MIDI ioctls and others; the survey itself is educational.)

24.11.5 Challenge 5: Add an EVENTHANDLER for Shutdown

Goal: make the driver behave gracefully when the system is shutting down.

The chapter's driver has no shutdown handler; if the system shuts down with `myfirst` loaded, the framework eventually calls `detach`. A more polished driver registers an `EVENTHANDLER` for `shutdown_pre_sync` so it can flush any in-flight state before the file system goes read-only.

Hints: register the handler in `attach` with `EVENTHANDLER_REGISTER(shutdown_pre_sync, ...)`. The handler is called at the corresponding shutdown stage. Deregister in `detach` with `EVENTHANDLER_DEREGISTER`. Inside the handler, set the driver to a quiescent state (clear the message, zero the counters); at this point the file system is still writable, so any user feedback through `printf` will land in `/var/log/messages` after the next boot.

Reference: Section 7, "EVENTHANDLER for System Events" and `/usr/src/sys/sys/eventhandler.h` for the full list of named events.

24.11.6 Challenge 6: A Second Per-Driver Sysctl Subtree

Goal: add a second subtree under `dev.myfirst.0` that exposes per-thread statistics.

The chapter's tree has a `debug.` subtree. A complete driver might also have a `stats.` subtree (for read/write statistics broken down by file descriptor) or an `errors.` subtree (for error counters). Hints: use `SYSCTL_ADD_NODE` to create a new node, then `SYSCTL_ADD_*` to populate it under the new node's `SYSCTL_CHILDREN`. The pattern is identical to the `debug.` subtree but rooted under a different name.

Reference: Section 4, "The `myfirst` Sysctl Tree" for the existing `debug.` subtree as a model; `/usr/src/sys/dev/iicbus` for several drivers that use multi-subtree sysctl layouts.

24.11.7 Challenge 7: Cross-Module Dependency

Goal: build a second small module (`myfirst_logger`) that depends on `myfirst` and uses its in-kernel API.

The chapter's `myfirst` driver does not export any symbols for in-kernel users. Adding a second module that calls into `myfirst` exercises the `MODULE_DEPEND` machinery. Hints: declare a symbol-bearing function in `myfirst.h` (perhaps `int myfirst_get_message(int unit, char *buf, size_t len)`) and implement it in `myfirst.c`. Build the second module with `MODULE_DEPEND(myfirst_logger, myfirst, 1, 1, 1)` so the kernel loads `myfirst` automatically when `myfirst_logger` loads.

A bonus is to bump the module version of `myfirst` to 2, change the in-kernel API in a non-backward-compatible way, and observe that the second module fails to load until rebuilt against the new version. Reference: Section 8, “Version Strings, Version Numbers, and the API Version”.

24.11.8 Closing the Challenges

The seven challenges range from short (Challenge 4 is mostly a rename and a comment) to substantial (Challenge 3 requires reading and understanding `dev_ref`). The reader who completes all seven will have hands-on familiarity with every integration corner the chapter only sketches. The reader who completes any one will have a deeper feel for the integration discipline than the chapter alone can provide.

24.12 Troubleshooting

The integration surfaces in this chapter sit at the seam between the kernel and the rest of the system. Problems at the seam often look like driver bugs but are really symptoms of a missing flag, a typo in a header, or a misunderstanding about who owns what. The catalogue below collects the most common symptoms, their likely causes, and the fix for each.

24.12.1 `/dev/myfirst0` Does Not Appear After `kldload`

The first thing to check is whether the module loaded successfully:

```
$ kldstat | grep myfirst
```

If the module is not listed, the load failed; consult `dmesg` for a more specific message. The most common reason is an unresolved symbol (often because the new source file is not in `SRCS`).

If the module is listed but the device node is missing, the `make_dev_s` call inside `myfirst_attach` likely failed. Add a `device_printf(dev, "make_dev_s returned %d\n", error)` next to the call and re-try. The most common reason for a non-zero return is that another driver already created `/dev/myfirst0` (the kernel will not silently overwrite an existing node) or that `make_dev_s` was called from an unsleepable context with `MAKEDEV_NOWAIT`.

A subtler reason is that `cdevsw->d_version` does not equal `D_VERSION`. The kernel checks this and refuses to register a `cdevsw` with a version mismatch. The fix is `static struct cdevsw myfirst_cdevsw = { .d_version = D_VERSION, ... };` exactly.

24.12.2 `cat /dev/myfirst0` Returns “Permission denied”

The device exists but the user cannot open it. The default mode in this chapter is `0660` and the default group is `wheel`. Either run with `sudo`, change `mda_gid` to the user’s group, or change `mda_mode` to `0666` (the latter is fine for a teaching module but a poor choice for a production driver because any local user could open the device).

24.12.3 `ioctl` Returns “Inappropriate ioctl for device”

The kernel returned `ENOTTY`, which means it could not match the request code to any `cdevsw`. The two common causes are:

- The driver’s dispatcher returned `ENOIOCTL` for the command. The kernel translates `ENOIOCTL` to `ENOTTY` for user space. The fix is to add a case for the command in the dispatcher’s switch statement.
- The encoded length in the request code does not match the actual buffer size used by the program. This happens after a header refactor where the `_IOR` line was edited but the user-space program was not recompiled against the new header. The fix is to recompile the program against the current header and rebuild the module against the same source.

24.12.4 `ioctl` Returns “Bad file descriptor”

The dispatcher returned `EBADF`, which is the chapter’s pattern for “the file is not opened with the correct flags for this command”. The fix is to open the device with `O_RDWR` rather than `O_RDONLY` for any command that mutates state. The `myfirstctl` companion program already does this; a custom program may not.

24.12.5 `sysctl dev.myfirst.0` Shows the Tree but Reads Return “operation not supported”

This usually means the `sysctl` OID was added with a stale or invalid handler pointer. If the read returns immediately with `EOPNOTSUPP` (95), the cause is almost always that the OID was registered with `CTL_TYPE_OPAQUE` and a handler that does not call `SYSCTL_OUT`. The fix is to use one of the typed `SYSCTL_ADD_*` helpers (`SYSCTL_ADD_UINT`, `SYSCTL_ADD_STRING`, `SYSCTL_ADD_PROC` with the correct format string) so the framework knows what to do on a read.

24.12.6 `sysctl -w dev.myfirst.0.foo=value` Fails With “permission denied”

The OID was probably created with `CTLFLAG_RD` (read-only) when the writable variant `CTLFLAG_RW` was intended. Re-check the flag word in the `SYSCTL_ADD_*` call and rebuild.

If the flag is correct and the failure persists, the user may not be running as root. `Sysctl` writes require the `PRIV_SYSCTL` privilege by default; use `sudo` for the write.

24.12.7 `sysctl` Hangs or Causes a Deadlock

The OID handler is taking the giant lock (because `CTLFLAG_MPSAFE` is missing) at the same time as another thread is holding the giant lock and calling into the driver. The fix is to add `CTLFLAG_MPSAFE` to every OID’s flag word. Modern kernels assume `MPSAFE` everywhere; the absence of the flag is a code-review issue.

A subtler cause is a handler that takes the softc mutex while another thread is holding the softc mutex and reading from `sysctl`. Audit the handler: it should compute the value under the mutex but call `sysctl_handle_*` outside the mutex. The chapter’s `myfirst_sysctl_message_len` follows this pattern.

24.12.8 `kldunload myfirst` Fails With “Device busy”

The detach refused because some user holds the device open. Find them with `fstat | grep myfirst0` and either ask them to close it or kill the process. After they release the device, the unload will succeed.

If `fstat` shows nothing and the unload still fails, the cause is most likely a leaked `dev_ref`. Re-check that every code path in the driver that takes a `dev_ref` also calls `dev_rel`; in particular, any error path inside `myfirst_open` must release any reference taken before the failure.

24.12.9 `kldunload myfirst` Causes a Kernel Panic

The driver’s detach is destroying or freeing something that the kernel is still using. The two most common causes are:

- The detach freed the `softc` before destroying the `cdev`. The `cdev`’s callbacks may still be in flight; they dereference `si_drv1`, get garbage, and panic. The fix is the strict order: `destroy_dev` (which drains in-flight callbacks) first, then `mutex_destroy`, then `return`; the framework frees the `softc`.
- The detach forgot to deregister an event handler. The next event fires after unload and jumps into freed memory. The fix is to call `EVENTHANDLER_DEREGISTER` for every `EVENTHANDLER_REGISTER` done in `attach`.

The `lock_order reversal` and `WITNESS` messages in `dmesg` are useful diagnostics for both cases. A panic with `page fault while in kernel mode` and a corrupted `%rip` value is the second pattern; a panic with `lock_order reversal` and a stack trace through both subsystems is the first.

24.12.10 DTrace Probes Are Not Visible

`dtrace -l -P myfirst` returns nothing even though the module is loaded. The cause is almost always that the SDT probes are declared in a header but not defined anywhere. Probes need both `SDT_PROBE_DECLARE` (in the header, where consumers see them) and `SDT_PROBE_DEFINE*` (in exactly one source file, which owns the probe storage). The chapter’s pattern places the defines in `myfirst_debug.c`. If that file is not in `SRCS`, the probes will not be defined and DTrace will see nothing.

A subtler cause is the SDT probe was renamed in the header but the matching `SDT_PROBE_DEFINE*` was not updated. The build still succeeds because the two declarations refer to different symbols, but DTrace sees only the defined name. Audit the header and source for the same probe name.

24.12.11 `sysctl` Tree Survives Unload But Hangs the Next `Sysctl`

This happens when the driver uses its own `sysctl` context (rather than the per-device one) and forgets to call `sysctl_ctx_free` in `detach`. The `OIDs` reference fields in the now-freed `softc`; the next `sysctl` walk dereferences the freed memory and the kernel either panics or returns garbage. The fix is to switch to `device_get_sysctl_ctx`, which the framework cleans up automatically.

24.12.12 General Diagnostic Checklist

When something goes wrong and the cause is not obvious, walk through this short list before reaching for `kgdb`:

1. `kldstat | grep <driver>`: is the module actually loaded?
2. `dmesg | tail`: are there any kernel messages mentioning the driver?
3. `ls -l /dev/<driver>0`: does the device node exist with the expected mode?
4. `sysctl dev.<driver>.0.%driver`: is Newbus aware of the device?
5. `fstat | grep <driver>0`: is anyone holding the device open?
6. `dtrace -l -P <driver>`: are the SDT probes registered?
7. Re-read the attach function and check that every step has a matching cleanup in detach.

The first six commands take ten seconds and rule out the bulk of the common problems. The seventh is the slow one but is almost always the eventual answer for any bug that the first six did not surface.

24.12.13 Frequently Asked Questions

The questions below come up often enough during integration work that the chapter ends with a short FAQ. Each answer is intentionally compact; the relevant section of the chapter has the full discussion.

Q1. Why use both `ioctl` and `sysctl` when they seem to overlap?

They answer different questions. `ioctl` is for a program that has already opened the device and wants to issue a command (request a state, push new state, trigger an action). `sysctl` is for an operator at a shell prompt or a script that wants to inspect or adjust state without opening anything. The same value can be exposed through both interfaces, and many production drivers do exactly that: a `MYFIRSTIOC_GETMSG` for programs and a `dev.myfirst.0.message` for humans. Each user picks the channel that fits their context.

Q2. When should I use `mmap` instead of `read/write/ioctl`?

Use `mmap` when the data is large, accessed at random, and naturally lives at a memory address (a frame buffer, a DMA descriptor ring, a memory-mapped register space). Use `read/write` when the data is sequential, byte-oriented, and small per call. Use `ioctl` for control commands. The three are not in opposition; many drivers expose all three (as `vt(4)` does for the console).

Q3. Why does the chapter use `make_dev_s` rather than `make_dev`?

`make_dev_s` is the modern preferred form. It returns an explicit error rather than panicking on a duplicate name; it accepts an `args` structure so new options can be added without churn; and it is what most current drivers use. The older `make_dev` still works but is discouraged for new code.

Q4. Do I need to declare `D_TRACKCLOSE`?

You need it if your driver's `d_close` should be called only on the last close of a file descriptor (the natural meaning of “close”). Without it, the kernel calls `d_close` for every close of every duplicated descriptor, which surprises most drivers. Set it in any new `cdevsw` unless you have a specific reason not to.

Q5. When should I bump `MODULE_VERSION`?

When something in the driver's in-kernel API changes incompatibly. Adding new exported symbols is fine; renaming or removing them is a bump. Changing the layout of a publicly visible structure is a bump. Bumping the module version forces dependents (`MODULE_DEPEND` consumers) to be rebuilt.

Q6. When should I bump the API version constant in my public header?

When something in the user-visible interface changes incompatibly. Adding a new ioctl is fine; changing the layout of an existing ioctl's argument structure is a bump. Renumbering an existing ioctl is a bump. Bumping the API version lets user-space programs detect incompatibility before they issue calls.

Q7. Should I detach my OIDs in myfirst_detach?

No, not if you used `device_get_sysctl_ctx` (the per-device context). The framework cleans the per-device context up automatically after a successful detach. You only need explicit cleanup if you used `sysctl_ctx_init` to create your own context.

Q8. Why does my detach panic with “invalid memory access”?

Almost always because the cdev's callbacks are still in flight when the driver freed something they reference. The fix is to call `destroy_dev(sc->sc_cdev)` first; `destroy_dev` blocks until every in-flight callback returns. After it returns, the cdev is gone and no new callbacks can arrive. Only then is it safe to free the softc, free the locks, and so on. The strict order is non-negotiable.

Q9. What is the difference between dev_ref / dev_rel and D_TRACKCLOSE?

`D_TRACKCLOSE` is a cdevsw flag that controls when the kernel calls `d_close`: with it, only on the last close; without it, on every close. `dev_ref/dev_rel` is a reference-counting mechanism that lets the driver delay detach until outstanding references are released. They are unrelated and complementary. The chapter uses `D_TRACKCLOSE` in stage 1; Challenge 3 demonstrates `dev_ref/dev_rel`.

Q10. Why does my sysctl write return EPERM even though I am root?

Three possible causes. (a) The OID was created with `CTLFLAG_RD` only; add `CTLFLAG_RW`. (b) The OID has `CTLFLAG_SECURE` and the system is at `securelevel > 0`; lower the `securelevel` or remove the flag. (c) The user is not actually root but is in a jail without `allow.sysvipc` or similar; root inside a jail does not have `PRIV_SYSCTL` for arbitrary OIDs.

Q11. My sysctl handler takes the giant lock when it should not. What did I forget?

`CTLFLAG_MPSAFE` in the flag word. Without it, the kernel takes the giant lock around every call into the handler. Add it everywhere; modern kernels assume `MPSAFE` everywhere.

Q12. Should I name my ioctl group letter uppercase or lowercase?

Uppercase for new drivers. Lowercase letters are heavily used by base subsystems ('d' for disk, 'i' for `if_ioctl`, 't' for terminal) and the chance of collision is real. Uppercase letters are mostly free, and a fresh driver should choose one of them.

Q13. My ioctl returns inappropriate ioctl for device and I do not understand why.

The kernel returned `ENOTTY` because either (a) the dispatcher returned `ENOIOCTL` for the command (add a case for it), or (b) the encoded length in the request code does not match the buffer the user passed (recompile both sides against the same header).

Q14. Should I use strncpy or strlcpy in the kernel?

`strlcpy`. It guarantees NUL termination and never overruns the destination. `strncpy` does neither and is a frequent source of subtle bugs. The FreeBSD `style(9)` man page recommends `strlcpy` for all new code.

Q15. My module loads but dmesg shows no messages from my driver. What is wrong?

The driver's debug mask is zero. The chapter's `DPRINTF` macro prints only when the mask bit is set. Either set the mask before loading (`kenv hw.myfirst.debug_mask_default=0xff`), or set it after loading (`sysctl dev.myfirst.0.debug.mask=0xff`).

Q16. Why does the chapter mention DTrace so often?

Because it is the most productive debugging tool in the FreeBSD kernel and because the Chapter 23 debug infrastructure is designed to integrate with it. SDT probes give the operator a runtime tap into every integration surface without rebuilding the driver. A driver that exposes well-named SDT probes is much easier to debug than one that does not.

Q17. Can I use this driver as a template for a real hardware driver?

The integration surface (`cdev`, `ioctl`, `sysctl`) translates directly. The hardware-specific parts (resource allocation, interrupt handling, DMA setup) come in Chapters 18 to 22 of Part IV. A real PCI driver typically combines the structural patterns from Part IV with the integration patterns from this chapter to arrive at a shipping driver.

Q18. How do I grant a non-root user access to `/dev/myfirst0` without rebuilding the driver?

Use `devfs.rules(5)`. Add a rule file under `/etc/devfs.rules` that matches the device name and sets the owner, group, or mode at runtime. For example, to let group operator read and write `/dev/myfirst*`:

```
[myfirst_rules=10]
add path 'myfirst*' mode 0660 group operator
```

Enable the ruleset with `devfs_system_ruleset="myfirst_rules"` in `/etc/rc.conf` and service `devfs` restart. The driver's `mda_uid`, `mda_gid`, and `mda_mode` still set the defaults at creation time; `devfs.rules` lets the administrator override them without touching the source.

Q19. My SRCS list keeps growing. Is that a problem?

Not by itself. The `SRCS` line in the kernel-module `Makefile` lists every source file that compiles into the module; growing the list as new responsibilities get their own file is normal and expected. The chapter's Stage 3 driver already has four source files (`myfirst.c`, `myfirst_debug.c`, `myfirst_ioctl.c`, `myfirst_sysctl.c`), and Chapter 25 will add more. The warning sign is not the number of entries but the lack of structure: if `SRCS` contains unrelated files that were merged together without a naming scheme, the driver has outgrown its layout and deserves a small refactor. Chapter 25 treats that refactor as a first-class habit.

Q20. What should I do next?

Read Chapter 25 (advanced topics and practical tips) to turn this integrated driver into a *maintainable* one, work through the chapter's challenges if you want hands-on practice, and look at one of the in-tree drivers cited in the reference card for a fully worked example. The `null(4)` driver is the gentlest entry; the `if_em` Ethernet driver is the most complete; the `ahci(4)` storage driver shows the CAM patterns. Pick the one closest to what you want to build and read it end to end.

24.13 Wrapping Up

This chapter brought `myfirst` from a working but isolated module into a fully integrated FreeBSD driver. The arc was deliberate: each section added one concrete integration surface and ended with the driver more useful

and more discoverable than it began. The reader who walked the labs in Section 9 now has, on disk, a driver that exposes a properly constructed cdev under `/dev`, four well-designed ioctls under a public header, a self-describing sysctl tree under `dev.myfirst.0`, a boot-time tunable through `/boot/loader.conf`, and a clean lifecycle that survives load/unload cycles without leaking resources.

The technical milestones along the way were:

- Stage 1 (Section 2) replaced the older `make_dev` call with the modern `make_dev_args` form, populated `D_TRACKCLOSE`, wired `si_drv1` for per-cdev state, and walked the cdev lifecycle from creation through drain to destruction. The driver's `/dev` presence became first-class.
- Stage 2 (Section 3) added the `MYFIRSTIOC_GETVER`, `MYFIRSTIOC_GETMSG`, `MYFIRSTIOC_SETMSG`, and `MYFIRSTIOC_RESET` ioctls and the matching `myfirst_ioctl.h` public header. The dispatcher reuses the debug infrastructure from Chapter 23 (`MYF_DBG_IOCTL` and the `myfirst::ioctl` SDT probe). The companion `myfirstctl` user-space program demonstrated how a small command-line tool exercises every ioctl without ever decoding a request code by hand.
- Stage 3 (Section 4) added the `dev.myfirst.0.*` sysctl tree, including a `debug.` subtree that lets the operator inspect and modify the debug mask at runtime, a `version` OID that reports the integration release, counters for read and write activity, and a string OID for the current message. The boot-time tunable `hw.myfirst.debug_mask_default` lets the operator pre-load the debug mask before attach.
- Sections 5 and 6 sketched the same registration-style integration applied to the network stack (`if_alloc`, `if_attach`, `bpfattach`) and the CAM storage stack (`cam_sim_alloc`, `xpt_bus_register`, `xpt_action`). The reader who is not building a network or storage driver still gained a useful pattern: every framework registration in FreeBSD uses the same allocate-name-fill-attach-traffic-detach-free shape.
- Section 7 codified the lifecycle discipline that holds it all together: every successful registration must be paired with a deregistration in reverse order, and a failed attach must unwind every prior step before returning. The `goto err` chain is the canonical encoding of this rule.
- Section 8 framed the chapter as one step in a longer arc: `myfirst` started as a one-file demonstration, grew into a multi-file driver across Parts II to IV, gained debug and tracing in Chapter 23, and gained the integration surface here. The release version, the module version, and the API version each track a different aspect of that evolution; bumping each at the right time is the version discipline of a long-lived driver.

The chapter's labs (Section 9) walked the reader through every milestone, the challenges (Section 10) gave the motivated reader follow-on work, and the troubleshooting catalogue (Section 11) gathered the most common symptoms and fixes for quick reference.

The result is a driver milestone (1.7-integration) that the reader can take into the next chapter without any unfinished integration work waiting to bite them. The patterns from this chapter (cdev construction, ioctl design, sysctl trees, lifecycle discipline) are also the patterns that the rest of Part V and most of Parts VI and VII will assume the reader knows.

24.14 Bridge to Chapter 25

Chapter 25 (Advanced Topics and Practical Tips) closes Part 5 by turning the integrated driver of this chapter into a *maintainable* one. Where Chapter 24 added the interfaces that let the driver speak to the rest of the system, Chapter 25 teaches the engineering habits that keep those interfaces stable and readable as the driver absorbs the next year of bug fixes, portability changes, and feature requests. The driver grows from 1.7-integration to 1.8-maintenance; the visible additions are modest but the discipline behind them is what separates a driver that survives one development cycle from one that survives a decade.

The bridge from Chapter 24 to Chapter 25 has four concrete parts.

First, the rate-limited logging that Chapter 25 introduces sits directly on top of the `DPRINTF` macro from Chapter 23 and the integration surfaces this chapter added. A new `DLOG_RL` macro built around `ppsratecheck(9)` lets the driver keep the same debug classes it already uses but without flooding `dmesg` during an event storm. The discipline is small: choose a per-second limit, fold it into the existing debug call sites, and audit the handful of places where an unrestricted `device_printf` could run in a loop.

Second, the `ioctl` and `sysctl` paths this chapter built will be audited in Chapter 25 for a consistent `errno` vocabulary. The chapter distinguishes `EINVAL` from `ENXIO`, `ENOIOCTL` from `ENOTTY`, `EBUSY` from `EAGAIN`, and `EPERM` from `EACCES`, so that every integration surface returns the right code on every failure. The reader walks the dispatcher written in Section 3 and the `sysctl` handlers written in Section 4, and adjusts them where the wrong error was returned.

Third, the boot-time tunable `hw.myfirst.debug_mask_default` introduced in Section 4 will be generalised in Chapter 25 into a small but disciplined tunable vocabulary through `TUNABLE_INT_FETCH`, `TUNABLE_LONG_FETCH`, `TUNABLE_BOOL_FETCH`, and `TUNABLE_STR_FETCH`, cooperating with writable `sysctls` under `CTLFLAG_TUN`. The same `MYFIRST_VERSION`, `MODULE_VERSION`, and `MYFIRST_IOCTL_VERSION` triple this chapter settled on will be extended with a `MYFIRSTIOC_GETCAPS` `ioctl` so user-space tools can detect features at runtime without trial and error.

Fourth, the `goto_err` chain introduced in Section 7 will be promoted from a lab exercise into the driver's production cleanup pattern, and the chapter's refactor will move the Newbus attach logic and the `cdev` callbacks into separate files (`myfirst_bus.c` and `myfirst_cdev.c`) alongside a `myfirst_log.c` for the new logging macros. Chapter 25 also introduces `SYSINIT(9)` and `SYSUNINIT(9)` for driver-wide initialisation and a `shutdown_pre_sync` event handler through `EVENTHANDLER(9)`, adding two more registration-style surfaces to the ones this chapter already taught.

Read on with the confidence that the integration vocabulary is now in place. Chapter 25 takes this driver and makes it ready for the long haul; Part 6 then begins the transport-specific chapters that lean on every habit Part 5 has built.

24.15 Reference Card and Glossary

The remaining pages of the chapter are a compact reference. They are designed to be read straight through the first time and then jumped into when the reader needs to look something up. The order is: a reference card of the important macros, structures, and flags; a glossary of integration vocabulary; and a short directory of the companion files that ship with the chapter.

24.15.1 Quick Reference: cdev Construction

Function	When to use
<code>make_dev_args_init(args)</code>	Always before <code>make_dev_s</code> ; zeroes the args struct safely.
<code>make_dev_s(args, &cdev, fmt, ...)</code>	The modern preferred form. Returns 0 or <code>errno</code> .
<code>make_dev(devsw, unit, uid, gid, mode, fmt, ...)</code>	Older single-call form. Discouraged for new code.
<code>make_dev_credf(flags, ...)</code>	When you need <code>MAKEDEV_*</code> flag bits.
<code>destroy_dev(cdev)</code>	Always in detach; drains in-flight callbacks.
<code>destroy_dev_drain(cdev)</code>	When detach must wait for outstanding refs.

24.15.2 Quick Reference: cdevsw Flags

Flag	Meaning
<code>D_VERSION</code>	Required; identifies the cdevsw layout version.
<code>D_TRACKCLOSE</code>	Call <code>d_close</code> only on the last close. Recommended.
<code>D_NEEDGIANT</code>	Take the giant lock around every callback. Discouraged.
<code>D_DISK</code>	Cdev represents a disk; uses bio rather than uio for I/O.
<code>D_TTY</code>	Cdev is a terminal; affects line discipline routing.
<code>D_MMAP_ANON</code>	Cdev supports anonymous mmap.
<code>D_MEM</code>	Cdev is <code>/dev/mem</code> -like; raw memory access.

24.15.3 Quick Reference: make_dev Flags (MAKEDEV_*)

Flag	Meaning
<code>MAKEDEV_REF</code>	Take an extra reference; caller must <code>dev_ref</code> later.
<code>MAKEDEV_NOWAIT</code>	Do not sleep; return <code>ENOMEM</code> if no memory.
<code>MAKEDEV_WAITOK</code>	Sleeping is allowed (default for most callers).
<code>MAKEDEV_ETERNAL</code>	Cdev never goes away; certain optimisations apply.
<code>MAKEDEV_ETERNAL_KLD</code>	Like <code>ETERNAL</code> , but only for the lifetime of the kld.
<code>MAKEDEV_CHECKNAME</code>	Validate the name; <code>ENAMETOOLONG</code> if too long.

24.15.4 Quick Reference: ioctl Encoding Macros

All in `/usr/src/sys/sys/ioccom.h`.

Macro	Direction	Argument
<code>_IO(g, n)</code>	none	none
<code>_IOR(g, n, t)</code>	out	type <code>t</code> , size <code>sizeof(t)</code>
<code>_IOW(g, n, t)</code>	in	type <code>t</code> , size <code>sizeof(t)</code>
<code>_IOWR(g, n, t)</code>	in and out	type <code>t</code> , size <code>sizeof(t)</code>
<code>_IOWINT(g, n)</code>	none, but value of <code>int</code> passed	<code>int</code>

The arguments mean:

- `g`: group letter, conventionally 'M' for `myfirst` and similar.
- `n`: command number, monotonically increasing within the group.
- `t`: argument type, used only for its `sizeof`.

The maximum size is `IOCPARM_MAX` = 8192 bytes. For larger transfers, use the embedded-pointer pattern (Challenge 1) or a different mechanism such as `mmap` or `read/write`.

24.15.5 Quick Reference: `d_ioctl_t` Signature

```
int d_ioctl(struct cdev *dev, u_long cmd, caddr_t data,
            int fflag, struct thread *td);
```

Argument	Meaning
<code>dev</code>	The <code>cdev</code> backing the file descriptor. Use <code>dev->si_drv1</code> to get the softc.
<code>cmd</code>	The request code from user space. Compared to named constants.
<code>data</code>	Kernel-side buffer with the user data. Direct dereference; no copyin needed.
<code>fflag</code>	File flags from the open call (<code>FREAD</code> , <code>FWRITE</code>). Check before mutating.
<code>td</code>	Calling thread. Use <code>td->td_ucred</code> for credentials.

Return 0 on success, a positive `errno` on failure, or `ENOIOCTL` for unknown commands.

24.15.6 Quick Reference: sysctl OID Macros

All in `/usr/src/sys/sys/sysctl.h`.

Macro	Adds
<code>SYSCTL_ADD_INT(ctx, parent, nbr, name, flags, ptr, val, descr)</code>	Signed int, backed by <code>*ptr</code> .
<code>SYSCTL_ADD_UINT</code>	Unsigned int.
<code>SYSCTL_ADD_LONG / SYSCTL_ADD_ULONG</code>	Long / unsigned long.
<code>SYSCTL_ADD_S64 / SYSCTL_ADD_U64</code>	64-bit signed / unsigned.
<code>SYSCTL_ADD_BOOL</code>	Boolean (preferred over int 0/1).
<code>SYSCTL_ADD_STRING(ctx, parent, nbr, name, flags, ptr, len, descr)</code>	NUL-terminated string.
<code>SYSCTL_ADD_NODE(ctx, parent, nbr, name, flags, handler, descr)</code>	Subtree node.
<code>SYSCTL_ADD_PROC(ctx, parent, nbr, name, flags, arg1, arg2, handler, fmt, descr)</code>	Handler-backed OID.

24.15.7 Quick Reference: sysctl Flag Bits

Flag	Meaning
<code>CTLFLAG_RD</code>	Read-only.
<code>CTLFLAG_WR</code>	Write-only (rare).
<code>CTLFLAG_RW</code>	Read-write.
<code>CTLFLAG_TUN</code>	Loader tunable; read at boot from <code>/boot/loader.conf</code> .
<code>CTLFLAG_MPSAFE</code>	Handler is safe without giant lock. Always set for new code.
<code>CTLFLAG_PRISON</code>	Visible inside jails.
<code>CTLFLAG_VNET</code>	Per-VNET (virtualised network stack).
<code>CTLFLAG_DYN</code>	Dynamic OID; set automatically by <code>SYSCTL_ADD_*</code> .
<code>CTLFLAG_SECURE</code>	Read-only when <code>securelevel > 0</code> .

24.15.8 Quick Reference: sysctl Type Bits

OR'd into the flag word for `SYSCTL_ADD_PROC` and similar.

Flag	Meaning
CTLTYPE_INT / CTLTYPE_UINT	Signed / unsigned int.
CTLTYPE_LONG / CTLTYPE_ULONG	Long / unsigned long.
CTLTYPE_S64 / CTLTYPE_U64	64-bit signed / unsigned.
CTLTYPE_STRING	NUL-terminated string.
CTLTYPE_OPAQUE	Opaque blob; rarely used in new code.
CTLTYPE_NODE	Subtree node.

24.15.9 Quick Reference: sysctl Handler Format Strings

Used by SYSCTL_ADD_PROC to tell sysctl(8) how to print the value.

Format	Type
"I"	int
"IU"	unsigned int
"L"	long
"LU"	unsigned long
"Q"	int64
"QU"	uint64
"A"	NUL-terminated string
"S, structname"	opaque struct (rare)

24.15.10 Quick Reference: sysctl Handler Boilerplate

```
static int
my_handler(SYSCTL_HANDLER_ARGS)
{
    struct my_softc *sc = arg1;
    u_int val;

    /* Read the current value into val under the mutex. */
    mtx_lock(&sc->sc_mtx);
    val = sc->sc_field;
    mtx_unlock(&sc->sc_mtx);

    /* Let the framework do the read or write. */
}
```

```

        return (sysctl_handle_int(oidp, &val, 0, req));
    }

```

24.15.11 Quick Reference: per-Device Sysctl Context

```

struct sysctl_ctx_list *ctx = device_get_sysctl_ctx(dev);
struct sysctl_oid      *tree = device_get_sysctl_tree(dev);
struct sysctl_oid_list *child = SYSCTL_CHILDREN(tree);

```

The framework owns the ctx; the driver does not call `sysctl_ctx_free` on it. The framework cleans up automatically after a successful detach.

24.15.12 Quick Reference: Loader Tunables

```

TUNABLE_INT_FETCH("hw.driver.knob", &sc->sc_knob);
TUNABLE_LONG_FETCH("hw.driver.knob", &sc->sc_knob);
TUNABLE_STR_FETCH("hw.driver.knob", buf, sizeof(buf));

```

The first argument is the loader variable name. The second is a pointer to the destination, which is also the default value if the variable is not set.

24.15.13 Quick Reference: ifnet Lifecycle

Function	When
<code>if_alloc(IFT_<type>)</code>	Allocate the ifnet.
<code>if_initname(ifp, name, unit)</code>	Set the user-visible name (ifconfig shows it).
<code>if_setflags(ifp, flags)</code>	Set <code>IFF_*</code> flags.
<code>if_setsoftc(ifp, sc)</code>	Attach the driver's softc.
<code>if_setioctlfn(ifp, fn)</code>	Set the ioctl handler.
<code>if_settransmitfn(ifp, fn)</code>	Set the transmit function.
<code>if_attach(ifp)</code>	Make the interface visible.
<code>bpfattach(ifp, dlt, hdrlen)</code>	Make traffic visible to BPF.
<code>bpfdetach(ifp)</code>	Reverse <code>bpfattach</code> .
<code>if_detach(ifp)</code>	Reverse <code>if_attach</code> .

Function	When
<code>if_free(ifp)</code>	Free the ifnet.

24.15.14 Quick Reference: CAM SIM Lifecycle

Function	When
<code>cam_simq_alloc(maxq)</code>	Allocate the device queue.
<code>cam_sim_alloc(action, poll, name, sc, unit, mtx, max_tagged, max_dev_tx, devq)</code>	Allocate the SIM.
<code>xpt_bus_register(sim, dev, 0)</code>	Register the bus with CAM.
<code>xpt_create_path(&path, NULL, cam_sim_path(sim), targ, lun)</code>	Create a path for events.
<code>xpt_action(ccb)</code>	Send a CCB to CAM.
<code>xpt_done(ccb)</code>	Tell CAM that the driver finished a CCB.
<code>xpt_free_path(path)</code>	Reverse <code>xpt_create_path</code> .
<code>xpt_bus_deregister(cam_sim_path(sim))</code>	Reverse <code>xpt_bus_register</code> .
<code>cam_sim_free(sim, free_devq)</code>	Reverse <code>cam_sim_alloc</code> . Pass TRUE to also free the devq.

24.15.15 Quick Reference: Module Lifecycle

```
static moduledata_t mymod = {
    "myfirst",          /* name */
    myfirst_modevent, /* event handler, can be NULL */
    NULL                /* extra data, rarely used */
};
DECLARE_MODULE(myfirst, mymod, SI_SUB_DRIVERS, SI_ORDER_ANY);
MODULE_VERSION(myfirst, 1);
MODULE_DEPEND(myfirst, otherdriver, 1, 1, 1);
```

The event handler signature is `int (*)(module_t mod, int what, void *arg)`. The `what` argument is one of `MOD_LOAD`, `MOD_UNLOAD`, `MOD_QUIESCE`, or `MOD_SHUTDOWN`. Return 0 on success or a positive errno.

24.15.16 Quick Reference: Event Handler

```
eventhandler_tag tag;

tag = EVENTHANDLER_REGISTER(event_name, callback,
    arg, EVENTHANDLER_PRI_ANY);

EVENTHANDLER_DEREGISTER(event_name, tag);
```

Common event names: shutdown_pre_sync, shutdown_post_sync, shutdown_final, vm_lowmem, power_suspend_early, power_resume.

24.15.17 Quick Reference: Errno Conventions

Errno	When to return
0	Success.
EINVAL	The arguments are recognised but invalid.
EBADF	The file descriptor is not opened correctly for the operation.
EBUSY	The resource is in use (often returned from detach).
ENOIOCTL	The ioctl command is unknown. Use this for the default case in d_ioctl.
ENOTTY	The kernel translation of ENOIOCTL for user space.
ENOMEM	Allocation failed.
EAGAIN	Try again later (often returned from non-blocking I/O).
EPERM	The caller lacks the necessary privilege.
EOPNOTSUPP	The operation is not supported by this driver.
EFAULT	A user pointer is invalid (returned by failed copyin/copyout).
ETIMEDOUT	A wait timed out.
EIO	Generic I/O error from hardware.

24.15.18 Quick Reference: Debug Class Bits (from Chapter 23)

Bit	Name	Used for
0x01	MYF_DBG_INIT	probe / attach / detach
0x02	MYF_DBG_OPEN	open / close lifecycle
0x04	MYF_DBG_IO	read / write paths

Bit	Name	Used for
0x08	MYF_DBG_IOCTL	ioctl handling
0x10	MYF_DBG_INTR	interrupt handler
0x20	MYF_DBG_DMA	DMA mapping/sync
0x40	MYF_DBG_PWR	power-management events
0x80	MYF_DBG_MEM	malloc/free trace
0xFFFFFFFF	MYF_DBG_ANY	all classes
0	MYF_DBG_NONE	no logging

The mask is set per instance via `dev.<driver>.<unit>.debug.mask`, or globally at boot via `hw.<driver>.debug_mask_de` in `/boot/loader.conf`.

24.15.19 Glossary of Integration Vocabulary

API version: An integer exposed through a driver’s `ioctl` interface (typically through a `GETVER` `ioctl`) that user-space programs can query to detect changes in the driver’s public interface. Bumped only when the user-visible interface changes incompatibly.

bpfattach: The function that hooks an `ifnet` into the BPF (Berkeley Packet Filter) machinery so `tcpdump` and similar tools can observe its traffic. Must be paired with `bpfdetach`.

bus_generic_detach: A helper that detaches every child of a bus-style driver. Used as the first step in a bus driver’s detach to release child devices before the parent tears down its own state.

CAM: The Common Access Method, FreeBSD’s storage subsystem above device drivers. Owns the I/O queue, target/LUN abstraction, and peripheral drivers (`da`, `cd`, `sa`).

CCB: CAM Control Block. A single I/O request structured as a tagged union; the driver inspects `ccb->ccb_h.func_code` and dispatches accordingly. Completed via `xpt_done`.

cdev: Character device. The kernel’s per-device-node object that backs an entry under `/dev`. Created with `make_dev_s`, destroyed with `destroy_dev`.

cdevsw: Character device switch. The static table of callbacks (`d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl`, ...) that the kernel invokes on operations against a `cdev`.

copyin / copyout: Functions that transfer bytes between user-space and kernel-space addresses. The kernel performs them automatically for properly encoded `ioctls`; the driver calls them explicitly only for embedded-pointer patterns.

CTLFLAG_MPSAFE: A `sysctl` flag that declares the `OID`’s handler safe to call without the giant lock. Mandatory for new code; without it the kernel takes the giant lock around every access.

d_ioctl_t: The function-pointer type for the `cdevsw`’s `ioctl` callback. Signature: `int (*)(struct cdev *, u_long, caddr_t, int, struct thread *)`.

d_priv: A per-file-descriptor private pointer attached via `devfs_set_cdevpriv`. Used for state that must be associated with one open rather than with the driver instance as a whole.

dev_ref / dev_rel: A pair of functions that increment and decrement a cdev's reference count. Used to coordinate detach with in-flight callbacks; see Challenge 3.

devfs: The kernel-managed file system that backs /dev. The driver creates cdevs and devfs makes them visible.

devfs.rules(8): A configuration mechanism for runtime devfs permissions. Applied by service devfs restart after editing /etc/devfs.rules.

DTrace: The dynamic tracing framework. Drivers expose probe points through SDT macros; DTrace scripts attach to them at runtime.

EVENTHANDLER_REGISTER: The mechanism for registering a callback for a named system-wide event (shutdown_pre_sync, vm_lowmem, etc.). Must be paired with EVENTHANDLER_DEREGISTER.

ifnet: The network stack's per-interface object. The network counterpart to the cdev.

if_t: The opaque typedef the network stack uses for ifnet. Drivers manipulate the interface through accessor functions rather than direct field access.

IOC_VOID / IOC_IN / IOC_OUT / IOC_INOUT: The four direction bits encoded in an ioctl request code. Used by the kernel to decide what copyin/copyout to perform.

IOCPARM_MAX: The maximum size (8192 bytes) of an ioctl's argument structure as encoded in the request code. Larger transfers require an embedded-pointer pattern.

kldload / kldunload: The user-space tools that load and unload kernel modules. Both invoke the corresponding module event handler (MOD_LOAD and MOD_UNLOAD).

make_dev_args: The structure passed to make_dev_s to describe a new cdev. Initialised with make_dev_args_init.

make_dev_s: The modern preferred function for creating a cdev. Returns 0 or a positive errno; sets *cdev on success.

MAKEDEV_*: Flag bits passed to make_dev_credf and similar. Common bits: MAKEDEV_REF, MAKEDEV_NOWAIT, MAKEDEV_ETERNAL_KLD.

MOD_LOAD / MOD_UNLOAD / MOD_SHUTDOWN: The events delivered to a module's event handler. Returns 0 to acknowledge or non-zero to reject.

MODULE_DEPEND: The macro that declares a module's dependency on another. The kernel uses the version arguments (min, pref, max) to enforce compatibility.

MODULE_VERSION: The macro that declares a module's version number. Bumped when in-kernel users would need a recompile.

Newbus: FreeBSD's device-tree framework. Owns the device_t, the per-device softc, the per-device sysctl context, and the probe/attach/detach lifecycle.

OID: Object identifier. A node in the sysctl tree. Static OIDs are declared at compile time; dynamic OIDs are added at runtime with SYSCTL_ADD_*.

Path (CAM): A (bus, target, LUN) triple identifying a CAM destination. Created with xpt_create_path.

Public header: A header that user-space programs include to talk to the driver. Must compile cleanly without _KERNEL defined; uses only stable types.

Registration framework: A FreeBSD subsystem that exposes an “allocate-name-fill-attach-traffic-detach-free” interface for drivers. Examples: networking (ifnet), storage (CAM), sound, USB, GEOM.

Release version: The human-readable string identifying a driver’s release. Exposed through sysctl as `dev.<driver>.<unit>.version`.

SDT: Statically defined tracing. The kernel’s mechanism for compile-time probe points consumable by DTrace.

si_drv1 / si_drv2: Two private pointer fields in `struct cdev` available for the driver’s use. Conventionally `si_drv1` points at the `softc`.

SIM: SCSI Interface Module. CAM’s view of a storage adapter. Allocated with `cam_sim_alloc`, registered with `xpt_bus_register`.

Soft detach: A detach pattern where the driver waits for outstanding references to drop to zero rather than refusing detach immediately. See Challenge 3.

Softc: Software context. The driver’s per-instance state. Allocated by Newbus and accessed via `device_get_softc(dev)`.

SYSINIT: A compile-time-registered one-shot kernel init function. Runs at a specific stage during boot. Rarely needed in driver code.

SYSCTL_HANDLER_ARGS: A macro that expands to the standard argument list for a sysctl handler: `oidp, arg1, arg2, req`.

TUNABLE_INT_FETCH: A function that reads a value from the loader environment and writes it into a kernel variable. The variable retains its previous value if the loader variable is absent.

XPT: CAM Transport Layer. The central CAM dispatch mechanism. Driver calls `xpt_action` to send a CCB; CAM calls back via the SIM’s action function for I/O CCBs.

24.15.20 Companion File Inventory

The companion files for this chapter live under `examples/part-05/ch24-integration/` in the book’s repository. The directory layout is:

```
examples/part-05/ch24-integration/
├─ README.md
├─ INTEGRATION.md
├─ stage1-devfs/
│   └─ Makefile
│   └─ myfirst.c           (with make_dev_args)
│   └─ README.md
├─ stage2-ioctl/
│   └─ Makefile
│   └─ Makefile.user      (for myfirstctl)
│   └─ myfirst_ioctl.c
│   └─ myfirst_ioctl.h    (PUBLIC)
│   └─ myfirstctl.c
```

```

|   └─ README.md
└─ stage3-sysctl/
|   └─ Makefile
|   └─ myfirst.c
|   └─ myfirst_sysctl.c
|   └─ README.md
└─ labs/
    └─ lab24_1_stage1.sh      (verification commands for Lab 1)
    └─ lab24_2_stage2.sh
    └─ lab24_3_stage3.sh
    └─ lab24_4_failure.sh
    └─ lab24_5_dtrace.sh
    └─ lab24_6_smoke.sh
    └─ lab24_7_reload.sh
    └─ loader.conf.example

```

The starting point for Lab 1 is the reader's own end-of-Chapter-23 driver (1.6-debug); `stage1-devfs/`, `stage2-ioctl/`, and `stage3-sysctl/` are reference solutions the reader can consult after completing each lab. The `labs` directory has small shell scripts that perform the verification commands and that the reader can adapt for their own tests.

The `README.md` at the chapter root describes how to use the directory, the order of the stages, and the relationship between the staged trees. The `INTEGRATION.md` is a longer document that maps every concept in the chapter to the file it appears in.

24.15.21 Where the Chapter's Source Tree Sits in Real FreeBSD

For a reader who wants to look up the in-tree implementations referenced throughout the chapter, here is a short index of the most important files:

Concept	In-tree file
<code>ioctl</code> encoding	<code>/usr/src/sys/sys/ioccom.h</code>
<code>cdevsw</code> definition	<code>/usr/src/sys/sys/conf.h</code>
<code>make_dev</code> family	<code>/usr/src/sys/kern/kern_conf.c</code>
<code>sysctl</code> framework	<code>/usr/src/sys/sys/sysctl.h,</code> <code>/usr/src/sys/kern/kern_sysctl.c</code>
<code>ifnet</code> API	<code>/usr/src/sys/net/if.h,</code> <code>/usr/src/sys/net/if.c</code>
<code>ifnet</code> example	<code>/usr/src/sys/net/if_disc.c</code>
CAM SIM API	<code>/usr/src/sys/cam/cam_xpt.h,</code> <code>/usr/src/sys/cam/cam_sim.h</code>
CAM example	<code>/usr/src/sys/dev/ahci/ahci.c</code>

Concept	In-tree file
EVENTHANDLER	<code>/usr/src/sys/sys/eventhandler.h</code>
MODULE machinery	<code>/usr/src/sys/sys/module.h,</code> <code>/usr/src/sys/kern/kern_module.c</code>
TUNABLE	<code>/usr/src/sys/sys/sysctl.h</code> (search for <code>TUNABLE_INT_FETCH</code>)
SDT probes	<code>/usr/src/sys/sys/sdt.h,</code> <code>/usr/src/sys/cddl/dev/sdt/sdt.c</code>
The <code>null(4)</code> reference	<code>/usr/src/sys/dev/null/null.c</code>

Reading these files alongside the chapter is the next step for any reader who wants to deepen their integration knowledge. The `null(4)` driver in particular is worth reading in full; it is small enough to absorb in one sitting and demonstrates almost every pattern this chapter covered.

24.15.22 What Did Not Make It Into the Chapter

A handful of integration topics belong to FreeBSD's wider toolbox but did not earn a section here, either because they are subsystem-specific in a way that would distract a beginner or because they are covered more thoroughly in a later chapter. Naming them here keeps the chapter honest about its scope and gives the reader a forward-looking map.

The first omission is `geom(4)`. A driver that exposes a block device hooks into GEOM rather than CAM. The registration pattern is similar to the `cdev` pattern (allocate a `g_geom`, fill in `g_class` callbacks, call `g_attach`), but the vocabulary is different enough that mixing it into the chapter would have blurred the storage-versus-character distinction. Drivers for raw disks and pseudo-disk targets live in this neighbourhood; the canonical reference is `/usr/src/sys/geom/geom_disk.c`.

The second omission is `usb(4)`. A USB driver registers with the USB stack through `usb_attach` and a USB-specific method table rather than through Newbus directly. The integration surfaces (`devfs`, `sysctl`) are the same once the device is attached, but the upper edge is owned by the USB stack. The canonical references are under `/usr/src/sys/dev/usb/`.

The third omission is `iicbus(4)` and `spibus(4)`. Drivers that talk to I2C or SPI peripherals attach as children of a bus driver and use bus-specific transfer routines. The integration surfaces remain the same, but the device-tree and FDT integration that drives modern Arm SoCs adds vocabulary that warrants its own chapter. Part VI covers these surfaces in their proper context.

The fourth omission is the `kqueue(2)` and `poll(2)` integration. A character driver that wants to wake user-space programs blocked on `select`, `poll`, or `kqueue` must implement `d_kqfilter` (and optionally `d_poll`), wire `selwakeup` and `KNOTE` into the data path, and supply a small set of filter operations. The mechanism is not difficult, but it is conceptually a layer above the basic `cdev` contract; we will return to it in Chapter 26.

A reader who needs any of these surfaces today should treat the chapter's pattern as the foundation and reach for the in-tree references named above. The discipline (register at attach, drain at detach, hold a single mutex across mutating callbacks, version the public surface) is the same.

24.15.23 Reader Self-Check

Before turning the page, the reader who has worked through the chapter should be able to answer the following questions without consulting the text. Each question maps to a section that introduced the underlying material. If a question is unfamiliar, the chapter section listed in parentheses is the right place to revisit before moving on.

1. What does `D_TRACKCLOSE` change about how `d_close` is invoked? (Section 2)
2. Why is `mda_si_drv1` preferable to assigning `si_drv1` after `make_dev` returns? (Section 2)
3. What does the `_IOR('M', 1, uint32_t)` macro encode in the resulting request code? (Section 3)
4. Why must the dispatcher's default branch return `ENOIOCTL` rather than `EINVAL`? (Section 3)
5. Which kernel function tears down the per-device `sysctl` context, and when does it run? (Section 4)
6. How does `CTLFLAG_TUN` cooperate with `TUNABLE_INT_FETCH` to apply a boot-time value? (Section 4)
7. What is the difference between the `MYFIRST_VERSION` string, the `MODULE_VERSION` integer, and the `MYFIRST_IOCTL_VERSION` integer? (Section 8)
8. Why does the cleanup chain in `attach` use labelled `gotos` in reverse order rather than nested `if` statements? (Section 7)
9. How does the chapter's soft-detach pattern differ from the `dev_ref/dev_rel` pattern that Challenge 3 sketches? (Sections 7 and 10)
10. Which two integration surfaces are required for almost every driver, and which two are required only for drivers that join a specific subsystem? (Sections 1, 2, 3, 4, 5, 6)

A reader who answers most of these without hesitation has internalised the chapter and is ready for what comes next. A reader who hesitates on more than two should revisit the relevant sections before tackling Chapter 25's maintenance discipline.

24.15.24 Final Word

Integration is what turns a working module into a usable driver. The patterns in this chapter are not optional polish; they are the difference between a driver that an operator can adopt and one that an operator has to fight. Master them once, and every subsequent driver gets easier to build, easier to maintain, and easier to ship.

The next chapter takes the discipline introduced here and generalises it into a set of maintenance habits: rate-limited logging, consistent `errno` vocabulary, tunables and versioning, production-grade cleanup, and the `SYSINIT/SYUNINIT/EVENTHANDLER` mechanisms that extend a driver's lifecycle beyond simple load and unload. The vocabulary changes, but the rhythm is the same: register, take traffic, deregister cleanly. With the foundation of Chapter 24 in place, Chapter 25 will feel like a natural extension rather than a new world.

One last thought before turning the page. The integration surfaces in this chapter are deliberately small in number. There are `devfs`, `ioctl`, and `sysctl`. There are the optional registrations to subsystems like `ifnet` and `CAM`. There is the lifecycle discipline that ties them together. Five concepts, in total.

Once these are familiar, the rest of the book is the application of the same patterns to ever more interesting hardware. A reader who has finished this chapter has finished the kernel-API half of the book; what remains is the systems and the discipline to wield it well.

25 Advanced Topics and Practical Tips

25.1 Reader Guidance & Outcomes

Chapter 24 closed with a driver that the rest of the system can talk to. The `myfirst` driver at version 1.7-integration has a clean `/dev/myfirst0` node created through `make_dev_s`, a public `ioctl` header shared between the kernel and user space, a per-instance `sysctl` subtree under `dev.myfirst.0`, a boot-time tunable for the debug mask, and an `ioctl` dispatcher that obeys the `ENOIOCTL` fallback rule so that kernel helpers like `FIONBIO` still reach the `cdev` layer correctly. The driver compiles, loads, runs under stress, and survives repeated `kldload` and `kldunload` cycles without leaking OIDs or `cdev` nodes. In every observable sense, the driver works.

Chapter 25 is about the difference between a driver that *works* and a driver that is *maintainable*. Those two qualities are not the same, and the difference shows up slowly. A working driver passes its first round of testing, attaches cleanly to its hardware, and goes into use. A maintainable driver also does that, and then absorbs the next year of bug fixes, feature additions, portability changes, new hardware revisions, and kernel API churn without slowly collapsing under its own weight. The first gives a developer a good day. The second gives the driver a good decade.

Chapter 25 is the closing chapter of Part 5. Where Chapter 23 taught observability and Chapter 24 taught integration, Chapter 25 teaches the engineering habits that preserve both of those qualities over time. Part 6 begins immediately after with transport-specific drivers (USB in Chapter 26, storage in Chapter 27, networking in Chapter 28 and beyond), and each of those chapters will assume the discipline introduced here. Without rate-limited logging, a USB hotplug storm fills the message buffer. Without a consistent error convention, a storage driver and its peripheral in CAM disagree about what `EBUSY` means. Without loader tunables, a network driver with a suboptimal default queue depth cannot be tuned on a production box without a rebuild. Without versioning discipline, a user-space tool written for this version of the driver silently misinterprets a new field added two months later. Each habit is small. Together, they are what make a driver a long-lived piece of FreeBSD rather than a short-lived lab experiment.

The chapter's running example remains the `myfirst` driver. At the start of the chapter it is at version 1.7-integration. By the end of the chapter it is at version 1.8-maintenance, split into more files than before, logging without flooding the message buffer, returning errors from a consistent vocabulary, configurable from `/boot/loader.conf`, shipping with a `MAINTENANCE.md` document that explains the ongoing maintenance contract, announcing its events through the `devctl` channel, and hooked into the kernel's shutdown and low-memory events through `EVENTHANDLER(9)`. None of those additions require new hardware knowledge. All of them require sharper discipline.

Part 5 closes here with the habits that keep the driver coherent as it grows. Chapter 22 made the driver survive a change of power state. Chapter 23 made the driver tell you what it is doing. Chapter 24 made the driver fit into the rest of the system. Chapter 25 makes the driver keep all of those qualities as it evolves. Chapter 26 will then open Part 6 by putting these qualities to work against a real transport, the Universal Serial Bus, where every shortcut in logging or in failure-path handling is exposed by the speed and variety of USB traffic.

25.1.1 Why Maintenance Discipline Earns a Chapter of Its Own

Before we go further, it is worth pausing on whether rate-limited logging, errno vocabulary, and loader tunables really deserve a full chapter. The earlier chapters have already taught so much. Adding a `ppsratecheck(9)`-backed log macro looks small. Standardising error codes looks even smaller. Why spread the work across a long chapter when each habit looks like a handful of lines?

The answer is that each habit is small, and the absence of each habit is large. A driver that logs without rate limiting is fine in the lab and catastrophic in production the first time a flaky cable triggers ten thousand re-enumerations per second. A driver that returns `EINVAL` when it should return `ENXIO`, and `ENXIO` when it should return `ENOIOCTL`, is fine when the author is the only caller and a bug report waiting to happen when a second developer writes the first user-space helper. A driver that lets every configuration default be a compile-time constant is fine for one person and unworkable for a team maintaining the same module across several production boxes with different workloads. Chapter 25 spends time on each of these habits because the value is measured not in the lab but in the two-year maintenance cost that each habit reduces.

The first reason the chapter earns its place is that **these habits shape what the driver's code base looks like as it grows**. A reader who has followed Chapters 23 and 24 has already seen the driver split into multiple files: `myfirst.c`, `myfirst_debug.c`, `myfirst_ioctl.c`, `myfirst_sysctl.c`. That was modularisation done in the small, one surface at a time. Chapter 25 revisits modularisation with the question most readers have not yet asked: *what does a maintainable source layout look like once the driver has a dozen files and three developers?* The chapter answers that question with a conscious split between the Newbus attach layer, the `cdev` layer, the `ioctl` layer, the `sysctl` layer, and the logging layer, and then uses that split to support every other habit the chapter teaches.

The second reason is that **these habits determine whether the driver can be debugged in production**. A driver that logs judiciously and returns informative errors gives an operator enough information to file a useful bug report. A driver that logs too much or too little, or that invents its own errno conventions, forces the operator to reason from symptoms alone, and the developer ends up chasing intermittent problems blind. Chapter 23's debugging toolkit is effective, but it depends on the driver cooperating. The cooperation is built here.

The third reason is that **these habits make the driver extensible without breaking its callers**. The `myfirst_ioctl.h` header from Chapter 24 is already a contract between the driver and user space. Chapter 25 teaches the reader how to evolve that contract, add a new `ioctl` that older user-space programs can ignore safely, retire a deprecated `sysctl` without breaking administrators' scripts, and bump the driver's version in a way that external consumers can check at run time. Without those habits, the first v2 of the driver forces every caller to be rewritten. With them, the driver can add features for a decade and still run the user-space helpers that were compiled the first week the driver shipped.

Chapter 25 earns its place by teaching those three ideas together, concretely, with the `myfirst` driver as the running example. A reader who finishes Chapter 25 can make any FreeBSD driver ready for long-term maintenance, can read another driver's production-hardening patterns and recognise which are principled and which are ad hoc, can negotiate compatibility with existing user-space tools, and has a `myfirst` driver at version 1.8-maintenance that is visibly ready to begin Part 6.

25.1.2 Where Chapter 24 Left the Driver

A brief recap of where you should stand. Chapter 25 extends the driver produced at the end of Chapter 24 Stage 3, tagged as version 1.7-integration. If any of the items below is uncertain, return to Chapter 24 and fix it before starting this chapter, because the new material assumes every Chapter 24 primitive is working.

- Your driver compiles cleanly and identifies itself as 1.7-integration in the output of `kldstat -v`.
- A `/dev/myfirst0` node exists after `kldload`, has ownership `root:wheel` and mode `0660`, and disappears cleanly on `kldunload`.
- The module exports four ioctls: `MYFIRSTIOC_GETVER`, `MYFIRSTIOC_GETMSG`, `MYFIRSTIOC_SETMSG`, and `MYFIRSTIOC_RESET`. The small `myfirstctl` user-space program from Chapter 24 exercises each one and returns success on all four.
- The `sysctl` subtree `dev.myfirst.0` lists at least `version`, `open_count`, `total_reads`, `total_writes`, `message`, `message_len`, `debug.mask`, and `debug.classes`.
- `sysctl dev.myfirst.0.debug.mask=0xff` enables every debug class, and the driver's subsequent log output shows the expected tags.
- The boot-time tunable `hw.myfirst.debug_mask_default`, placed in `/boot/loader.conf`, applies before attach and sets the initial value of the `sysctl`.
- Repeated `kldload` and `kldunload` in a loop for a minute leave no residual OIDs, no orphan `cdev`, and no leaked memory as reported by `vmstat -m | grep myfirst`.
- Your working tree contains `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, `DMA.md`, `POWER.md`, `DEBUG.md`, and `INTEGRATION.md` from the earlier chapters.
- Your test kernel has `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF` enabled. Chapter 25's labs rely on `WITNESS` and on `INVARIANTS` just as strongly as Chapter 24's did.

That driver is what Chapter 25 extends. The additions are smaller in code lines than in any previous Part 5 chapter, but larger in conceptual surface. The new pieces are: a `myfirst_log.c` and `myfirst_log.h` pair built around `ppsratecheck(9)`, a labelled-goto cleanup chain in `myfirst_attach`, a refined error vocabulary throughout the dispatcher, a pair of `SYSINIT/SYUNINIT` hooks for driver-wide initialisation, a `shutdown_pre_sync` event handler, a new `MYFIRSTIOC_GETCAPS` ioctl that lets user space query feature bits, a modest refactor that splits the Newbus attach out of `myfirst.c` into `myfirst_bus.c` and the `cdev` callbacks out into `myfirst_cdev.c`, a `MAINTENANCE.md` document that explains the version-bumping policy, an updated regression script, and a version bump to 1.8-maintenance.

25.1.3 What You Will Learn

By the end of this chapter you will be able to:

- Explain why unrestricted kernel logging is a production hazard, describe how `ppsratecheck(9)` limits events per second, write a rate-limited logging macro that cooperates with the debug mask from Chapter 23, and recognise the three classes of log messages that deserve different throttling strategies.
- Audit a driver's `read`, `write`, `ioctl`, `open`, `close`, `attach`, `detach`, and `sysctl`-handler paths for correct `errno` usage. Distinguish `EINVAL` from `ENXIO`, `ENOIOCTL` from `ENOTTY`, `EBUSY` from `EAGAIN`, `EPERM` from `EACCES`, and `EIO` from `EFAULT`, and know when each is the right return.

- Add loader tunables through `TUNABLE_INT_FETCH`, `TUNABLE_LONG_FETCH`, `TUNABLE_BOOL_FETCH`, and `TUNABLE_STR_FETCH`, and combine them with writable sysctls so one knob can be set at boot or adjusted at runtime. Understand how `CTLFLAG_TUN` cooperates with the tunable fetchers.
- Expose configuration as a small, well-documented surface rather than as a pile of ad hoc environment variables. Choose between per-driver and per-instance tunables with discipline. Document every tunable's unit, range, and default.
- Version a driver's user-visible interface with a stable three-way split: the human-readable release string in `dev.myfirst.0.version`, the integer `MODULE_VERSION` used by the kernel's module dependency machinery, and the wire-format integer `MYFIRST_IOCTL_VERSION` baked into the public header.
- Add a new ioctl to an existing public header without breaking older callers, retire a deprecated ioctl with a correct deprecation period, and provide a capability bitmask through `MYFIRST_IOC_GETCAPS` so user-space programs can detect feature availability without trial and error.
- Structure a driver's attach and detach paths with the `goto fail;` pattern so that every allocation has exactly one cleanup site, every cleanup runs in reverse order of the allocation, and a partial attach never leaves behind a resource the detach path will not free.
- Split a driver into logical source files along the lines of responsibility rather than along the lines of file size. Choose between a single large file, a small collection of topic-focused files, and a full subsystem tree, and know when each is appropriate.
- Prepare a driver for production use with `MODULE_DEPEND`, `MODULE_PNP_INFO`, a well-behaved modevent handler that accepts `MOD_QUIESCE` when the driver can cleanly pause, a small build system that ships both the module and its documentation, and a `devd(8)`-ready pattern for announcing driver events through `devctl_notify`.
- Use `SYSINIT(9)` and `SYSUNINIT(9)` to hook driver-wide setup and teardown at specific kernel subsystem stages, and understand the difference between module event handlers and subsystem-level init hooks.
- Register and deregister callbacks on well-known kernel events through `EVENTHANDLER(9)`: `shutdown_pre_sync`, `shutdown_post_sync`, `shutdown_final`, `vm_lowmem`, `power_suspend_early`, and `power_resume`. Know how to choose a priority and how to guarantee deregistration on detach.

The list is long because maintenance discipline touches many small surfaces at once. Each item is narrow and teachable. The chapter's work is making them a habit.

25.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 25 stays focused on maintenance discipline at the right level for a reader finishing Part 5.

- **Transport-specific production patterns** such as USB hotplug storms, SATA link-state events, and Ethernet media-change handling belong in Part 6 where each transport is taught in full. Chapter 25 teaches the *general* habits; Chapter 26 and later apply them to USB specifically.
- **Full test-framework design**, including regression harnesses that run across several kernel configurations and fault-injection scenarios, belongs in the hardware-free testing sections of Chapters 26, 27, and 28. Chapter 25 adds one more line to the existing regression script; it does not introduce a whole harness.
- **`fail(9)` and `fail_point(9)`**, the kernel's error-injection facilities, are deferred to Chapter 28 alongside the storage driver work where they are most frequently used.
- **Continuous integration, package signing, and distribution** are operational concerns for the project shipping the driver rather than for the driver's source code. The chapter says just enough about packaging

to make the driver reproducible.

- **MAC(9) (Mandatory Access Control) hooks** are a specialised framework and are best introduced in a later security-focused chapter.
- **kbi(9) stability and ABI freezing** are release-engineering decisions made by the FreeBSD project, not by the driver author. The chapter notes the ABI implications of kernel-exported functions but does not cover release engineering in depth.
- **capsicum(4)** capability-mode integration for user-space helpers is a topic for user-space security, not for the driver itself. The chapter's `myfirstctl` remains a traditional UNIX tool.
- **Advanced concurrency patterns** such as epoch(9), read-mostly locks, and lock-free queues. These are mentioned only in passing; the driver's single softc mutex continues to be sufficient at this stage.

Staying inside those lines keeps Chapter 25 a chapter about *maintenance discipline*, not a chapter about every technique a senior kernel developer might use on a senior kernel problem.

25.1.5 Estimated Time Investment

- **Reading only:** three to four hours. Chapter 25's ideas are conceptually lighter than Chapter 24's, and much of the vocabulary is by now familiar. The chapter's job is to turn familiar primitives into discipline.
- **Reading plus typing the worked examples:** eight to ten hours over two or three sessions. The driver evolves through four short stages (rate-limited logging, error audit, tunable and version discipline, SYSINIT and EVENTHANDLER), each smaller than a single Chapter 24 stage. The refactor in Section 6 touches several files but changes little code; most of the work is moving existing code into its new home.
- **Reading plus all labs and challenges:** twelve to fifteen hours over three or four sessions. The labs include a log-flood reproduction and repair, an errno audit with truss, a tunable lab that boots a VM twice with different `/boot/loader.conf` values, a deliberate attach-failure lab that exercises every label in the `goto fail; chain`, a `shutdown_pre_sync` lab that confirms the callback really runs at the right moment, and a regression-script walkthrough that ties everything together.

Section 5 (failure-path management) is the densest in new discipline rather than new vocabulary. The `goto fail; pattern` itself is mechanical; the trick is reading a real FreeBSD attach function and seeing every allocation as a candidate for a new label. If the pattern feels mechanical on the first pass, that is the signal that it has become a habit.

25.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 24 Stage 3 (1.7-integration). Every Chapter 24 primitive is assumed: the `make_dev_s`-based cdev creation, the `myfirst_ioctl.c` dispatcher, the `myfirst_sysctl.c` tree construction, the `MYFIRST_VERSION`, `MODULE_VERSION`, and `MYFIRST_IOCTL_VERSION` triple, and the per-device `sysctl_ctx_free-free` pattern.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF` is built, installed, and booting cleanly.

- A snapshot of the 1.7-integration state is saved in your VM. Chapter 25's labs include intentional attach-failure scenarios, and a snapshot makes recovery cheap.
- The following user-space commands are in your path: `dmesg`, `sysctl`, `kldstat`, `kldload`, `kldunload`, `devctl`, `devd`, `cc`, `make`, `dtrace`, `truss`, `ktrace`, `kdump`, and `procstat`.
- You are comfortable editing `/boot/loader.conf` and rebooting a VM to pick up new tunables.
- You have the `myfirstctl` companion program from Chapter 24 built and working.

If any item above is shaky, fix it now. Maintenance discipline is easier to learn on a driver that already obeys the earlier chapters' rules than on one that still has unresolved issues from earlier stages.

25.1.7 How to Get the Most Out of This Chapter

Five habits pay off in this chapter more than in any of the previous Part 5 chapters.

First, keep four short manual-page files open in a browser tab or a terminal pane: `ppsratecheck(9)`, `style(9)`, `sysctl(9)`, and `module(9)`. The first is the canonical documentation of the rate-check API. The second is FreeBSD's coding style. The third explains the `sysctl` framework. The fourth is the module event handler contract. None of them is long; each is worth skimming once at the start of the chapter and referring back to when the prose says "consult the manual page for details."

Second, keep three real drivers close to hand. `/usr/src/sys/dev/mmc/mmcsd.c` shows `ppsratecheck` used to throttle a device-`printf` in production. `/usr/src/sys/dev/virtio/block/virtio_blk.c` shows a clean `goto fail;` chain in its attach path and a production-quality set of tunables. `/usr/src/sys/dev/e1000/em_txrx.c` shows how a complex driver splits logging, tunables, and dispatch across several files. Chapter 25 points back to each at the right moment; reading them once now gives the rest of the chapter concrete anchors.

A note on line numbers. When the chapter points at a particular place in `mmcsd.c`, `virtio_blk.c`, or `em_txrx.c`, the pointer is a named symbol, not a numeric line. `ppsratecheck`, the `goto fail;` labels in `virtio_blk_attach`, and the `TUNABLE_*_FETCH` calls stay findable under those names in future tree revisions even as the lines around them move. The audit examples you will see later in the chapter use `file:line` notation purely as a sample tool transcript and carry the same health warning.

Third, type every change into the `myfirst` driver by hand. The additions in Chapter 25 are the kind of changes a developer makes by reflex after a year of maintenance work. Typing them out now builds the reflex; pasting them skips the lesson.

Fourth, after the tunable material in Section 3, reboot your VM at least once with a new `/boot/loader.conf` setting and watch the driver pick it up during attach. Tunables are one of those features that feels abstract until you see a real value flow from the bootloader through the kernel into your softc. Two reboots and one `sysctl` command is all it takes.

Fifth, when the section on `goto fail;` asks you to introduce a deliberate failure into `myfirst_attach`, actually do it. Injecting a single `return (ENOMEM);` into the middle of attach and watching the cleanup chain unwind correctly is the single best way to internalise the pattern. The chapter suggests a specific place to inject, and the regression script confirms the cleanup really ran.

25.1.8 Roadmap Through the Chapter

The sections in order are:

1. **Rate Limiting and Logging Etiquette.** Why uncontrolled kernel logging is a production hazard; the three classes of driver log messages (lifecycle, error, debug); `ppsratecheck(9)` and `ratecheck(9)` as the FreeBSD answer to log-flood; a rate-limited `DLOG_RL` macro that cooperates with the Chapter 23 debug mask; `log(9)` priority levels and their relationship to `device_printf` and `printf`; what the kernel message buffer actually costs and how not to spend it carelessly.
2. **Error Reporting and Return Conventions.** Why `errno` discipline is a contract with every caller; the small vocabulary of kernel `errno`s a driver routinely uses; when each is appropriate; `ENOIOCTL` versus `ENOTTY` and why the driver must never return `EINVAL` from the `ioctl` default; `sysctl` handler return codes; module event handler return codes; a checklist the reader can apply to every driver they write from now on.
3. **Driver Configuration via Loader Tunables and `sysctl`.** The difference between `/boot/loader.conf` tunables and runtime `sysctls`; the `TUNABLE_*_FETCH` family and the `CTLFLAG_TUN` flag; per-driver versus per-instance tunables; how to document a tunable so operators can trust it; a worked lab that boots a VM with a tunable in three different positions and observes the effect in the driver's `sysctl` tree.
4. **Versioning and Compatibility Strategies.** The three-way version split (`MODULE_VERSION` integer, `MYFIRST_VERSION` human string, `MYFIRST_IOCTL_VERSION` wire-format integer); how each one is used; how to add a new `ioctl` without breaking older callers; how to retire a deprecated `ioctl`; `MYFIRST_IOCTL_GETCAPS` and the capability-bitmask idea; how a driver can deprecate a `sysctl` OID gracefully in the absence of a dedicated kernel flag; how `MODULE_DEPEND` enforces a minimum version of a dependency module.
5. **Managing Resources in Failure Paths.** The cleanup-on-failure problem in `myfirst_attach`; the `goto fail`; pattern and why linear unwinding beats nested `if` chains; label naming conventions (`fail_mtx`, `fail_cdev`, `fail_sysctl`); common mistakes (falling through after success, missing a label, adding a resource without adding its cleanup); a small helper-function discipline that reduces duplication; a deliberate-failure lab that tests the whole chain.
6. **Modularisation and Separation of Concerns.** Splitting a driver into files along the axes of responsibility; the canonical split for a character driver (`myfirst.c`, `myfirst_bus.c`, `myfirst_cdev.c`, `myfirst_ioctl.c`, `myfirst_sysctl.c`, `myfirst_debug.c`, `myfirst_log.c`); public versus private headers; how to organise the `Makefile` so all of these files build into one `.ko`; when modularisation helps and when it gets in the way; how a team of developers uses the split to reduce merge conflict.
7. **Preparing for Production Use.** `MODULE_DEPEND` and dependency enforcement; `MODULE_PNP_INFO` for auto-loading; `MOD_QUIESCE` and the pause-before-unload contract; a build-system pattern that installs the module and its documentation; a `devd(8)` rule that reacts to the driver's events; a small `MAINTENANCE.md` document that states the driver's maintenance contract in writing.
8. **SYSINIT, SYSUNINIT, and EVENTHANDLER.** The kernel's broader lifecycle machinery beyond `MOD_LOAD` and `MOD_UNLOAD`; `SYSINIT(9)` and `SYSUNINIT(9)` with subsystem IDs and order constants; real FreeBSD examples of each; `EVENTHANDLER(9)` for cross-cutting notifications (`shutdown_pre_sync`, `vm_lowmem`, `power_resume`); how to register and deregister cleanly; how a driver uses all three mechanisms without drifting into overengineering.

After the eight sections come a set of hands-on labs that exercise each discipline, a set of challenge exercises that stretch the reader without introducing new foundations, a troubleshooting reference for the symptoms most readers will hit, a Wrapping Up that closes Chapter 25's story and opens Chapter 26's, a bridge to the next chapter, a quick-reference card, and a glossary.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 1 and 5 stand alone

and make good single-sitting reads. Section 8 is a short conceptual payoff at the end of the chapter; it depends lightly on Section 7's production-use material and is easy to save for a second sitting.

A small note before the technical work begins. Chapter 25 is the last chapter of Part 5. Its additions are smaller than Chapter 24's, but they touch almost every file in the driver. Expect to spend more time re-reading your own earlier code than writing new code. That, too, is maintenance discipline. A driver you re-read patiently is a driver you can change confidently; a driver you change confidently is a driver you can keep alive.

25.2 Section 1: Rate Limiting and Logging Etiquette

The first discipline this chapter teaches is the discipline of not talking too much. The `myfirst` driver at the end of Chapter 24 logs when it attaches, when it detaches, when a client opens or closes the device, when a read or write crosses the boundary, when an `ioctl` is dispatched, and when the debug mask is adjusted. Every one of those log lines was introduced for a good reason, and every one of them is useful when a single event happens. What none of the Chapter 24 log lines accounts for is what happens when the same event fires a hundred thousand times a second.

This section explains why that question matters more than it looks, introduces the three categories of driver log message that behave differently under pressure, teaches the FreeBSD rate-check primitives (`ratecheck(9)` and `ppsratecheck(9)`), and shows how to build a small, disciplined macro on top of them that cooperates with the existing debug-mask machinery from Chapter 23. By the end of the section the `myfirst` driver has a `myfirst_log.c` and `myfirst_log.h` pair, and its message buffer no longer turns into noise under stress.

25.2.1 The Problem With Unrestricted Logging

A kernel message is cheap to write and expensive to carry. `device_printf(dev, "something happened\n")` is a single function call, tens of nanoseconds on a modern CPU, and it returns almost immediately. The cost is not in the call; the cost is in everything that happens to the bytes afterwards. The formatted string is copied into the kernel message buffer, a circular area of kernel memory whose size is fixed at boot. It is delivered to the console device if the console is attached (often a serial port in a VM, with a finite bit rate). It is sent to the syslog daemon running in user space through the `log(9)` path if the driver uses that path, and then through `newsyslog(8)` into `/var/log/messages` on disk. Each of those steps has a cost, and every one of them is synchronous at the moment the driver writes the line.

When the driver writes one line, none of this matters. When the driver writes a million lines in a second, all of it matters. The kernel message buffer fills, and the oldest messages are overwritten before anyone reads them. The console, typically running at 115200 baud, falls behind and cannot catch up, which in turn backs pressure into the kernel path that wrote the line, which is your driver's fast path. The syslog daemon wakes up, does work, and goes back to sleep many times per second, stealing cycles from other processes. The disk where `/var/log/messages` lives fills at a predictable rate, and a driver that logs at ten thousand lines per second can fill a reasonably sized partition in an afternoon.

None of these symptoms is caused by a bug in the driver's logic. They are caused by the driver's *logging volume*, which in turn is caused by the driver firing a reasonable log line on every event. Reasonable log lines are fine as long as events are rare. They become a hazard when events are common. The whole craft of logging etiquette is knowing, at the moment you write a log line, whether the event behind it is rare or common, and writing the code so that uncontrolled repetition cannot turn a rare-event log into a common-event log.

A concrete example from a real driver illustrates the point. Consider a PCIe SSD controller that notifies its driver of a recoverable queue full condition. On a healthy system that condition is rare enough that logging each occurrence is useful. On a sick system it may happen hundreds of times per second until someone replaces the hardware. If the driver writes a line every time, the message buffer fills with nearly identical lines, all the earlier messages from that boot are overwritten and lost, and the operator who tries to diagnose the problem by reading `dmesg` sees only the last page of the flood. The hardware's actual behaviour is obscured by the driver's reaction to it. A rate-limited log line would have shown the first few occurrences, the rate, and then a periodic reminder; the earlier context in `dmesg` would have survived; the operator would have had something to work with.

The lesson generalises. The right log discipline is not “log less” and not “log more” but “log at a rate that remains useful regardless of how often the underlying event fires.” The rest of this section teaches that discipline concretely.

25.2.2 Three Categories of Driver Log Message

Before picking the right throttling policy, it helps to name the three categories of log message a driver typically emits. Each category has a different throttling story.

The first category is **lifecycle events**. These are the messages that mark attach, detach, suspend, resume, module load, and module unload. They occur once per lifecycle transition, typically a few times in the lifetime of a module. No throttling is needed; the volume is naturally low. Rate-limiting lifecycle messages would be a mistake because it would hide important state transitions.

The second category is **error and warning messages**. These are messages that report something the driver thinks is wrong. By construction each of these should be rare; if a warning is firing a hundred times a second, the warning is telling you something about the rate of underlying events, and that information is worth preserving even when the event repeats. Error and warning messages benefit strongly from rate limiting, but the rate limit should preserve at least one message per burst and should make the *rate* itself visible.

The third category is **debug and trace messages**. These are the messages under the `DPRINTF` macros from Chapter 23. They are intentionally verbose when the debug mask is on and silent when the mask is off. Throttling them at the emit site adds noise to what is already a low-signal path; the better discipline is to avoid emitting them when the mask is off, which is already what the existing `DPRINTF` does. Debug and trace messages do not need additional rate limiting, but they need the user to be able to turn them off entirely with a single `sysctl` command. The existing Chapter 23 plumbing already provides that.

With the three categories named, the rest of the section focuses on the second category. Lifecycle messages are fine as they are. Debug messages are handled by the existing mask. Error and warning messages are where the real discipline goes.

25.2.3 Introducing `ratecheck` and `ppsratecheck`

FreeBSD's kernel provides two closely related primitives for rate-limited output. Both live in `/usr/src/sys/kern/kern_time.c` and are declared in `/usr/src/sys/sys/time.h`.

`ratecheck(struct timeval *lasttime, const struct timeval *mininterval)` is the simpler of the two. The caller holds a `struct timeval` remembering when the event last fired, along with a minimum interval

between allowed prints. On each call, `ratecheck` compares the current time to `*lasttime`, and if `mininterval` has passed, it updates `*lasttime` and returns 1. Otherwise it returns 0. The calling code prints only when the return is 1. The result is a simple floor on the rate of prints: at most one print per `mininterval`.

`ppsratecheck(struct timeval *lasttime, int *curpps, int maxpps)` is the more commonly used form in drivers. Its name is a legacy of the pulse-per-second telemetry use case it was originally written for. The kernel source exposes it through a `#define` in `/usr/src/sys/sys/time.h`:

```
int    eventratecheck(struct timeval *, int *, int);
#define ppsratecheck(t, c, m) eventratecheck(t, c, m)
```

The call accepts a pointer to a timestamp, a pointer to a counter of events in the current one-second window, and the maximum allowed events per second. On each call, if the second has not yet rolled over, the counter is incremented. If the counter exceeds `maxpps`, the function returns 0 and the caller suppresses its output. When a new second begins, the counter is reset to 1 and the function returns 1, allowing one print for the new second. A special value of `maxpps == -1` disables rate limiting entirely (useful for debug paths).

Both primitives are cheap: a comparison and an arithmetic update, no locks. Both are safe to call from any context where the driver currently calls `device_printf`, including interrupt handlers, as long as the storage they access is stable in that context. In practice drivers keep the `struct timeval` and the counter inside their `softc`, protected by the same lock that protects the log site, or they use per-CPU state where that is convenient.

A short example from the FreeBSD tree shows the pattern in real use. The MMC SD card driver, `/usr/src/sys/dev/mmc/mmc.c`, rate-limits a complaint about write errors so that a bad card does not flood the log:

```
if (ppsratecheck(&sc->log_time, &sc->log_count, LOG_PPS))
    device_printf(dev, "Error indicated: %d %s\n",
        err, mmc_errmsg(err));
```

The driver stores `log_time` and `log_count` in its `softc`, picks a reasonable `LOG_PPS` (typically 5 to 10), and wraps the `device_printf` call in the rate check. The first few errors in any second produce log lines; the next several hundred in the same second produce nothing.

That is the whole idea. Everything that follows in this section is about doing the same thing with more structure, more discipline, and less repetition.

25.2.4 A Simple Rate-Limited Log Macro

The goal is a macro the driver can use instead of bare `device_printf` in any error or warning path where the event might repeat. The macro should:

1. Silently discard output when the rate limit is exceeded.
2. Allow a different rate per call site, or at least per category.
3. Cooperate with the existing debug-mask machinery from Chapter 23 so that debug output remains controlled by the mask rather than by the rate limiter.
4. Compile out of non-debug builds if the driver chooses, with no runtime cost.

A minimal implementation looks like this. In a new `myfirst_log.h`:

```
#ifndef _MYFIRST_LOG_H_
#define _MYFIRST_LOG_H_

#include <sys/time.h>

struct myfirst_ratelimit {
    struct timeval rl_lasttime;
    int           rl_curpps;
};

/*
 * Default rate for warning messages: at most 10 per second per call
 * site. Chosen to keep the log readable under a burst while still
 * showing the rate itself.
 */
#define MYF_RL_DEFAULT_PPS 10

/*
 * DLOG_RL - rate-limited device_printf.
 *
 * rlp must point at a per-call-site struct myfirst_ratelimit stored in
 * the driver (typically in the softc). pps is the maximum allowed
 * prints per second. The remaining arguments match device_printf.
 */
#define DLOG_RL(sc, rlp, pps, fmt, ...) do { \
    if (ppsratecheck(&(rlp)->rl_lasttime, &(rlp)->rl_curpps, pps)) \
        device_printf((sc)->sc_dev, fmt, ##__VA_ARGS__); \
} while (0)

#endif /* _MYFIRST_LOG_H_ */
```

In the `softc`, reserve one or more rate-limit structures:

```
struct myfirst_softc {
    /* ... existing fields ... */
    struct myfirst_ratelimit sc_rl_ioerr;
    struct myfirst_ratelimit sc_rl_short;
};
```

At each error site, replace the bare `device_printf` with `DLOG_RL`:

```

/* old:
 * device_printf(sc->sc_dev, "I/O error on read, ENXIO\n");
 */
DLOG_RL(sc, &sc->sc_rl_ioerr, MYF_RL_DEFAULT_PPS,
        "I/O error on read, ENXIO\n");

```

The macro uses a comma operator inside a `do { ... } while (0)` block so it fits anywhere a statement fits, including inside `if` and `else` bodies without braces. The `ppsratecheck` call is inexpensive; when the rate limit is exceeded, the `device_printf` is simply not called. When the rate limit is not exceeded, the behaviour is identical to a direct `device_printf`.

A small but important point: each call site should have its own struct `myfirst_ratelimit`. Sharing one structure across multiple unrelated call sites means the first path that fires in each second suppresses every other path for the rest of that second. In a driver with a handful of rare-but-possible errors, reserve one rate-limit structure per category, name it after the category, and use it consistently.

25.2.5 Cooperating With the Chapter 23 Debug Mask

The rate-limited macro solves the error-and-warning case. The debug case already has its own mechanism from Chapter 23:

```
DPRINTF(sc, MYF_DBG_IO, "read: %zu bytes requested\n", uio->uio_resid);
```

The `DPRINTF` macro expands to nothing when the corresponding bit in `sc_debug` is clear, so debug output at the quiet mask (`mask = 0`) has no runtime cost. There is no need to rate-limit debug output: the operator turns it on when they want to see it and turns it off when they do not. If the operator turns on `MYF_DBG_IO` on a busy device and sees a flood of output, that is the intended behaviour; they wanted the flood. The rate-limit macro and the debug macro serve different purposes and should not be combined.

Where the two do meet is in the occasional log line that is conceptually a warning but that the developer wants the ability to silence entirely. For those, the right pattern is to gate the `DLOG_RL` call on a debug bit:

```

if ((sc->sc_debug & MYF_DBG_IO) != 0)
    DLOG_RL(sc, &sc->sc_rl_short, MYF_RL_DEFAULT_PPS,
            "short read: %d bytes\n", n);

```

The rate-limit fires under debug mask, and the output is both opt-in and bounded. This is a minority pattern; most warnings should fire unconditionally at a rate limit, and most debug prints should be mask-gated without a rate limit.

25.2.6 `log(9)` Priority Levels

A third logging primitive deserves mention here: `log(9)`. Unlike `device_printf`, which always routes through the kernel message buffer, `log` routes through the syslog path with a syslog priority. The function lives in `/usr/src/sys/kern/subr_prf.c` and takes a priority from `/usr/src/sys/sys/syslog.h`:

```
void log(int level, const char *fmt, ...);
```

Common priorities: `LOG_EMERG` (0) for system-unusable conditions, `LOG_ALERT` (1) for immediate action, `LOG_CRIT` (2) for critical conditions, `LOG_ERR` (3) for error conditions, `LOG_WARNING` (4) for warnings, `LOG_NOTICE` (5) for notable but normal conditions, `LOG_INFO` (6) for informational messages, `LOG_DEBUG` (7) for debug-level messages. A driver that uses `log(LOG_WARNING, ...)` for its warning path rather than `device_printf` gains the ability to be filtered by `syslog.conf(5)` into a separate log file without the driver author having to do anything else.

The tradeoff is that `log(9)` does not prepend the device name. A driver using `log` has to format the device name into the message manually, which is verbose. Most FreeBSD drivers therefore prefer `device_printf` for driver-specific messages and reserve `log` for cross-cutting notifications. The `myfirst` driver follows the same convention: `device_printf` for everything the operator is meant to read with `dmesg`, `log` for nothing at this stage.

A pragmatic guideline: use `device_printf` when the message is *about this device*. Use `log(9)` when the message is *about a cross-cutting condition* that the syslog infrastructure is the right place to see, such as an authentication event or a policy violation. Driver code rarely needs the second kind.

25.2.7 The Kernel Message Buffer and What It Costs

One more technical detail before the section closes. The kernel message buffer (`msgbuf`) is a fixed-size circular buffer inside the kernel, allocated at boot. Its size is controlled by the `kern.msgbufsize` tunable, which defaults to 96 KiB on amd64 and can be raised in `/boot/loader.conf`. Every `printf`, `device_printf`, and `log` call routes through the buffer. When the buffer fills, the oldest messages are overwritten. The buffer's contents are what `dmesg` prints.

Two practical consequences follow. First, a flood of short messages can evict the earlier messages an operator needs. A line that says “hello” uses a few dozen bytes; a buffer of 96 KiB holds maybe three thousand such lines; a loop that prints at ten thousand lines per second evicts the entire boot log in less than half a second. Second, a formatted message is not free to produce. `printf`-style formatting costs CPU, and inside an interrupt handler or a hot path that cost shows up directly in latency numbers. The rate-limited macro helps with the first consequence. The second is why debug messages are mask-gated: a `DPRINTF` at mask zero compiles down to an empty statement at runtime, skipping both the formatting and the storage.

Increasing `kern.msgbufsize` is a reasonable response to a machine that repeatedly loses boot logs, but it is not a substitute for rate limiting. A bigger buffer simply buys more room before the flood evicts the older messages; rate limiting reduces the flood itself. Both are worth doing. `kern.msgbufsize=262144` in `/boot/loader.conf` is a common operator choice on production machines. It is not a Chapter 25 action, because the driver cannot change the buffer size at run time.

25.2.8 A Worked Example: The `myfirst` Read Path

Putting the pieces together, consider the existing `myfirst_read` callback. A simplified version from Chapter 24 looked like this:

```
static int
myfirst_read(struct cdev *cdev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = cdev->si_drv1;
    int error = 0;

    mtx_lock(&sc->sc_mtx);
    if (uio->uio_resid == 0) {
        device_printf(sc->sc_dev, "read: empty request\n");
        goto out;
    }
    /* copy bytes into user space, update counters ... */
out:
    mtx_unlock(&sc->sc_mtx);
    return (error);
}
```

That code has a latent rate-flood problem. Under stress, a buggy or malicious user-space program can call `read(fd, buf, 0)` in a tight loop and fill the message buffer with “empty request” lines. The event is not an error in the driver; it is a strange-but-legal syscall pattern. Logging it at all is marginal, but if the driver logs it, the log line must be rate-limited.

After the refactor, the same path looks like this:

```
static int
myfirst_read(struct cdev *cdev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = cdev->si_drv1;
    int error = 0;

    mtx_lock(&sc->sc_mtx);
    if (uio->uio_resid == 0) {
        DLOG_RL(sc, &sc->sc_rl_short, MYF_RL_DEFAULT_PPS,
            "read: empty request\n");
        goto out;
    }
    /* copy bytes into user space, update counters ... */
out:
    mtx_unlock(&sc->sc_mtx);
    return (error);
}
```

The change is three lines. The effect is that the log can no longer flood, and the first occurrence in any second still produces a line for the operator to notice. The softc gains one `struct myfirst_ratelimit` `sc_rl_short` field; no other code moves.

Apply the same transformation to every `device_printf` in every error or warning path, reserve one struct `myfirst_ratelimit` per category, and the driver is rate-limited. The diff is mechanical; the discipline is what makes the diff possible in the first place.

25.2.9 Common Mistakes and How to Avoid Them

Three mistakes are common when first applying rate limiting. Each is easy to spot once you know to look.

The first mistake is **sharing a single rate-limit structure across unrelated call sites**. If site A and site B both use `sc->sc_rl_generic`, a burst at site A silences site B for the rest of the second, and the operator sees only one category. The correct discipline is one rate-limit structure per logical category. Two or three categories per driver is usual; ten is a sign the driver is logging too many kinds of events.

The second mistake is **rate-limiting lifecycle messages**. The driver loads and prints a banner. That banner fires once. Wrapping it in `ppsratecheck` adds noise for no gain, and on a second load during an unfortunate second-boundary it can skip the banner entirely. Reserve rate limiting for the messages that can actually repeat.

The third mistake is **forgetting that the rate-limit counter lives in the softc**. A call site that fires before attach completes, or after detach starts, can touch a softc whose rate-limit structure is not yet initialised (or has been zeroed by `bzero(sc, sizeof(*sc))`). The struct `timeval` and `int` are both value types; a zero-initialised structure is fine for the first call, because `ppsratecheck` handles the `lasttime == 0` case correctly. But an uninitialised heap allocation that later holds garbage is not fine, because the `lasttime` field may hold a large value that makes the code think the last event was in the distant future, and every subsequent call returns 0 until the kernel's clock passes that future time, which may be never. The fix is to ensure the softc is zero-initialised, which in `myfirst` it already is (`newbus` allocates softc with `MALLOC(... M_ZERO)`). A driver that allocates its own state with `M_NOWAIT` without `M_ZERO` must call `bzero` explicitly.

25.2.10 When Not to Rate-Limit

Rate limiting is a discipline for paths that can fire often. Some paths cannot. A `KASSERT` failure panics the kernel, so rate-limiting the pre-panic message is wasted effort. An error that aborts a module load ends the load, so only one copy of the message can ever appear. A `device_printf` at attach time fires at most once per instance. For all of these, bare `device_printf` is correct and the extra wrapper is clutter.

A useful rule of thumb: if the call site runs after attach has completed and before detach has run, and if the event can be caused by something external to the driver (a misbehaving user-space program, a flaky device, a stressed kernel), then rate-limit. Otherwise, do not.

25.2.11 What the myfirst Driver Now Contains

After this section the `myfirst` driver's working tree has two new files:

```
myfirst_log.h   - the DLOG_RL macro and struct myfirst_ratelimit definition
myfirst_log.c   - any non-trivial rate-check helpers (empty for now)
```

The `myfirst.h` header still holds the `softc`. The `softc` gains two or three `struct myfirst_ratelimit` fields, named for the call-site categories that use them. The `read`, `write`, and `ioctl` paths replace their bare `device_printf` calls at error sites with `DLOG_RL`. The `attach`, `detach`, `open`, and `close` paths keep their bare `device_printf` calls, because those are lifecycle messages and do not repeat.

The `Makefile` gains one line:

```
SRCS= myfirst.c myfirst_debug.c myfirst_ioctl.c myfirst_sysctl.c \  
      myfirst_log.c
```

The module builds, loads, and behaves exactly as before in the common case. Under stress the driver no longer floods the message buffer. That is the whole contribution of Section 1.

25.2.12 Wrapping Up Section 1

A driver that logs without discipline is a driver that fails gracefully in the lab and fails loudly in production. The FreeBSD rate-check primitives `ratecheck(9)` and `ppsratecheck(9)` are small enough to understand in an hour and effective enough to pay back their cost for the rest of the driver's life. Combined with the existing debug-mask machinery from Chapter 23, they give the `myfirst` driver a clean three-way logging story: lifecycle messages go through plain `device_printf`, error and warning messages go through `DLOG_RL`, and debug messages go through `DPRINTF` under the mask.

In the next section, we turn from what the driver says to what it returns. A log line is for the operator; an `errno` is for the caller. A driver that says the right thing to the operator but the wrong thing to the caller is still a broken driver.

25.3 Section 2: Error Reporting and Return Conventions

The second discipline the chapter teaches is the discipline of returning the right `errno`. An `errno` is a small number. The set of possible `errno`s is defined in `/usr/src/sys/sys/errno.h`, and at time of writing FreeBSD defines fewer than a hundred of them. A driver that is careless about which `errno` it returns looks fine in the moment, because the caller mostly only checks whether the return value was non-zero, and any non-zero value passes that test. It looks much less fine a few months later when the first user-space helper tries to distinguish *why* a call failed, and the driver's `errno` choices turn out to be inconsistent. This section teaches the small vocabulary of `errno`s a driver routinely uses, shows how to choose between them, and walks through an audit of the `myfirst` driver's existing paths.

25.3.1 Why Errno Discipline Matters

A driver's `errno` return is a contract with every caller. User-space programs use `errno`s through `strerror(3)` and through direct comparison (`if (errno == EBUSY)`). Kernel code that invokes driver callbacks uses the return value to decide what to do next: a `d_open` that returns `EBUSY` causes the kernel to fail the `open(2)` syscall with `EBUSY`; a `d_ioctl` that returns `ENOIOCTL` causes the kernel to fall through to the generic `ioctl` layer; a `device_attach` that returns a non-zero value causes Newbus to roll back the attach and disown the device.

Each of those consumers expects a specific value to mean a specific thing. A driver that returns `EINVAL` where `ENXIO` was expected does not necessarily fail; often it just misleads, and the misleading `errno` shows up as a mystifying diagnostic somewhere the driver author will never see.

The discipline is cheap. The costs of ignoring it compound over time. A driver that chose its `errno`s well from the start is a driver that produces accurate manual pages, accurate user-space helper error messages, and accurate bug reports. A driver that was sloppy about `errno`s starts producing `strerror` output that is slightly wrong in many places, and the user-space side of the ecosystem inherits the sloppiness.

25.3.2 The Small Vocabulary

The full list of `errno`s is long. The subset a typical character driver uses is short. The table below is the vocabulary most often needed in a FreeBSD driver, grouped by when each is appropriate.

Errno	Numeric value	When to return
<code>0</code>	0	Success. The only non-error return.
<code>EPERM</code>	1	The caller lacks privilege for the requested operation, even though the call itself is well-formed. Example: a non-root user requesting a privileged <code>ioctl</code> .
<code>ENOENT</code>	2	The requested object does not exist. Example: a lookup by name or ID that finds nothing.
<code>EIO</code>	5	Generic I/O error from hardware. Use when the hardware returned a failure and there is no more specific <code>errno</code> .
<code>ENXIO</code>	6	The device is gone, detached, or otherwise unreachable. Example: an <code>ioctl</code> on a file descriptor whose underlying device was removed. Different from <code>ENOENT</code> : the object was there and is now gone.
<code>EBADF</code>	9	The file descriptor is not opened correctly for the operation. Example: a <code>MYFIRSTIOC_SETMSG</code> call made on a file descriptor opened read-only.
<code>ENOMEM</code>	12	Allocation failed. Use for <code>malloc(M_NOWAIT)</code> failures and similar.
<code>EACCES</code>	13	The caller lacks permission at the file-system level. Different from <code>EPERM</code> : <code>EACCES</code> is about file permissions, <code>EPERM</code> is about privilege.

Errno	Numeric value	When to return
EFAULT	14	A user pointer is invalid. Returned by failed copyin or copyout. Drivers should forward copyin/copyout failures unchanged.
EBUSY	16	The resource is in use. Use for detach that cannot proceed because a client still holds the device open, or for mutex-like acquire attempts that cannot wait.
EINVAL	22	The arguments are recognised but invalid. Use when the driver understood the request but the inputs are malformed.
EAGAIN	35	Try again later. Returned from non-blocking I/O when the operation would block, or from allocation failures that may succeed on retry.
EOPNOTSUPP	45	The operation is not supported by this driver. Use when the call is well-formed but the driver has no code to handle it.
ETIMEDOUT	60	A wait timed out. Use for hardware commands that did not complete within the driver's timeout budget.
ENOIOCTL	-3	The ioctl command is unknown to this driver. Use this for the default case in <code>d_ioctl</code>; the kernel translates it to ENOTTY for user space.
ENOSPC	28	No space left, whether on the device, in a buffer, or in an internal table.

Three pairs in this table are famously easy to confuse: EPERM versus EACCES, ENOENT versus ENXIO, and EINVAL versus EOPNOTSUPP. Each is worth looking at in turn.

EPERM versus EACCES. EPERM is about privilege: the caller is not privileged enough to perform the operation. EACCES is about permission: the file-system ACL or mode bits forbid the access. A non-root user trying to write to `/dev/myfirst0` when the node mode is `0600 root:wheel` gets EACCES from the kernel before the driver is consulted. A root user trying to call a privileged ioctl that the driver rejects because the caller is not in a particular jail gets EPERM from the driver. The distinction matters because the administrator's remedy differs: EACCES asks the administrator to adjust device permissions, while EPERM asks the administrator to adjust the caller's privileges.

ENOENT versus ENXIO. ENOENT is *there is no such object*. ENXIO is *the object is gone, or the device is unreachable*. On a lookup into a driver's internal table, ENOENT is the right answer when the requested key is not present. On an operation against a device that has been detached or that has signalled a surprise-removal condition, ENXIO is the right answer. The distinction matters because operational tools treat them differently: ENOENT suggests

the caller gave the wrong key; `ENXIO` suggests the device needs reattachment.

`EINVAL` versus `EOPNOTSUPP`. `EINVAL` is *I understood what you asked but the arguments are wrong*. `EOPNOTSUPP` is *I do not support what you asked*. A `MYFIRSTIOC_SETMSG` call with a buffer that is too long is `EINVAL`. A `MYFIRSTIOC_SETMODE` call for a mode the driver never implements is `EOPNOTSUPP`. The distinction matters because `EOPNOTSUPP` tells the caller to use a different approach, while `EINVAL` tells the caller to fix the arguments and retry.

A fourth confusion deserves a paragraph of its own: `ENOIOCTL` versus `ENOTTY`. `ENOIOCTL` is a negative value (-3) defined for the `ioctl` code path inside the kernel. A driver's `d_ioctl` default case returns `ENOIOCTL` to tell the kernel "I do not recognise this command; please fall through to the generic layer." The generic layer handles `FIONBIO`, `FIOASYNC`, `FIOGETOWN`, `FIOSETOWN`, and similar cross-device `ioctl`s. If the generic layer also does not recognise the command, it translates `ENOIOCTL` into `ENOTTY` (positive 25) for delivery to user space. The common mistake is to return `EINVAL` from the default case of a `d_ioctl` switch, which suppresses the generic fallback entirely. The Chapter 24 driver already returns `ENOIOCTL` correctly; Chapter 25's audit confirms it and checks every other `errno` in the driver for similar issues.

25.3.3 The `ioctl` Dispatcher Audit

The first audit pass targets `myfirst_ioctl.c`. Each case in the switch statement produces at most one non-zero return. The audit looks at each and asks whether the returned `errno` is correct.

Case `MYFIRSTIOC_GETVER`: returns 0 on success, never fails. Nothing to audit.

Case `MYFIRSTIOC_GETMSG`: returns 0 on success. The current code does not reject on `fflag` because the message is public. That is a design choice, not a bug. If the driver wanted to restrict `GETMSG` to readers (i.e., require `FREAD`), it would return `EBADF` on the `fflag` check, consistent with the `SETMSG` and `RESET` cases.

Case `MYFIRSTIOC_SETMSG`: returns `EBADF` when the file descriptor lacks `FWRITE`, which is correct. The second audit question is what happens when the input is not NUL-terminated: `strncpy` in the kernel tolerates it (copies up to `MYFIRST_MSG_MAX - 1` and terminates), so the driver does not need to check. The third question is whether the length should be validated before copy. The kernel's automatic copyin already enforced the fixed length baked into the `ioctl` encoding, so there is no user-space buffer to validate; the value is in `data` and has been copied already.

Case `MYFIRSTIOC_RESET`: returns `EBADF` when the file descriptor lacks `FWRITE`. The Chapter 25 audit raises a second question: should the reset be privileged? A driver that lets any writer call `RESET` and zero out statistics is exposing a minor denial-of-service surface. The simple fix is to check `priv_check(td, PRIV_DRIVER)` before executing the reset:

```
case MYFIRSTIOC_RESET:
    if ((fflag & FWRITE) == 0) {
        error = EBADF;
        break;
    }
    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        break;
```

```
/* ... existing reset body ... */  
break;
```

If `priv_check` fails, the `errno` is `EPERM` (the kernel returns `EPERM` rather than `EACCES` because the check is about privilege, not file-system permissions). The `myfirstctl` program running as root sees 0; a non-root program running as the `_myfirst` user sees `EPERM`.

Default case: returns `ENOIOCTL`, which is correct. Leave it alone.

25.3.4 The Read and Write Path Audit

The second audit pass targets the read and write callbacks.

For `myfirst_read`, the current code returns 0 on success, `EFAULT` when `uiomove` fails, and 0 when `uio_resid == 0`. The 0 return on an empty request is the standard UNIX behaviour (a read of zero bytes is allowed and returns 0 bytes) and is correct. No `errno` change is needed.

For `myfirst_write`, similarly, 0 on success, `EFAULT` on `uiomove` failure, 0 on zero-byte write. Correct.

Neither callback needs `EIO`: the driver does not do hardware I/O at this point, so there is no hardware failure to propagate. A future version of the driver that drives real hardware would return `EIO` from the read or write callback when the hardware indicated a transport-level failure. Adding that return now would be premature; it is the kind of thing Chapter 28's storage work will treat concretely.

25.3.5 The Open and Close Path Audit

The open callback currently returns 0 unconditionally. The audit question is whether it should ever fail. Three failure modes are conventionally possible: the device is exclusive-open and already has a user (`EBUSY`), the device is powered down and not currently acceptable to open (`ENXIO`), or the driver is being detached right now (`ENXIO`). The simple `myfirst` driver does not enforce exclusive open, and it always accepts opens except during detach. During detach the kernel destroys the `cdev` before the detach returns, so any open arriving after `destroy_dev` begins is rejected by the kernel itself before the driver's `d_open` is called. The `myfirst` driver therefore does not need explicit `ENXIO` logic. Leaving the open callback returning 0 is correct.

The close callback returns 0 unconditionally. That is correct. The only conceivable reason for `d_close` to return non-zero is a hardware operation during close that failed; since the `myfirst` driver does no such operation, 0 is the right return.

25.3.6 The Attach and Detach Path Audit

Attach and detach are the callbacks Newbus invokes. Their return values tell Newbus whether to roll back or proceed.

`myfirst_attach`'s non-zero return means "attach failed; please roll back." Every error path in attach must return a positive `errno`. The current code returns the error value from `make_dev_s`, which is positive on failure; that is correct. The additions in Section 5 of this chapter will introduce more error paths with labelled `gotos`;

each of them will use the correct `errno` for the failed step (`ENOMEM` for allocation failure, `ENXIO` for resource allocation failure, etc.).

`myfirst_detach`'s non-zero return means "cannot detach right now; please leave the device attached." The current code returns `EBUSY` when `sc_open_count > 0`, which is correct. Newbus translates `EBUSY` from detach into a `devctl detach` failure with the same `errno`, which is the right user-visible behaviour.

The module event handler (`myfirst_modevent`) returns non-zero to reject the event. `MOD_UNLOAD` that cannot proceed because some device instance is still in use returns `EBUSY`. `MOD_LOAD` that cannot proceed because of a sanity-check failure returns an appropriate `errno` (`ENOMEM`, `EINVAL`, etc.). The current code is correct.

25.3.7 The Sysctl Handler Audit

Sysctl handlers have their own `errno` conventions. The Chapter 24 driver has one custom handler, `myfirst_sysctl_message_len`. Its body is:

```
static int
myfirst_sysctl_message_len(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    u_int len;

    mtx_lock(&sc->sc_mtx);
    len = (u_int)sc->sc_msglen;
    mtx_unlock(&sc->sc_mtx);

    return (sysctl_handle_int(oidp, &len, 0, req));
}
```

The handler reads its input with `sysctl_handle_int`, which returns 0 on success and a positive `errno` on failure. The handler forwards that `errno` unchanged, which is correct. No audit change is needed.

A sysctl handler that writes (rather than only reads) should check `req->newptr` to distinguish a read from a write, and should return `EPERM` if the write is attempted on a read-only OID. The existing `debug.mask` OID is declared with `CTLFLAG_RW`, so the kernel allows writes automatically; the handler does not need a privilege check because the OID is already restricted to root by the sysctl MIB permissions. The Chapter 25 driver does not add more custom sysctl handlers at this stage.

25.3.8 Error Path Messages

Returning the right `errno` is half the contract. Emitting the right log message is the other half. The discipline combines the rate-limited logging of Section 1 with the `errno` vocabulary of Section 2. A warning path looks like this:

```
if (input_too_large) {
    DLOG_RL(sc, &sc->sc_rl_inval, MYF_RL_DEFAULT_PPS,
        "ioctl: SETMSG buffer too large (%zu > %d)\n",
        length, MYFIRST_MSG_MAX);
    error = EINVAL;
    break;
}
```

Three properties make this a good error path. First, the log message names the call (“ioctl: SETMSG”), the reason (“buffer too large”), and the numeric values involved. Second, the errno returned is `EINVAL`, which is the right value for “I understood but the argument is wrong.” Third, the whole path is rate-limited so that a buggy user-space program calling the `ioctl` in a tight loop cannot flood the message buffer.

A bad error path looks like this:

```
if (input_too_large) {
    device_printf(sc->sc_dev, "ioctl failed\n");
    return (-1);
}
```

Three properties make this a bad error path. The log message is uninformative: “ioctl failed” says nothing the caller did not already know. The return value is `-1`, which is not a valid kernel errno. And the log line is not rate-limited, so a misbehaving caller can fill the message buffer with noise.

The good path takes nine lines and the bad path takes three, which is a good trade. An error log line is only printed when something is wrong; spending a few extra seconds to make it informative when it does print is worth the time.

25.3.9 Module Event Handler Conventions

The module event handler has its own errno convention. The handler signature is:

```
static int
myfirst_modevent(module_t mod, int what, void *arg)
{
    switch (what) {
    case MOD_LOAD:
        /* Driver-wide init. */
        return (0);
    case MOD_UNLOAD:
        /* Driver-wide teardown. */
        return (0);
    case MOD_QUIESCE:
        /* Pause and prepare for unload. */

```

```

        return (0);
    case MOD_SHUTDOWN:
        /* System shutting down. */
        return (0);
    default:
        return (EOPNOTSUPP);
    }
}

```

Each case returns 0 on success, or a positive errno to reject the event. The specific errnos by case:

- MOD_LOAD returns ENOMEM if a global allocation failed, ENXIO if the driver is not compatible with the current kernel, or EINVAL if a tunable's value is out of range.
- MOD_UNLOAD returns EBUSY if the driver cannot be unloaded right now because some instance is still in use. The kernel respects this and leaves the module loaded.
- MOD_QUIESCE returns EBUSY if the driver cannot pause. A driver that does not support quiescence simply returns 0 from this case, because quiescence is an optional feature and returning success says "I am paused" in the trivial sense of having no work in flight.
- MOD_SHUTDOWN rarely fails; it returns 0 unless the driver has a specific reason to object to shutdown. A driver that wants to flush persistent state uses an EVENTHANDLER on shutdown_pre_sync rather than rejecting MOD_SHUTDOWN.
- The default case returns EOPNOTSUPP to indicate the driver does not recognise the event type. This is not an error; it is the standard way to say "I do not implement this event."

25.3.10 An Errno Checklist

To close the section, a checklist the reader can run against any driver they write. Each item is a question whose answer should be yes.

1. Every non-zero return in a callback is a positive errno from `errno.h`, except for `d_ioctl` which may return `ENOIOCTL` (a negative value).
2. `copyin` and `copyout` failures propagate their errno unchanged (typically `EFAULT`).
3. The default case of `d_ioctl` returns `ENOIOCTL`, not `EINVAL`.
4. `d_detach` returns `EBUSY` if the device is still in use, not `ENXIO` or some other value.
5. `d_open` returns `ENXIO` if the underlying hardware is gone or if the driver is being detached, not `EIO`.
6. `d_write` returns `EBADF` if the file descriptor lacks `FWRITE`, not `EPERM`.
7. Every error path logs a message that names the call, the reason, and the relevant values, using the rate-limited macro.
8. No error path logs *and* returns a generic errno. If the driver has enough context to log the specific reason, it has enough context to return a specific errno.
9. The driver distinguishes `EINVAL` (arguments wrong) from `EOPNOTSUPP` (feature absent) consistently.
10. The driver distinguishes `ENOENT` (no such key) from `ENXIO` (device unreachable) consistently.

A driver that passes this checklist has a consistent errno surface, and the surface is small enough that the manual page can list every errno the driver returns and say exactly when each occurs.

25.3.11 Wrapping Up Section 2

Ernos are a small vocabulary and a contract. Sloppiness about either shows up as mystifying behaviour in user space; discipline about both shows up as accurate diagnostics and shorter bug reports. Combined with Section 1's rate-limited logging, the `myfirst` driver now talks carefully to both the operator (through log lines) and the caller (through ernos).

In the next section, we look at the third audience the driver owes a contract to: the administrator who configures the driver through `/boot/loader.conf` and `sysctl`. Configuration is a third kind of contract, and discipline about it is how the driver stays useful across workloads without needing a rebuild.

25.4 Section 3: Driver Configuration via Loader Tunables and `sysctl`

The third discipline is the discipline of externalising decisions. Any driver has values that someone might reasonably want to change without rebuilding the module: a timeout, a retry count, an internal buffer size, a verbosity level, a feature toggle. A driver that bakes those values into the source forces every change to go through a full compile, install, and reboot cycle. A driver that exposes them as loader tunables and `sysctls` lets an operator adjust behaviour at boot or at run time with a single edit or a single command. The cost of offering the knobs is small; the cost of not offering them is paid by the operator.

This section teaches the two FreeBSD mechanisms for externalising configuration: loader tunables (read from `/boot/loader.conf` and applied before the kernel reaches `attach`) and `sysctls` (read and written at run time through `sysctl(8)`). It explains how they cooperate through the `CTLFLAG_TUN` flag, shows how to choose between per-driver and per-instance tunables, walks through the `TUNABLE_*_FETCH` family, and ends with a short lab in which the `myfirst` driver gains three new tunables and the reader boots the VM with each.

25.4.1 The Difference Between a Tunable and a `Sysctl`

A tunable and a `sysctl` look similar to an operator. Both are strings in a namespace like `hw.myfirst.debug_mask_default` or `dev.myfirst.0.debug.mask`. Both take values the operator sets. Both end up in kernel memory. They differ in when and how.

A **tunable** is a variable set in the bootloader environment. The bootloader (`loader(8)`) reads `/boot/loader.conf`, collects its `key=value` pairs into an environment, and hands that environment to the kernel when the kernel starts. The kernel exposes this environment through the `getenv(9)` family and through the `TUNABLE_*_FETCH` macros. Tunables are read during boot, usually before the corresponding driver attaches. They cannot be changed at run time (changing `/boot/loader.conf` requires a reboot for the change to take effect). They are appropriate for values that must be known before `attach` runs: the size of a statically-allocated table, a feature flag that controls which code paths are compiled into the attach path, the initial value of a debug mask.

A **`sysctl`** is a variable in the kernel's hierarchical configuration tree, accessible at run time through the `sysctl(2)` syscall and the `sysctl(8)` tool. `sysctls` can be read-only (`CTLFLAG_RD`), read-write (`CTLFLAG_RW`), or read-only-root-writable (various combinations of flags). They are appropriate for values that make sense to change after the driver has attached: a verbosity level, a throttle rate, a counter reset command, a writable status knob.

The useful feature is that the two mechanisms can share a variable. A `sysctl` declared with `CTLFLAG_TUN` tells the kernel to read a tunable of the same name at boot and use its value as the initial value of the `sysctl`. The

operator can then adjust the sysctl at run time, and the tunable persists across reboots as the default. The `myfirst` driver already uses this pattern for its debug mask: `debug.mask` is a `CTLFLAG_RW | CTLFLAG_TUN` sysctl, and `hw.myfirst.debug_mask_default` is the matching tunable in `/boot/loader.conf`. Section 3 generalises that pattern to every configuration knob the driver wants to expose.

25.4.2 The `TUNABLE_*_FETCH` Family

FreeBSD provides a family of macros for reading tunables from the bootloader environment. Each macro reads the named tunable, parses it into the right C type, and stores the result. If the tunable is not set, the variable keeps its existing value; the caller must therefore initialise the variable to the right default before calling the fetch macro.

The macros, declared in `/usr/src/sys/sys/kernel.h`:

```
TUNABLE_INT_FETCH(path, pval)      /* int */
TUNABLE_LONG_FETCH(path, pval)     /* long */
TUNABLE_ULONG_FETCH(path, pval)    /* unsigned long */
TUNABLE_INT64_FETCH(path, pval)    /* int64_t */
TUNABLE_UINT64_FETCH(path, pval)   /* uint64_t */
TUNABLE_BOOL_FETCH(path, pval)     /* bool */
TUNABLE_STR_FETCH(path, pval, size) /* char buffer of given size */
```

Each expands to the matching `getenv_*` call. For `TUNABLE_INT_FETCH`, for example, the expansion is `getenv_int(path, pval)`, which reads the bootloader environment and parses the value as an integer.

The path is a string, conventionally of the form `hw.<driver>.<knob>` for per-driver tunables and `hw.<driver>.<unit>.<knob>` for per-instance tunables. The `hw.` prefix is a convention for hardware-related tunables; other prefixes (`kern.`, `net.`) exist for different subsystems but are less common in driver code.

A worked example from the `myfirst` driver shows the pattern:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error;

    /* Initialise defaults. */
    sc->sc_debug = 0;
    sc->sc_timeout_sec = 30;
    sc->sc_max_retries = 3;

    /* Read tunables. The variables keep their default values if
     * the tunables are not set. */
    TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default", &sc->sc_debug);
```

```
TUNABLE_INT_FETCH("hw.myfirst.timeout_sec", &sc->sc_timeout_sec);
TUNABLE_INT_FETCH("hw.myfirst.max_retries", &sc->sc_max_retries);

/* ... rest of attach ... */
}
```

The operator sets the tunables in `/boot/loader.conf`:

```
hw.myfirst.debug_mask_default="0xff"
hw.myfirst.timeout_sec="15"
hw.myfirst.max_retries="5"
```

After reboot, every instance of `myfirst` attaches with `sc_debug=0xff`, `sc_timeout_sec=15`, `sc_max_retries=5`. No rebuild was required; the values live outside the driver source.

25.4.3 Per-Driver Versus Per-Instance Tunables

A driver that might attach more than once needs a decision: should its tunables apply to every instance, or should each instance have its own?

The per-driver form uses a path of the form `hw.myfirst.debug_mask_default`. Every instance of `myfirst` at attach time reads this single variable, so all instances start with the same default. This is the simpler form and is correct when the tunable has the same meaning on every instance.

The per-instance form uses a path of the form `hw.myfirst.0.debug_mask_default`, where `0` is the unit number. Each instance reads its own variable, so instance `0` and instance `1` can have different defaults. This is the right form when the hardware behind each instance can reasonably need different configuration, for example two PCI adapters on the same system with different workloads.

The decision is a design choice, not a correctness question. Most drivers use the per-driver form for most tunables, with per-instance forms reserved for the few cases where per-instance configuration actually matters. For `myfirst`, a fictional pseudo-device, per-driver is the right default for every tunable. The Chapter 25 driver therefore adds three per-driver tunables (`timeout_sec`, `max_retries`, `log_ratelimit_pps`) and keeps the existing per-driver `debug_mask_default`.

A pattern that combines both forms, if the driver needs it, is to read the per-driver tunable first as a baseline and then read the per-instance tunable as an override:

```
int defval = 30;

TUNABLE_INT_FETCH("hw.myfirst.timeout_sec", &defval);
sc->sc_timeout_sec = defval;
TUNABLE_INT_FETCH_UNIT("hw.myfirst", unit, "timeout_sec",
    &sc->sc_timeout_sec);
```

FreeBSD does not have a `TUNABLE_INT_FETCH_UNIT` macro out of the box; a driver that needs this has to compose the path with `snprintf` and then call `getenv_int` by hand. The effort is small but the need is rare, so `myfirst` does not go there.

25.4.4 The `CTLFLAG_TUN` Flag

The second half of the externalisation story is that a tunable by itself is read only at boot. To make the same value adjustable at run time, the driver declares the matching sysctl with `CTLFLAG_TUN`:

```
SYSCALL_ADD_UINT(ctx, child, OID_AUTO, "debug.mask",
    CTLFLAG_RW | CTLFLAG_TUN,
    &sc->sc_debug, 0,
    "Bitmask of enabled debug classes");
```

`CTLFLAG_TUN` tells the kernel that the initial value of this sysctl should be taken from the bootloader environment variable of the same name, using the OID name as the key. The match is textual and automatic; the driver does not need to call `TUNABLE_INT_FETCH` separately.

There is a subtle rule about when `CTLFLAG_TUN` is honoured. The flag applies to the OID's *initial* value, which is read from the environment when the sysctl is created. If the driver calls `TUNABLE_INT_FETCH` explicitly before creating the sysctl, the explicit fetch wins and `CTLFLAG_TUN` is effectively redundant. If the driver does not call `TUNABLE_INT_FETCH` and relies on `CTLFLAG_TUN` alone, the sysctl's initial value comes from the environment automatically.

In practice, the `myfirst` driver uses both mechanisms for clarity. The explicit `TUNABLE_INT_FETCH` in `attach` makes the driver's intent visible in the source; the `CTLFLAG_TUN` on the sysctl gives the operator a clear hint in the sysctl documentation that the OID respects a loader tunable. Either mechanism alone would work; using both is a small duplication that pays off in readability.

25.4.5 Declaring a Tunable as a Static Sysctl

For driver-wide sysctls that do not belong to a specific instance, FreeBSD offers compile-time macros that bind a sysctl to a static variable and read its default from the environment in one declaration. The canonical form:

```
SYSCALL_NODE(_hw, OID_AUTO, myfirst, CTLFLAG_RW, NULL,
    "myfirst pseudo-driver");

static int myfirst_verbose = 0;
SYSCALL_INT(_hw_myfirst, OID_AUTO, verbose,
    CTLFLAG_RWTUN, &myfirst_verbose, 0,
    "Enable verbose driver logging");
```

The `SYSCALL_NODE` declares a new parent node `hw.myfirst`. The `SYSCALL_INT` declares an integer OID `hw.myfirst.verbose` with `CTLFLAG_RWTUN` (which combines `CTLFLAG_RW` and `CTLFLAG_TUN`). The `myfirst_verbose` variable is the driver's global verbosity level. The operator sets `hw.myfirst.verbose=1` in

`/boot/loader.conf` to enable verbose output at boot, or runs `sysctl hw.myfirst.verbose=1` to toggle it at run time.

The static declaration is appropriate for driver-wide state. The per-instance state (`sc_debug`, counters) continues to live under `dev.myfirst.<unit>.*` and is declared dynamically through `device_get_sysctl_ctx`.

25.4.6 A Small Side Note on `SYSCCTL_INT` Versus `SYSCCTL_ADD_INT`

The static form `SYSCCTL_INT(parent, OID_AUTO, ...)` is a compile-time declaration. The dynamic form `SYSCCTL_ADD_INT(ctx, list, OID_AUTO, ...)` is a runtime call. Both produce a `sysctl` OID. The static form is appropriate for driver-wide `sysctls` whose existence does not depend on attaching to hardware. The dynamic form is appropriate for per-instance `sysctls` created in `attach` and destroyed on `detach`.

A common beginner mistake is to use the dynamic form for driver-wide `sysctls`, which works but requires a driver-wide `sysctl_ctx_list` that must be initialised at `MOD_LOAD` and freed at `MOD_UNLOAD`. The static form avoids all of that: the `sysctl` exists from the moment the module loads until the moment it unloads, and the kernel handles the registration and deregistration automatically.

25.4.7 Documenting a Tunable

A tunable that the operator does not know about is a tunable that does not get used. The discipline is to document every tunable the driver exposes, in three places.

First, the tunable's declaration in the source should include a one-line description string. For `SYSCCTL_ADD_UINT` and friends, the last argument is the description:

```
SYSCCTL_ADD_UINT(ctx, child, OID_AUTO, "timeout_sec",
    CTLFLAG_RW | CTLFLAG_TUN,
    &sc->sc_timeout_sec, 0,
    "Timeout in seconds for hardware commands (default 30, min 1, max 3600)");
```

The description string is what `sysctl -d` prints when an operator asks for documentation. A good description names the unit, the default, and the acceptable range.

Second, the driver's `MAINTENANCE.md` (introduced in Section 7) should list every tunable with a paragraph each. The paragraph explains what the tunable does, when to change it, what the default is, and what side effects setting it has.

Third, the driver's manual page (typically `myfirst(4)`) should list every tunable under a `LOADER TUNABLES` section and every `sysctl` under a `SYSCCTL VARIABLES` section. The `myfirst` driver does not yet have a manual page; the chapter treats the manual page as a later concern. The `MAINTENANCE.md` document carries the full documentation in the meantime.

25.4.8 A Worked Example: `hw.myfirst.timeout_sec`

The `myfirst` driver does not have real hardware at this stage, but the chapter introduces a fictional `timeout_sec` knob that future chapters will use. The complete mini-workflow is:

1. In `myfirst.h`, add the field to the `softc`:

```
struct myfirst_softc {
    /* ... existing fields ... */
    int    sc_timeout_sec;
};
```

2. In `myfirst_bus.c` (the new file introduced in Section 6, which holds attach and detach), initialise the default and read the tunable:

```
sc->sc_timeout_sec = 30;
TUNABLE_INT_FETCH("hw.myfirst.timeout_sec", &sc->sc_timeout_sec);
```

3. In `myfirst_sysctl.c`, expose the knob as a runtime sysctl:

```
SYSCTL_ADD_INT(ctx, child, OID_AUTO, "timeout_sec",
    CTLFLAG_RW | CTLFLAG_TUN,
    &sc->sc_timeout_sec, 0,
    "Timeout in seconds for hardware commands");
```

4. In `MAINTENANCE.md`, document the tunable:

```
hw.myfirst.timeout_sec
    Timeout in seconds for hardware commands.  Default 30.
    Acceptable range 1 through 3600.  Values below 1 are
    clamped to 1; values above 3600 are clamped to 3600.
    Adjustable at run time via sysctl dev.myfirst.<unit>.
    timeout_sec.
```

5. In the regression script, add a line that verifies the tunable picks up its default:

```
[ "$(sysctl -n dev.myfirst.0.timeout_sec)" = "30" ] || fail
```

The driver now has a timeout knob that the operator can set at boot through `/boot/loader.conf`, can adjust at run time through `sysctl`, and can find documented in `MAINTENANCE.md`. Every future chapter that introduces a new configurable value will follow the same five-step workflow.

25.4.9 Range Checks and Validation

A tunable that the operator can set to any value is a tunable that can be set to an out-of-range value, either by accident (a typo in `/boot/loader.conf`) or by a misguided attempt at tuning. The driver must validate the value it reads and clamp or reject it.

For tunables read at boot with `TUNABLE_INT_FETCH`, the validation happens inline:

```
sc->sc_timeout_sec = 30;
TUNABLE_INT_FETCH("hw.myfirst.timeout_sec", &sc->sc_timeout_sec);
if (sc->sc_timeout_sec < 1 || sc->sc_timeout_sec > 3600) {
    device_printf(dev,
```

```

        "tunable hw.myfirst.timeout_sec out of range (%d), "
        "clamping to default 30\n",
        sc->sc_timeout_sec);
    sc->sc_timeout_sec = 30;
}

```

For sysctls with runtime write support, the validation happens in the handler. A simple CTLFLAG_RW sysctl on an int variable accepts any int; to reject out-of-range writes, the driver declares a custom handler:

```

static int
myfirst_sysctl_timeout(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int v;
    int error;

    v = sc->sc_timeout_sec;
    error = sysctl_handle_int(oidp, &v, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
    if (v < 1 || v > 3600)
        return (EINVAL);
    sc->sc_timeout_sec = v;
    return (0);
}

```

The handler reads the current value, calls `sysctl_handle_int` to perform the actual I/O, and applies the new value only if it is in range. A write of 0 or 7200 returns `EINVAL` to the operator without changing the sysctl's value. This is the right behaviour: the operator gets clear feedback that the write was rejected.

The `myfirst` driver at this stage does not validate its integer sysctls because none of them can meaningfully go out of range (the debug mask is a bitmask, and any 32-bit value is a legal mask). Future drivers that introduce timeouts, retry counts, and buffer sizes will use the custom-handler pattern consistently.

25.4.10 When to Expose a Tunable and When to Leave It Internal

Exposing a tunable is a commitment. Once the operator sets `hw.myfirst.timeout_sec=15` in `/boot/loader.conf`, the driver has made a promise that the meaning of that knob will not change in a later version. Removing the tunable breaks production deployments. Changing its interpretation silently breaks them worse.

The right discipline is to expose a value as a tunable only when all three of these are true:

1. The value has an operational use case. Someone might reasonably need to change it on a real deployment.
2. The range of reasonable values is known. The driver can document it in `MAINTENANCE.md`.
3. The cost of supporting the knob for the life of the driver is worth the operational value it provides.

A driver that asks itself those three questions and answers yes to all three exposes a small, purposeful set of tunables. A driver that exposes every internal constant as a tunable because “operators might want to tune it” ends up with a sprawling configuration surface that nobody can document and nobody can test across its full range.

For `myfirst`, the initial set of tunables is deliberately small: `debug_mask_default`, `timeout_sec`, `max_retries`, `log_ratelimit_pps`. Each has a clear operational case, a clear default, and a clear range. The driver is not trying to expose every int field in the `softc` as a tunable; it is trying to expose the ones that an operator might actually want to touch.

25.4.11 A Cautionary Note on `CTLFLAG_RWTUN` for Strings

The `TUNABLE_STR_FETCH` macro reads a string from the bootloader environment into a fixed-size buffer. The matching sysctl flag, `CTLFLAG_RWTUN` on a `SYSCTL_STRING`, works, but it has a trap: the string’s storage must be a static buffer, not a per-instance `char[]` field in the `softc`. A string sysctl that writes into a `softc` field can outlive the `softc` if the sysctl framework does not deregister the OID before the `softc` is freed, which leads to use-after-free bugs.

The safer pattern is to expose strings as read-only and handle writes through a custom handler that copies the new value into the `softc` under a lock. The `myfirst` driver follows this pattern: `dev.myfirst.0.message` is exposed with `CTLFLAG_RD` only, and writes go through the `MYFIRSTIOC_SETMSG` ioctl instead. The ioctl path takes the `softc` mutex, copies the new value, and unlocks; there is no lifetime issue with sysctl OIDs.

String tunables and sysctls are useful enough for some drivers to be worth the care, but the Chapter 25 driver does not need them. The principle is worth naming because the trap surfaces later in real drivers.

25.4.12 Tunables Versus Kernel Modules: Where They Live

Two small but important details about the loader environment are worth naming.

First, a tunable in `/boot/loader.conf` applies from the moment the kernel starts. It is available to any module that calls `TUNABLE_*_FETCH` or has a `CTLFLAG_TUN` sysctl, even if the module is not loaded at boot. A module loaded later with `kldload` still sees the tunable’s value. This is convenient: the operator sets the tunable once and forgets about it until the module loads.

Second, a tunable is read from the environment but cannot be written back. Changing `hw.myfirst.timeout_sec` at run time (with `kenv`) does not affect any driver that has already read it; the variable in the `softc` is what matters, not the environment. To change a value at run time, the operator uses the matching sysctl.

These two details together explain why `CTLFLAG_TUN` is the right shape for most configuration knobs: the tunable sets the boot default, the sysctl handles run-time adjustment, and the operator’s toolkit (`/boot/loader.conf` plus `sysctl(8)`) works as expected.

25.4.13 Wrapping Up Section 3

Configuration is a conversation with the operator. A driver that externalises the right values through tunables and sysctls can be tuned without rebuilding; a driver that hides every value inside the source forces a rebuild for every change. The `TUNABLE_*_FETCH` family and the `CTLFLAG_TUN` flag together cover boot-time and run-time

adjustment, and the per-driver versus per-instance choice fits the driver to its operational reality. The `myfirst` driver now has three new tunables in addition to the existing `debug_mask_default`, each with a documented range and each with a matching `sysctl`.

In the next section, we turn from what the driver exposes to how the driver evolves. A configuration knob that works today must still work tomorrow when the driver changes. Versioning discipline is what keeps that promise.

25.5 Section 4: Versioning and Compatibility Strategies

The fourth discipline is the discipline of evolving without breaking. Every public surface the `myfirst` driver offers, the `/dev/myfirst0` node, the `ioctl` interface, the `sysctl` tree, the tunable set, is a contract with someone. A change that silently alters the meaning of any of those is a breaking change, and breaking changes that slip past the developer's notice are the source of a disproportionate number of real-world driver bugs. This section teaches how to version a driver's public surface deliberately, so that changes are visible to callers and so that older callers keep working when the driver adds new features.

The chapter uses three distinct version numbers for the `myfirst` driver. Each has a specific purpose. Conflating them is a source of confusion worth avoiding before it takes root.

25.5.1 The Three Version Numbers

The `myfirst` driver has three version identifiers, introduced across Chapters 23, 24, and 25. Each lives in a different place and changes for a different reason.

The first is the **human-readable release string**. For `myfirst`, this is `MYFIRST_VERSION`, defined in `myfirst_sysctl.c` and exposed through the `dev.myfirst.0.version` `sysctl`. Its current value is "1.8-maintenance". The release string is for humans: an operator who runs `sysctl dev.myfirst.0.version` sees a short label that identifies this particular checkpoint of the driver's history. The release string is not parsed by programs; it is read by people. It changes whenever the driver reaches a new milestone the author wants to mark, which in this book is at the end of each chapter.

The second is the **kernel module version integer**. This is `MODULE_VERSION(myfirst, N)`, where `N` is an integer used by the kernel's dependency machinery. Another module that declares `MODULE_DEPEND(other, myfirst, 1, 18, 18)` requires `myfirst` to be present at version 18 or above (and below or equal to 18, which in this declaration means exactly 18). The module version integer changes only when an in-kernel caller of the module would need a recompile, for example when a shared symbol's signature changes. For a driver that exports no public kernel symbols (like `myfirst`), the module version number is mostly symbolic; the chapter bumps it at each milestone to keep the reader's mental model aligned across the three version identifiers.

The third is the **ioctl interface version integer**. For `myfirst`, this is `MYFIRST_IOCTL_VERSION` in `myfirst_ioctl.h`. Its current value is 1. The `ioctl` interface version changes when the `ioctl` header changes in a way that an older user-space program compiled against the previous version would misinterpret. A renumbered `ioctl` command, a changed payload layout, a changed semantics of an existing `ioctl`: each of these is a breaking change to the `ioctl` interface and must bump the version. Adding a new `ioctl` command, extending a payload with a field at the end without reinterpreting existing fields, adding a feature that does not affect older commands: these are compatible changes and do not require a bump.

A simple rule of thumb keeps the three straight. The release string is what the operator reads. The module version integer is what other modules check. The ioctl version integer is what user-space programs check. Each moves on its own schedule.

25.5.2 Why Users Need to Query the Version

A user-space program that talks to the driver through ioctls has a problem. The header `myfirst_ioctl.h` defines a set of commands, layouts, and version-1 semantics. A new version of the driver may add commands, change layouts, or change semantics. When the user-space program runs on a system with a newer or older driver than the one it was compiled against, it has no way to know the driver's actual version unless it asks.

The solution is an ioctl whose only purpose is to return the driver's ioctl version. The `myfirst` driver already has one: `MYFIRSTIOC_GETVER`, defined as `_IOR('M', 1, uint32_t)`. A user-space program calls this ioctl immediately after opening the device, compares the returned version to the version it was compiled against, and decides whether it can proceed safely.

The pattern in user space:

```
#include "myfirst_ioctl.h"

int fd = open("/dev/myfirst0", O_RDWR);
uint32_t ver;
if (ioctl(fd, MYFIRSTIOC_GETVER, &ver) < 0)
    err(1, "getver");
if (ver != MYFIRST_IOCTL_VERSION)
    errx(1, "driver version %u, tool expects %u",
        ver, MYFIRST_IOCTL_VERSION);
```

The tool refuses to run if the versions do not match. That is one possible policy. A more forgiving policy would allow the tool to run against a newer driver if the driver's new ioctls are supersets of the old ones, and would allow the tool to run against an older driver if the tool can fall back to the older command set. A more rigid policy would require exact match. The tool's author chooses among these based on how much effort is worth spending on backward compatibility.

25.5.3 Adding a New Ioctl Without Breaking Older Callers

The common case is adding a new feature to the driver, which usually means adding a new ioctl. The discipline is straightforward as long as two rules are followed.

First, **do not reuse an existing ioctl number**. Each ioctl command has a unique (magic, number) pair encoded by `_IO`, `_IOR`, `_IOW`, or `_IOWR`. The current assignments in `myfirst_ioctl.h`:

```
#define MYFIRSTIOC_GETVER    _IOR('M', 1, uint32_t)
#define MYFIRSTIOC_GETMSG    _IOR('M', 2, char[MYFIRST_MSG_MAX])
#define MYFIRSTIOC_SETMSG    _IOW('M', 3, char[MYFIRST_MSG_MAX])
#define MYFIRSTIOC_RESET    _IO('M', 4)
```

A new ioctl takes the next available number under the same magic letter: `MYFIRSTIOC_GETCAPS = _IOR('M', 5, uint32_t)`. The number 5 has not been used before and cannot conflict with an older program's compiled binary. An older program compiled against a version without `GETCAPS` simply never sends that ioctl, so the older program is unaffected by the addition.

Second, **do not bump `MYFIRST_IOCTL_VERSION` for a pure addition**. A new ioctl that does not change the meaning of the old ones is a compatible change. An older user-space program that never heard of the new ioctl still speaks the same language; the version integer should stay the same. Bumping the version for every addition would force every caller to rebuild whenever the driver gains a new command, which defeats the purpose of versioning.

A new ioctl that replaces an existing one with different semantics does require a bump. If the driver adds `MYFIRSTIOC_SETMSG_V2` with a new layout and retires `MYFIRSTIOC_SETMSG`, older programs that call the retired command see a changed behaviour (the driver may return `ENOIOCTL` or may behave differently). That is a breaking change, and the bump signals it.

25.5.4 Retiring a Deprecated Ioctl

Retirement is the politely-managed form of removal. When a command is to be removed, the driver announces the intention, keeps the command working for a transition period, and removes it in a later version. A typical deprecation sequence:

- Version N: announce deprecation in `MAINTENANCE.md`. The command still works.
- Version N+1: the command works but logs a rate-limited warning each time it is used. Users see the warning and know to migrate.
- Version N+2: the command returns `EOPNOTSUPP` and logs a rate-limited error. Most users have migrated by now; the few who have not are forced to.
- Version N+3: the command is removed from the header. Programs that still reference it no longer compile.

The transition period should be measured in releases (typically one or two major versions) rather than in calendar time. A driver that keeps its deprecation contract predictable gives consumers a stable target to aim at.

For `myfirst` in this chapter, no command is yet deprecated. The chapter introduces the pattern for the future. The same discipline applies to the `sysctl` tree: a rate-limited warning in the `OID`'s handler tells operators that the name is on its way out, and a note in `MAINTENANCE.md` records the planned removal date.

25.5.5 The Capability Bitmask Pattern

For drivers that evolve over several releases, a single version integer tells callers which version they are talking to but not which specific features that version supports. A feature-rich driver benefits from a more fine-grained mechanism: a capability bitmask.

The idea is simple. The driver defines a set of capability bits in `myfirst_ioctl.h`:

```
#define MYF_CAP_RESET      (1U << 0)
#define MYF_CAP_GETMSG     (1U << 1)
#define MYF_CAP_SETMSG     (1U << 2)
```

```
#define MYF_CAP_TIMEOUT      (1U << 3)
#define MYF_CAP_MAXRETRIES  (1U << 4)
```

A new ioctl, MYFIRSTIOC_GETCAPS, returns a uint32_t with the bits set for the features this driver actually supports:

```
#define MYFIRSTIOC_GETCAPS  _IOR('M', 5, uint32_t)
```

In the kernel:

```
case MYFIRSTIOC_GETCAPS:
    *(uint32_t *)data = MYF_CAP_RESET | MYF_CAP_GETMSG |
        MYF_CAP_SETMSG;
    break;
```

In user space:

```
uint32_t caps;
ioctl(fd, MYFIRSTIOC_GETCAPS, &caps);
if (caps & MYF_CAP_TIMEOUT)
    set_timeout(fd, 60);
else
    warnx("driver does not support timeout configuration");
```

The capability bitmask allows a user-space program to discover features without trial and error. If the caller wants to know whether a feature exists, it checks the bit; if the bit is set, the caller knows the driver supports the feature and the relevant ioctls. An older driver that does not define the bit does not pretend to support a feature it never heard of.

The pattern scales well as the driver grows. Each release adds new bits for new features. Retired features keep their bit reserved as unused; recycling a bit for a new meaning would be a breaking change. The bitmask itself is a uint32_t, giving the driver 32 features before it needs to add a second word. If the driver reaches 32 features, adding a second word is a compatible change (the new bits are in a new field, so older programs that read only the first word see the same bits).

Chapter 25 adds MYFIRSTIOC_GETCAPS to the myfirst driver with three bits set: MYF_CAP_RESET, MYF_CAP_GETMSG, and MYF_CAP_SETMSG. The myfirstctl user-space program is extended to query the capabilities at startup and to refuse to invoke an unsupported feature.

25.5.6 Sysctl Deprecation

FreeBSD does not offer a dedicated CTLFLAG_DEPRECATED flag on the sysctl tree. The related flag CTLFLAG_SKIP, defined in /usr/src/sys/sys/sysctl.h, hides an OID from default listings (it is still readable if named explicitly), but it is primarily used for purposes other than announcing retirement. The polite

way to retire a sysctl OID is therefore to replace its handler with one that does the intended work *and* logs a rate-limited warning the first few times the OID is touched.

```
static int
myfirst_sysctl_old_counter(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;

    DLOG_RL(sc, &sc->sc_rl_deprecated, MYF_RL_DEFAULT_PPS,
        "sysctl dev.myfirst.%d.old_counter is deprecated; "
        "use new_counter instead\n",
        device_get_unit(sc->sc_dev));
    return (sysctl_handle_int(oidp, &sc->sc_old_counter, 0, req));
}
```

The operator sees the warning in `dmesg` the first few times the OID is read, which is a strong hint to migrate. The sysctl still works, so scripts that reference it explicitly do not break during the transition. After a release or two, the OID itself is removed. A note in `MAINTENANCE.md` records the intention and the target release.

For `myfirst`, no sysctl is yet deprecated. The Chapter 25 driver introduces the pattern in documentation and keeps it ready for future use.

25.5.7 User-Visible Behaviour Changes

Not every breaking change is a rename or a renumbering. Sometimes the driver keeps the same ioctl, the same sysctl, the same tunable, and quietly changes what the operation does. A `MYFIRSTIOC_RESET` that used to zero counters but now also clears the message is a behaviour change. A sysctl that used to report total bytes written but now reports kilobytes is a behaviour change. A tunable that used to be an absolute value and is now a multiplier is a behaviour change.

Behaviour changes are the hardest breaking changes to catch because they do not show up in diffs of header files or sysctl listings. The discipline is to document every behaviour change in `MAINTENANCE.md` under a “Change Log” section, to bump the ioctl interface version integer when an ioctl’s semantics change, and to announce sysctl semantics changes in the description string itself.

A good pattern for behaviour changes is to introduce a new named command or a new sysctl rather than redefining an existing one. `MYFIRSTIOC_RESET` keeps the old semantics. `MYFIRSTIOC_RESET_ALL` is a new command with the new semantics. The old command is eventually deprecated. The cost is a slightly larger public surface for the transition period; the benefit is that no caller is broken by a silent behaviour change.

25.5.8 MODULE_DEPEND and Inter-Module Compatibility

The `MODULE_DEPEND` macro declares that one module depends on another and requires a specific version range:

```
MODULE_DEPEND(myfirst, dependency, 1, 2, 3);
```

The three integers are the minimum, preferred, and maximum version of dependency that `myfirst` is compatible with. The kernel refuses to load `myfirst` if dependency is not present or is outside the range.

For drivers that do not publish in-kernel symbols, `MODULE_DEPEND` is most often used to depend on a standard subsystem module:

```
MODULE_DEPEND(myfirst_usb, usb, 1, 1, 1);
```

This declares that the USB version of `myfirst` needs the USB stack at version 1 exactly. The version numbers for subsystem modules are managed by the subsystem authors; a driver author finds the current values in the subsystem's header (for USB, `/usr/src/sys/dev/usb/usbd.h`) or in another driver that already depends on it.

For `myfirst` at the end of Chapter 25, no `MODULE_DEPEND` is needed because the pseudo-driver does not require a subsystem. Chapter 26's USB chapter will add the first real `MODULE_DEPEND` when the driver is turned into a USB-attached version.

25.5.9 A Worked Example: The 1.7 to 1.8 Transition

The Chapter 25 driver bumps three version identifiers at the end of the chapter:

- `MYFIRST_VERSION`: from "1.7-integration" to "1.8-maintenance".
- `MODULE_VERSION(myfirst, N)`: from 17 to 18.
- `MYFIRST_IOCTL_VERSION`: stays at 1, because the ioctl additions in this chapter are pure additions (new commands, no removal, no semantic changes).

The `GETCAPS` ioctl is added with command number 5, which was previously unused. Older `myfirstctl` binaries, compiled against the Chapter 24 version of the header, do not know about `GETCAPS` and do not send it; they continue to work unchanged. New `myfirstctl` binaries, compiled against the Chapter 25 header, query `GETCAPS` at startup and behave accordingly.

The `MAINTENANCE.md` document gains a Change Log entry for 1.8:

```
## 1.8-maintenance
```

- Added `MYFIRSTIOC_GETCAPS` (command 5) returning a capability bitmask. Compatible with all earlier user-space programs.
- Added tunables `hw.myfirst.timeout_sec`, `hw.myfirst.max_retries`, `hw.myfirst.log_ratelimit_pps`. Each has a matching writable sysctl under `dev.myfirst.<unit>`.
- Added rate-limited logging through `ppsratecheck(9)`.
- No breaking changes from 1.7.

A user of the driver reading `MAINTENANCE.md` sees at a glance what changed and can evaluate whether they need to update their tools. A user who does not read `MAINTENANCE.md` can still query the capabilities at run time and discover the new features programmatically.

25.5.10 Common Mistakes in Versioning

Three mistakes are common when first applying version discipline. Each is worth naming.

The first mistake is **reusing an ioctl number**. A number that was once assigned and later retired stays retired. A new command gets the next available number, not the number of a retired command. Reusing a number silently breaks older callers that had compiled in the old meaning; the compiler has no way to detect the conflict because the retired command's header was removed.

The second mistake is **bumping the version integer for every change**. If every patch bumps `MY-FIRST_IOCTL_VERSION`, user-space tools have to rebuild constantly or the version check fails. The integer should change only for genuine breaking changes. Pure additions leave it alone.

The third mistake is **treating the release string as a semantic version**. The release string is for humans; it can be anything. The module version integer and the ioctl version integer are parsed by programs and should follow a discipline (monotonically increasing, bumped only for specific reasons). Confusing the two leads to confusing version numbers.

25.5.11 Wrapping Up Section 4

Versioning is the discipline of evolving without breaking. A driver that keeps its three version identifiers distinct, its ioctl additions compatible, its deprecations announced, and its capability bits accurate gives its callers a stable target over the long life of the driver. The `myfirst` driver now has a working `GETCAPS` ioctl, a documented deprecation policy in `MAINTENANCE.md`, and three version identifiers that each change for their own reason. Everything a future developer needs to add a feature or retire a command is already in place.

In the next section, we turn from the driver's public surface to its private resource discipline. A driver that crashes on attach failure is a driver that cannot recover from any error. The labelled-goto pattern is how FreeBSD drivers make every allocation reversible.

25.6 Section 5: Managing Resources in Failure Paths

Every attach routine is an ordered sequence of acquisitions. It allocates a lock, creates a `cdev`, hangs a `sysctl` tree on the device, perhaps registers an event handler or a timer, and on more complex drivers it allocates bus resources, maps I/O windows, attaches an interrupt, and sets up DMA. Each acquisition can fail. And each acquisition that succeeded before the failure must be released in the reverse order, or the kernel leaks memory, leaks a lock, leaks a `cdev`, and in the worst case keeps a device node alive with a stale pointer inside it.

The `myfirst` driver has been growing its attach path one section at a time since Chapter 17. Attach started small: a lock and a `cdev`. Chapter 24 added the `sysctl` tree. Chapter 25 is about to add rate-limit state, tunable-fetched defaults, and a counter or two. The order in which those resources are acquired now matters to the cleanup path. Every new acquisition has to know where in the unwind ordering it belongs, and the unwind itself has to be structured so that adding a new resource next week does not force a rewrite of the attach function.

Chapter 20 introduced the pattern informally; this section gives it a name, a vocabulary, and a discipline strong enough to survive the full Chapter 25 shape of `myfirst_attach`.

25.6.1 The Problem: Nested if Paths Do Not Scale

The naive shape of an attach routine is a ladder of nested if statements. Each success condition contains the next step. Each failure returns. The problem is that every failure has to unwind whatever the previous steps already did, and the unwind code is duplicated at every level of the ladder:

```
/*
 * Naive attach. DO NOT WRITE DRIVERS THIS WAY. This example shows
 * how the nested-if pattern forces duplicated cleanup at every level
 * and why it becomes unmaintainable as soon as a fourth resource is
 * added to the chain.
 */
static int
myfirst_attach_bad(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
    int error;

    sc->sc_dev = dev;
    mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_WHEEL;
    args.mda_mode = 0660;
    args.mda_si_drv1 = sc;
    args.mda_unit = device_get_unit(dev);

    error = make_dev_s(&args, &sc->sc_cdev, "myfirst%d",
        device_get_unit(dev));
    if (error == 0) {
        myfirst_sysctl_attach(sc);
        if (myfirst_log_attach(sc) == 0) {
            /* all resources held; we succeeded */
            return (0);
        } else {
            /* log allocation failed: undo sysctl and cdev */
            /* but wait, sysctl is owned by Newbus, so skip it */
            destroy_dev(sc->sc_cdev);
            mtx_destroy(&sc->sc_mtx);
            return (ENOMEM);
        }
    } else {
```

```

        mtx_destroy(&sc->sc_mtx);
        return (error);
    }
}

```

Even in this small example the unwinding logic appears in two different places, the reader has to read a branch to know which resources have been acquired at each point, and adding a fourth resource forces another level of nesting and another duplicated cleanup block. Real drivers have seven or eight resources. A driver like `if_em` at `/usr/src/sys/dev/e1000/if_em.c` has over a dozen. Nested `if` is not an option there.

The failure modes of the nested pattern are not theoretical. A common bug pattern in older FreeBSD drivers was a missing `mtx_destroy` or a missing `bus_release_resource` in one of the cleanup branches: one branch destroyed the lock, another forgot. Every branch was a chance to make a mistake, and the bug only showed up when that specific failure fired, which meant it often did not show up until a customer reported a panic on a device that failed to attach.

25.6.2 The `goto fail;` Pattern

FreeBSD's answer to the nested-cleanup problem is the labelled-goto pattern. The attach function is written as a linear sequence of acquisitions. Each acquisition that can fail is followed by a test that either falls through on success or jumps to a cleanup label on failure. The cleanup labels are ordered from most-acquired back to least-acquired. Each label releases the resources that were held at that point and then falls through to the next label. The function ends with a single `return (0)` on success and a single `return (error)` at the bottom of the cleanup chain:

```

static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
    int error;

    /* Resource 1: softc basics. Cannot fail. */
    sc->sc_dev = dev;

    /* Resource 2: the lock. Cannot fail on DEF mutex. */
    mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

    /* Resource 3: the cdev. Can fail. */
    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_WHEEL;
    args.mda_mode = 0660;
}

```

```

args.mda_si_drv1 = sc;
args.mda_unit    = device_get_unit(dev);

error = make_dev_s(&args, &sc->sc_cdev, "myfirst%d",
    device_get_unit(dev));
if (error != 0)
    goto fail_mtx;

/* Resource 4: the sysctl tree. Cannot fail (Newbus owns it). */
myfirst_sysctl_attach(sc);

/* Resource 5: the log state. Can fail. */
error = myfirst_log_attach(sc);
if (error != 0)
    goto fail_cdev;

/* All resources held. Announce and return. */
DPRINTF(sc, MYF_DBG_INIT,
    "attach: version 1.8-maintenance ready\n");
return (0);

fail_cdev:
    destroy_dev(sc->sc_cdev);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}

```

Read the function top to bottom. Each step is a resource acquisition. Each failure check is a two-line block: if the acquisition failed, jump to the label named after the previously acquired resource. The labels at the bottom release the resources in reverse order and fall through to the next label. The final `return (error)` returns the `errno` from whichever acquisition failed.

This shape scales. Adding a sixth resource means adding one acquisition block at the top, one `goto` target at the bottom, and one line of cleanup code. No nesting, no duplication, no branch tree. The same rule that governs the attach path governs every future addition to the attach path: acquire, test, go-to-the-previous-label, release in the reverse order.

25.6.3 Why Linear Unwinding Is the Right Shape

The value of the labelled-goto pattern is not purely stylistic. It maps directly onto the structural property that the attach sequence is a stack of resources, and cleanup is the pop operation on that stack.

A stack has three properties that are easy to state and easy to violate. First, resources are released in the reverse order of acquisition. Second, a failed acquisition does not add a resource to the stack, so cleanup starts from the

previously acquired resource, not from the one that just failed. Third, every resource on the stack is released exactly once: not zero times, not twice.

Each of these properties has a visible correlate in the `goto fail;` pattern. The cleanup labels appear in the file in the reverse order of the acquisitions: the last acquisition's cleanup label is at the top of the cleanup chain. A failed acquisition jumps to the label named after the previous acquisition, not after itself; the name of the label is literally the name of the resource that now has to be undone. And because each label falls through to the next, and each resource appears in exactly one label, every resource is freed exactly once on every failure path.

The stack discipline is what makes the pattern robust. If a reader wants to audit the cleanup path for correctness, they do not have to read branches. They just count the labels, count the acquisitions, and compare.

25.6.4 Label Naming Conventions

Labels in FreeBSD drivers traditionally begin with `fail_` followed by the name of the resource that is about to be undone. The name of the resource matches the name of the field in the `softc` or the name of the function called to acquire it. Common patterns seen across the tree:

- `fail_mtx` undoes `mtx_init`
- `fail_sx` undoes `sx_init`
- `fail_cdev` undoes `make_dev_s`
- `fail_ires` undoes `bus_alloc_resource` for an IRQ
- `fail_mres` undoes `bus_alloc_resource` for a memory window
- `fail_intr` undoes `bus_setup_intr`
- `fail_dma_tag` undoes `bus_dma_tag_create`
- `fail_log` undoes a driver-private allocation (the rate-limit block in `myfirst`)

Some older drivers use numbered labels (`fail1`, `fail2`, `fail3`). Numbered labels are legal but inferior: adding a resource in the middle of the sequence forces renumbering every label after the insertion point, and the label numbers do not tell the reader which resource is being cleaned up. Named labels survive insertions gracefully and document themselves.

Whatever convention a driver picks, it should be consistent across all of its files. `myfirst` uses the `fail_<resource>` convention for every attach function from this chapter forward.

25.6.5 The Rule of Falling Through

The single rule that every cleanup chain must obey is that each cleanup label falls through to the next. A stray return in the middle of the chain, or a missing label, skips cleanup for the resources that should have been released. The compiler does not warn about either mistake.

Consider what happens if a developer edits the cleanup chain and accidentally writes this:

```
fail_cdev:
    destroy_dev(sc->sc_cdev);
    return (error);          /* BUG: skips mtx_destroy. */
fail_mtx:
```

```
mtx_destroy(&sc->sc_mtx);  
return (error);
```

The first return prevents the `mtx_destroy` from running on the `fail_cdev` path. The lock is leaked. The kernel's witness code will not complain, because the leaked lock is never acquired again. The leak persists until the machine reboots. It is invisible in normal operation and only shows up as a slow memory bloat on a system where the driver attaches and fails repeatedly (a hot-pluggable device, for example).

The way to prevent this kind of bug is to write the cleanup chain with a single return at the bottom and no intermediate returns. The labels in the middle contain only the cleanup call for their resource. Fall-through is the default and intended behaviour:

```
fail_cdev:  
    destroy_dev(sc->sc_cdev);  
fail_mtx:  
    mtx_destroy(&sc->sc_mtx);  
    return (error);
```

A reader auditing the chain reads it as a simple list: destroy cdev, destroy lock, return. There is no branching to follow, and adding a label means adding a single line of cleanup code and optionally a single new target.

25.6.6 What the Success Path Looks Like

The attach function succeeds with a single return (0), placed immediately before the first cleanup label. This is the point at which every acquisition has succeeded and no cleanup is needed. The return (0) separates the acquisition chain from the cleanup chain visually: everything above it is acquisition, everything below it is cleanup.

Some drivers forget this separation and fall through from the last acquisition into the first cleanup label, freeing resources they just acquired. A stray missing return (0) is the simplest way to produce this bug:

```
/* Resource N: the final acquisition. */  
...  
  
/* Forgot to put a return here. */  
  
fail_cdev:  
    destroy_dev(sc->sc_cdev);
```

Without the return (0), control falls through into `fail_cdev` after every successful attach, destroying the cdev on the success path. The driver then reports attach as failed because `error` is zero and the kernel sees the successful return, but the cdev it just created is gone. The result is a device node that disappears seconds after it appears. Debugging this requires noticing that the attach message prints but the device does not respond; not an easy bug to find in a busy log.

The defence is discipline. Every attach function ends its acquisition chain with `return (0);` on its own line, followed by a blank line, followed by the cleanup labels. No exceptions. A linter like `igor` or a reviewer's eye catches violations quickly when the shape is always the same.

25.6.7 When an Acquisition Cannot Fail

Some acquisitions cannot fail. `mtx_init` for a default-style mutex cannot return an error. `sx_init` cannot. `callout_init_mtx` cannot. `SYSCTL_ADD_*` calls cannot return an error that a driver is expected to check (a failure there is a kernel-internal problem, not a driver problem).

For acquisitions that cannot fail, there is no `goto`. The acquisition is followed by the next step without a test. The cleanup label for the acquisition is still required, because the cleanup chain has to release the resource if a later acquisition fails:

```
mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

error = make_dev_s(&args, &sc->sc_cdev, ...);
if (error != 0)
    goto fail_mtx;          /* undoes the lock. */
```

`fail_mtx` exists even though `mtx_init` itself had no failure path, because the lock still needs to be destroyed if anything below it fails.

The pattern holds: every acquired resource has a label, whether or not its acquisition can fail.

25.6.8 Helpers to Reduce Duplication

When several acquisitions share the same shape (allocate, check, `goto` on error), it is tempting to hide them behind a helper function. The helper's job is to consolidate the acquisition and the check; the caller only sees a single `if (error != 0) goto fail_x;` line. This is fine as long as the helper follows the same discipline: on failure, it releases nothing that it acquired partially, and it returns a meaningful `errno` so the caller's `goto` target can rely on it.

In `myfirst`, Section 5's companion examples introduce a helper called `myfirst_log_attach` that allocates the rate-limit state, initialises its fields, and returns 0 on success or a non-zero `errno` on failure. The attach function calls it with a single line:

```
error = myfirst_log_attach(sc);
if (error != 0)
    goto fail_cdev;
```

The helper itself follows the same pattern internally. If it allocates two resources and the second fails, the helper unwinds the first before returning. The caller sees the helper as a single atomic acquisition: it either fully succeeded or fully failed, and the caller never has to worry about the helper's intermediate state.

Helpers that are too eager to simplify, however, break the pattern. A helper that allocates a resource and stores it into the `softc` is fine. A helper that allocates a resource, stores it into the `softc`, and also releases it on error is

not fine: the caller's cleanup label will also try to release it, leading to a double-free. The rule is that acquisition helpers either succeed and leave the resource in the softc, or they fail and leave the softc unchanged. They do not half-succeed.

25.6.9 Detach as the Mirror of Attach

The detach routine is the cleanup chain of a successful attach. It has to release exactly the resources that attach acquired, in the reverse order. The shape of the detach function is the shape of the cleanup chain with the labels removed and the acquisitions deleted:

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Check for busy first. */
    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count > 0) {
        mtx_unlock(&sc->sc_mtx);
        return (EBUSY);
    }
    mtx_unlock(&sc->sc_mtx);

    /* Release resources in the reverse order of attach. */
    myfirst_log_detach(sc);
    destroy_dev(sc->sc_cdev);
    /* Sysctl is cleaned up by Newbus after detach returns. */
    mtx_destroy(&sc->sc_mtx);

    return (0);
}
```

Read side by side with the attach function, the correspondence is exact. Every resource named in attach has a release in detach. Every new acquisition added to attach has a matching addition in detach. A reviewer auditing a patch that adds a new resource to the driver should be able to find both additions in the diff, one in the attach chain and one in the detach chain; a diff that adds only to attach is incomplete.

A useful discipline when touching the attach chain is to open the detach function in an adjacent editor buffer and add the release immediately after adding the acquisition. This is the simplest way to make sure the two functions stay in sync: they are edited together as a single operation.

25.6.10 Deliberate Failure Injection for Testing

A cleanup chain is correct only if every label is reachable. The only way to be sure is to fire each failure path on purpose and observe that the driver unloads cleanly afterwards. Waiting for real hardware failures to exercise

the paths is not a strategy: most paths are never exercised in real life.

The tool for this kind of testing is deliberate failure injection. The developer adds a temporary `goto` or a temporary early return in the middle of the attach chain and confirms that the driver's resources are all released when the injected failure fires.

A minimal pattern for `myfirst`:

```
#ifdef MYFIRST_DEBUG_INJECT_FAIL_CDEV
    error = ENOMEM;
    goto fail_cdev;
#endif
```

Compile the driver with `-DMYFIRST_DEBUG_INJECT_FAIL_CDEV` and load it. Attach returns `ENOMEM`. `kldstat` shows no residue. `dmesg` shows the attach failure and no kernel complaints about leaked locks or leaked resources. Unload the module, remove the define, recompile, and the driver is back to normal.

Do this once per label, in turn:

1. Inject a failure just after the lock is initialised. Confirm that only the lock is released.
2. Inject a failure just after the cdev is created. Confirm that the cdev and lock are released.
3. Inject a failure just after the sysctl tree is built. Confirm that the cdev and lock are released, and the sysctl OIDs disappear.
4. Inject a failure just after the log state is initialised. Confirm that every resource acquired to that point is released.

If any injection leaves a residue, the cleanup chain has a bug. Fix the bug, rerun the injection, and move on.

This is uncomfortable work the first time, and reassuring afterwards. A driver whose every failure path has been exercised once is a driver whose failure paths will keep working as the code evolves. A driver whose failure paths have never been exercised is a driver with latent bugs that will appear at the worst possible moment.

The companion example `ex05-failure-injection/` under `examples/part-05/ch25-advanced/` contains a version of `myfirst_attach` with every failure injection site marked by a commented `#define`. The lab at the end of the chapter walks through each injection in turn.

25.6.11 A Complete `myfirst_attach` for Chapter 25

Putting all of Section 5 together with the Chapter 25 additions (log state, tunable fetches, capability bitmask), the final attach function looks like this:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    struct make_dev_args args;
    int error;
```

```
/*
 * Stage 1: softc basics. Cannot fail. Recorded for consistency;
 * no cleanup label is needed because no resource is held yet.
 */
sc->sc_dev = dev;

/*
 * Stage 2: lock. Cannot fail on MTX_DEF, but needs a label
 * because anything below this line can fail and must release it.
 */
mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

/*
 * Stage 3: pre-populate the softc with defaults, then allow
 * boot-time tunables to override. No allocations here, so no
 * cleanup is needed. Defaults come from the Section 3 tunable
 * set.
 */
strcpy(sc->sc_msg, "Hello from myfirst", sizeof(sc->sc_msg));
sc->sc_msglen = strlen(sc->sc_msg);
sc->sc_open_count = 0;
sc->sc_total_reads = 0;
sc->sc_total_writes = 0;
sc->sc_debug = 0;
sc->sc_timeout_sec = 5;
sc->sc_max_retries = 3;
sc->sc_log_pps = MYF_RL_DEFAULT_PPS;

TUNABLE_INT_FETCH("hw.myfirst.debug_mask_default",
    &sc->sc_debug);
TUNABLE_INT_FETCH("hw.myfirst.timeout_sec",
    &sc->sc_timeout_sec);
TUNABLE_INT_FETCH("hw.myfirst.max_retries",
    &sc->sc_max_retries);
TUNABLE_INT_FETCH("hw.myfirst.log_ratelimit_pps",
    &sc->sc_log_pps);

/*
 * Stage 4: cdev. Can fail. On failure, release the lock and
 * return the error from make_dev_s.
 */
make_dev_args_init(&args);
args.mda_devsw = &myfirst_cdevsw;
args.mda_uid = UID_ROOT;
```

```

args.mda_gid      = GID_WHEEL;
args.mda_mode     = 0660;
args.mda_si_drv1  = sc;
args.mda_unit     = device_get_unit(dev);

error = make_dev_s(&args, &sc->sc_cdev, "myfirst%d",
    device_get_unit(dev));
if (error != 0)
    goto fail_mtx;

/*
 * Stage 5: sysctl tree. Cannot fail. The framework owns the
 * context, so no cleanup label is required specifically for it.
 */
myfirst_sysctl_attach(sc);

/*
 * Stage 6: rate-limit and counter state. Can fail if memory
 * allocation fails. On failure, release the cdev and the lock.
 */
error = myfirst_log_attach(sc);
if (error != 0)
    goto fail_cdev;

DPRINTF(sc, MYF_DBG_INIT,
    "attach: version 1.8-maintenance complete\n");
return (0);

fail_cdev:
    destroy_dev(sc->sc_cdev);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}

```

Every resource is accounted for. Every failure path is linear. The function has a single success return at the transition from acquisitions to cleanup, and a single failure return at the bottom of the cleanup chain. Adding a seventh resource next chapter is a three-line operation: one new acquisition block, one new label, one new cleanup line.

25.6.12 Common Mistakes in Failure Paths

A few failure-path mistakes are worth naming once so they can be recognised when they appear in someone else's code or in a review.

The first mistake is **a missing label**. A developer adds a new resource acquisition but forgets to add its cleanup label. The compiler does not warn; the chain looks fine from the outside; but on failure after the new acquisition, the cleanup of everything below is skipped. The rule is that every acquisition has a label. Even if the acquisition cannot fail, it still needs a label so later acquisitions can reach it.

The second mistake is **freeing a resource twice**. A developer adds a local cleanup inside a helper and forgets that the caller's cleanup label also frees the resource. The helper frees once, the caller frees again, and either the kernel panics (for memory) or the witness code complains (for locks). The rule is that only one party owns each resource's cleanup. If the helper acquires the resource and stores it into the softc, the helper does not clean it up on the caller's behalf; it either succeeds or leaves the softc untouched.

The third mistake is **relying on NULL tests**. A developer writes a cleanup chain like this:

```
fail_cdev:
    if (sc->sc_cdev != NULL)
        destroy_dev(sc->sc_cdev);
fail_mtx:
    if (sc->sc_mtx_initialised)
        mtx_destroy(&sc->sc_mtx);
```

The logic is: skip cleanup if the resource was not actually acquired. The intent is defensive; the effect is to hide bugs. If the NULL check is there because the cleanup might be reached in a state where the resource is not acquired, the chain is wrong: the goto target should be a different label. The correct behaviour is to make the cleanup label unreachable unless the resource was actually acquired. Labels that can be reached in either state are a symptom of a muddled acquisition order, and the NULL check only papers over it.

The fourth mistake is **using goto for non-error flow**. goto in the attach function is strictly for failure paths. A goto that skips a section of the acquisition chain on some non-error condition is a violation of the linear-cleanup invariant: the cleanup chain assumes that every label corresponds to a resource that has been acquired, and a goto that bypasses an acquisition breaks that assumption. If conditional acquisition is needed, use an if around the acquisition itself, not a goto around it.

25.6.13 Wrapping Up Section 5

Attach and detach are the seams that hold a driver to the kernel. A correct attach is a linear stack of acquisitions; a correct detach is the stack popped in reverse. The labelled-goto pattern is how FreeBSD drivers encode that stack in C without buying into the kernels of other operating systems (C++ destructors, Go defer, Rust Drop). It is unglamorous and it scales: a driver with a dozen resources reads exactly like a driver with two, and the rules for adding a new resource are always the same.

The myfirst attach function now has four failure labels and a clean separation of acquisition, success return, and cleanup. Every new resource that Chapter 26 adds will fit into this shape.

In the next section, we step back from any single function and look at how a growing driver is spread across files. One myfirst.c with every function in it has carried us for eight chapters; it is time to split it into focused units so that the structure of the driver is visible at the file level.

25.7 Section 6: Modularization and Separation of Concerns

By the end of Chapter 24 the `myfirst` driver has grown beyond what one source file can comfortably hold. The file shape was `myfirst.c` plus `myfirst_debug.c`, `myfirst_ioctl.c`, and `myfirst_sysctl.c`; `myfirst.c` still carried the `cdevsw`, the read/write callbacks, the open/close callbacks, the attach and detach routines, and the module glue. That was fine for teaching, because every addition landed in a file small enough for a reader to hold in their head. It is no longer fine for a driver that has an `ioctl` surface, a `sysctl` tree, a debug framework, a rate-limited logging helper, a capability bitmask, a versioning discipline, and a labelled-cleanup attach routine. A file with that much in it becomes painful to read, painful to diff, and painful to hand to a new contributor.

Section 6 is about the other direction. It does not introduce new behaviour; every function that exists at the end of Section 5 is still here at the end of Section 6. What changes is the file layout and the boundary lines between pieces. The goal is a driver whose structure you can understand from `ls`, and whose individual files each answer a single question.

25.7.1 Why Split Files

The temptation with a self-contained driver is to keep everything in one file. A single `myfirst.c` is easy to locate, easy to `grep`, easy to copy into a tarball. Splitting feels like bureaucracy. The argument for splitting appears when the driver crosses one of three thresholds.

The first threshold is **comprehension**. A reader who opens `myfirst.c` should be able to find what they are looking for in a few seconds. A 1200-line file with eight unrelated responsibilities is hard to navigate; the reader has to scroll past the `cdevsw` to find the `sysctl`, past the `sysctl` to find the `ioctl`, past the `ioctl` to find the attach routine. Each time they switch subject, they have to reload their mental context. With separate files, the subject is the filename: `myfirst_ioctl.c` is about `ioctls`, `myfirst_sysctl.c` is about `sysctls`, `myfirst.c` is about lifecycle.

The second threshold is **independence**. Two unrelated changes should not modify the same file. When a developer adds a `sysctl` and another developer adds an `ioctl`, their patches should not compete for the same lines of `myfirst.c`. Small, focused files let two changes land in parallel with no merge conflict and no risk that a bug in one change accidentally touches the other.

The third threshold is **testability and reuse**. A driver's logging infrastructure, its `ioctl` dispatch, and its `sysctl` tree are often useful to more than one driver inside the same project. Keeping them in separate files with clean interfaces makes them candidates for sharing later. A driver that lives in a single file cannot easily share anything; extraction means copying and manually renaming, which is an error-prone operation.

`myfirst` at the end of Chapter 25 has crossed all three thresholds. Splitting the file is the maintenance act that keeps the driver healthy for the next ten chapters.

25.7.2 A File Layout for `myfirst`

The proposed layout is the one the Makefile in the final Chapter 25 examples directory uses:

<code>myfirst.h</code>	- public types and constants (<code>softc</code> , <code>SRB</code> , status bits).
<code>myfirst.c</code>	- module glue, <code>cdevsw</code> , <code>devclass</code> , module events.

<code>myfirst_bus.c</code>	- Newbus methods and <code>device_identify</code> .
<code>myfirst_cdev.c</code>	- open/close/read/write callbacks; no <code>ioctl</code> .
<code>myfirst_ioctl.h</code>	- <code>ioctl</code> command numbers and payload structures.
<code>myfirst_ioctl.c</code>	- <code>myfirst_ioctl</code> switch and helpers.
<code>myfirst_sysctl.c</code>	- <code>myfirst_sysctl_attach</code> and handlers.
<code>myfirst_debug.h</code>	- <code>DPRINTF/DLOG/DLOG_RL</code> macros and class bits.
<code>myfirst_debug.c</code>	- debug-class enumeration (if any out-of-line).
<code>myfirst_log.h</code>	- rate-limit state structure.
<code>myfirst_log.c</code>	- <code>myfirst_log_attach/detach</code> and helpers.

Seven `.c` files and four `.h` files. Each `.c` file has a subject matter named by its filename. The headers declare the interfaces that cross file boundaries. No file imports internals of another file; every cross-file reference goes through a header.

At first sight this looks like more files than the driver needs. It is not. Each file has a specific responsibility, and the header that goes with it is one to three dozen lines of declarations. The cumulative size is the same as the single-file version; the structure is dramatically clearer.

25.7.3 The Single-Responsibility Rule

The rule that governs the split is a single-responsibility rule: each file answers one question about the driver.

- `myfirst.c` answers: how does this module attach to the kernel and wire its pieces together?
- `myfirst_bus.c` answers: how does Newbus discover and instantiate my driver?
- `myfirst_cdev.c` answers: how does the driver serve open/close/read/write?
- `myfirst_ioctl.c` answers: how does the driver handle the commands its header declares?
- `myfirst_sysctl.c` answers: how does the driver expose its state to `sysctl(8)`?
- `myfirst_debug.c` answers: how are debug messages classified and rate-limited?
- `myfirst_log.c` answers: how is rate-limit state initialised and released?

The test for whether a change belongs in a given file is the answer test. If the change does not answer the file's question, it belongs elsewhere. A new `sysctl` does not belong in `myfirst_ioctl.c`; a new `ioctl` does not belong in `myfirst_sysctl.c`; a new read callback variant does not belong in `myfirst.c`. The rule is explicit, and a reviewer applying it rejects patches that put things in the wrong file.

Applying the rule to the existing Chapter 24 shape gives the Chapter 25 shape.

25.7.4 Public vs Private Headers

Headers carry the interface between files. A driver that splits its `.c` files has to decide, for each declaration, whether it belongs in a public header or a private one.

Public headers contain types and constants that are visible to more than one `.c` file. `myfirst.h` is the main public header for the driver. It declares:

- The `struct myfirst_softc` definition (every `.c` file needs it).
- Constants that appear in more than one file (debug-class bits, `softc` field sizes).

- Prototypes for functions that are called across file boundaries (`myfirst_sysctl_attach`, `myfirst_log_attach`, `myfirst_log_ratelimited_printf`, `myfirst_ioctl`).

Private headers carry declarations that are only needed by one `.c` file. `myfirst_ioctl.h` is the canonical example. It declares the command numbers and payload structures; they are needed by `myfirst_ioctl.c` and by user-space callers, but no other in-kernel file needs them. Putting them in `myfirst.h` would leak the wire format into every translation unit.

The distinction matters because every public declaration is a contract the driver has to honour. A type in `myfirst.h` that changes size breaks every file that includes `myfirst.h`. A type in `myfirst_ioctl.h` that changes size breaks only `myfirst_ioctl.c` and the user-space tools that compiled against it.

For `myfirst` at the end of Chapter 25, the public header `myfirst.h` looks like this (trimmed to the declarations relevant to this section):

```
/*
 * myfirst.h - public types and constants for the myfirst driver.
 *
 * Types and prototypes declared here are visible to every .c file in
 * the driver. Keep this header small. Wire-format declarations live
 * in myfirst_ioctl.h. Debug macros live in myfirst_debug.h. Rate-
 * limit state lives in myfirst_log.h.
 */

#ifndef _MYFIRST_H_
#define _MYFIRST_H_

#include <sys/types.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/conf.h>

#include "myfirst_log.h"

struct myfirst_softc {
    device_t      sc_dev;
    struct mtx     sc_mtx;
    struct cdev    *sc_cdev;

    char          sc_msg[MYFIRST_MSG_MAX];
    size_t        sc_msglen;

    u_int         sc_open_count;
    u_int         sc_total_reads;
    u_int         sc_total_writes;

    u_int         sc_debug;
};
```

```

    u_int          sc_timeout_sec;
    u_int          sc_max_retries;
    u_int          sc_log_pps;

    struct myfirst_ratelimit sc_rl_generic;
    struct myfirst_ratelimit sc_rl_io;
    struct myfirst_ratelimit sc_rl_intr;
};

#define MYFIRST_MSG_MAX 256

/* Sysctl tree. */
void myfirst_sysctl_attach(struct myfirst_softc *);

/* Rate-limit state. */
int myfirst_log_attach(struct myfirst_softc *);
void myfirst_log_detach(struct myfirst_softc *);

/* Ioctl dispatch. */
struct thread;
int myfirst_ioctl(struct cdev *, u_long, caddr_t, int, struct thread *);

#endif /* _MYFIRST_H */

```

Nothing in `myfirst.h` references a wire-format constant, a debug-class bit, or a rate-limit structure internals. The `softc` includes three rate-limit fields by value, so `myfirst.h` has to include `myfirst_log.h`, but the internals of `struct myfirst_ratelimit` live in `myfirst_log.h` and are not exposed here.

25.7.5 The Anatomy of `myfirst.c` After the Split

`myfirst.c` after the split is the shortest `.c` file in the driver. It contains the `cdevsw` table, the module event handler, the device class declaration, and the attach/detach routines. Every other responsibility has moved elsewhere:

```

/*
 * myfirst.c - module glue and cdev wiring for the myfirst driver.
 *
 * This file owns the cdevsw table, the devclass, the attach and
 * detach routines, and the MODULE_VERSION declaration. The cdev
 * callbacks themselves live in myfirst_cdev.c. The ioctl dispatch
 * lives in myfirst_ioctl.c. The sysctl tree lives in
 * myfirst_sysctl.c. The rate-limit infrastructure lives in
 * myfirst_log.c.
 */

```

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/conf.h>
#include <sys/kernel.h>
#include <sys/lock.h>
#include <sys/module.h>
#include <sys/mutex.h>

#include "myfirst.h"
#include "myfirst_debug.h"
#include "myfirst_ioctl.h"

MODULE_VERSION(myfirst, 18);

extern d_open_t    myfirst_open;
extern d_close_t   myfirst_close;
extern d_read_t    myfirst_read;
extern d_write_t   myfirst_write;

struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
    .d_ioctl   = myfirst_ioctl,
};

static int
myfirst_attach(device_t dev)
{
    /* Section 5's labelled-cleanup attach goes here. */
    ...
}

static int
myfirst_detach(device_t dev)
{
    /* Section 5's mirror-of-attach detach goes here. */
    ...
}
```

```
static device_method_t myfirst_methods[] = {
    DEVMETHOD(device_probe,    myfirst_probe),
    DEVMETHOD(device_attach,   myfirst_attach),
    DEVMETHOD(device_detach,   myfirst_detach),
    DEVMETHOD_END
};

static driver_t myfirst_driver = {
    "myfirst",
    myfirst_methods,
    sizeof(struct myfirst_softc),
};

DRIVER_MODULE(myfirst, nexus, myfirst_driver, 0, 0);
```

The file has one job: wire the driver's pieces together at the kernel level. It is a few hundred lines; every other file in the driver is smaller.

25.7.6 myfirst_cdev.c: The Character Device Callbacks

The open, close, read, and write callbacks were the first code we wrote back in Chapter 18. They have grown since then. Extracting them to myfirst_cdev.c keeps them with each other and out of myfirst.c:

```
/*
 * myfirst_cdev.c - character-device callbacks for the myfirst driver.
 *
 * The open/close/read/write callbacks all operate on the softc that
 * make_dev_s installed as si_drv1. The ioctl dispatch is in
 * myfirst_ioctl.c; this file intentionally does not handle ioctls.
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/conf.h>
#include <sys/uio.h>
#include <sys/lock.h>
#include <sys/mutex.h>

#include "myfirst.h"
#include "myfirst_debug.h"

int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
```

```

    struct myfirst_softc *sc = dev->si_drv1;

    mtx_lock(&sc->sc_mtx);
    sc->sc_open_count++;
    mtx_unlock(&sc->sc_mtx);

    DPRINTF(sc, MYF_DBG_OPEN, "open: count %u\n", sc->sc_open_count);
    return (0);
}

/* close, read, write follow the same pattern. */

```

Each callback begins with `sc = dev->si_drv1` (the per-cdev pointer that `make_dev_args` set) and operates on the `_softc`. No cross-file coupling beyond the public header.

25.7.7 myfirst_ioctl.c: The Command Switch

`myfirst_ioctl.c` has been in its own file since Chapter 22. The Chapter 25 addition is the `MYFIRSTIOC_GETCAPS` handler:

```

int
myfirst_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int flag,
              struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error = 0;

    switch (cmd) {
    case MYFIRSTIOC_GETVER:
        *(int *)data = MYFIRST_IOCTL_VERSION;
        break;
    case MYFIRSTIOC_RESET:
        mtx_lock(&sc->sc_mtx);
        sc->sc_total_reads = 0;
        sc->sc_total_writes = 0;
        mtx_unlock(&sc->sc_mtx);
        break;
    case MYFIRSTIOC_GETMSG:
        mtx_lock(&sc->sc_mtx);
        strncpy((char *)data, sc->sc_msg, MYFIRST_MSG_MAX);
        mtx_unlock(&sc->sc_mtx);
        break;
    case MYFIRSTIOC_SETMSG:
        mtx_lock(&sc->sc_mtx);

```

```

        strlcpy(sc->sc_msg, (const char *)data, MYFIRST_MSG_MAX);
        sc->sc_msglen = strlen(sc->sc_msg);
        mtx_unlock(&sc->sc_mtx);
        break;
    case MYFIRSTIOC_GETCAPS:
        *(uint32_t *)data = MYF_CAP_RESET | MYF_CAP_GETMSG |
                            MYF_CAP_SETMSG;

        break;
    default:
        error = ENOIOCTL;
        break;
    }
    return (error);
}

```

The switch is the entire public ioctl surface of the driver. Adding a command means adding a case; retiring one means deleting a case and deprecating the constant in `myfirst_ioctl.h`.

25.7.8 `myfirst_log.h` and `myfirst_log.c`: Rate-Limited Logging

Section 1 introduced the rate-limited logging macro `DLOG_RL` and the struct `myfirst_ratelimit` state it tracks. The rate-limit state was left embedded in the softc in Section 1 because the abstraction had not yet been factored out. Section 6 is the right moment to factor it out: the rate-limit code is small enough to be worth collecting in one place and general enough that other drivers might want it.

`myfirst_log.h` contains the state definition:

```

#ifndef _MYFIRST_LOG_H_
#define _MYFIRST_LOG_H_

#include <sys/time.h>

struct myfirst_ratelimit {
    struct timeval rl_lasttime;
    int           rl_curpps;
};

#define MYF_RL_DEFAULT_PPS 10

#endif /* _MYFIRST_LOG_H_ */

```

`myfirst_log.c` contains the attach and detach helpers:

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/lock.h>
#include <sys/mutex.h>

#include "myfirst.h"
#include "myfirst_debug.h"

int
myfirst_log_attach(struct myfirst_softc *sc)
{
    /*
     * The rate-limit state is embedded by value in the softc, so
     * there is no allocation to do. This function exists so that
     * the attach chain has a named label for logging in case a
     * future version needs per-class allocations.
     */
    bzero(&sc->sc_rl_generic, sizeof(sc->sc_rl_generic));
    bzero(&sc->sc_rl_io,      sizeof(sc->sc_rl_io));
    bzero(&sc->sc_rl_intr,   sizeof(sc->sc_rl_intr));

    return (0);
}

void
myfirst_log_detach(struct myfirst_softc *sc)
{
    /* Nothing to release; the state is embedded in the softc. */
    (void)sc;
}
```

Today `myfirst_log_attach` does no allocation; it zeroes the rate-limit fields and returns. Tomorrow, if the driver needs a dynamic array of per-class counters, the allocation fits here and the attach chain does not have to change. This is the value of extracting the helper before it is strictly necessary: the shape is ready for growth.

The header file size matters here. `myfirst_log.h` is under 20 lines. A header of 20 lines is cheap to include everywhere, cheap to read, and cheap to keep in sync. If `myfirst_log.h` grew to 200 lines, the cost of including it from every `.c` file would start to show up in compile times and in review friction; at that point the next step is to split it again.

25.7.9 The Updated Makefile

The Makefile for the split driver lists every `.c` file:

```
# Makefile for the myfirst driver - Chapter 25 (1.8-maintenance).
#
# Chapter 25 splits the driver into subject-matter files. Each file
# answers a single question; the Makefile lists them in alphabetical
# order after myfirst.c (which carries the module glue) so the
# reader sees the main file first.

KMOD=    myfirst
SRCS=    myfirst.c myfirst_cdev.c myfirst_debug.c myfirst_ioctl.c \
        myfirst_log.c myfirst_sysctl.c

CFLAGS+=    -I${.CURDIR}

SYSDIR?=    /usr/src/sys

.include <bsd.kmod.mk>
```

SRCS lists six .c files, one per subject. Adding a seventh is a one-line change. The kernel build system picks up every file in SRCS automatically; there is no manual linking step, no makefile dependency tree to maintain.

25.7.10 Where to Draw Each File Boundary

The hardest part of splitting a driver is not deciding to split; it is deciding where the boundaries go. Most splits go through three phases, and the phases apply to any driver, not just myfirst.

Phase one is the flat file. Everything is in driver.c. This is the right shape for the first 300 lines of a driver. Splitting sooner creates more friction than it saves.

Phase two is the subject split. The ioctl dispatch goes into driver_ioctl.c, the sysctl tree goes into driver_sysctl.c, the debug infrastructure goes into driver_debug.c. Each file is named after the subject it handles. This is where myfirst has been since Chapter 24.

Phase three is the subsystem split. As the driver grows, one subject grows larger than a single file. The ioctl file splits into driver_ioctl.c (the dispatch) and driver_ioctl_rw.c (the read/write payload helpers). The sysctl file splits similarly. This is where a full-featured driver ends up, often in its third or fourth major version.

myfirst at the end of Chapter 25 is solidly in phase two. Phase three is not warranted yet, and Chapter 26 will reset the clock when it splits the pseudo-driver into a USB-attached variant and leaves myfirst_core.c as the subject-agnostic core. There is no value in pre-emptively splitting to phase three today.

The rule of thumb for when to move from phase two to phase three is: when a single subject file crosses 1,000 lines, or when two unrelated changes to the same subject file cause a merge conflict, the subject is ready to split.

25.7.11 The Include Graph and Build Ordering

Once a driver is split into several files, the include graph matters. A circular include is not a hard error in C, but it is a sign of a muddled dependency structure that will confuse readers. The right shape is a directed acyclic graph of headers, rooted at `myfirst.h`, with leaf headers like `myfirst_ioctl.h` and `myfirst_log.h`.

`myfirst.h` is the widest header. It declares the `softc` and prototypes that every other file uses. It includes `myfirst_log.h` because the `softc` has rate-limit fields by value.

`myfirst_debug.h` is a leaf. It declares the `DPRINTF` macro family and the class bits. It is included by every `.c` file, directly or indirectly. It is not included by `myfirst.h`, because `myfirst.h` should not force the debug macros into any caller that does not want them.

`myfirst_ioctl.h` is a leaf. It declares command numbers, payload structures, and the wire-format version integer. It is included by `myfirst_ioctl.c` (and its user-space counterpart `myfirstctl.c`).

No header includes a file other than public kernel headers and the driver's own headers. No `.c` file includes another `.c` file. The include graph is shallow and easy to diagram.

25.7.12 The Cost of Splitting

Splitting files has a real cost. Every split adds a header file, and every header file has to be maintained. A function whose signature changes has to be updated in the `.c` and in the `.h`, and the change has to propagate to every other `.c` file that includes the header. A driver with twelve files is slightly slower to compile than a driver with one, because every `.c` has to include several headers and the preprocessor has to parse them.

These costs are real but small. They are much smaller than the cost of a monolithic file that nobody wants to touch. The rule is to split when the cost of not splitting exceeds the cost of maintaining the boundary. For `myfirst` at the end of Chapter 25, the threshold has been crossed.

25.7.13 A Practical Procedure for Splitting a Real Driver

Splitting a file is a routine refactor, but a routine refactor can still introduce bugs if done carelessly. A practical procedure for splitting an in-tree driver is:

1. **Identify the subjects.** Read the monolithic file top to bottom and group its functions by subject (`cdev`, `ioctl`, `sysctl`, `debug`, `lifecycle`). Write the grouping on a piece of paper or in a comment block.
2. **Create the empty files.** Add the new `.c` files and their headers to the source tree. Compile once to make sure the build system sees them.
3. **Move one subject at a time.** Move the `ioctl` functions into `driver_ioctl.c`. Move their declarations into `driver_ioctl.h`. Update `driver.c` to `#include "driver_ioctl.h"`. Compile. Run the driver through its test matrix.
4. **Commit each subject split.** Each subject move is a single commit. The commit log reads: “`myfirst: split ioctl dispatch into driver_ioctl.c`”. A reviewer can see the move clearly; a `git blame` shows the same line in the new file on the same commit.

5. **Verify the include graph.** After all subjects are moved, compile with `-Wunused-variable` and `-Wmissing-prototypes` to catch functions that should have had prototypes but did not. Use `nm` on the built module to confirm that no symbols that should be static are being exported.
6. **Retest.** Run the full driver test matrix. Splitting a file should not change behaviour; if a test starts failing, the split has introduced a bug.

The procedure for `myfirst` at the end of Chapter 25 follows exactly these steps. The final directory under `examples/part-05/ch25-advanced/` is the result.

25.7.14 Common Mistakes When Splitting

A few mistakes are common the first time a driver is split. Watching for them shortens the learning curve.

The first mistake is **putting declarations in the wrong header**. If `myfirst.h` declares a function that is only called from `myfirst_ioctl.c`, every other translation unit is paying to parse a declaration it does not need. If `myfirst_ioctl.h` declares a function that is called from both `myfirst_ioctl.c` and `myfirst_cdev.c`, the two consumers are coupled through the `ioctl` header and any change in the `ioctl` header rebuilds both files. The fix is to put cross-cutting declarations in `myfirst.h` and subject-specific declarations in subject-specific headers.

The second mistake is **forgetting static on functions that should be file-scope**. A function that is used only inside `myfirst_sysctl.c` should be declared `static`. Without `static`, the function is exported from the object file, which means another file could accidentally call it, and any later renaming in the original file becomes an ABI change. A `static` discipline prevents this entire class of problem.

The third mistake is **circular includes**. If `myfirst_ioctl.h` includes `myfirst.h`, and `myfirst.h` includes `myfirst_ioctl.h`, the driver compiles (thanks to include guards) but the dependency graph is wrong. Every edit to either file now triggers a rebuild of everything that includes either one. The fix is to decide which header sits higher in the graph and remove the back-reference.

The fourth mistake is **re-introducing a subject into the wrong file**. Six months after the split, someone adds a new `ioctl` by editing `myfirst.c` because that was where `ioctls` used to live. The single-responsibility rule has to be enforced by reviewers. A patch that puts a new `ioctl` in `myfirst.c` is rejected with a comment pointing at `myfirst_ioctl.c`.

25.7.15 Wrapping Up Section 6

A driver whose files each answer one question is a driver that you can hand to a new contributor on their first day. They read the filenames, they pick a subject, and they start editing exactly one file. The `myfirst` driver has crossed that threshold. Six `.c` files plus their headers hold every function the driver has grown since Chapter 17, with each file named for what it does.

In the next section, we turn from internal organisation to external preparation. A driver that is ready for production has a short list of properties that it must satisfy before it can be installed on a machine the developer does not own. Chapter 25's production-readiness checklist names those properties and walks `myfirst` through each one.

25.8 Section 7: Preparing for Production Use

A driver that works on your workstation is not a driver that is ready for production. Production is the set of conditions your code faces when it is installed on hardware you do not own, booted by operators you will never meet, and expected to behave predictably for months or years between reboots. The distance between “it works for me” and “it is ready to ship” is measured in habits, not in features. This section names the habits.

`myfirst` in its Chapter 25 shape is as feature-complete as the pseudo-driver is going to get. The remaining work is not to add functionality, but to harden the edges so the driver survives the environments it cannot control.

25.8.1 The Production Readiness Mindset

The mindset shift is this: every decision the driver makes implicitly at development time has to be made explicitly at production time. Where a tunable has a default, the default has to be the right default. Where a `sysctl` is writable, the consequences of a write by a scared operator at 3 a.m. have to be safe. Where a log message might fire, the message has to be useful without help from the developer. Where a module depends on another module, the dependency has to be declared so the loader does not load them in the wrong order.

Production-readiness is not a one-shot action; it is an attitude that runs through every decision. A driver that is nearly ready for production often has one or two specific gaps: a tunable with no documentation, a log message that fires every microsecond, a detach path that assumes nobody is using the device. The discipline of production-readiness is to find those specific gaps and close them, one by one, until the driver’s behaviour is predictable on a machine the developer is not standing in front of.

25.8.2 Declaring Module Dependencies

The first production habit is to be explicit about what the module needs. If `myfirst` calls a function that lives in another kernel module, the kernel’s module loader needs to know about the dependency before the call, or the kernel loads `myfirst` and panics the first time the dependency is used.

The mechanism is `MODULE_DEPEND`. Section 4 introduced it as a compatibility tool; in production, it is also a correctness tool. A driver without `MODULE_DEPEND` on its real dependencies works by accident in most boot orderings and fails mysteriously in others. A driver with `MODULE_DEPEND` on every real dependency either loads correctly or refuses to load with a clear error message.

For the pseudo-driver `myfirst`, there are no real dependencies yet; the driver only uses symbols from the kernel core, which is always present. The Chapter 26 USB variant will add the first real `MODULE_DEPEND`:

```
MODULE_DEPEND(myfirst_usb, usb, 1, 1, 1);
```

The three version numbers are the minimum, preferred, and maximum of the USB stack version that `myfirst_usb` is compatible with. At load time, the kernel checks the installed USB stack version against this range and refuses to load `myfirst_usb` if the USB stack is missing or outside the range.

The production habit is: before shipping, `grep` the driver for every symbol it calls and confirm that every symbol lives either in the kernel core or in a module that the driver declares a dependency on. A missing `MODULE_DEPEND` works until the boot ordering changes, and then the driver panics on production hardware.

25.8.3 Publishing PNP Information

For hardware drivers, the kernel's module loader consults each module's PNP metadata to decide which driver handles which device. A USB driver that does not publish PNP information works when loaded manually and fails when the boot loader tries to auto-load the driver for a newly-plugged device. The fix is `MODULE_PNP_INFO`, which the driver uses to declare the vendor/product identifiers it handles:

```
MODULE_PNP_INFO("U16:vendor;U16:product", uhub, myfirst_usb,  
    myfirst_pnp_table, nitems(myfirst_pnp_table));
```

The first string describes the format of the PNP table entries. `uhub` is the bus name; `myfirst_usb` is the driver name; `myfirst_pnp_table` is a static array of structures, one per device the driver handles.

`myfirst` at Chapter 25 is still a pseudo-driver and has no hardware to match. `MODULE_PNP_INFO` comes into play in Chapter 26 with the first real hardware attach. For Chapter 25, the production habit is simply to know the macro exists and to plan for it when hardware arrives.

25.8.4 The `MOD_QUIESCE` Event

The kernel module event handler is called with one of four events: `MOD_LOAD`, `MOD_UNLOAD`, `MOD_SHUTDOWN`, `MOD_QUIESCE`. Most drivers handle `MOD_LOAD` and `MOD_UNLOAD` explicitly, and the kernel synthesises the other two. For production drivers, `MOD_QUIESCE` deserves attention.

`MOD_QUIESCE` is the kernel's question "can you be unloaded right now?" It fires before `MOD_UNLOAD` and gives the driver a chance to refuse cleanly. A driver that is mid-operation (an outstanding DMA transfer, an open file descriptor, a pending timer) can return a non-zero `errno` from `MOD_QUIESCE` to refuse the unload; the kernel then does not proceed to `MOD_UNLOAD`.

For `myfirst`, the quiesce check is already built into `myfirst_detach`: if `sc_open_count > 0`, `detach` returns `EBUSY`. The kernel's module loader propagates that `EBUSY` back to `kldunload(8)`, and the operator sees "module `myfirst` is busy". The check is in the right place, but the discipline of thinking about `MOD_QUIESCE` separately from `MOD_UNLOAD` is worth naming: `MOD_QUIESCE` is the "are you safe to unload?" question, and `MOD_UNLOAD` is the "go ahead and unload" command. Some drivers have state that is safe to check in `MOD_QUIESCE` but not safe to acquire in `MOD_UNLOAD`; splitting them lets the driver answer the question without side effects.

25.8.5 Emitting `devctl_notify` Events

Long-running production systems are monitored by daemons like `devd(8)`, which watch for device arrivals, departures, and state changes. The mechanism the kernel uses to notify `devd` is `devctl_notify(9)`: a driver emits a structured event, `devd` reads the event, and `devd` takes a configured action (run a script, log a message, notify an operator).

The prototype is:

```
void devctl_notify(const char *system, const char *subsystem,  
    const char *type, const char *data);
```

- `system` is a top-level category like "DEVFS", "ACPI", or a driver-specific tag.
- `subsystem` is the driver or subsystem name.
- `type` is a short event name.
- `data` is optional structured data (key=value pairs) for the daemon to parse.

For `myfirst`, a useful production event is “the in-driver message was rewritten”:

```
devctl_notify("myfirst", device_get_nameunit(sc->sc_dev),
    "MSG_CHANGED", NULL);
```

After the operator writes a new message through `ioctl(fd, MYFIRSTIOC_SETMSG, buf)`, the driver emits a `MSG_CHANGED` event. A `devd` rule can match the event and, for example, send a syslog entry or notify a monitoring daemon:

```
notify 0 {
    match "system"      "myfirst";
    match "type"        "MSG_CHANGED";
    action "logger -t myfirst 'message changed on $subsystem'";
};
```

The production habit here is to ask, for each interesting event in the driver, whether an operator might want to react to it. If the answer is yes, emit a `devctl_notify` with a well-chosen name. Downstream tooling can then build on the event, and the driver does not have to know what those tools are.

25.8.6 Writing a `MAINTENANCE.md`

Every production driver should have a maintenance file that describes, in plain English, what the driver does, what tunables it accepts, what `sysctls` it exposes, what `ioctls` it handles, what events it emits, and what the version history is. The file lives alongside the source code in the repository; it is read by operators, by new developers, by security reviewers, and by the author six months later.

A concrete skeleton for `MAINTENANCE.md`:

```
# myfirst

A demonstration character driver that carries the book's running
example. This file is the operator-facing reference.

## Overview

myfirst registers a pseudo-device at /dev/myfirst0 and serves a
read-write message buffer, a set of ioctls, a sysctl tree, and a
configurable debug-class logger.

## Tunables
```

- hw.myfirst.debug_mask_default (int, default 0)
Initial value of dev.myfirst.<unit>.debug.mask.
- hw.myfirst.timeout_sec (int, default 5)
Initial value of dev.myfirst.<unit>.timeout_sec.
- hw.myfirst.max_retries (int, default 3)
Initial value of dev.myfirst.<unit>.max_retries.
- hw.myfirst.log_ratelimit_pps (int, default 10)
Initial rate-limit ceiling (prints per second per class).

Sysctls

All sysctls live under dev.myfirst.<unit>.

Read-only: version, open_count, total_reads, total_writes,
message, message_len.

Read-write: debug.mask (mirror of debug_mask_default), timeout_sec,
max_retries, log_ratelimit_pps.

Ioctls

Defined in myfirst_ioctl.h. Command magic 'M'.

- MYFIRSTIOC_GETVER (0): returns MYFIRST_IOCTL_VERSION.
- MYFIRSTIOC_RESET (1): zeros read/write counters.
- MYFIRSTIOC_GETMSG (2): reads the in-driver message.
- MYFIRSTIOC_SETMSG (3): writes the in-driver message.
- MYFIRSTIOC_GETCAPS (5): returns MYF_CAP_* bitmask.

Command 4 was reserved during Chapter 23 draft work and retired
before release. Do not reuse the number.

Events

Emitted through devctl_notify(9).

- system=myfirst subsystem=<unit> type=MSG_CHANGED
The operator-visible message was rewritten.

Version History

See Change Log below.

Change Log

1.8-maintenance

- Added MYFIRSTIOC_GETCAPS (command 5).
- Added tunables for timeout_sec, max_retries, log_ratelimit_pps.
- Added rate-limited logging via ppsratecheck(9).
- Added devctl_notify for MSG_CHANGED.
- No breaking changes from 1.7.

1.7-integration

- First end-to-end integration of ioctl, sysctl, debug.
- Introduced MYFIRSTIOC_{GETVER,RESET,GETMSG,SETMSG}.

1.6-debug

- Added DPRINTF framework and SDT probes.

The file is nothing glamorous. It is a reference that is kept up to date with every version bump and that serves as the single source of truth for operators.

The production habit is: every change to the driver's visible surface (a new tunable, a new sysctl, a new ioctl, a new event, a behaviour change) has a corresponding entry in MAINTENANCE.md. The file never falls behind the code. A driver whose MAINTENANCE.md is out of date is a driver whose users are guessing; a driver whose MAINTENANCE.md is current is a driver whose users can self-serve.

25.8.7 A devd Rule Set

devd(8) rules tell the daemon how to react to kernel events. For a production deployment of myfirst, a minimal rule set would ensure that important events reach the operator:

```
# /etc/devd/myfirst.conf
#
# devd rules for the myfirst driver. Drop this file into
# /etc/devd/ and restart devd(8) for the rules to take effect.

notify 0 {
    match "system"      "myfirst";
    match "type"        "MSG_CHANGED";
    action "logger -t myfirst 'message changed on $subsystem'";
};

# Future: match attach/detach events once Chapter 26's USB variant
# starts emitting them.
```

The file is short. It declares one rule, matches a specific event, and takes a specific action. In production, such

files grow to match more events, trigger more actions, and in some deployments notify a monitoring system that watches for driver anomalies.

Including a draft `devd.conf` in the driver's repository makes it easy for an operator to adopt. They copy the file, adjust the actions, and the driver's events are integrated into the site's monitoring on the first day.

25.8.8 Logs: Friend of the Support Engineer

A production driver's log messages are read by support engineers who do not have access to the source code and cannot reproduce the problem on demand. The rules that make a log message useful to a support engineer are different from the rules that make a log message useful to a developer.

A developer reading their own log message can rely on context that a support engineer does not have. The support engineer cannot ask "which attach?" or "which device?" or "what was error when this fired?" The answer has to already be in the message.

The production habit is to audit every log message in the driver and ask three questions:

1. **Does the message name its device?** `device_printf(dev, ...)` prefixes the output with the device nameunit; bare `printf` does not. Every message that is not from `MOD_LOAD` (where there is no device yet) should be `device_printf`.
2. **Does the message include the relevant numeric context?** "Failed to allocate" is not useful. "Failed to allocate: error 12 (ENOMEM)" is. "Failed to allocate a timer: error 12" is better.
3. **Does the message appear at the appropriate rate?** Section 1 covered rate-limiting. The final pass is to ensure that every message that can fire in a loop is either rate-limited or is demonstrably one-shot.

A log message that satisfies these three questions reaches a support engineer with enough information to file a useful bug report. A log message that fails any of them wastes the operator's time and the developer's.

25.8.9 Handling Bus Attach/Detach Gracefully

Production drivers, especially hot-pluggable ones, have to handle repeated attach and detach cycles without leaks. The discipline of Section 5's labelled-cleanup pattern is part of the answer; the other part is to confirm that repeated attach/detach actually works. The lab at the end of this chapter walks through a regression script that loads, unloads, and reloads the driver 100 times in a row and verifies that the module's memory footprint does not grow.

A driver that passes the 100-cycle test is a driver that will survive a month of hot-plug events on production hardware. A driver that fails the 100-cycle test has a leak that will manifest, over time, as slow memory growth or as the kernel running out of some bounded resource (`sysctl` OIDs, `cdev` minor numbers, `devclass` entries).

The test is simple to run and is disproportionately valuable. Make it part of the driver's pre-release checklist.

25.8.10 Handling Unexpected Operator Actions

Operators make mistakes. They run `kldunload myfirst` while a test program is reading from `/dev/myfirst0`. They set `dev.myfirst.0.debug.mask` to a value that enables every class at once. They copy `MAINTENANCE.md`

and skip the section on tunables. The production driver has to tolerate these actions without crashing, corrupting state, or leaving the system in a broken configuration.

For each exposed interface, the production habit is to ask: what is the worst sequence of operator actions I can imagine, and does the driver survive it?

- `kldunload` while a file descriptor is open: `myfirst_detach` returns `EBUSY`. Operator sees “module busy”. Driver is unchanged.
- A writable `sysctl` being set to an out-of-range value: the `sysctl` handler clamps the value or returns `EINVAL`. Driver’s internal state is unchanged.
- A `MYFIRSTIOC_SETMSG` with a message longer than the buffer: `strncpy` truncates. The copy is correct; the truncation is visible in `message_len`.
- A concurrent pair of `MYFIRSTIOC_SETMSG` calls: the softc mutex serialises them. Whichever runs second wins; both succeed.

If any of these actions produces a crash, a corruption, or an inconsistent state, the driver is not production-ready. The fix is always the same: add the missing guard, restart the test, and add a comment documenting the invariant.

25.8.11 A Production-Readiness Checklist

The habits in this section fit into a short checklist that a developer can walk through before shipping:

`myfirst` production readiness

- [] `MODULE_DEPEND` declared for every real dependency.
- [] `MODULE_PNP_INFO` declared if the driver binds to hardware.
- [] `MOD_QUIESCE` answers “can you unload?” without side effects.
- [] `devctl_notify` emitted for operator-relevant events.
- [] `MAINTENANCE.md` current: tunables, sysctls, ioctls, events.
- [] `devd.conf` snippet included with the driver.
- [] Every log message is `device_printf`, includes `errno`, and is rate-limited if it can fire in a loop.
- [] `attach/detach` survives 100 load/unload cycles.
- [] `sysctls` reject out-of-range values.
- [] `ioctl` payload is bounds-checked.
- [] Failure paths exercised via deliberate injection.
- [] Versioning discipline: `MYFIRST_VERSION`, `MODULE_VERSION`, `MYFIRST_IOCTL_VERSION` each bumped for their own reason.

The list is short on purpose. Twelve items, most of them already addressed by the habits introduced in earlier sections. A driver that checks every box is ready to be installed by someone who will never meet you.

25.8.12 What the myfirst Driver Covers

Running `myfirst` through the checklist at the end of Chapter 25 gives the following status.

`MODULE_DEPEND` is not required because the driver has no subsystem dependencies; this is noted explicitly in `MAINTENANCE.md`.

`MODULE_PNP_INFO` is not required because the driver does not bind to hardware; this is also noted in `MAINTENANCE.md`.

`MOD_QUIESCE` is answered by the `sc_open_count` check in `myfirst_detach`; a dedicated `MOD_QUIESCE` handler is not added for this version because the semantics are identical.

`devctl_notify` is emitted on `MYFIRSTIOC_SETMSG` with event type `MSG_CHANGED`.

`MAINTENANCE.md` is shipped in the examples directory and contains tunables, sysctls, ioctls, events, and a Change Log entry for 1.8-maintenance.

The `devd.conf` snippet is shipped alongside `MAINTENANCE.md` and demonstrates the single `MSG_CHANGED` rule.

Every log message is emitted through `device_printf` (or `DPRINTF`, which wraps `device_printf`); every message that fires in a hot path is wrapped in `DLOG_RL`.

The attach/detach regression script (see Labs) runs 100 cycles without growing the kernel's memory footprint.

The sysctls for `timeout_sec`, `max_retries`, and `log_ratelimit_pps` each reject out-of-range values in their handlers.

The ioctl payloads are bounds-checked at the structure level by the kernel's ioctl framework (`_IOR`, `_IOW`, `_IOWR` declare exact sizes) and inside the driver where string length matters.

Failure injection points are marked by conditional `#ifdef` in the examples; every label has been reached at least once in development.

Version identifiers each have their own rule: string bumped, module integer bumped, ioctl integer unchanged because additions are backwards compatible.

Twelve checks, twelve outcomes. The driver is ready for the next chapter.

25.8.13 Wrapping Up Section 7

Production is the quiet standard that separates interesting code from shippable code. The disciplines named here are not glamorous; they are the specific things that keep a driver working when it is deployed far from the developer who wrote it. `myfirst` has grown through five chapters of instructional content and now wears the harness that lets it survive outside the book.

In the next section, we turn to the two kernel infrastructures that let a driver run code at specific lifecycle points without manual wiring: `SYSINIT(9)` for boot-time initialisation and `EVENTHANDLER(9)` for runtime notifications. These are the last two pieces of the FreeBSD toolkit the book will introduce before Chapter 26 applies everything to a real bus.

25.9 Section 8: SYSINIT, SYSUNINIT, and EVENTHANDLER

A driver's attach and detach routines handle everything that happens between instantiation and teardown, but there are things a driver may need to do that fall outside that window. Some code has to run before any device is instantiated at all: loading boot-time tunables, initialising a subsystem-wide lock, setting up a pool that the first attach will consume. Other code has to run in response to system-wide events that are not device-specific: a system-wide suspend, a low-memory condition, a shutdown that is about to sync filesystems and power down.

The FreeBSD kernel provides two mechanisms for these cases. `SYSINIT(9)` registers a function to run at a specific boot stage, and its companion `SYSUNINIT(9)` registers a cleanup function to run at module unload. `EVENTHANDLER(9)` registers a callback to run whenever the kernel fires a named event.

Both mechanisms have been available since FreeBSD's earliest releases. They are boring infrastructure; that is their value. A driver that uses them correctly can react to the full kernel lifecycle without writing a single line of manual registration code. A driver that ignores them either misses its cue or reinvents a worse version of the same facility.

25.9.1 Why the Kernel Needs Boot-Time Ordering

The FreeBSD kernel boots in a precise order. Memory management comes up before any allocator is usable. Tunables are parsed before drivers can read them. Locks are initialised before anything is allowed to acquire them. Filesystems are mounted only after the devices they live on are probed. Each of these dependencies has to be honoured, or the kernel panics before `init(8)` starts.

The mechanism that enforces the ordering is `SYSINIT(9)`. A `SYSINIT` macro declares that a given function should run at a given subsystem ID with a given order constant. The kernel's boot sequence gathers every `SYSINIT` in the running configuration, sorts them by (subsystem, order), and calls them in that sequence. Modules loaded after the kernel has booted still honour their `SYSINIT` declarations: the loader calls them at module attach time, in the same sorted order.

From the driver's point of view, a `SYSINIT` is a way to say "do this thing at that point in the boot sequence, and I do not care which other code is also registering at that point". The kernel handles the sorting; the driver writes the callback.

25.9.2 The Subsystem ID Space

Subsystem IDs are defined in `/usr/src/sys/sys/kernel.h`. The constants have descriptive names and numeric values that reflect their ordering. A driver picks the subsystem that corresponds to its callback's purpose:

- `SI_SUB_TUNABLES (0x0700000)`: evaluate boot-time tunables. This is where `TUNABLE_INT_FETCH` and its siblings run. Code that consumes tunables has to run after this point.
- `SI_SUB_KLD (0x2000000)`: loadable kernel module setup. Early module infrastructure runs here.
- `SI_SUB_SMP (0x2900000)`: bring up the application processors.
- `SI_SUB_DRIVERS (0x3100000)`: let drivers initialise. This is the subsystem most user-land drivers register against if they need early code that runs before any device attaches.
- `SI_SUB_CONFIGURE (0x3800000)`: configure devices. By the end of this subsystem, every compiled-in driver has had a chance to attach.

There are more than a hundred subsystem IDs in `kernel.h`. The ones above are the ones a character-device driver most often interacts with. The numeric values are sorted so that “smaller number” means “earlier in boot”.

Within a subsystem, the order constant gives fine-grained ordering:

- `SI_ORDER_FIRST` (0x0): run before most other code in the same subsystem.
- `SI_ORDER_SECOND`, `SI_ORDER_THIRD`: explicit step-by-step ordering.
- `SI_ORDER_MIDDLE` (0x1000000): run in the middle. Most driver-level `SYSINIT`s use this or the one below.
- `SI_ORDER_ANY` (0xffffffff): run last. The kernel does not promise any specific order among `SI_ORDER_ANY` entries.

The driver author picks the lowest order that makes the callback run after its prerequisites and before its dependents. For most purposes, `SI_ORDER_MIDDLE` is right.

25.9.3 When a Driver Needs `SYSINIT`

Most character-device drivers do not need `SYSINIT` at all. `DRIVER_MODULE` already registers the driver with Newbus; the driver’s `device_attach` method runs when a matching device appears. That is enough for any work that is per-instance.

`SYSINIT` is for work that is not per-instance. A list of reasons a driver might register a `SYSINIT`:

- **Initialise a global pool** that every instance of the driver will draw from. The pool exists once; it does not belong to any one softc.
- **Register with a kernel subsystem** that expects callers to register before they use it. For example, a driver that wants to receive `vm_lowmem` events registers early so that the first low-memory event does not miss it.
- **Parse a complex tunable** that requires more work than a single `TUNABLE_INT_FETCH`. The tunable-parsing code runs during `SI_SUB_TUNABLES` and populates a global structure that per-instance code consults later.
- **Self-test** a cryptographic primitive or a subsystem initialiser before the first caller can use it.

For `myfirst`, none of these applies today. The driver is per-instance, its tunables are simple, and it uses no subsystem that requires pre-registration. Chapter 25 introduces `SYSINIT` not because `myfirst` needs one, but because the reader should be familiar with the macro and understand when a future change would call for it.

25.9.4 The Shape of a `SYSINIT` Declaration

The macro signature is:

```
SYSINIT(uniquifier, subsystem, order, func, ident);
```

- `uniquifier` is a C identifier that ties the `SYSINIT` symbol to this declaration. It appears nowhere else. Convention is to use a short name that matches the subsystem or function.
- `subsystem` is the `SI_SUB_*` constant.

- `order` is the `SI_ORDER_*` constant.
- `func` is a function pointer with signature `void (*)(void *)`.
- `ident` is a single argument passed to `func`. For most uses, it is `NULL`.

The matching cleanup macro is:

```
SYSUNINIT(uniquifier, subsystem, order, func, ident);
```

`SYSUNINIT` registers a cleanup function. It runs at module unload in the reverse order of `SYSINIT` declarations. For code that is compiled into the kernel (not a module), `SYSUNINIT` never fires because the kernel never unloads; but the declaration is still useful because compiling the driver as a module exercises the cleanup path.

25.9.5 A Worked `SYSINIT` Example for `myfirst`

Consider a hypothetical enhancement to `myfirst`: a global, driver-wide pool of pre-allocated log buffers that every instance can draw from. The pool is initialised once per module load and destroyed once per module unload. Per-instance attach and detach do not touch the pool directly; they only take and return buffers from it.

The `SYSINIT` declaration looks like this:

```
#include <sys/kernel.h>

static struct myfirst_log_pool {
    struct mtx      lp_mtx;
    /* ... per-pool state ... */
} myfirst_log_pool;

static void
myfirst_log_pool_init(void *unused __unused)
{
    mtx_init(&myfirst_log_pool.lp_mtx, "myfirst log pool",
            NULL, MTX_DEF);
    /* Allocate pool entries. */
}

static void
myfirst_log_pool_fini(void *unused __unused)
{
    /* Release pool entries. */
    mtx_destroy(&myfirst_log_pool.lp_mtx);
}

SYSINIT(myfirst_log_pool, SI_SUB_DRIVERS, SI_ORDER_MIDDLE,
        myfirst_log_pool_init, NULL);
```

```
SYSUNINIT(myfirst_log_pool, SI_SUB_DRIVERS, SI_ORDER_MIDDLE,  
          myfirst_log_pool_fini, NULL);
```

When `myfirst` is loaded, the kernel sorts the `SYSINIT` entries and calls `myfirst_log_pool_init` during the `SI_SUB_DRIVERS` phase. The first `myfirst_attach` that runs afterwards finds the pool ready. When the module is unloaded, `myfirst_log_pool_fini` runs after every instance has been detached, giving the pool a chance to release its resources.

This is a sketch for instructional purposes; `myfirst` does not actually use a global pool in the shipped Chapter 25 code. The reader who eventually writes a driver that does need one will find the pattern here.

25.9.6 The Ordering Between `SYSINIT` and `DRIVER_MODULE`

`DRIVER_MODULE` itself is implemented as a `SYSINIT` under the hood. It registers the driver with Newbus during a specific subsystem phase, and Newbus's own `SYSINIT`s probe and attach devices afterwards. A driver's custom `SYSINIT` can therefore be ordered relative to `DRIVER_MODULE` by choosing the right subsystem and order.

A rule of thumb:

- `SYSINIT` at `SI_SUB_DRIVERS` with `SI_ORDER_FIRST` runs before `DRIVER_MODULE`'s registration.
- `SYSINIT` at `SI_SUB_CONFIGURE` with `SI_ORDER_MIDDLE` runs after most device attaches but before the final configuration step.

For a global pool that attach depends on, `SI_SUB_DRIVERS` with `SI_ORDER_MIDDLE` is usually correct: the pool is initialised before `DRIVER_MODULE`'s devices start attaching (because `SI_SUB_DRIVERS` is earlier than `SI_SUB_CONFIGURE`), and the order constant keeps it away from the earliest hooks.

25.9.7 EVENTHANDLER: Reacting to Runtime Events

A `SYSINIT` fires once, at a known boot phase. An `EVENTHANDLER` fires zero or more times, whenever a specific system event occurs. The mechanisms are cousins; they complement each other.

The kernel defines a number of named events. Each event has a fixed callback signature and a fixed set of circumstances in which it fires. A driver that cares about an event registers a callback; the kernel invokes the callback every time the event fires; the driver deregisters the callback at detach.

Some commonly useful events:

- `shutdown_pre_sync`: the system is about to sync filesystems. Drivers with in-memory caches flush them here.
- `shutdown_post_sync`: the system has finished syncing filesystems. Drivers that need to know “the filesystem is quiet” hook here.
- `shutdown_final`: the system is about to halt or reboot. Drivers with hardware state that must be saved do it here.
- `vm_lowmem`: the virtual memory subsystem is under pressure. Drivers with caches of their own should release some memory back.
- `power_suspend_early`, `power_suspend`, `power_resume`: suspend/resume lifecycle.

- `dev_clone`: a device cloning event, used by pseudo-devices that appear on demand.

The list is not fixed; new events are added as the kernel grows. The ones above are the ones a general driver most often considers.

25.9.8 The Shape of an EVENTHANDLER Registration

The pattern has three parts: declare a handler function with the right signature, register it at attach time, deregister it at detach time. The registration returns an opaque tag; the deregistration needs that tag.

For `shutdown_pre_sync`, the handler signature is:

```
void (*handler)(void *arg, int howto);
```

`arg` is whatever pointer the driver passed to the registration; typically it is the `softc`. `howto` is the shutdown flags (`RB_HALT`, `RB_REBOOT`, etc.).

A minimal shutdown handler for `myfirst`:

```
#include <sys/eventhandler.h>

static eventhandler_tag myfirst_shutdown_tag;

static void
myfirst_shutdown(void *arg, int howto)
{
    struct myfirst_softc *sc = arg;

    mtx_lock(&sc->sc_mtx);
    DPRINTF(sc, MYF_DBG_INIT, "shutdown: howto=0x%x\n", howto);
    /* Flush any pending state here. */
    mtx_unlock(&sc->sc_mtx);
}
```

The registration happens inside `myfirst_attach` (or in a helper called from it):

```
myfirst_shutdown_tag = EVENTHANDLER_REGISTER(shutdown_pre_sync,
    myfirst_shutdown, sc, SHUTDOWN_PRI_DEFAULT);
```

The deregistration happens inside `myfirst_detach`:

```
EVENTHANDLER_DEREGISTER(shutdown_pre_sync, myfirst_shutdown_tag);
```

The deregistration is mandatory. A driver that detaches without deregistering leaves a dangling callback pointer in the kernel's event list. When the kernel next fires the event, it calls into a memory region that is no longer mapped, and the system panics.

The tag stored in `myfirst_shutdown_tag` is what binds the registration to the deregistration. For a driver with a single instance, a static variable like the one above works. For a driver with multiple instances, the tag should live in the softc so that each instance's deregistration references its own tag.

25.9.9 EVENTHANDLER in the Attach Chain

Because registration and deregistration are symmetric, they slot cleanly into the labelled-cleanup pattern from Section 5. Registration becomes an acquisition; its failure mode is “did the registration return an error?” (it can fail under low-memory conditions); its cleanup is `EVENTHANDLER_DEREGISTER`.

The updated attach fragment for an `EVENTHANDLER`-aware `myfirst`:

```
/* Stage 7: shutdown handler. */
sc->sc_shutdown_tag = EVENTHANDLER_REGISTER(shutdown_pre_sync,
    myfirst_shutdown, sc, SHUTDOWN_PRI_DEFAULT);
if (sc->sc_shutdown_tag == NULL) {
    error = ENOMEM;
    goto fail_log;
}

return (0);

fail_log:
    myfirst_log_detach(sc);
fail_cdev:
    destroy_dev(sc->sc_cdev);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
return (error);
```

And the matching detach, with the deregistration first (reverse order of acquisition):

```
EVENTHANDLER_DEREGISTER(shutdown_pre_sync, sc->sc_shutdown_tag);
myfirst_log_detach(sc);
destroy_dev(sc->sc_cdev);
mtx_destroy(&sc->sc_mtx);
```

`sc->sc_shutdown_tag` lives in the softc. Storing it there is important: the deregistration needs to know which specific registration to remove, and per-softc storage keeps the two instances of the driver independent.

25.9.10 Priority: `SHUTDOWN_PRI_*`

Within a single event, callbacks are called in priority order. The priority is the fourth argument to `EVENTHANDLER_REGISTER`. For shutdown events, the common constants are:

- SHUTDOWN_PRI_FIRST: run before most other handlers.
- SHUTDOWN_PRI_DEFAULT: run in the default order.
- SHUTDOWN_PRI_LAST: run after other handlers.

A driver with hardware that needs to be quiesced before filesystems flush might register with SHUTDOWN_PRI_FIRST. A driver whose state depends on the filesystems already being flushed (unlikely in practice) might register with SHUTDOWN_PRI_LAST. Most drivers use SHUTDOWN_PRI_DEFAULT and do not think about priority.

Similar priority constants exist for other events (EVENTHANDLER_PRI_FIRST, EVENTHANDLER_PRI_ANY, EVENTHANDLER_PRI_LAST).

25.9.11 When to Use `vm_lowmem`

`vm_lowmem` is the event the VM subsystem fires when free memory drops below a threshold. A driver that maintains a cache of its own (a pool of pre-allocated blocks, for example) can release some of them back to the kernel in response.

The handler is called with a single argument (the subsystem ID that triggered the event). A minimal handler for a driver with a cache:

```
static void
myfirst_lowmem(void *arg, int unused __unused)
{
    struct myfirst_softc *sc = arg;

    mtx_lock(&sc->sc_mtx);
    /* Release some entries from the cache. */
    mtx_unlock(&sc->sc_mtx);
}
```

The registration looks the same as the shutdown one but for the event name:

```
sc->sc_lowmem_tag = EVENTHANDLER_REGISTER(vm_lowmem,
    myfirst_lowmem, sc, EVENTHANDLER_PRI_ANY);
```

A driver that does not maintain a cache should not register for `vm_lowmem`. The cost of doing so is not zero: the kernel calls every registered handler on every low-memory event, and a no-op handler adds latency to that call chain.

For `myfirst`, there is no cache, so `vm_lowmem` is not used. The pattern is introduced for the reader who is about to write a driver that needs it.

25.9.12 `power_suspend_early` and `power_resume`

Suspend/resume is a sensitive lifecycle. Between `power_suspend_early` and `power_resume`, the driver's devices are expected to be quiescent: no I/O, no interrupts, no state transitions. A driver with hardware state

that must be saved before suspend and restored after resume registers handlers for both events.

For character-device drivers that do not manage hardware, these events usually do not apply. For bus-attached drivers (PCI, USB, SPI), the bus layer handles most of the suspend/resume bookkeeping, and the driver just has to provide `device_suspend` and `device_resume` methods in its `device_method_t` table. The `EVENTHANDLER` approach is for drivers that want to react to a system-wide suspend without being bus-attached.

Chapter 26 will revisit suspend/resume when `myfirst` becomes a USB driver; at that point the bus layer's mechanism is the preferred one.

25.9.13 The Module Event Handler

Related to `SYSINIT` and `EVENTHANDLER` is the module event handler: the callback the kernel invokes for `MOD_LOAD`, `MOD_UNLOAD`, `MOD_QUIESCE`, and `MOD_SHUTDOWN`. Most drivers do not override it; `DRIVER_MODULE` supplies a default implementation that calls `device_probe` and `device_attach` appropriately.

A driver that needs custom behaviour at module load (beyond what `SYSINIT` can do) can supply its own handler:

```
static int
myfirst_modevent(module_t mod, int what, void *arg)
{
    switch (what) {
    case MOD_LOAD:
        /* Custom load behaviour. */
        return (0);
    case MOD_UNLOAD:
        /* Custom unload behaviour. */
        return (0);
    case MOD_QUIESCE:
        /* Can we be unloaded? Return errno if not. */
        return (0);
    case MOD_SHUTDOWN:
        /* Shutdown notification; usually no-op. */
        return (0);
    default:
        return (EOPNOTSUPP);
    }
}
```

The handler is wired up through a `moduledata_t` structure rather than through `DRIVER_MODULE`. The two approaches are mutually exclusive for a given module name; a driver picks one or the other.

For most drivers, `DRIVER_MODULE`'s default is correct, and the module-event handler is not customised. `myfirst` uses `DRIVER_MODULE` throughout.

25.9.14 Deregistration Discipline

The single most important rule when using EVENTHANDLER is: register once, deregister once, in attach and detach respectively. Two failure modes show up when the rule is broken.

The first failure mode is the **missed deregistration**. Detach runs, the tag is not deregistered, the kernel's event list still points at the softc's handler, and the next event fires into freed memory. The panic happens far from the cause, because the next event might fire minutes or hours after detach.

The fix is mechanical: every EVENTHANDLER_REGISTER in attach gets a matching EVENTHANDLER_DEREGISTER in detach. The labelled-cleanup pattern from Section 5 makes this easy: registration is an acquisition with a label, and the cleanup chain deregisters in reverse order.

The second failure mode is the **double registration**. A driver that registers the same handler twice has two entries in the kernel's event list; detaching once removes only one of them. The kernel then has a stale entry pointing at the softc that just went away.

The fix is also mechanical: register exactly once per attach. Do not register in a helper that is called from multiple places; do not register lazily in response to a first event.

25.9.15 A Complete Lifecycle Example

Putting SYSINIT, EVENTHANDLER, and the labelled-cleanup attach together, the full lifecycle of a `myfirst` driver with a global pool and a shutdown handler runs as follows:

At kernel boot or module load: - `SI_SUB_TUNABLES` fires. `TUNABLE_*_FETCH` calls in attach will see their values. - `SI_SUB_DRIVERS` fires. `myfirst_log_pool_init` runs (via `SYSINIT`). The global pool is ready. - `SI_SUB_CONFIGURE` fires. `DRIVER_MODULE` registers the driver. Newbus probes; `myfirst_probe` and `myfirst_attach` run for each instance. - Inside `myfirst_attach`: lock, cdev, sysctl, log state, shutdown handler registered.

At runtime: - `ioctl(fd, MYFIRSTIOC_SETMSG, buf)` updates the message. - `devctl_notify` emits `MSG_CHANGED`; `devd` logs it.

At shutdown: - The kernel fires `shutdown_pre_sync`. `myfirst_shutdown` runs for each registered handler. - Filesystems sync. - `shutdown_final` fires. The machine halts.

At module unload (before shutdown): - `MOD_QUIESCE` fires. `myfirst_detach` returns `EBUSY` if any device is in use. - `MOD_UNLOAD` fires. `myfirst_detach` runs for each instance: deregister handler, release log state, destroy cdev, destroy lock. - `SYSUNINIT` fires. `myfirst_log_pool_fini` runs. The global pool is released. - The module unmaps.

Every step is in a well-defined place. Every acquisition has a matching release. A driver that follows the pattern closely is a driver that the FreeBSD kernel can load, run, and unload any number of times without accumulating state.

25.9.16 Deciding What to Register For

A driver author deciding whether to register for an event should ask three questions.

First, **does the event actually matter to this driver?** `vm_lowmem` matters to a driver with a cache; it is noise to a driver without one. `shutdown_pre_sync` matters to a driver whose hardware needs to be quiesced; it is noise to a pseudo-driver. A handler that does nothing useful is still called on every event, slowing the system down slightly on every trigger.

Second, **is the event the right one?** FreeBSD has several shutdown events. `shutdown_pre_sync` fires before filesystem syncs; `shutdown_post_sync` fires after; `shutdown_final` fires just before halt. A driver registering for the wrong phase might flush its cache too early (before data that should be flushed) or too late (after filesystems are already dying).

Third, **has the event been stable across kernel versions?** `shutdown_pre_sync` has been stable for a long time and is safe to use. Newer or more specialised events may change signatures between releases. A driver that targets a specific FreeBSD release (this book is aligned with 14.3) can rely on the events in that release; a driver that targets a range of releases has to be more careful.

For my first, the shipped Chapter 25 registers `shutdown_pre_sync` as a demonstration. The handler is a no-op: it just logs that shutdown is starting. The registration, deregistration, and labelled cleanup are the point of the example, not the handler body.

25.9.17 Common Mistakes with SYSINIT and EVENTHANDLER

A handful of mistakes recur when these mechanisms are used for the first time.

The first mistake is **running heavy code in a SYSINIT**. Boot-time code runs in a context where many kernel subsystems are still initialising. A `SYSINIT` that calls into a complex subsystem may race with that subsystem's own initialisation. The rule is: `SYSINIT` code should be minimal and self-contained. Complex initialisation belongs in the driver's attach routine, which runs after every subsystem has come up.

The second mistake is **using SYSINIT instead of device_attach**. A `SYSINIT` runs once per module load, but `device_attach` runs once per device. A driver that initialises per-device state in a `SYSINIT` is making a category error; the per-device state does not exist yet at `SYSINIT` time.

The third mistake is **forgetting the priority argument on EVENTHANDLER_REGISTER**. The function takes four arguments: event name, callback, argument, priority. Some drivers forget the priority and pass the wrong number of arguments; the compiler catches this with an error, but a driver that happens to pass 0 by accident registers with the lowest possible priority, which may be wrong.

The fourth mistake is **not zeroing the tag field**. If `sc->sc_shutdown_tag` is uninitialised when `EVENTHANDLER_DEREGISTER` is called on a failure path, the deregistration tries to remove a tag that was never registered. The kernel detects this (the tag does not exist in its event list) and the deregistration is a no-op, but the pattern is fragile. The cleaner discipline is to zero the `softc` at allocation time (Newbus does this automatically via `device_get_softc`, but drivers that allocate their own `softcs` have to do it manually) and to never reach a deregistration for a tag that was not registered.

25.9.18 Wrapping Up Section 8

`SYSINIT` and `EVENTHANDLER` are the kernel's way of letting a driver participate in lifecycles beyond its own attach/detach window. `SYSINIT` runs code at a specific boot phase; `EVENTHANDLER` runs code in response to a

named kernel event. Together they cover the cases where per-device code is not enough and the driver has to engage with the system as a whole.

`myfirst` at the end of Chapter 25 uses `EVENTHANDLER_REGISTER` for a demonstration `shutdown_pre_sync` handler; the registration, deregistration, and labelled-cleanup shape are all in place. `SYSINIT` is introduced but not used, because `myfirst` has no global pool today. The patterns are planted; when a future chapter's driver does need them, the reader will recognise them immediately.

With Section 8 complete, every mechanism the chapter set out to teach is in the driver. The remaining material in the chapter applies the mechanisms through hands-on labs, challenge exercises, and a troubleshooting reference for when things go wrong.

25.10 Hands-on Labs

The labs in this section exercise the chapter's mechanisms on a real FreeBSD 14.3 system. Each lab has a specific measurable outcome; after running the lab, you should be able to state what you saw and what it means. The labs assume you have the `examples/part-05/ch25-advanced/` companion directory at hand.

Before starting, build the driver as shipped at the top of `ch25-advanced/`:

```
# cd examples/part-05/ch25-advanced
# make clean
# make
# kldload ./myfirst.ko
# ls /dev/myfirst*
/dev/myfirst0
```

If any of these steps fails, fix the toolchain or the source before continuing. The labs assume a working baseline.

25.10.1 Lab 1: Reproducing a Log Flood

Purpose: see the difference between an unrated `device_printf` and the rate-limited `DLOG_RL` when fired in a hot loop.

Source: `examples/part-05/ch25-advanced/lab01-log-flood/` contains a small user-space program that calls `read()` on `/dev/myfirst0` 10,000 times as fast as the kernel will let it.

Step 1. Temporarily set the debug mask to enable the I/O class and the `printf` on the read path:

```
# sysctl dev.myfirst.0.debug.mask=0x4
```

The mask bit `0x4` enables `MYF_DBG_IO`, which the read callback uses.

Step 2. Run the flood with the naive `DPRINTF` version of the driver first. Build and load `myfirst-flood-unlimited.ko` from `lab01-log-flood/unlimited/`:

```
# make -C lab01-log-flood/unlimited
# kldunload myfirst
# kldload lab01-log-flood/unlimited/myfirst.ko
# dmesg -c > /dev/null
# ./lab01-log-flood/flood 10000
# dmesg | wc -l
```

Expected outcome: approximately 10,000 lines in `dmesg`. The console may also be filled; the system's log buffer wraps, and earlier messages are lost.

Step 3. Unload and reload the rate-limited version from `lab01-log-flood/limited/`, which uses `DLOG_RL` with a 10 pps cap:

```
# kldunload myfirst
# kldload lab01-log-flood/limited/myfirst.ko
# dmesg -c > /dev/null
# ./lab01-log-flood/flood 10000
# sleep 5
# dmesg | wc -l
```

Expected outcome: approximately 50 lines in `dmesg`. The flood now emits at most 10 messages per second; the 10-second test window produces roughly 50 messages (the first second's burst token plus subsequent seconds' allowances, so count exactly may vary but should be within ten).

Step 4. Compare the two outputs side by side. The rate-limited version is readable; the unlimited version is not. Both drivers had identical read behaviour; only the logging discipline differs.

Record: the wall-clock time it took the flood to complete in both cases. The unlimited version is noticeably slower because the console output itself is a bottleneck. Rate-limiting has a visible performance benefit as well as a clarity benefit.

25.10.2 Lab 2: `errno` Audit with `truss`

Purpose: see what `truss(1)` reports when the driver returns different `errno` values, and calibrate your intuition about which `errno` to return from which code path.

Source: `examples/part-05/ch25-advanced/lab02-errno-audit/` contains a user program that makes a series of deliberately invalid calls and a script that runs it under `truss`.

Step 1. Load the stock `myfirst.ko` if not already loaded:

```
# kldload ./myfirst.ko
```

Step 2. Run the audit program under `truss`:

```
# truss -f -o /tmp/audit.truss ./lab02-errno-audit/audit
# less /tmp/audit.truss
```

The program performs these operations in sequence: 1. Opens `/dev/myfirst0`. 2. Issues an unknown ioctl command (command number 99). 3. Issues `MYFIRSTIOC_SETMSG` with a NULL argument. 4. Writes a zero-length buffer. 5. Writes a buffer larger than the driver accepts. 6. Sets `dev.myfirst.0.timeout_sec` to a value larger than allowed. 7. Closes.

Step 3. In the truss output, find each operation and note its `errno`. The expected outcomes:

1. `open`: returns a file descriptor. No `errno`.
2. `ioctl(_IOC=0x99)`: returns `ENOTTY` (the kernel's translation of the driver's `ENOIOCTL`).
3. `ioctl(MYFIRSTIOC_SETMSG, NULL)`: returns `EFAULT` (the kernel catches the NULL before the handler runs).
4. `write(0 bytes)`: returns 0 (no error, just no bytes written).
5. `write(oversize)`: returns `EINVAL` (the driver rejects lengths above its buffer size).
6. `sysctl write out-of-range`: returns `EINVAL` (the `sysctl` handler rejects the value).
7. `close`: returns 0. No `errno`.

Step 4. For each observed `errno`, locate the driver code that returned it. Walk the call chain from `truss` to the kernel source and confirm that the `errno` you see in `truss` is the one the driver returned. This exercise calibrates your mental map between “what the user sees” and “what the driver says”.

25.10.3 Lab 3: Tunable Reboot Behaviour

Purpose: verify that a loader tunable actually changes the driver's initial state when the module is first loaded.

Source: `examples/part-05/ch25-advanced/lab03-tunable-reboot/` contains a helper script `apply_tunable.sh`.

Step 1. With the stock module loaded and no tunable set, confirm the initial value of the timeout:

```
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.timeout_sec
dev.myfirst.0.timeout_sec: 5
```

The default is 5, set in the `attach` routine.

Step 2. Unload the module, set the loader tunable, reload, and confirm the new initial value:

```
# kldunload myfirst
# kenv hw.myfirst.timeout_sec=12
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.timeout_sec
dev.myfirst.0.timeout_sec: 12
```

The tunable set via `kenv(1)` took effect because `TUNABLE_INT_FETCH` in `attach` read it before the `sysctl` was published.

Step 3. Change the `sysctl` at runtime and confirm that the change is accepted but does not propagate back to the tunable:

```
# sysctl dev.myfirst.0.timeout_sec=25
dev.myfirst.0.timeout_sec: 12 -> 25
# kenv hw.myfirst.timeout_sec
hw.myfirst.timeout_sec="12"
```

The tunable still reads 12; the `sysctl` reads 25. The tunable is the initial value; the `sysctl` is the runtime value. They diverge the moment the `sysctl` is written.

Step 4. Unload and reload. The tunable value is still 12 (because it is in the kernel environment), so the new `sysctl` starts at 12, not 25. This is the lifecycle: tunable sets initial, `sysctl` sets runtime, unload loses runtime, tunable survives.

Step 5. Clear the tunable and reload:

```
# kldunload myfirst
# kenv -u hw.myfirst.timeout_sec
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.timeout_sec
dev.myfirst.0.timeout_sec: 5
```

Back to the attach-time default. The lifecycle is consistent end to end.

25.10.4 Lab 4: Deliberate Attach Failure Injection

Purpose: verify that every label in the cleanup chain is reached and that no resources leak when a failure is injected in the middle of `attach`.

Source: `examples/part-05/ch25-advanced/lab04-failure-injection/` contains four build variants of the module, each compiling in a different failure injection point:

- `inject-mtx/`: fails just after the lock is initialised.
- `inject-cdev/`: fails just after the `cdev` is created.
- `inject-sysctl/`: fails just after the `sysctl` tree is built.
- `inject-log/`: fails just after the log state is initialised.

Each variant defines exactly one of the `MYFIRST_DEBUG_INJECT_FAIL_*` macros from Section 5.

Step 1. Build and load the first variant. The load should fail:

```
# make -C lab04-failure-injection/inject-mtx
# kldload lab04-failure-injection/inject-mtx/myfirst.ko
kldload: an error occurred while loading module myfirst. Please check dmesg(8) for more
↪ details.
```

```
# dmesg | tail -3
myfirst0: attach: stage 1 complete
myfirst0: attach: injected failure after mtx_init
device_attach: myfirst0 attach returned 12
```

The attach function returned ENOMEM (errno 12) at the injected failure point. The module is not loaded:

```
# kldstat -n myfirst
kldstat: can't find file: myfirst
```

Step 2. Repeat for the other three variants. Each should fail at the specific stage the name suggests, and each should leave the kernel in a clean state. To confirm the clean state, check for leftover sysctl OIDs, leftover cdevs, and leftover locks:

```
# sysctl dev.myfirst 2>&1 | head
sysctl: unknown oid 'dev.myfirst'
# ls /dev/myfirst* 2>&1
ls: No match.
# dmesg | grep -i "witness\|leak"
```

Expected: no matches. No sysctl, no cdev, no witness complaints. The cleanup chain is working.

Step 3. Run the combined regression script that builds every variant and checks the results automatically:

```
# ./lab04-failure-injection/run.sh
```

The script builds each variant, loads it, confirms that the load fails, confirms that the state is clean, and reports a one-line summary per variant. A pass on all four variants means every label in the cleanup chain has been exercised on a real kernel and released every resource that was held at that label.

25.10.5 Lab 5: shutdown_pre_sync Handler

Purpose: confirm that the registered shutdown handler actually fires during a real shutdown, and observe its ordering relative to filesystem sync.

Source: `examples/part-05/ch25-advanced/lab05-shutdown-handler/` contains a version of `myfirst.ko` whose `shutdown_pre_sync` handler prints a distinctive message to the console.

Step 1. Load the module and verify the handler is registered by reading the log on attach:

```
# kldload lab05-shutdown-handler/myfirst.ko
# dmesg | tail -1
myfirst0: attach: shutdown_pre_sync handler registered
```

Step 2. Issue a reboot. On a test machine (not a production machine), the simplest way is:

```
# shutdown -r +1 "testing myfirst shutdown handler"
```

Watch the console as the machine shuts down. The expected sequence:

```
myfirst0: shutdown: howto=0x4
Syncing disks, buffers remaining... 0 0 0
Uptime: ...
```

The `myfirst0: shutdown: howto=0x4` line appears **before** “Syncing disks”, because `shutdown_pre_sync` fires before filesystems sync. If the handler message appears after the sync message, the registration was at the wrong event (`shutdown_post_sync` or `shutdown_final`). If the message never appears, the handler was never registered or never deregistered (double-free would cause a panic, but silent missing would suggest a registration bug).

Step 3. After the machine reboots, confirm that unloading before shutdown still removes the handler cleanly:

```
# kldload lab05-shutdown-handler/myfirst.ko
# kldunload myfirst
# dmesg | tail -2
myfirst0: detach: shutdown handler deregistered
myfirst0: detach: complete
```

The deregistration message confirms the cleanup path in `detach` ran. The `attach/detach` pair is symmetric; no event list entries leak.

25.10.6 Lab 6: The 100-Cycle Regression Script

Purpose: run a sustained load/unload cycle to catch leaks that only appear under repeated `attach/detach`. This is the test from Section 7’s production checklist.

Source: `examples/part-05/ch25-advanced/lab06-100-cycles/` contains `run.sh`, which performs 100 cycles of `kldload / sleep / kldunload` and records the kernel’s memory footprint before and after.

Step 1. Record the kernel’s initial memory footprint:

```
# vmstat -m | awk '$1=="Solaris" || $1=="kernel"' > /tmp/before.txt
# cat /tmp/before.txt
```

Step 2. Run the cycle script:

```
# ./lab06-100-cycles/run.sh
cycle 1/100: ok
cycle 2/100: ok
...
cycle 100/100: ok
done: 100 cycles, 0 failures, 0 leaks detected.
```

Step 3. Record the final memory footprint:

```
# vmstat -m | awk '$1=="Solaris" || $1=="kernel"' > /tmp/after.txt
# diff /tmp/before.txt /tmp/after.txt
```

Expected: no significant difference. If there is a difference of more than a few kilobytes (the kernel's own bookkeeping fluctuates), the driver has a leak.

Step 4. If the script reports any failure, examine `/tmp/myfirst-cycles.log` (which `run.sh` populates) for the first failing cycle. The failure is usually at the deregistration step: a missing `EVENTHANDLER_DEREGISTER` or a missing `mtx_destroy`.

A clean 100-cycle run is one of the simplest ways to gain confidence in a driver's lifecycle discipline. Repeat it after every material change to the attach or detach chain.

25.10.7 Lab 7: Capability Discovery in User Space

Purpose: confirm that a user-space program can discover the driver's capabilities at run time and behave accordingly, as designed in Section 4.

Source: `examples/part-05/ch25-advanced/lab07-getcaps/` contains `mfctl25.c`, an updated version of `myfirstctl` that issues `MYFIRSTIOC_GETCAPS` before each operation and skips unsupported ones.

Step 1. Build `mfctl25`:

```
# make -C lab07-getcaps
```

Step 2. Run against the stock Chapter 25 driver and observe the capability report:

```
# ./lab07-getcaps/mfctl25 caps
Driver reports capabilities:
  MYF_CAP_RESET
  MYF_CAP_GETMSG
  MYF_CAP_SETMSG
```

The driver reports three capabilities. The `MYF_CAP_TIMEOUT` bit is defined but not set because the timeout behaviour is a `sysctl`, not an `ioctl`.

Step 3. Run each operation and confirm that the program only attempts supported ones:

```
# ./lab07-getcaps/mfctl25 reset
# ./lab07-getcaps/mfctl25 getmsg
Current message: Hello from myfirst
# ./lab07-getcaps/mfctl25 setmsg "new message"
# ./lab07-getcaps/mfctl25 timeout
Timeout ioctl not supported; use sysctl dev.myfirst.0.timeout_sec instead.
```

The last line is the capability check firing: the program asked for `MYF_CAP_TIMEOUT`, the driver did not advertise it, and the program printed a helpful message instead of issuing an `ioctl` that would return `ENOTTY`.

Step 4. Load an older build (Chapter 24's `myfirst.ko` in `lab07-getcaps/ch24/`) and rerun:

```
# kldunload myfirst
# kldload lab07-getcaps/ch24/myfirst.ko
# ./lab07-getcaps/mfctl25 caps
GETCAPS ioctl not supported. Falling back to default feature set:
  MYF_CAP_RESET
  MYF_CAP_GETMSG
  MYF_CAP_SETMSG
```

When `GETCAPS` itself returns `ENOTTY`, the program falls back to a safe default set that matches Chapter 24's known behaviour. This is the forward-compatibility pattern in action.

Step 5. Reload the Chapter 25 driver to restore the test state:

```
# kldunload myfirst
# kldload ./myfirst.ko
```

The exercise demonstrates that capability discovery lets one user-space program work correctly across two driver versions, which is the whole point of the pattern.

25.10.8 Lab 8: Sysctl Range Validation

Purpose: confirm that every writable sysctl the driver exposes rejects out-of-range values and leaves the internal state untouched on rejection.

Source: `examples/part-05/ch25-advanced/lab08-sysctl-validation/` contains the driver built with range checks and a test script `run.sh` that drives every sysctl to its limits.

Step 1. Load the driver and list its writable sysctls:

```
# kldload ./myfirst.ko
# sysctl -W dev.myfirst.0 | grep -v "^dev.myfirst.0.debug.classes"
dev.myfirst.0.timeout_sec: 5
dev.myfirst.0.max_retries: 3
```

```
dev.myfirst.0.log_ratelimit_pps: 10
dev.myfirst.0.debug.mask: 0
```

Four writable sysctls. Each has a specific valid range.

Step 2. Try to set each sysctl to zero, to its maximum allowed, and to one above its maximum:

```
# sysctl dev.myfirst.0.timeout_sec=0
sysctl: dev.myfirst.0.timeout_sec: Invalid argument
# sysctl dev.myfirst.0.timeout_sec=60
dev.myfirst.0.timeout_sec: 5 -> 60
# sysctl dev.myfirst.0.timeout_sec=61
sysctl: dev.myfirst.0.timeout_sec: Invalid argument
# sysctl dev.myfirst.0.timeout_sec
dev.myfirst.0.timeout_sec: 60
```

The out-of-range attempts are rejected with `EINVAL`; the internal value is unchanged. The valid assignment to 60 succeeds.

Step 3. Repeat for the other sysctls:

- `max_retries`: valid range 1-100. Try 0, 100, 101.
- `log_ratelimit_pps`: valid range 1-10000. Try 0, 10000, 10001.
- `debug.mask`: valid range 0-0xff (the defined bits). Try 0, 0xff, 0x100.

For each, the script reports pass or fail. A driver that passes every case has correct handler-level validation.

Step 4. Examine the sysctl handlers in `examples/part-05/ch25-advanced/myfirst_sysctl.c` and note the pattern:

```
static int
myfirst_sysctl_timeout_sec(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    u_int new_val;
    int error;

    mtx_lock(&sc->sc_mtx);
    new_val = sc->sc_timeout_sec;
    mtx_unlock(&sc->sc_mtx);

    error = sysctl_handle_int(oidp, &new_val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    if (new_val < 1 || new_val > 60)
```

```
    return (EINVAL);

    mtx_lock(&sc->sc_mtx);
    sc->sc_timeout_sec = new_val;
    mtx_unlock(&sc->sc_mtx);
    return (0);
}
```

Note the order of operations: copy the current value out for the read side, call `sysctl_handle_int` to handle the copy, validate on write, commit under the lock only after validation succeeds. A handler that commits before validation exposes inconsistent state to concurrent readers.

Step 5. Confirm that the `sysctl` description is helpful (`sysctl -d`):

```
# sysctl -d dev.myfirst.0.timeout_sec
dev.myfirst.0.timeout_sec: Operation timeout in seconds (range 1-60)
```

The description states the unit and the range. A user reading the `sysctl` without consulting any documentation can still set it correctly.

25.10.9 Lab 9: Log Message Audit Across the Driver

Purpose: inventory every log message in the driver and confirm that each one follows the Section 1 and Section 2 disciplines (`device_printf`, includes `errno` where relevant, rate-limited when on a hot path).

Source: `examples/part-05/ch25-advanced/lab09-log-audit/` contains an audit script `audit.sh` and a `grep`-based checker.

Step 1. Run the audit script against the driver's source:

```
# cd examples/part-05/ch25-advanced
# ./lab09-log-audit/audit.sh
```

The script greps for every `printf`, `device_printf`, `log`, `DPRINTF`, and `DLOG_RL` call in the source tree and categorises each into:

- PASS: uses `device_printf` or `DPRINTF`, device name is implicit.
- PASS: uses `DLOG_RL` on a hot path.
- WARN: uses `printf` without device context (may be legitimate at `MOD_LOAD`).
- FAIL: uses `device_printf` on a hot path without rate limiting.

Expected output (for the Chapter 25 stock driver):

```
myfirst.c:    15 log messages - 15 PASS
myfirst_cdev.c: 6 log messages - 6 PASS
```

```
myfirst_ioctl.c: 4 log messages - 4 PASS
myfirst_sysctl.c: 0 log messages
myfirst_log.c: 2 log messages - 2 PASS
Total: 27 log messages - 0 WARN, 0 FAIL
```

Step 2. Intentionally break one message (for example, change a `DPRINTF(sc, MYF_DBG_IO, ...)` in the read callback to a bare `device_printf(sc->sc_dev, ...)`) and rerun:

```
myfirst_cdev.c: 6 log messages - 5 PASS, 1 FAIL
  myfirst_cdev.c:83: device_printf on hot path not rate-limited
Total: 27 log messages - 0 WARN, 1 FAIL
```

The audit caught the regression. Revert the change and rerun to confirm the count returns to zero failures.

Step 3. Add a new log message to a non-hot path (for example, a one-time initialisation message at attach). Confirm the audit accepts it as a PASS:

```
device_printf(dev, "initialised with timeout %u\n",
  sc->sc_timeout_sec);
```

One-shot messages at attach do not need rate limiting because they fire exactly once per instance per load.

Step 4. For each message the audit categorises as a PASS, confirm that the message includes meaningful context. A message like “error” is a PASS for the audit tool but a FAIL for the human reader. A second manual pass over the grep output is required to confirm the messages are actually useful.

The lab demonstrates two points. First, a mechanical audit catches the categorical rules (rate limiting on hot paths, `device_printf` over bare `printf`) but cannot judge message quality. Second, the human pass is what confirms that the messages contain enough context to be diagnosed from. Both passes together give the driver a log surface that will actually help a future support engineer.

25.10.10 Lab 10: Multi-Version Compatibility Matrix

Purpose: confirm that the capability-discovery pattern introduced in Section 4 actually allows a single user-space program to work with three different versions of the driver.

Source: `examples/part-05/ch25-advanced/lab10-compat-matrix/` contains three pre-built `.ko` files corresponding to driver versions 1.6-debug, 1.7-integration, and 1.8-maintenance, plus a single user-space program `mfctl-universal` that uses `MYFIRSTIOC_GETCAPS` (or a fallback) to decide which operations to attempt.

Step 1. Load each driver version in turn and run `mfctl-universal --caps` against it:

```
# kldload lab10-compat-matrix/v1.6/myfirst.ko
# ./lab10-compat-matrix/mfctl-universal --caps
Driver: version 1.6-debug
GETCAPS ioctl: not supported
```

```
Using fallback capability set:
    MYF_CAP_GETMSG
    MYF_CAP_SETMSG

# kldunload myfirst
# kldload lab10-compat-matrix/v1.7/myfirst.ko
# ./lab10-compat-matrix/mfctl-universal --caps
Driver: version 1.7-integration
GETCAPS ioctl: not supported
Using fallback capability set:
    MYF_CAP_RESET
    MYF_CAP_GETMSG
    MYF_CAP_SETMSG

# kldunload myfirst
# kldload lab10-compat-matrix/v1.8/myfirst.ko
# ./lab10-compat-matrix/mfctl-universal --caps
Driver: version 1.8-maintenance
GETCAPS ioctl: supported
Driver reports capabilities:
    MYF_CAP_RESET
    MYF_CAP_GETMSG
    MYF_CAP_SETMSG
```

Three driver versions, one user-space program, three different capability decisions. The program works with each version.

Step 2. Exercise each capability in turn and confirm the program skips unsupported ones:

```
# kldunload myfirst
# kldload lab10-compat-matrix/v1.6/myfirst.ko
# ./lab10-compat-matrix/mfctl-universal reset
reset: not supported on this driver version (1.6-debug)
# ./lab10-compat-matrix/mfctl-universal getmsg
Current message: Hello from myfirst
```

The reset operation, which was added in 1.7, is skipped cleanly on 1.6. The program prints a helpful message rather than issuing an ioctl that would return ENOTTY.

Step 3. Read the `mfctl-universal` source and note the three-tier fallback:

```
uint32_t
driver_caps(int fd, const char *version)
{
    uint32_t caps;
```

```

if (ioctl(fd, MYFIRSTIOC_GETCAPS, &caps) == 0)
    return (caps);
if (errno != ENOTTY)
    err(1, "GETCAPS ioctl");

/* Fallback by version string. */
if (strstr(version, "1.8-") != NULL)
    return (MYF_CAP_RESET | MYF_CAP_GETMSG |
            MYF_CAP_SETMSG);
if (strstr(version, "1.7-") != NULL)
    return (MYF_CAP_RESET | MYF_CAP_GETMSG |
            MYF_CAP_SETMSG);
if (strstr(version, "1.6-") != NULL)
    return (MYF_CAP_GETMSG | MYF_CAP_SETMSG);

/* Unknown version: use the minimal safe set. */
return (MYF_CAP_GETMSG);
}

```

The first tier asks the driver directly. The second tier matches known version strings. The third tier falls back to a minimal set that every version of the driver has supported.

Step 4. Reflect on what happens when version 1.9 ships with a new capability bit. The program does not need to be updated: MYFIRSTIOC_GETCAPS on 1.9 will report the new bit, the program will see it, and if the program knows the corresponding operation it will use it. If the program does not know the operation, the bit is ignored. Either way, the program continues to work.

The lab demonstrates that capability discovery is not an abstract pattern; it is the specific mechanism that lets one user-space program span three driver versions without modification.

25.11 Challenge Exercises

The challenges in this section go beyond the labs. Each one asks you to extend the driver in a direction the chapter pointed at but did not complete. Work through them when you are ready; none of them requires new kernel knowledge beyond what the chapter covered, but each one requires a careful walk through the existing code.

25.11.1 Challenge 1: Per-Class Rate Limits

Section 1 sketched three rate-limit slots in the softc (`sc_rl_generic`, `sc_rl_io`, `sc_rl_intr`), but the `DLOG_RL` macro uses a single pps value (`sc_log_pps`). Extend the driver so that each class has its own sysctl-configurable pps cap:

- Add `sc_log_pps_io` and `sc_log_pps_intr` fields to the `softc` alongside `sc_log_pps` (which stays as the generic cap).
- Add matching `sysctls` under `dev.myfirst.<unit>.log.pps_*` and matching `tunables` under `hw.myfirst.log_pps_*`.
- Update `DLOG_RL_IO` and `DLOG_RL_INTR` helpers (or a generic helper that takes both the class and the pps value) to honour the per-class cap.

Write a short test program that fires a burst of messages in each class and confirm from `dmesg` that each class is rate-limited independently. The generic bucket should not starve the I/O bucket, and vice versa.

Hint: the most reusable shape is a helper function `myfirst_log_ratelimited(sc, class, fmt, ...)` that looks up the right rate-limit state and the right pps cap given the class bit. The `DLOG_RL_*` macros become thin wrappers over the helper.

25.11.2 Challenge 2: A Writable String `sysctl`

Section 3 warned about the complication of writable string `sysctls`. Implement one correctly. The `sysctl` should be `dev.myfirst.<unit>.message`, with `CTLFLAG_RW`, and should let an operator rewrite the in-driver message with a single `sysctl(8)` call.

Requirements:

1. The handler must take the `softc` mutex around the update.
2. The handler must validate the length against `sizeof(sc->sc_msg)` and reject oversized strings with `EINVAL`.
3. The handler must use `sysctl_handle_string` for the copy; do not reimplement user-space access.
4. On successful update, the handler must emit a `devctl_notify` for `MSG_CHANGED`, just like the `ioctl` does.

Test with:

```
# sysctl dev.myfirst.0.message="hello from sysctl"
# sysctl dev.myfirst.0.message
dev.myfirst.0.message: hello from sysctl
# sysctl dev.myfirst.0.message="$(printf 'A%.0s' {1..1000})"
sysctl: dev.myfirst.0.message: Invalid argument
```

The second `sysctl` should fail (oversize), and the driver's message should be unchanged.

Consider: should the `ioctl` and the `sysctl` emit the same `MSG_CHANGED` event, or different ones? Both sides are updating the same underlying state; a single event type is probably correct. Document your decision in `MAINTENANCE.md`.

25.11.3 Challenge 3: A `MOD_QUIESCE` Handler Separate from `Detach`

Section 7 noted that `MOD_QUIESCE` and `MOD_UNLOAD` are conceptually distinct but that `myfirst` handles both through `myfirst_detach`. Split them so the quiesce question can be answered without side effects.

Requirements:

1. Add an explicit `MOD_QUIESCE` check to a module event handler. The handler returns `EBUSY` if any device is open, `0` otherwise.
2. The handler does not call `destroy_dev`, does not destroy locks, does not alter state. It only reads `sc_open_count`.
3. For each attached instance, iterate via `devclass` and check every `softc`. Use the `myfirst_devclass` symbol that `DRIVER_MODULE` exports.

Hint: look at `/usr/src/sys/kern/subr_bus.c` for `devclass_get_softc` and related helpers. They are the way to enumerate `softcs` from a module-level function that does not have a `device_t`.

Test: open `/dev/myfirst0`, try `kldunload myfirst`, confirm that it reports “module busy” and that the driver is unchanged. Close the fd, retry the unload, confirm that it succeeds.

25.11.4 Challenge 4: A Drain-Based Detach Instead of `EBUSY`

The chapter’s detach pattern refuses to unload if the driver is in use. A more elaborate pattern drains in-flight references rather than refusing. Implement it.

Requirements:

1. Add an `is_dying` boolean to the `softc`, protected by `sc_mtx`.
2. In `myfirst_open`, check `is_dying` under the lock and return `ENXIO` if true.
3. In `myfirst_detach`, set `is_dying` under the lock. Wait for `sc_open_count` to reach zero, using `mtx_sleep` with a condition variable or a simple polling loop with a timeout.
4. After `sc_open_count` reaches zero, proceed with `destroy_dev` and the rest of the detach chain.

Add a timeout: if `sc_open_count` does not reach zero within (say) 30 seconds, return `EBUSY` from detach. The operator gets a clear signal that the driver is not draining; they can kill the offending process and retry.

Test: open `/dev/myfirst0` in a loop from one shell, call `kldunload myfirst` from another shell, and observe the drain behaviour.

25.11.5 Challenge 5: A Sysctl-Driven Version Bump Check

Write a small user-space program that reads `dev.myfirst.<unit>.version`, parses the version string, and compares it against a minimum version the program requires. The program should print “ok” if the driver is new enough and “driver too old, please update” if not.

Requirements:

1. Parse the string `X.Y-tag` into integers. Reject malformed strings with a clear error.
2. Compare against a minimum of “1.8”. A driver reporting “1.7-integration” should fail the check; a driver reporting “1.8-maintenance” should pass; a driver reporting “2.0-something” should pass.
3. Exit with status `0` on success, non-zero on failure, so the check can be used in shell scripts.

Reflect: could a well-designed program rely on the version string for compatibility checking, or is the capability bitmask from Section 4 the better signal? There is no single right answer; the exercise is to think about the trade-off.

25.11.6 Challenge 6: Add a Sysctl That Enumerates Open File Descriptors

Add a new sysctl `dev.myfirst.<unit>.open_fds` that returns, as a string, the PIDs of the processes that currently have the device open. This is harder than it sounds: the driver does not normally track which process opened each fd.

Hint: in `myfirst_open`, store the calling thread's PID in a linked list under the `softc`. In `myfirst_close`, remove the corresponding entry. In the sysctl handler, walk the list under the `softc` mutex and build a comma-separated string of PIDs.

Edge cases:

1. A process that is open multiple times (multiple fds, forked children) should appear once or multiple times? Decide and document.
2. The list must be bounded in length (attackers could open the device millions of times).
3. The sysctl value is read-only; the handler must not modify the list.

Reflect: is this information actually useful, or is `fstat(1)` a better tool for the same job? The answer depends on whether the driver can provide information that user-space tools cannot derive themselves.

25.11.7 Challenge 7: A Second EVENTHANDLER for `vm_lowmem`

`myfirst` does not have a cache today, but imagine it did: a pool of pre-allocated 4 KB buffers used for read/write operations. Under low memory, the driver should release some of the buffers back.

Implement a synthetic cache: allocate an array of 64 `malloc(M_TEMP, 4096)` pointers at attach. Register a `vm_lowmem` handler that, when fired, releases half of the cached buffers. Reattach reallocates them.

Requirements:

1. The cache allocations happen under the `softc` mutex.
2. The `vm_lowmem` handler takes the mutex, scans the array, and `free()`s the first 32 buffers.
3. A sysctl `dev.myfirst.<unit>.cache_free` reports the current number of free (NULL) slots; an operator can confirm that the handler fired.

Test: use a `stress -m 10 --vm-bytes 512M` loop to drive the system into low-memory pressure, and watch the `cache_free` sysctl. Over time, it should grow as `vm_lowmem` fires repeatedly.

Reflect: is this what the event is meant to be used for? Many drivers that register for `vm_lowmem` have caches that are much larger than 64 buffers; the cost/benefit is different. This is a teaching exercise; a real driver would think harder about whether its cache is worth the complexity.

25.11.8 Challenge 8: A `MYFIRSTIOC_GETSTATS` Ioctl Returning a Structured Payload

So far every ioctl the driver handles returns a scalar: an integer, a `uint32`, or a fixed-size string. Add a `MYFIRSTIOC_GETSTATS` ioctl that returns a structured payload with every counter the driver maintains.

Requirements:

1. Define `struct myfirst_stats` in `myfirst_ioctl.h` with fields for `open_count`, `total_reads`, `total_writes`, `log_drops` (a new counter you add), and `last_error_errno` (another new counter).

2. Add `MYFIRSTIOC_GETSTATS` with command number 6, declared as `_IOR('M', 6, struct my-first_stats)`.
3. The handler copies the softc's counters into the payload under `sc_mtx` and returns.
4. Advertise a new capability bit `MYF_CAP_STATS` in the `GETCAPS` response.
5. Update `MAINTENANCE.md` to document the new `ioctl` and the new capability.

Edge cases:

1. What happens if the struct size changes later? The `_IOR` macro bakes the size into the command number. Adding a field bumps the command number, which breaks old callers. The fix is to include a version and a reserved space in the struct from day one; any future addition reuses the reserved space.
2. Is it safe to return all counters atomically, or do they need separate locking? Holding `sc_mtx` for the duration of the copy is the simplest discipline.

Reflect: this is where `ioctl` design starts to feel complex. For a simple counter snapshot, a `sysctl` with a string-format output might be easier than an `ioctl` with a versioned struct. Which would you pick, and why?

25.11.9 Challenge 9: Devctl-Based Live Monitoring

Add a second `devctl_notify` event that fires every time the rate-limit bucket drops a message. The event should include the class name and the current bucket state as `key=value` data.

Requirements:

1. When `ppsratecheck` returns zero (message dropped), increment a per-class drop counter and emit a `devctl_notify` with `system="myfirst"`, `type="LOG_DROPPED"`, and data `"class=io drops=42"`.
2. The `devctl` event itself must be rate-limited; otherwise the act of reporting drops becomes another flood. Use a second `ppsratecheck` with a slow cap (e.g. 1 pps) for the `devctl` emissions.
3. Write a `devd` rule that matches the event and logs a summary every time it fires.

Test: run Lab 1's flood program and confirm that `devctl` emits the drop report without flooding itself.

25.12 Troubleshooting Guide

When the mechanisms in this chapter misbehave, the symptoms are often indirect: a silent missing log line, a driver that refuses to load for the wrong reason, a `sysctl` that does not appear, a reboot that does not call your handler. This reference maps common symptoms to the mechanism that is most likely responsible, with the first places to look in the driver source.

25.12.1 Symptom: `kldload` returns “Exec format error”

The module was built against a kernel ABI that does not match the running kernel. The typical cause is a mismatch between the running kernel version and the `SYSDIR` used at compile time.

Check: `uname -r` and the value of `SYSDIR` in the Makefile. If the kernel is 14.3-RELEASE but the build picked up headers from a newer 15.0-CURRENT tree, the ABI is different.

Fix: point `SYSDIR` at the source tree that matches the running kernel. The Chapter 25 Makefile uses `/usr/src/sys` by default; on a 14.3 system with matching `/usr/src`, this is correct.

25.12.2 Symptom: `kldload` returns “No such file or directory” for an obvious-looking file

The file is present but the kernel’s module loader cannot parse it. Common causes: the file is a stale build artefact from a different machine, or the file is corrupt.

Check: file `myfirst.ko` should report it as an ELF 64-bit LSB shared object. If it reports anything else, rebuild from source.

25.12.3 Symptom: `kldload` succeeds but `kldstat` does not show the module

The loader decided to auto-unload the module. This happens when `MOD_LOAD` returned zero but `DRIVER_MODULE`’s `device_identify` did not find any device. For `myfirst`, which uses `nexus` as its parent, this should not happen; the pseudo-driver always finds `nexus`.

Check: `dmesg | tail -20` for any line like `module "myfirst" failed to register`. The message points at what went wrong.

25.12.4 Symptom: `kldload` reports “module busy”

A previous instance of the driver is still loaded and has an open file descriptor somewhere. The `MOD_QUIESCE` path in the old instance returned `EBUSY`.

Check: `fstat | grep myfirst` should show the process holding the fd. Kill the process or close the fd, then retry `kldunload`.

25.12.5 Symptom: `sysctl dev.myfirst.0.debug.mask=0x4` returns “Operation not permitted”

The caller is not root. `sysctls` with `CTLFLAG_RW` typically require root privilege unless they are explicitly marked otherwise.

Check: are you running as root? `sudo sysctl ...` or `su - first`.

25.12.6 Symptom: A new `sysctl` does not appear in the tree

`SYSCTL_ADD_*` either was not called, or was called with the wrong context/tree pointer. The most common bug is to use `SYSCTL_STATIC_CHILDREN` for a per-device OID instead of `device_get_sysctl_tree`.

Check: inside `myfirst_sysctl_attach`, confirm that `ctx = device_get_sysctl_ctx(dev)` and `tree = device_get_sysctl_tree(dev)` are used, and that every `SYSCTL_ADD_*` call passes `ctx` as the first argument.

25.12.7 Symptom: A tunable seems to be ignored

TUNABLE_*_FETCH runs at attach time, but only if the tunable is in the kernel environment at that moment. The common mistakes are (a) setting the tunable after the module is loaded, (b) typing the name wrong, (c) forgetting that kenv is not persistent.

Check: - kenv hw.myfirst.timeout_sec before reloading the module. The value should be what you expect. - The string passed to TUNABLE_INT_FETCH must match kenv exactly. A typo in one side is silent. - Setting via /boot/loader.conf requires a reboot (or a kldunload followed by kldload, which rereads loader.conf for the specific module's tunables).

25.12.8 Symptom: A log message should fire but does not appear in dmesg

Three common causes:

1. The debug-class bit is not set. Check `sysctl dev.myfirst.0.debug.mask`; the class bit must be enabled.
2. The rate-limit bucket is empty. If the message is emitted through `DLOG_RL`, the first few fire and the rest are suppressed silently. Set the pps cap higher via the `sysctl` or wait a second for the bucket to refill.
3. The message is emitted but filtered by the system's `sysctl kern.msgbuf_show_timestamp` setting or the `dmesg` buffer size (`sysctl kern.msgbuf_size`).

Check: `dmesg -c > /dev/null` to clear the buffer, reproduce the action, and re-read the buffer. The emptied buffer should contain only the driver's output.

25.12.9 Symptom: A log message appears once and is then silent forever

The rate-limit bucket permanently denies the message. This happens if `rl_curpps` becomes very large and the pps cap is very low. Check that `ppsratecheck` is being called with a stable `struct timeval` and a stable `int *` (both members of the `softc`); a per-call stack variable would be reset to zero every call and the algorithm would fire every time.

Check: the rate-limit state must be in the `softc` or another persistent location, not in local variables.

25.12.10 Symptom: Attach fails and the cleanup chain does not release a resource

The labelled-goto is missing a step or has a stray `return` that short-circuits the chain. Add a `device_printf(dev, "reached label fail_X\n")` at the top of each label and rerun the failure-injection lab. The label that does not print is the label that was skipped.

Common cause: an intermediate `return (error)` inserted for debugging and never removed. The compiler does not warn because the chain is still syntactically valid; the behaviour is wrong.

25.12.11 Symptom: Detach panics with a “witness” warning

A lock was destroyed while still held, or a lock was acquired after its owner was destroyed. The witness subsystem catches both. The backtrace points at the lock name, which maps to the `softc` field.

Check: the detach chain should be the exact reverse of attach. A common mistake is `mtx_destroy(&sc->sc_mtx)` called before `destroy_dev(sc->sc_cdev)`: the `cdev`'s callbacks can still be running, they try to take the lock, and the lock is gone. Fix: destroy the `cdev` first, then the lock.

25.12.12 Symptom: The driver panics at module unload with a dangling pointer

The `EVENTHANDLER_DEREGISTER` was not called, the kernel fired the event, and the callback pointer pointed at freed memory.

Check: for every `EVENTHANDLER_REGISTER` in attach, search detach for `EVENTHANDLER_DEREGISTER`. The count must match. If the count matches but the panic still happens, the tag stored in the `softc` was corrupted; audit the code path between registration and deregistration for memory scribbles.

25.12.13 Symptom: MYFIRSTIOC_GETVER returns an unexpected value

The `ioctl` version integer in `myfirst_ioctl.h` does not match what `myfirst_ioctl.c` writes into the buffer. This happens if the header is updated but the handler still returns a hard-coded constant.

Check: the handler should write `MYFIRST_IOCTL_VERSION` (the constant from the header), not a literal integer.

25.12.14 Symptom: devctl_notify events never appear in devd.log

`devd(8)` is not running, or its configuration does not match the event.

Check: `- service devd status` confirms the daemon is running. `- grep myfirst /etc/devd/*.conf` should find the rule. `- devd -Df` in the foreground prints every event as it arrives; reproduce the action and watch the output.

25.12.15 Symptom: The 100-cycle regression script grows the kernel's memory footprint

A resource is leaking per load/unload cycle. Common culprits: a `malloc` without a matching `free`, an `EVENTHANDLER_REGISTER` without a matching `deregister`, a `sysctl_ctx_init` that the driver calls manually without calling `sysctl_ctx_free` at detach (Chapter 25 uses `device_get_sysctl_ctx`, which is managed by `Newbus`; a driver that allocates its own context must free it).

Check: `vmstat -m | grep myfirst` before and after to see the driver's own memory consumption, and `vmstat -m | grep solaris` for kernel-level structures that the driver might be allocating indirectly.

25.12.16 Symptom: Two concurrent MYFIRSTIOC_SETMSG calls interleave their writes

The `softc` mutex is not being held around the update. The two threads are writing into `sc->sc_msg` simultaneously, producing a corrupt result.

Check: every access to `sc->sc_msg` and `sc->sc_msglen` in the `ioctl` handler must be inside `mtx_lock(&sc->sc_mtx) ... mtx_unlock(&sc->sc_mtx)`.

25.12.17 Symptom: A sysctl value resets on every module load

This is the intended behaviour, not a bug. The attach-time default is whatever the tunable evaluates to, which is either the `TUNABLE_INT_FETCH` default or the value set via `kenv`. The runtime `sysctl` write is lost at unload. If you want the value to persist, set it via `kenv` or `/boot/loader.conf`.

25.12.18 Symptom: MYFIRSTIOC_GETCAPS returns a value without the bits you just added

The `myfirst_ioctl.c` file was updated but not recompiled, or the wrong build was loaded. Also check that the handler in the switch statement uses the `|=` operator or a single assignment that includes every bit.

Check: `make clean && make` from the example directory. `kldstat -v | grep myfirst` to confirm the loaded module's path matches what you built.

25.12.19 Symptom: A SYSINIT fires before the kernel's allocator is ready

The `SYSINIT` is registered at too early a subsystem ID. Many subsystems (tunables, locks, early initcalls) are not allowed to call `malloc` with `M_NOWAIT` let alone `M_WAITOK`. If your callback calls `malloc` and the kernel panics at boot, look at the subsystem ID.

Check: the subsystem ID in `SYSINIT(...)`. For a callback that allocates memory, use `SI_SUB_DRIVERS` or later; do not use `SI_SUB_TUNABLES` or earlier.

25.12.20 Symptom: A handler registered with EVENTHANDLER_PRI_FIRST still runs late

`EVENTHANDLER_PRI_FIRST` is not a hard guarantee; it is a priority in a sorted queue. If another handler is also registered with `EVENTHANDLER_PRI_FIRST`, the order between them is undefined. The documented priorities are coarse; fine-grained ordering is not supported.

Check: accept that the priority is a hint, not a contract. If the driver absolutely requires running before or after a specific other handler, the design is wrong; restructure the driver so the ordering does not matter.

25.12.21 Symptom: dmesg does not show any output from the driver

The driver is using `printf` (the libc-like one) rather than `device_printf` or `DPRINTF`. Kernel `printf` still works but does not carry the device name, which makes messages hard to filter.

Check: every message in the driver should go through `device_printf(dev, ...)` or `DPRINTF(sc, class, fmt, ...)`. Bare `printf` is usually a mistake.

25.13 Quick Reference

The Quick Reference is a single-page summary of the macros, flags, and functions Chapter 25 introduced. Use it at the keyboard once the material is familiar.

25.13.1 Rate-limited logging

```

struct myfirst_ratelimit {
    struct timeval rl_lasttime;
    int          rl_curpps;
};

#define DLOG_RL(sc, rlp, pps, fmt, ...) do {                                \
    if (ppsratecheck(&(rlp)->rl_lasttime, &(rlp)->rl_curpps, pps)) \
        device_printf((sc)->sc_dev, fmt, ##__VA_ARGS__);          \
} while (0)

```

Use DLOG_RL for any message that can fire in a loop. Place the struct myfirst_ratelimit in the softc (not on the stack).

25.13.2 Errno vocabulary

Errno	Value	Use
0	0	success
EPERM	1	operation not permitted (root-only)
ENOENT	2	no such file
EBADF	9	bad file descriptor
ENOMEM	12	cannot allocate memory
EACCES	13	permission denied
EFAULT	14	bad address (user pointer)
EBUSY	16	resource busy
ENODEV	19	no such device
EINVAL	22	invalid argument
ENOTTY	25	inappropriate ioctl for device
ENOTSUP / EOPNOTSUPP	45	operation not supported
ENOIOCTL	-3	ioctl not handled by this driver (internal; kernel maps to ENOTTY)

25.13.3 Tunable families

```
TUNABLE_INT_FETCH("hw.myfirst.name",    &sc->sc_int_var);
TUNABLE_LONG_FETCH("hw.myfirst.name",   &sc->sc_long_var);
TUNABLE_BOOL_FETCH("hw.myfirst.name",   &sc->sc_bool_var);
TUNABLE_STR_FETCH("hw.myfirst.name",    sc->sc_str_var,
                                     sizeof(sc->sc_str_var));
```

Call each fetch once in attach after the default has been populated. The fetch updates the variable only if the tunable is present.

25.13.4 Sysctl flag summary

Flag	Meaning
CTLFLAG_RD	read-only
CTLFLAG_RW	read-write
CTLFLAG_TUN	cooperate with a loader tunable at attach time
CTLFLAG_RDTUN	shorthand for read-only + tunable
CTLFLAG_RWTUN	shorthand for read-write + tunable
CTLFLAG_MPSAFE	handler is MPSAFE
CTLFLAG_SKIP	hide the OID from default sysctl(8) listings

25.13.5 Version identifiers

- MYFIRST_VERSION: human-readable release string, e.g. "1.8-maintenance".
- MODULE_VERSION(myfirst, N): integer used by MODULE_DEPEND.
- MYFIRST_IOCTL_VERSION: integer returned by MYFIRSTIOC_GETVER; bumped only for wire-format breaks.

25.13.6 Capability bits

```
#define MYF_CAP_RESET      (1U << 0)
#define MYF_CAP_GETMSG     (1U << 1)
#define MYF_CAP_SETMSG     (1U << 2)
#define MYF_CAP_TIMEOUT    (1U << 3)

#define MYFIRSTIOC_GETCAPS _IOR('M', 5, uint32_t)
```

25.13.7 Labelled-cleanup skeleton

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error;

    /* acquire resources in order */
    mtx_init(&sc->sc_mtx, "myfirst", NULL, MTX_DEF);

    error = make_dev_s(...);
    if (error != 0)
        goto fail_mtx;

    myfirst_sysctl_attach(sc);

    error = myfirst_log_attach(sc);
    if (error != 0)
        goto fail_cdev;

    sc->sc_shutdown_tag = EVENTHANDLER_REGISTER(shutdown_pre_sync,
        myfirst_shutdown, sc, SHUTDOWN_PRI_DEFAULT);
    if (sc->sc_shutdown_tag == NULL) {
        error = ENOMEM;
        goto fail_log;
    }

    return (0);

fail_log:
    myfirst_log_detach(sc);
fail_cdev:
    destroy_dev(sc->sc_cdev);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}
```

25.13.8 File layout for a modular driver

<code>driver.h</code>	public types
<code>driver.c</code>	module glue, <code>cdevsw</code> , <code>attach/detach</code>
<code>driver_cdev.c</code>	<code>open/close/read/write</code>
<code>driver_ioctl.h</code>	<code>ioctl</code> command numbers
<code>driver_ioctl.c</code>	<code>ioctl</code> dispatch
<code>driver_sysctl.c</code>	<code>sysctl</code> tree
<code>driver_debug.h</code>	<code>DPRINTF</code> macros
<code>driver_log.h</code>	rate-limit structures
<code>driver_log.c</code>	rate-limit helpers

25.13.9 Production checklist

- [] `MODULE_DEPEND` declared for every real dependency.
- [] `MODULE_PNP_INFO` declared if the driver binds to hardware.
- [] `MOD_QUIESCE` answers "can you unload?" without side effects.
- [] `devctl_notify` emitted for operator-relevant events.
- [] `MAINTENANCE.md` current.
- [] `devd.conf` snippet included.
- [] Every log message is `device_printf`, includes `errno`, and is rate-limited if it can fire in a loop.
- [] `attach/detach` survives 100 load/unload cycles.
- [] `sysctls` reject out-of-range values.
- [] `ioctl` payload is bounds-checked.
- [] Failure paths exercised via deliberate injection.
- [] Versioning discipline: three independent version identifiers, each bumped for its own reason.

25.13.10 SYSINIT subsystem IDs

Constant	Value	Use
<code>SI_SUB_TUNABLES</code>	<code>0x0700000</code>	establish tunable values
<code>SI_SUB_KLD</code>	<code>0x2000000</code>	KLD and module setup
<code>SI_SUB_SMP</code>	<code>0x2900000</code>	start the APs
<code>SI_SUB_DRIVERS</code>	<code>0x3100000</code>	let drivers initialise
<code>SI_SUB_CONFIGURE</code>	<code>0x3800000</code>	configure devices

Within a subsystem: - `SI_ORDER_FIRST` = `0x0` - `SI_ORDER_SECOND` = `0x1` - `SI_ORDER_MIDDLE` = `0x1000000` - `SI_ORDER_ANY` = `0xffffffff`

25.13.11 Shutdown event priorities

- SHUTDOWN_PRI_FIRST: run early.
- SHUTDOWN_PRI_DEFAULT: default.
- SHUTDOWN_PRI_LAST: run late.

25.13.12 EVENTHANDLER skeleton

```
sc->sc_tag = EVENTHANDLER_REGISTER(shutdown_pre_sync,
    my_handler, sc, SHUTDOWN_PRI_DEFAULT);
/* ... in detach ... */
EVENTHANDLER_DEREGISTER(shutdown_pre_sync, sc->sc_tag);
```

25.13.13 Tunable name ladders

Tunables and sysctls follow a hierarchical naming convention. The table below lists the nodes this chapter introduces:

Name	Kind	Purpose
hw.myfirst.debug_mask_default	tunable	initial debug mask for every instance
hw.myfirst.timeout_sec	tunable	initial operation timeout in seconds
hw.myfirst.max_retries	tunable	initial retry count
hw.myfirst.log_ratelimit_pps	tunable	initial messages-per-second cap
dev.myfirst.<unit>.version	sysctl (RD)	release string
dev.myfirst.<unit>.open_count	sysctl (RD)	active fd count
dev.myfirst.<unit>.total_read	sysctl (RD)	lifetime read calls
dev.myfirst.<unit>.total_write	sysctl (RD)	lifetime write calls
dev.myfirst.<unit>.messages	sysctl (RD)	current buffer contents
dev.myfirst.<unit>.messagesize	sysctl (RD)	current buffer length
dev.myfirst.<unit>.timeout	sysctl (RWTUN)	runtime timeout
dev.myfirst.<unit>.max_retries	sysctl (RWTUN)	runtime retry count
dev.myfirst.<unit>.log_ratelimit	sysctl (RWTUN)	runtime pps cap
dev.myfirst.<unit>.debug_mask	sysctl (RWTUN)	runtime debug mask
dev.myfirst.<unit>.debug_classes	sysctl (RD)	class names and bit values

Read the table as the interface contract. The `hw.myfirst.*` family is set at boot; the `dev.myfirst.*` family is adjusted at run time. Every writable entry has a matching read-only counterpart the operator can use to confirm the current value.

25.13.14 ioctl command ladder

Chapter 25's `ioctl` header defines these commands under magic 'M':

Command	Number	Direction	Purpose
MYFIRSTIOC_GETVER	0	read	returns MYFIRST_IOCTL_VERSION
MYFIRSTIOC_RESET	1	no-data	zero read/write counters
MYFIRSTIOC_GETMSG	2	read	copy current message out
MYFIRSTIOC_SETMSG	3	write	copy new message in
(retired)	4	n/a	reserved; do not reuse
MYFIRSTIOC_GETCAPS	5	read	capability bitmask

Adding a new command means picking the next unused number. Retiring a command means leaving its number in the ladder with (retired) next to it, not reusing the number.

25.14 Real-World Driver Walkthroughs

The chapter so far has built its discipline on the `myfirst` pseudo-driver. This section turns the lens around and looks at how the same disciplines appear in drivers that ship as part of FreeBSD 14.3. Each walkthrough starts from a real source file in `/usr/src`, names the Chapter 25 pattern that is in play, and points at the lines where the pattern is visible. The goal is not to document the specific drivers (their own documentation does that), but to show that Chapter 25's habits are not invented: they are the habits that working in-tree drivers already practise.

Reading real drivers with a pattern vocabulary is the single fastest way to accelerate your own judgement. Once you recognise `ppsratecheck` on sight, every driver that uses it becomes faster to read.

25.14.1 `mmc`sd(4): Rate-Limited Error Logging on a Hot Path

The `mmc`sd driver at `/usr/src/sys/dev/mmc/mmc.c` serves MMC and SD card storage. A filesystem above it generates a continuous stream of block I/O, and each block that fails the underlying MMC request produces a potential error log line. Without rate limiting, a slow or flaky card would flood `dmesg` in seconds.

The driver declares its rate-limit state `per_softc`, as the chapter recommends:

```
struct mmc_softc {
    ...
    struct timeval log_time;
    int          log_count;
    ...
};
```

`log_time` and `log_count` are the `ppsratecheck` state. Every hot path that emits a log message wraps the `device_printf` the same way:

```
#define LOG_PPS 5 /* Log no more than 5 errors per second. */

...

if (req.cmd->error != MMC_ERR_NONE) {
    if (ppsratecheck(&sc->log_time, &sc->log_count, LOG_PPS))
        device_printf(dev, "Error indicated: %d %s\n",
            req.cmd->error,
            mmcsc_errmsg(req.cmd->error));
    ...
}
```

The pattern is exactly the `DLOG_RL` shape the chapter introduced, with the macro expanded in place. `LOG_PPS` is set to 5 messages per second, and the state lives in the `softc` so repeated calls into the hot path share the same bucket.

Three observations worth taking away. First, this pattern is not theoretical: a shipping FreeBSD driver uses it on a hot path that can fire thousands of times per second. Second, the macro-versus-inline choice is a matter of taste; `mmcsc.c` open-codes the call, and the pattern is just as readable. Third, the `LOG_PPS` constant is conservative (5 per second); the author preferred fewer messages over more. A driver author can tune the pps cap to match the expected error rate and the operator's tolerance.

25.14.2 `uftdi(4)`: Module Dependencies and PNP Metadata

The `uftdi` driver at `/usr/src/sys/dev/usb/serial/uftdi.c` attaches to USB-serial adapters based on FTDI chips. It is a textbook example of a driver that depends on another kernel module: it cannot work without the USB stack.

Near the bottom of the file:

```
MODULE_DEPEND(uftdi, ucom, 1, 1, 1);
MODULE_DEPEND(uftdi, usb, 1, 1, 1);
MODULE_VERSION(uftdi, 1);
```

Two dependencies are declared. The first is on `ucom`, the generic USB-serial framework that `uftdi` builds on. The second is on `usb`, the USB core. Both are bounded to version 1 exactly. Loading `uftdi.ko` on a kernel without `usb` or `ucom` fails with a clear error; loading it on a kernel where the subsystem version has bumped past 1 also fails until `uftdi`'s own declaration is updated.

The PNP metadata is published through a macro that expands to `MODULE_PNP_INFO`:

```
USB_PNP_HOST_INFO(uftdi_devs);
```

USB_PNP_HOST_INFO is the USB-specific helper defined in `/usr/src/sys/dev/usb/usbd.h`. It expands to `MODULE_PNP_INFO` with the correct format string for USB vendor/product tuples. `uftdi_devs` is a static array of `struct usb_device_id` entries, one per (vendor, product, interface) triple the driver handles.

This is the production-readiness pattern from Chapter 25 Section 7 applied to a real hardware driver: dependencies declared, metadata published, version integer present. A new USB serial adapter appearing on a system causes `devd(8)` to consult the PNP metadata, identify `uftdi` as the driver, and load it if it is not already loaded. The mechanism is fully automatic once the metadata is right.

Chapter 26's version of `myfirst` will use the same pattern and the same helper.

25.14.3 `iscsi(4)`: Shutdown Handler Registered in `attach`

The iSCSI initiator at `/usr/src/sys/dev/iscsi/iscsi.c` holds open connections to remote storage targets. When the system shuts down, the initiator must close those connections gracefully before the network layer is torn down; otherwise the remote end is left with stale sessions.

The shutdown handler is registered at `attach`:

```
sc->sc_shutdown_pre_eh = EVENTHANDLER_REGISTER(shutdown_pre_sync,  
        iscsi_shutdown_pre, sc, SHUTDOWN_PRI_FIRST);
```

Two details are important. First, the registration's tag is stored in the `softc` (`sc->sc_shutdown_pre_eh`), so the later deregistration can reference it. Second, the priority is `SHUTDOWN_PRI_FIRST`, not `SHUTDOWN_PRI_DEFAULT`: the iSCSI driver wants to close connections before anyone else begins shutdown work, because storage connections take time to close cleanly.

The deregistration happens in the `detach` path:

```
EVENTHANDLER_DEREGISTER(shutdown_pre_sync, sc->sc_shutdown_pre_eh);
```

One registration, one deregistration. The tag in the `softc` keeps them bound.

For `myfirst`, the chapter's demonstration used `SHUTDOWN_PRI_DEFAULT` because there is no good reason for the pseudo-driver to run early. Real drivers pick a priority based on what depends on what: drivers that must be quiet before other drivers pick `SHUTDOWN_PRI_FIRST`; drivers that depend on filesystems being intact pick `SHUTDOWN_PRI_LAST`. The priority is a design decision, and `iscsi` shows one way to make it.

25.14.4 `ufs_dirhash`: Cache Eviction on `vm_lowmem`

The UFS directory hash cache at `/usr/src/sys/ufs/ufs/ufs_dirhash.c` is a per-filesystem in-memory accelerator for directory lookups. Under normal operation the cache is beneficial; under memory pressure it becomes a liability, so the subsystem registers a `vm_lowmem` handler that discards cache entries:

```
EVENTHANDLER_REGISTER(vm_lowmem, ufsdirhash_lowmem, NULL,
    EVENTHANDLER_PRI_FIRST);
```

The fourth argument is `EVENTHANDLER_PRI_FIRST`, which asks to run early in the list of registered `vm_lowmem` handlers. The `dirhash` author picked early execution because the cache is pure reclaimable memory: freeing it promptly gives other handlers (which may hold dirtier or less easily released state) a better chance of succeeding.

The callback itself does the real work: walk the hash tables, release entries that can be released, account for the memory freed. The essential design point is that the callback does not panic if there is nothing to release; it simply returns having done nothing.

This is the Chapter 25 `vm_lowmem` pattern in a subsystem that is not a device driver but that shares the discipline. The lessons transfer: if `myfirst` ever gets a cache, the shape is already here.

25.14.5 tcp_subr: vm_lowmem Without a Softc

The TCP subsystem at `/usr/src/sys/netinet/tcp_subr.c` also registers for `vm_lowmem`, but its registration is different in an instructive way:

```
EVENTHANDLER_REGISTER(vm_lowmem, tcp_drain, NULL, LOWMEM_PRI_DEFAULT);
```

The third argument (the callback data) is `NULL`, not a `softc` pointer. The TCP subsystem does not have a single `softc`; its state is scattered across many structures. The callback has to find its state by other means (globals, per-CPU variables, hash table lookups).

This raises a question the chapter hinted at: when is it acceptable to pass `NULL` as the callback argument? The answer is: when the callback has another way to find its state. For a driver with a per-device `softc`, passing `sc` is almost always the right choice. For a subsystem with global state, passing `NULL` and letting the callback use its known globals is fine.

`myfirst` will always pass `sc` because `myfirst` is a per-device driver. A reader who finds themselves writing a subsystem-level callback should recognise that the pattern changes in subtle ways when the subject is global.

25.14.6 if_vtnet: Rate-Limited Logging Around a Specific Fault

The VirtIO network driver at `/usr/src/sys/dev/virtio/network/if_vtnet.c` provides a narrower but instructive counterpoint to `mmcsd`. Where `mmcsd` wraps every hot-path error in rate-limited logging, `if_vtnet` reaches for `ppsratecheck` only around a specific misbehaviour: a TSO packet with ECN bits set that the VirtIO host has not negotiated. The call site is small and self-contained:

```
static struct timeval lastecn;
static int curecn;
...
if (ppsratecheck(&lastecn, &curecn, 1))
```

```
if_printf(sc->vtnet_ifp,  
        "TSO with ECN not negotiated with host\n");
```

Two details are worth pointing out. First, the rate-limit state is declared `static` at file scope, not `per-softc`. The author decided that “the VirtIO host disagrees with the guest about ECN” is a system-level misconfiguration rather than a per-interface fault, so one shared bucket is enough; `per-softc` state would let a single virtual interface’s flood starve another’s. Second, the cap is 1 pps, which is deliberately aggressive: the warning is informational and should appear no more than once per second across the entire system. A driver designer who expected the warning to fire often could raise the cap.

FreeBSD also provides `ratecheck(9)`, the event-count sibling of `ppsratecheck`. `ratecheck` fires when the time since the last allowed event exceeds a threshold; `ppsratecheck` fires when the recent burst rate is below a cap. They are complementary: `ratecheck` is better when you want a minimum interval between messages, while `ppsratecheck` is better when you want a maximum burst rate.

The takeaway from `if_vtnet` is that rate-limit state can be global or per-instance, and the choice follows the expected shape of the failure. Chapter 25 put the state in the `softc` because `myfirst`’s errors are per-instance; a different driver might reasonably make a different choice.

25.14.7 vt_core: Multiple EVENTHANDLER Registrations in Sequence

The virtual terminal subsystem at `/usr/src/sys/dev/vt/vt_core.c` registers multiple event handlers at different points in its lifecycle. The shutdown handler for the console window is one:

```
EVENTHANDLER_REGISTER(shutdown_pre_sync, vt_window_switch,  
        vw, SHUTDOWN_PRI_DEFAULT);
```

`SHUTDOWN_PRI_DEFAULT` is the neutral priority: the VT switch runs after anything that asked for `SHUTDOWN_PRI_FIRST` and before anything that asked for `SHUTDOWN_PRI_LAST`. The choice is deliberate: the terminal switch has no ordering requirement against other subsystems, so the author picked the default rather than claiming a priority the driver did not need.

The point for our purposes is that `vt_core` registers this handler once, at boot time, and never deregisters it. A driver whose lifetime is the kernel’s lifetime does not need to deregister; the kernel never calls the handler after it is gone. A driver like `myfirst` that can be loaded and unloaded as a module does need to deregister, because unloading the module destroys the handler’s code. The rule is: deregister if your code can disappear while the kernel keeps running.

This distinction is important for module authors. Built-in code paths often look like they are missing their deregistration, but they are not; they just do not need it. A module that follows the built-in pattern verbatim will panic on unload.

25.14.8 FFS (`ffs_alloc.c`): Per-Condition Rate-Limit Buckets

The FFS allocator at `/usr/src/sys/ufs/ffs/ffs_alloc.c` is a filesystem rather than a device driver, but it faces exactly the log-flood problem Chapter 25 is about. A disk that repeatedly runs out of blocks or inodes can

emit one error per failed `write(2)` call, which is unbounded in practice. The allocator reaches for `ppsrate-check` at four distinct sites, and the way it scopes the rate-limit state is a good lesson in bucket design.

Each mounted filesystem carries rate-limit state in its mount structure. Two separate buckets handle two separate kinds of error:

```
/* "Filesystem full" reports: blocks or inodes exhausted. */
um->um_last_fullmsg
um->um_secs_fullmsg

/* Cylinder-group integrity reports. */
um->um_last_integritymsg
um->um_secs_integritymsg
```

The “filesystem full” bucket is shared across two code paths (`ffs_alloc` and `ffs_realloccg`, both writing a message like “write failed, filesystem is full”) plus inode exhaustion. The integrity bucket is shared across two different integrity failures (cylinder checkhash mismatch and magic-number mismatch). At each call site the shape is identical:

```
if (ppsratecheck(&ump->um_last_fullmsg,
    &ump->um_secs_fullmsg, 1)) {
    UFS_UNLOCK(ump);
    ffs_fserr(fs, ip->i_number, "filesystem full");
    uprintf("\n%s: write failed, filesystem is full\n",
        fs->fs_fsmnt);
    ...
}
```

Three design decisions are visible. First, the rate-limit state is per mount point, not global. A heavy-write filesystem should not suppress messages from a different filesystem that is also filling up. Second, the cap is 1 pps: at most one message per second per mount per bucket. Third, related messages share a bucket (all “fullness” messages; all “integrity” messages), while unrelated ones have their own. The author of `ffs_alloc.c` decided that an operator who is flooded with “filesystem full” should not also be flooded with “out of inodes” for the same mount point; the two are symptoms of the same condition and one message per second is enough.

A pseudo-driver like `myfirst` can borrow the pattern directly. If `myfirst` someday grows a class of errors related to capacity (say, “buffer full” for the write path and “no free slots” for the `ioctl` path), those belong in the same bucket. A completely different failure (say, “command version mismatch”) deserves its own. The discipline that `ffs_alloc.c` applies to a filesystem carries over unchanged to a device driver.

25.14.9 Reading More Drivers

Every FreeBSD driver is a case study in how a specific team solved the problems Chapter 25 names. A few areas of `/usr/src/sys` are particularly rich for pattern-hunting:

- `/usr/src/sys/dev/usb/` for USB drivers: `MODULE_DEPEND` and `MODULE_PNP_INFO` everywhere.

- `/usr/src/sys/dev/pci/` for PCI drivers: labelled-cleanup attach routines at industrial scale.
- `/usr/src/sys/dev/cxgbe/` for a complex modern driver: rate-limited logging, sysctl trees with hundreds of OIDs, versioning via module ABI.
- `/usr/src/sys/netinet/` for subsystem-level EVENTHANDLER usage.
- `/usr/src/sys/kern/subr_*.c` for examples of SYSINIT at many different subsystem IDs.

When you read a new driver, start by finding its attach function. Count the acquisitions and the labels; they should match. Find the detach function. Confirm it releases the resources in reverse order. Find the error paths and see which `errno` each one returns. Look for `ppsratecheck` or `ratecheck` near any log message that fires on a hot path. Look for `MODULE_DEPEND` declarations. Look for `EVENTHANDLER_REGISTER` and confirm there is a matching `deregister`.

Every one of these inspections takes seconds once the patterns are familiar. Each one strengthens your own instinct for when a pattern is or is not being applied correctly.

25.14.10 What You Will Not See

A few patterns that Chapter 25 recommends do not appear in every driver, and their absence is not always a bug. Knowing which patterns are optional keeps you from expecting them everywhere.

`MAINTENANCE.md` is a habit recommended by this book, not a FreeBSD requirement. Most in-tree drivers do not ship a per-driver maintenance file; instead, the manual page is the operator-facing reference, and the release notes carry the change log. Both solutions work; the choice between them is a project convention.

`devctl_notify` is optional. Many drivers do not emit any events, and there is no rule that they must. The pattern is valuable when there are events that operators would actually want to react to; for drivers with quiet behaviour and no operator-visible state changes, emitting events is unnecessary.

`SYSINIT` outside of `DRIVER_MODULE` is uncommon in modern drivers. Most driver-level work happens in `device_attach`, which runs per-instance. Explicit `SYSINIT` registrations are most common in subsystems and core kernel code; individual drivers rarely need one. Chapter 25 introduced `SYSINIT` because the reader will meet it eventually, not because most drivers use it.

The explicit module event handler (a driver-supplied `MOD_LOAD/MOD_UNLOAD` function instead of `DRIVER_MODULE`) is also uncommon. It is there when a driver needs custom behaviour at load time that does not fit the Newbus model, but most drivers happily use the default.

When you read a driver that omits one of these patterns, the absence usually reflects a design decision specific to that driver, not a failure of discipline. The patterns are tools; not every tool is needed on every job.

25.14.11 Wrapping Up the Walkthroughs

Every pattern the chapter introduced is visible somewhere in the FreeBSD source tree. The `mmc` driver rate-limits its hot-path logs. The `uftdi` driver declares its module dependencies and PNP metadata. The `iscsi` driver registers a prioritised `shutdown_pre_sync` handler. The UFS dirhash cache releases memory on `vm_lowmem`. Each of these is a real, shipping, tested application of a Chapter 25 discipline.

Reading these drivers with a pattern vocabulary accelerates your own intuition faster than any single-author textbook can. The patterns repeat; the drivers differ. Once you can name the pattern, every new driver you read reinforces it.

The `myfirst` driver at the end of Chapter 25 wears every discipline. You have just seen the same disciplines worn by eight other drivers. The next step is to wear them yourself, on a driver that is not in this book. That is the work of a career, and the foundations are now in your hands.

25.15 Wrapping Up

Chapter 25 is the longest chapter in Part 5, and its length is deliberate. Every section introduced a discipline that turns a working driver into a maintainable one. None of the disciplines are glamorous; each one is the specific habit that keeps a driver working when it is used by people other than its author.

The chapter began with rate-limited logging. A driver that cannot spam the console is a driver whose log messages are worth reading. `ppsratecheck(9)` and the `DLOG_RL` macro make the discipline mechanical: place the rate-limit state in the softc, wrap hot-path messages with the macro, and let the kernel do the per-second bookkeeping. Everything downstream of logging benefits, because a log you can read is a log you can debug from.

The second section named `errno` values and told them apart. `ENOTTY` is not `EINVAL`; `EPERM` is not `EACCES`; `ENOIOCTL` is the kernel's special signal that a driver did not recognise an `ioctl` command and wants the kernel to try another handler before giving up. Knowing the vocabulary turns vague bug reports into precise ones, and precise bug reports reach root causes faster.

Section 3 treated configuration as a first-class concern. A tunable is a boot-time initial value; a `sysctl` is a runtime handle. The two cooperate through `TUNABLE_*_FETCH` and `CTLFLAG_TUN`. A driver that exposes exactly the right tunables and `sysctls` gives operators enough control to solve their own problems without having to modify the source. The `hw.myfirst.timeout_sec` and `dev.myfirst.0.timeout_sec` pair is now the template every future tunable will follow.

Section 4 named the three version identifiers a driver needs (release string, module integer, `ioctl` wire integer) and pointed out that they change for different reasons. The `GETCAPS` `ioctl` gives user-space a run-time discovery mechanism that survives the addition and removal of capabilities over time, and the `MODULE_DEPEND` macro makes inter-module compatibility explicit. The `myfirst` driver's own jump from 1.7 to 1.8 is a small but complete case study.

Section 5 named the labelled-goto pattern and made it the unconditional discipline for attach and detach. Every resource gets a label; every label falls through to the next; the single `return (0)` separates the acquisition chain from the cleanup chain. The pattern scales from two resources to a dozen without changing shape. Deliberate failure injection confirms that every label is reachable.

Section 6 split `myfirst` into subject-matter files. One file per concern, a single responsibility rule for deciding where to put new code, and a small public header that carries only the declarations every file needs. The driver is now at phase two of the typical multi-file split, and the rules for reaching phase three are named explicitly.

Section 7 turned the focus outward. The production-readiness checklist covered module dependencies, PNP metadata, `MOD_QUIESCE`, `devctl_notify`, `MAINTENANCE.md`, `devd` rules, log message quality, the 100-cycle regression test, input validation, failure-path exercise, and versioning discipline. Every item on the checklist is a specific habit that catches a specific failure mode. `myfirst` at the end of Chapter 25 passes every item.

Section 8 closed the loop with `SYSINIT(9)` and `EVENTHANDLER(9)`. A driver that needs to participate in the kernel lifecycle beyond its own attach/detach window has a clean mechanism for doing so. `myfirst` registers

for `shutdown_pre_sync` as a demonstration; other drivers register for `vm_lowmem`, `suspend/resume`, or custom events.

The driver has grown from a single file with one message buffer into a modular, observable, version-disciplined, rate-limited, and production-ready pseudo-device. The mechanics of FreeBSD character-driver authorship are now in the reader's hands.

What has not been covered yet is the world of hardware. Every chapter so far has used a pseudo-driver; the character device backs a software buffer and a set of counters. A driver that actually talks to hardware has to allocate bus resources, map I/O windows, attach interrupt handlers, program DMA engines, and survive the specific failure modes of real devices. Chapter 26 starts that work.

25.16 Part 5 Checkpoint

Part 5 covered debugging, tracing, and the engineering practices that separate a driver that merely compiles from a driver that a team can maintain. Before Part 6 changes the terrain by attaching `myfirst` to real transports, confirm that the Part 5 habits are in your fingers and not just in your notes.

By the end of Part 5 you should be comfortable doing each of the following:

- Investigating driver behaviour with the right tool for the question: `ktrace` and `kdump` for per-process system calls, `ddb` for live or post-mortem kernel inspection, `kgdb` with a core dump for crashed kernels, `dtrace` and SDT probes for in-kernel tracing without source changes, and `procstat` together with `lockstat` for state and contention views.
- Reading a panic message and extracting the right breadcrumbs, turning a stack trace into a reproducible test case rather than a guessing game.
- Building and running the Chapter 24 integration stack `myfirst`: a driver that exposes its surfaces through `ioctl`, `sysctl`, DTrace probes, and `devctl_notify` while exercising a full lifecycle injection path.
- Applying the Chapter 25 production-readiness checklist item by item: `MODULE_DEPEND`, PNP metadata, `MOD_QUIESCE` as a separate handler, `devctl_notify`, `MAINTENANCE.md`, `devd` rules, log message quality, the 100-cycle regression test, input validation, deliberate failure-path exercise, and version discipline.
- Using `SYSINIT(9)` and `EVENTHANDLER(9)` when a driver must participate in the kernel lifecycle beyond its own attach and detach window, including graceful registration and deregistration.

If any of these still feels soft, the labs to revisit are:

- Debugging tools in practice: Lab 23.1 (A First DDB Session), Lab 23.2 (Measuring the Driver with DTrace), Lab 23.4 (Finding a Memory Leak with `vmstat -m`), and Lab 23.5 (Installing the 1.6-debug Refactor).
- Integration and observability: Lab 1 (Build and Load the Stage 1 Driver), Lab 4 (Walk the Lifecycle by Injecting a Failure), Lab 5 (Trace the Integration Surfaces with DTrace), and Lab 6 (Integration Smoke Test) in Chapter 24.
- Production discipline: Lab 3 (Tunable Reboot Behaviour), Lab 4 (Deliberate Attach Failure Injection), Lab 6 (The 100-Cycle Regression Script), and Lab 10 (Multi-Version Compatibility Matrix) in Chapter 25.

Part 6 expects the following as a baseline:

- Confidence reading a panic and following it to a root cause, since three new transports will introduce three new ways for things to go wrong.
- A `myfirst` that passes the Chapter 25 production checklist, so that Chapter 26 can add USB without the earlier discipline wobbling under new load.
- Awareness that Part 6 changes the running-example pattern: the `myfirst` thread will extend through Chapter 26 as `myfirst_usb`, then pause while Chapters 27 and 28 use fresh, transport-shaped demos. The discipline continues; only the code artefact changes. Chapter 29 returns to the cumulative shape.

If those hold, you are ready for Part 6. If one still looks unsteady, the fix is a single well-chosen lab, not a rush forward.

25.17 Bridge to Chapter 26

Chapter 26 turns the `myfirst` driver outward. Instead of serving a buffer in RAM, the driver will attach to a real bus and service a real device. The book's first hardware target is the USB subsystem: USB is ubiquitous, well-documented, and has a clean kernel interface that is easier to start with than PCI or ISA.

The habits you have built in Chapter 25 carry over unchanged. The labelled-goto pattern in `attach` scales to bus resource allocations: `bus_alloc_resource`, `bus_setup_intr`, `bus_dma_tag_create`, each becomes another acquisition in the chain, each with its own label. The modular file layout extends naturally: `myfirst_usb.c` joins `myfirst.c`, `myfirst_cdev.c`, and the rest. The production checklist adds two items: `MODULE_DEPEND(myfirst_usb, usb, ...)` and `MODULE_PNP_INFO` for the vendor/product identifiers the driver handles. The versioning discipline continues; the Chapter 26 driver will be `1.9-usb`.

What is genuinely new in Chapter 26 is not the driver's structure; it is the interfaces between the driver and the USB subsystem. You will meet `usb_request_methods`, transfer setup callbacks, the separation between control, bulk, interrupt, and isochronous transfers, and the USB-specific lifecycle (`attach` is per-device, just like Newbus; `detach` is per-device, just like Newbus; hot-plug is the normal operating condition, unlike most other buses).

Before you start Chapter 26, pause and confirm that the Chapter 25 material is solid. The labs are meant to be run; running them is the single best way to find the parts of the chapter that did not land. If you have run Labs 1 through 7 and the challenge exercises are clear, you are ready for hardware.

Chapter 26 begins with a simple USB device (a FTDI serial adapter, most likely) and walks through probe, attach, bulk transfer setup, read/write dispatch, and the detach/hot-unplug paths. By the end of Chapter 26, `myfirst_usb.ko` will serve real bytes from a real cable, and the discipline from Chapter 25 will keep it maintainable.

25.18 Glossary

The terms in this glossary all appear in Chapter 25 and are worth knowing by name. Definitions are short on purpose; the chapter body is where each concept is developed.

Attach chain. The ordered sequence of resource acquisitions in a driver's `device_attach` method. Each acquisition that can fail is followed by a goto to the label that undoes the previously acquired resources.

Capability bitmask. A 32-bit (or 64-bit) integer returned by MYFIRSTIOC_GETCAPS, with one bit per optional feature. Lets user-space query the driver at run time for which features it supports.

Cleanup chain. The ordered sequence of labels at the bottom of a driver's device_attach method. Each label releases one resource and falls through to the next. Reverse of the acquisition order.

CTLFLAG_SKIP. A sysctl flag that hides an OID from default sysctl(8) listings. The OID is still readable when its full name is given explicitly. Defined in /usr/src/sys/sys/sysctl.h.

CTLFLAG_RDTUN / CTLFLAG_RWTUN. Shorthand for CTLFLAG_RD | CTLFLAG_TUN and CTLFLAG_RW | CTLFLAG_TUN respectively. Declares a sysctl that cooperates with a loader tunable.

devctl_notify. Kernel function that emits a structured event readable by devd(8). Lets a driver notify user-space daemons of interesting state changes.

DLOG_RL. Macro wrapper over ppsratecheck and device_printf that caps a log message at a given messages-per-second rate.

Errno. A small positive integer representing a specific failure mode. FreeBSD's errno table is in /usr/src/sys/sys/errno.h.

Event handler. A callback registered with EVENTHANDLER_REGISTER that runs whenever the kernel fires a named event. Deregistered with EVENTHANDLER_DEREGISTER.

EVENTHANDLER(9). FreeBSD's generic event-notification framework. Defines events, lets subsystems publish them, lets drivers subscribe.

Failure injection. A deliberate test technique that causes a code path to fail in order to exercise its cleanup. Usually implemented as a conditional return guarded by an #ifdef.

Labelled-goto pattern. See "attach chain" and "cleanup chain". The idiomatic FreeBSD shape for attach and detach that uses goto label; for linear unwinding rather than nested if.

MOD_QUIESCE. The module event that asks "can you be unloaded right now?". A driver returns EBUSY to refuse; 0 to accept.

MODULE_DEPEND. Macro that declares a dependency on another kernel module. The kernel enforces load order and version compatibility.

MODULE_PNP_INFO. Macro that publishes the vendor/product identifiers a driver handles. The kernel uses the metadata to auto-load drivers when matching hardware appears.

MODULE_VERSION. Macro that declares a module's version integer. Used by MODULE_DEPEND for compatibility checks.

myfirst_ratelimit. The struct holding the per-class rate-limit state (lasttime and curpps). Must live in the softc, not on the stack.

MYFIRST_VERSION. The driver's human-readable release string, e.g. "1.8-maintenance". Exposed via dev.myfirst.<unit>.version.

MYFIRST_IOCTL_VERSION. The driver's ioctl wire-format version integer. Returned by MYFIRSTIOC_GETVER. Bumped only for breaking changes.

Pps. Events per second. A rate-limit cap expressed in pps (e.g. 10 pps = 10 messages per second).

ppsratecheck(9). The FreeBSD rate-limit primitive. Takes a struct `timeval`, an `int *`, and a pps cap; returns nonzero to allow the event.

Production-ready. A driver that satisfies the Section 7 checklist: declared dependencies, documented surface, rate-limited logging, exercised failure paths, passed the 100-cycle test.

SHUTDOWN_PRI*. Priority constants passed to `EVENTHANDLER_REGISTER` for shutdown events. `FIRST` runs early; `LAST` runs late; `DEFAULT` runs in the middle.

SI_SUB*. Subsystem identifiers for `SYSINIT`. Numeric values sort by boot order. Common constants: `SI_SUB_TUNABLES`, `SI_SUB_DRIVERS`, `SI_SUB_CONFIGURE`.

SI_ORDER*. Order constants for `SYSINIT` within a subsystem. `FIRST` runs first; `MIDDLE` runs in the middle; `ANY` runs last (no guaranteed order among `ANY` entries).

Single-responsibility rule. Each source file answers one question about the driver. Violations mean new `ioctl`s creeping into `myfirst_sysctl.c` or new `sysctls` creeping into `myfirst_ioctl.c`.

Softc. The per-device state structure. Newbus allocates it, zeroes it, and hands it to `device_attach` via `device_get_softc`.

sysctl(8). The user-space command and kernel interface for runtime parameters. Node names live under a fixed hierarchy (`kern.*`, `hw.*`, `net.*`, `dev.*`, `vm.*`, `debug.*`, etc.).

SYSINIT(9). FreeBSD's boot-time initialisation macro. Registers a function to run at a specific subsystem and order during kernel startup or module load.

SYSUNINIT(9). Companion to `SYSINIT`. Registers a cleanup function to run at module unload in the reverse of the `SYSINIT` order.

Tag (event handler). The opaque value returned by `EVENTHANDLER_REGISTER` and consumed by `EVENTHANDLER_DEREGISTER`. Must be stored (usually in the `softc`) so the deregistration can locate the registration.

Tunable. A value parsed from the kernel environment at boot or module load and consumed via `TUNABLE_*_FETCH`. Sets initial values; lives at the `hw.`, `kern.`, or `debug.` level.

TUNABLE_INT_FETCH, _LONG_FETCH, _BOOL_FETCH, _STR_FETCH. The family of macros that read a tunable from the kernel environment and populate a variable. Silent if the tunable is absent.

Version split. The practice of using three independent version identifiers (release string, module integer, `ioctl` integer) that change for different reasons.

vm_lowmem event. An `EVENTHANDLER` event fired when the virtual memory subsystem is under pressure. Drivers with caches can release some memory back.

Wire format. The layout of data that crosses a user/kernel boundary. The `ioctl` wire format is determined by the `_IOR`, `_IOW`, `_IOWR` declarations and the payload structure. A wire-format change is a breaking change and requires a `MYFIRST_IOCTL_VERSION` bump.

26 USB and Serial Drivers

26.1 Introduction

Chapter 25 closed Part 5 with a driver that the rest of the system could talk to. The `myfirst` driver at version 1.8-maintenance had a rate-limited logging macro, a careful `errno` vocabulary, loader tunables and writable sysctls, a three-way version split, a labelled-goto cleanup chain in `attach` and `detach`, a clean modular source layout, `MODULE_DEPEND` and `MODULE_PNP_INFO` metadata, a `MAINTENANCE.md` document, a `shutdown_pre_sync` event handler, and a regression script that could load and unload the driver a hundred times without leaking a single resource. What the driver did not have was any contact with real hardware. The character device backed a buffer in kernel memory. The sysctl counters tracked operations against that buffer. The `MYFIRSTIOC_GETCAPS` ioctl announced capabilities that were implemented entirely in software. Everything the driver did, it did without ever reading a byte off a wire.

Chapter 26 begins the step outward. Instead of serving a buffer in RAM, the driver will attach to a real bus and service a real device. The bus will be the Universal Serial Bus, because USB is the most approachable transport in FreeBSD: it is ubiquitous, its subsystem is extremely well organised, the kernel interface is designed around a small handful of structures and macros, and every FreeBSD developer already has a dozen USB devices on their desk. After USB, the chapter pivots to the subject that historically preceded USB and still lives alongside it everywhere from debug consoles to GPS modules: the serial port, in its classical form as a UART-driven RS-232 interface and in its modern form as a USB-to-serial bridge. By the end of the chapter, the `myfirst` driver family has grown a new transport-specific sibling, `myfirst_usb`, at version 1.9-usb. That sibling knows how to attach to a real USB device, how to set up a bulk-in and a bulk-out transfer, how to echo received bytes through a `/dev` node, and how to survive the device being yanked out of the port while the driver is in use.

Chapter 26 is the opening chapter of Part 6. Part 6 is organised around the observation that up to this point the book has been teaching the parts of FreeBSD driver development that are *transport-neutral*: the Newbus model, the character device interface, synchronisation, interrupts, DMA, power management, debugging, integration, and maintenance. All of those disciplines apply to every driver regardless of how the device is attached. Part 6 shifts the focus. USB, storage, and networking each have their own bus, their own lifecycle, their own data-flow pattern, and their own idiomatic way of integrating with the rest of the kernel. The disciplines you have built in Parts 1 through 5 carry over unchanged; what is new is the shape of the interface between your driver and the specific subsystem it plugs into. Chapter 26 teaches that shape for USB and for serial devices. Chapter 27 teaches it for storage devices and the VFS layer. Chapter 28 teaches it for network interfaces. Each of the three chapters is structurally parallel: the transport is introduced, the subsystem is mapped, a minimal driver is built, and the reader is shown how to test without the specific hardware everyone happens not to have.

There is a deliberate pairing of USB and serial in this chapter. The two topics sit together because they are both first-class citizens of the same larger mental model: a transport is a *protocol plus a lifecycle*, and the driver is the piece of code that carries data across the protocol boundary and keeps the lifecycle consistent with the kernel's view of the device. USB is a protocol with a rich four-transfer-type vocabulary and a hot-plug lifecycle. A

UART is a protocol with a much simpler byte-framing vocabulary and a statically-attached lifecycle. Studying them together makes the pattern visible. A student who has seen the USB callback state machine and the UART interrupt handler side by side understands that “FreeBSD’s driver model” is not a single shape but a family of shapes, each one adapted to the demands of its own transport.

The second reason to pair USB and serial is historical and practical. A very large number of what the operating system calls “USB devices” are in fact serial ports in disguise. The FTDI FT232R chip, the Prolific PL2303, the Silicon Labs CP210x, and the WCH CH340 all expose a standard serial-port API to user space, but physically they sit on the USB bus. FreeBSD handles that with the `ucom(4)` framework: a USB driver registers callbacks with `ucom`, and `ucom` produces the user-visible `/dev/ttyU0` and `/dev/cuaU0` device nodes and arranges for the `termios`-aware line discipline to operate correctly on top of a USB bulk-in and bulk-out pair. The reader who is about to write a USB driver is likely, sooner or later, to write a USB-to-serial driver, and that driver will be an intersection of the two worlds the chapter introduces. Putting the material into a single chapter makes the intersection visible.

A third reason is pedagogical. The `myfirst` driver so far has been a pseudo-device. The transition to real hardware is a conceptual step, not just a coding step. Many readers will find their first attempt at a hardware-backed driver unsettling: interrupts arrive without asking, transfers can stall or time out, the device can be unplugged mid-operation, and the kernel has opinions about how fast you are allowed to respond. USB is the friendliest possible introduction to that world because the USB subsystem does an unusually large amount of work on the driver’s behalf. Setting up a bulk transfer in USB is not the same kind of problem as setting up a DMA ring on a PCI Express NIC. The USB core manages the low-level DMA bookkeeping; your driver works at the level of “tell me when this transfer completes”. Learning the USB pattern first makes the later hardware chapters (storage, networking, embedded buses in Part 7) less intimidating because by then the basic shape of a transport-specific driver is familiar.

The `myfirst` driver’s path through this chapter is concrete. It picks up at version 1.8-maintenance from the end of Chapter 25. It adds a new source file, `myfirst_usb.c`, compiled into a new kernel module, `myfirst_usb.ko`. The new module declares itself dependent on `usb`, lists a single vendor and product identifier in its match table, probes and attaches on hot-plug, allocates one bulk-in and one bulk-out transfer, exposes a `/dev/myfirst_usb0` node, echoes incoming bytes to the kernel log and copies them back out on a read, handles detach cleanly when the cable is pulled, and carries forward every Chapter 25 discipline without exception. The labs exercise each piece in turn. By the end of the chapter, there is a second driver in the family, a new source layout to accommodate it, and a working example of a FreeBSD USB driver that the reader has typed themselves.

Because this is also a chapter about serial devices, the chapter spends time on the serial half of its scope even though `myfirst_usb` itself is not a serial driver. The serial material teaches how `uart(4)` is laid out, how `ucom(4)` fits in, how `termios` carries baud rate and parity and flow control from user space down to hardware, and how to test serial interfaces without physical hardware using `nmdm(4)`. The serial material does not build a new UART hardware driver from scratch. Writing a UART hardware driver is a specialised undertaking that is almost never the right choice in a modern environment: the existing `ns8250` driver in the base system already handles every PC-compatible serial port, every common PCI serial card, and the ARM PL011 that most virtualised platforms present. The chapter teaches the serial subsystem at the level the reader actually needs: how it is organised, how to read existing drivers, how `termios` reaches a driver’s `param` method, how to use the subsystem from user space, and what to do when the goal is a USB-to-serial driver (the common case) rather than a new hardware driver (the rare case).

The rhythm of Chapter 26 is the rhythm of pattern recognition. The reader will leave the chapter knowing what a USB driver looks like, what a serial driver looks like, where the two overlap, where they differ from the pseudo-drivers of Parts 2 through 5, and how to test both without a lab full of adapters. Those are the foundations of transport-specific driver development. Chapter 27 will then apply the same discipline to storage, and Chapter 28 will apply it to networking, each time taking the same general pattern and bending it to a new transport's rules.

26.1.1 Where Chapter 25 Left the Driver

A short checkpoint before the new work starts. Chapter 26 extends the driver family produced at the end of Chapter 25, tagged as version 1.8-maintenance. If any of the items below is uncertain, return to Chapter 25 and resolve it before starting this chapter, because the new material assumes every Chapter 25 primitive is working and every habit is in place.

- Your driver source matches Chapter 25 Stage 4. `myfirst.ko` compiles cleanly, identifies itself as 1.8-maintenance in `kldstat -v`, and carries the full `MYFIRST_VERSION`, `MODULE_VERSION`, and `MYFIRST_IOCTL_VERSION` triple.
- The source layout is split: `myfirst_bus.c`, `myfirst_cdev.c`, `myfirst_ioctl.c`, `myfirst_sysctl.c`, `myfirst_debug.c`, `myfirst_log.c`, with `myfirst.h` as the shared private header.
- The rate-limited log macro `DLOG_RL` is in place and tied to a struct `myfirst_ratelimit` inside the `softc`.
- The `goto fail`; cleanup chain in `myfirst_attach` is working and exercised by a deliberate failure lab.
- The regression script passes a hundred consecutive `kldload/kldunload` cycles with no residual OIDs, no orphaned `cdev` nodes, and no leaked memory.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk, a debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF`, and a VM snapshot at the 1.8-maintenance state you can revert to.

That driver, those files, and those habits are what Chapter 26 extends. The additions introduced in this chapter live almost entirely in a new file, `myfirst_usb.c`, which becomes a second kernel module sharing the same conceptual family as `myfirst.ko` but building a separate `myfirst_usb.ko`. The chapter's labs exercise each stage of the new module: probe, attach, transfer setup, callback handling, `/dev` exposure, and detach. The chapter does not modify `myfirst.ko` itself; the existing driver remains a reference implementation of Parts 2 through 5, and the new driver is its USB-transport sibling.

26.1.2 What You Will Learn

By the end of this chapter you will be able to:

- Explain what makes a transport-specific driver different from the pseudo-drivers built in Parts 2 through 5, and name the three broad categories of work a transport-specific driver has to add to its Newbus foundation: matching rules, transfer mechanics, and lifecycle hot-plug handling.
- Describe the USB mental model at the level needed to write a driver: host versus device roles, hubs and ports, device classes (CDC, HID, Mass Storage, Vendor), the descriptor hierarchy (device, configuration, interface, endpoint), the four transfer types (control, bulk, interrupt, isochronous), and the hot-plug lifecycle.

- Read the output of `usbconfig` and `dmesg` for a USB device and identify its vendor identifier, product identifier, interface class, endpoint addresses, endpoint types, and packet sizes.
- Describe the serial mental model at the level needed to write a driver: the UART as a shift register with a baud generator, RS-232 framing, start and stop bits, parity, hardware flow control via RTS and CTS, software flow control via XON and XOFF, and the relationship between `struct termios`, `tty(9)`, and the driver's `param` callback.
- Explain the difference between FreeBSD's `uart(4)` subsystem for real UART hardware and the `ucom(4)` framework for USB-to-serial bridges, and name the two worlds a serial-driver author must never confuse.
- Write a USB device driver that attaches to `uhub`, declares a `STRUCT_USB_HOST_ID` match table, implements `probe` and `attach` and `detach` methods, uses `usbd_transfer_setup` to configure a bulk-in and a bulk-out transfer, and unwinds cleanly through a labelled-goto chain.
- Write a USB transfer callback that follows the `USB_GET_STATE` state machine, handles `USB_ST_SETUP` and `USB_ST_TRANSFERRED` correctly, distinguishes `USB_ERR_CANCELLED` from other errors, and responds to a stalled endpoint with `usbd_xfer_set_stall`.
- Expose a USB device to user space through the `usb_fifo` framework or through a custom `make_dev_s`-registered `cdevsw`, and know when each is the right choice.
- Read an existing UART driver in `/usr/src/sys/dev/uart/` with a pattern vocabulary that makes the code's intent clear on first pass, including the `uart_class/uart_ops` split, the method dispatch, the baud-divisor calculation, and the `tty`-side wakeup machinery.
- Translate a `struct termios` into the four arguments of a UART `param` method (baud, databits, stopbits, parity), and know which `termios` flags belong to the hardware layer and which belong to the line discipline.
- Test a USB driver against a simulated device using QEMU USB redirection or `usb_template(4)`, and test a serial driver against a `nmdm(4)` null-modem pair without any hardware at all.
- Use `cu(1)`, `tip(1)`, `stty(1)`, `comcontrol(8)`, and `usbconfig(8)` to drive, configure, and inspect serial and USB devices from user space.
- Handle hot-unplug cleanly in a USB driver's `detach` path: cancel outstanding transfers, drain callouts and taskqueues, release bus resources, and destroy `cdev` nodes, all while knowing that the device may already be gone by the time the `detach` method runs.

The list is long because transport-specific drivers touch many surfaces at once. Each item is narrow and teachable. The chapter's work is making the set of items into a coherent, reusable mental picture.

26.1.3 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred to later chapters so Chapter 26 stays focused on the foundations of USB and serial driver development.

- **USB isochronous transfers and high-bandwidth video/audio streaming** are mentioned at a conceptual level in Section 1 but not developed. Isochronous transfers are the most complex of the four transfer types and are almost always used through higher-level frameworks (audio, video capture) that deserve their own treatment. Chapter 26 focuses on control, bulk, and interrupt transfers, which together cover the vast majority of USB driver work.
- **USB device-mode and gadget programming** through `usb_template(4)` is introduced briefly for testing purposes but not built out. Writing a custom USB gadget is a specialised project outside the scope of a first transport-specific chapter.

- **The internals of the USB host controller drivers** (`xhci`, `ehci`, `ohci`, `uhci`) are outside scope. These drivers implement the low-level protocol machinery that `usbd_transfer_setup` eventually calls; a driver author almost never has to modify them. The chapter treats them as a stable platform.
- **Writing a new UART hardware driver from scratch** is outside scope. The existing `ns8250` driver handles every common PC serial port, the `pl011` driver handles most ARM platforms, and the embedded SoC drivers handle the rest. Writing a new UART driver is the specialised work of porting FreeBSD to a new system-on-chip, which is its own topic (touched on in Part 7 alongside Device Tree and ACPI). Chapter 26 teaches the reader how to *read* and *understand* a UART driver rather than how to write one.
- **Storage drivers** (GEOM providers, block devices, VFS integration) are the subject of Chapter 27. USB mass storage is touched on only as an example of a USB device class, not as a driver target.
- **Network drivers** (`ifnet(9)`, `mbufs`, RX/TX ring bookkeeping) are the subject of Chapter 28. USB network adapters are mentioned as an example of CDC Ethernet, not as a driver target.
- **USB/IP for remote USB device testing over a network** is mentioned as an option for readers who truly cannot obtain any USB pass-through, but is not developed. The standard testing pathway in this chapter is a local VM with device redirection.
- **Quirks and vendor-specific workarounds** through `usb_quirk(4)` are mentioned but not developed. A driver author who needs quirks is already past the level this chapter teaches.
- **Bluetooth, Wi-Fi, and other wireless transports that happen to use USB** as their physical bus are outside scope. Those stacks involve protocols well beyond USB itself and are their own bodies of work.
- **Transport-agnostic abstraction for multi-bus drivers** (the same driver logic plugging into PCI, USB, and serial via a common interface) is deferred to Part 7's portability chapter.

Staying inside those lines keeps Chapter 26 a chapter about *the USB and serial transports*, not a chapter about every technique a senior transport-specific kernel developer might use on a senior transport-specific kernel problem.

26.1.4 Where We Are in Part 6

Part 6 has three chapters. Chapter 26 is the opening chapter and teaches transport-specific driver development through USB and serial devices. Chapter 27 teaches transport-specific driver development through storage devices and the VFS layer. Chapter 28 teaches it through network interfaces. The three chapters are structurally parallel in the sense that each introduces a transport, maps the subsystem, builds a minimal driver, and teaches hardware-free testing.

Chapter 26 is the right place to start Part 6 for three reasons. The first is that USB is the most gentle introduction to hardware-backed drivers: its core abstractions are smaller than storage's (no GEOM graph, no VFS), smaller than networking's (no `mbuf` chains, no ring buffers with head/tail pointers and interrupts mitigation), and the subsystem handles a large share of the hard parts on the driver's behalf. The second is that USB appears everywhere. Even a reader who will never write a storage or network driver will probably write a USB driver at some point: a thermometer, a data logger, a custom serial adapter, a factory test fixture. The third is pedagogical. The pattern USB teaches, a subsystem with probe-and-attach lifecycles, transfer setup through a config array, callback-based completion, and a clean detach on unplug, is the same pattern (with different specifics) that storage and networking teach. Seeing it first in USB makes the next two chapters recognisable.

Chapter 26 bridges forward to Chapter 27 by closing on a note about lifecycle: the USB detach path is a dress rehearsal for the storage-device hot-removal path, and the patterns the reader has just practised will come back

the moment an external USB disk is pulled in Chapter 27. It also bridges backward to Chapter 25 by carrying every Chapter 25 discipline forward: `MODULE_DEPEND`, `MODULE_PNP_INFO`, the labelled-goto pattern, the `errno` vocabulary, rate-limited logging, version discipline, and a regression script that exercises the new module as rigorously as Chapter 25 exercised the old one.

26.1.5 A Small Note on Difficulty

If the transition from pseudo-drivers to real hardware looks daunting on the first reading, that feeling is entirely normal. Every experienced FreeBSD developer had a first USB driver that did not attach, a first serial session where `cu` refused to talk, and a first debug session where `dmesg` stayed silent. The chapter is structured to ease you into each of those moments with labs, troubleshooting notes, and exit points. If a section starts to feel overwhelming, the right move is not to push through but to stop, read the corresponding real driver in `/usr/src`, and return when the real code makes the concept visible. The existing FreeBSD drivers are the single best teaching resource this chapter can point to, and the chapter will point to them often.

26.2 Reader Guidance: How to Use This Chapter

Chapter 26 has three layers of engagement, and you can pick the layer that fits your current situation. The layers are independent enough that you can read for understanding now and return for hands-on practice later without losing continuity.

Reading only. Three to four hours. Reading gives you the USB and serial mental models, the shape of the FreeBSD subsystems, and pattern recognition for reading existing drivers. If you are not yet in a position to load kernel modules (because your lab VM is unavailable, you are reading on a commute, or you have a planning meeting in thirty minutes), a reading-only pass is a worthwhile investment. The chapter is written so that the prose carries the teaching load; the code blocks are there to anchor the prose, not to replace it.

Reading plus the hands-on labs. Eight to twelve hours over two or three sessions. The labs guide you through building `myfirst_usb.ko`, exploring real USB devices with `usbconfig`, setting up a simulated serial link with `nmdm(4)`, talking to it with `cu`, and running a hot-unplug stress test. The labs are where the chapter turns from explanation into reflex. If you can spare eight to twelve hours across two or three sessions, do the labs. The cost of skipping them is that the patterns stay abstract instead of becoming habit.

Reading plus the labs plus the challenge exercises. Fifteen to twenty hours over three or four sessions. The challenge exercises push beyond the chapter's worked example into the territory where you have to adapt the pattern to a new requirement: add a control-transfer ioctl, port the driver to the `usb_fifo` framework, read an unfamiliar USB driver end-to-end, simulate a flaky cable with failure injection, or extend the regression script to cover the new module. The challenge material does not introduce new foundations; it stretches the ones the chapter has just taught. Spend time on the challenges in proportion to how much autonomy you expect to have on your next driver project.

Do not rush. This is the first chapter in the book whose material depends on real hardware or convincing simulation. Set aside a block of time when you can watch `dmesg` after `kldload` and read it slowly. A USB driver that attaches without errors is usually right; a USB driver whose attach messages you have not actually read is often wrong in a way that will cost you an hour of debugging two days later. The small discipline of reading the attach output as it happens, rather than assuming it, is a habit worth forming in Chapter 26 because every subsequent transport-specific chapter depends on it.

26.2.1 Recommended Pacing

Three sitting structures work well for this chapter.

- **Two long sittings of four to six hours each.** First sitting: Introduction, Reader Guidance, How to Get the Most Out of This Chapter, Section 1, Section 2, and Lab 1. Second sitting: Section 3, Section 4, Section 5, Labs 2 through 5, and the Wrapping Up. The advantage of long sittings is that you stay in the mental model long enough to connect Section 1's vocabulary to Section 3's callback code.
- **Four medium sittings of two to three hours each.** Sitting 1: Introduction through Section 1 and Lab 1. Sitting 2: Section 2 and Lab 2. Sitting 3: Section 3 and Labs 3 and 4. Sitting 4: Section 4, Section 5, Lab 5, and Wrapping Up. The advantage is that each sitting has a crisp milestone.
- **A linear reading pass followed by a hands-on pass.** Day one: read the entire chapter start to finish without running any code, to get the full mental model in place. Day two or day three: return to the chapter with a kernel source tree and a lab VM open and work through the labs in sequence. The advantage of this approach is that the mental model is fully loaded before you touch code, which catches concept-level mistakes early.

Do not attempt the whole chapter in a single marathon session. The material is dense, and the USB callback state machine in particular does not reward tired reading.

26.2.2 What a Good Study Session Looks Like

A good study session for this chapter has five elements visible at once. Put the book chapter on one side of your screen. Put the relevant FreeBSD source files in a second pane: `/usr/src/sys/dev/usb/usbdi.h`, `/usr/src/sys/dev/usb/misc/uled.c`, and `/usr/src/sys/dev/uart/uart_bus.h` are the three most useful to keep open. Put a terminal on your lab VM in a third pane. Put `man 4 usb`, `man 4 uart`, and `man 4 ucom` in a fourth pane for quick reference. Finally, keep a small note file open for questions you will want to answer later. If a term comes up you cannot define, write it in the note file and keep reading; if the same term comes up twice, look it up before continuing. This is the study posture that gets the most out of a long technical chapter.

26.2.3 If You Do Not Have a USB Device to Test With

Many readers will not have a spare USB device that matches the vendor/product identifiers in the worked example. That is fine. Section 5 teaches three ways to proceed: QEMU USB device redirection from a host to a guest, `usb_template(4)` for FreeBSD-as-USB-device, and the simulated-device approach that tests driver logic without a real bus at all. The chapter's worked example is written so that the driver's match table can be swapped for one matching any USB device you do have on your desk. A USB flash drive will do. A mouse will do. A keyboard will do. The chapter explains how to point the driver at whatever device you happen to have, at the cost of temporarily stealing that device from the kernel's built-in driver, which the chapter also covers.

26.3 How to Get the Most Out of This Chapter

Five habits pay off in this chapter more than in any of the earlier chapters.

First, **keep four short manual-page files open in a browser tab or a terminal pane**: `usb(4)`, `usb_quirk(4)`, `uart(4)`, and `ucom(4)`. These four pages together are the tightest overview the FreeBSD project has of the subsystems this chapter introduces. None of them is long. `usb(4)` describes the subsystem from the user's perspective and lists the `/dev` entries that appear. `usb_quirk(4)` lists the quirks table and explains what a quirk is, which will save you puzzlement later when you see quirk code in real drivers. `uart(4)` describes the serial subsystem from the user's perspective. `ucom(4)` describes the USB-to-serial framework. Skim each once at the start of the chapter. When the prose refers to "consult the manual page for details," return to the appropriate page. The manual pages are authoritative; this book is commentary.

Second, **keep three real drivers close to hand**. `/usr/src/sys/dev/usb/misc/uled.c` is a very small USB driver that talks to a USB-attached LED. It uses the `usb_fifo` framework, which is one of the two user-visible patterns the chapter teaches, and its entire `attach` function is smaller than a page. `/usr/src/sys/dev/usb/misc/ugold.c` is a slightly larger USB driver that reads temperature data from a TEMPer thermometer through interrupt transfers. It demonstrates the other common transfer type and shows how a driver uses a callout to pace its reads. `/usr/src/sys/dev/uart/uart_dev_ns8250.c` is the canonical 16550 UART driver; every PC serial port in the world uses it. Read each of these three files once at the start of the chapter and once more at the end. The first read will feel largely opaque; the second will feel almost obvious. That change is the measure of progress this chapter offers.

Third, **type every code addition by hand**. The `myfirst_usb.c` file grows through the chapter in roughly a dozen small increments. Each increment corresponds to a paragraph or two of prose. Typing the code by hand is what turns the prose into muscle memory. Pasting the code skips the lesson. If that sounds pedantic, notice that every working USB driver author has written a USB driver's `attach` function at least a dozen times; typing this one is the first of that dozen.

Fourth, **read `dmesg` after every `kldload`**. A USB driver produces a predictable pattern of attach messages: the device is detected on a port, the driver probes, the match succeeds, the driver attaches, the `/dev` node appears. If any of those steps is missing, something is wrong, and the sooner you notice the missing step, the sooner you fix it. The smallest discipline this chapter can give you is the habit of running `dmesg | tail -30` immediately after `kldload` and reading every line. If the output is boring, the driver probably works. If the output surprises you, investigate before proceeding.

Fifth, **after every section, ask yourself what would happen if you pulled the cable**. The question sounds silly; it is central. A well-written transport-specific driver is always one that handles being removed while in use. A USB driver in particular runs in a world where hot-unplug is the normal operating condition. If you find yourself writing a section of code and cannot answer "what if the cable were pulled right here," the section is not yet finished. Chapter 26 returns to this question often, not as rhetoric but as a discipline.

26.3.1 What to Do When Something Does Not Work

It will not all work the first time. USB drivers have a few common failure modes, and the chapter documents each of them in the troubleshooting section at the end. A short preview of the most common ones:

- The driver compiles but does not attach when the device is plugged in. Usually the match table has the wrong vendor or product identifier. The fix is to verify the identifier with `usbconfig dump_device_desc`.
- The driver attaches but the `/dev` node does not appear. Usually the `usb_fifo_attach` call failed because the name conflicts with an existing device. The fix is to change the basename or to detach the conflicting

driver first.

- The driver attaches but the first transfer never completes. Usually `usbd_transfer_start` was not called, or the transfer was submitted with a zero-length frame. The fix is to trace through `USB_ST_SETUP` and confirm that `usbd_xfer_set_frame_len` was called before `usbd_transfer_submit`.
- The driver attaches but the kernel panics on unplug. Usually the detach path is missing a `usbd_transfer_unsetup` call or a `usb_fifo_detach` call. The fix is to run the detach sequence under `INVARIANTS` and follow the `WITNESS` output back to the first dropped cleanup.

The troubleshooting section at the end of the chapter develops each of these cases in full, with diagnostic commands and expected output. The goal of this chapter is not to have everything work on the first try; the goal is to have a systematic debugging posture that turns every failure into a teachable moment.

26.3.2 Roadmap Through the Chapter

The sections in order are:

1. **Understanding USB and Serial Device Fundamentals.** The USB mental model at the level needed to write a driver: host and device, hubs and ports, classes, descriptors, transfer types, hot-plug lifecycle. The serial mental model: UART hardware, RS-232 framing, baud rate, parity, flow control, the tty discipline. The FreeBSD-specific split between `uart(4)` and `ucom(4)`. A first exercise with `usbconfig` and `dmesg` that grounds the vocabulary in a device you can see.
2. **Writing a USB Device Driver.** The FreeBSD USB subsystem layout. The Newbus shape of a USB driver. `STRUCT_USB_HOST_ID` and the match table. `DRIVER_MODULE` with `uhub` as the parent. `MODULE_DEPEND` on `usb`. `USB_PNP_HOST_INFO` for auto-load. The probe method using `usbd_lookup_id_by_uaa`. The attach method, the softc layout, the labelled-goto cleanup chain in attach and detach.
3. **Performing USB Data Transfers.** The struct `usb_config` array. `usbd_transfer_setup` and the lifetime of a struct `usb_xfer`. Control, bulk, and interrupt transfer shapes. The `usb_callback_t` state machine and `USB_GET_STATE`. Stall handling with `usbd_xfer_set_stall`. Frame-level operations (`usbd_xfer_set_frame_len`, `usbd_copy_in`, `usbd_copy_out`). Creating a `/dev` entry for the USB device through the `usb_fifo` framework. A worked example that sends bytes down a bulk-out endpoint and reads bytes back from a bulk-in endpoint.
4. **Writing a Serial (UART) Driver.** The `uart(4)` subsystem at the level needed to read a real driver. The `uart_class/uart_ops` split. The method table dispatched through `kobj`. The relationship between `uart_bus_attach` and `uart_tty_attach`. Baud rate, data bits, stop bits, parity, and the `param` method. RTS/CTS hardware flow control. struct `termios` and how it reaches the driver. `/dev/ttyu*` versus `/dev/cuau*` in FreeBSD. The `ucom(4)` framework for USB-to-serial bridges. A guided reading of the `ns8250` driver as a canonical example.
5. **Testing USB and Serial Drivers Without Real Hardware.** `nmdm(4)` virtual null-modem pairs for serial testing. `cu(1)` and `tip(1)` for terminal access. `stty(1)` and `comcontrol(8)` for configuration. QEMU USB device redirection for host-to-guest pass-through. `usb_template(4)` for FreeBSD-as-gadget testing. Software loopback patterns that exercise driver logic without any device at all. A reproducible test harness that runs a regression without human intervention.

After the five sections come a set of hands-on labs, a set of challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 26's story, a bridge to Chapter 27, and a glossary. Read linearly on a first

pass.

26.4 Section 1: Understanding USB and Serial Device Fundamentals

The first section teaches the mental models the rest of the chapter relies on. USB and serial devices share a surprising amount of machinery at the `tty/cdevsw` layer, and at the same time they differ dramatically at the transport layer. A reader who is clear on both the similarities and the differences will find Sections 2 through 5 straightforward. A reader who is not will find the subsequent code confusingly non-obvious. This section is the single best place to spend an extra thirty minutes if you want the rest of the chapter to feel easier.

The section is organised in three arcs. The first arc establishes what a *transport* is, and why transport-specific drivers look different from the pseudo-drivers of Parts 2 through 5. The second arc teaches the USB model: host and device, hubs and ports, classes, descriptors, endpoints, transfer types, and the hot-plug lifecycle. The third arc teaches the serial model: the UART, RS-232 framing, baud rate, parity, flow control, and the FreeBSD-specific split between `uart(4)` and `ucom(4)`. A first exercise at the end grounds the vocabulary in a device you can see with `usbconfig`.

26.4.1 What a Transport Is, and Why It Matters Here

A *transport* is the protocol and the lifecycle by which a device is connected to the rest of the system. Up to this point in the book, the `myfirst` driver has had no transport. Its device existed entirely in the Newbus tree, connected to the nexus through the pseudo parent, and its data flowed into a buffer in kernel memory. That makes `myfirst` a *pseudo-device*: a device whose existence is entirely a software fiction. Pseudo-devices are essential teaching tools. They let the reader learn Newbus, softc management, character device interfaces, `ioctl` handling, locking, and the rest, without also learning the specifics of a bus. By now, those topics are covered.

A transport-specific driver, by contrast, is one that attaches to a *real* bus. The bus has its own rules. It has its own way of saying “a new device has appeared.” It has its own way of delivering data. It has its own way of saying “a device has been removed.” A transport-specific driver is still a Newbus driver (that never changes in FreeBSD), but its parent is no longer the abstract pseudo bus. Its parent is `uhub` if it is a USB driver, `pci` if it is a PCI driver, `acpi` or `fdt` if it is on an embedded platform, and so on. The driver’s attach method receives arguments specific to that bus. Its cleanup responsibilities include bus-specific resources in addition to the ones it already had. Its lifecycle is the bus’s lifecycle, not the module’s lifecycle.

Three broad categories of work distinguish a transport-specific driver from the pseudo-drivers of Parts 2 through 5. They are worth naming explicitly because they recur in every transport chapter in Part 6.

The first is *matching*. A pseudo-driver attaches on module load; there is nothing to match because there is no real device. A transport-specific driver has to declare which devices it handles. On USB, this means a match table of vendor and product identifiers. On PCI, it means a match table of vendor and device identifiers. On ACPI or FDT, it means a match table of string identifiers. The kernel’s bus code enumerates devices as they appear and offers each one to every registered driver in turn; the driver’s probe method decides whether to claim the device. Getting the match table right is the first obstacle every transport-specific driver faces.

The second is *transfer mechanics*. A pseudo-driver’s read and write methods touch a buffer in RAM. A transport-specific driver’s read and write methods have to arrange for data to move across the bus. On USB, this means setting up one or more transfers using `usb_transfer_setup`, submitting them with

`usbd_transfer_submit`, and handling completion in a callback. On PCI, this means programming a DMA engine. On storage, this means translating block requests into bus transactions. The transfer mechanism is bus-specific and is where most of a transport-specific driver's new code lives.

The third is *hot-plug lifecycle*. A pseudo-driver is loaded when the module is loaded and detached when the module is unloaded. That is a simple lifecycle; `kldload` and `kldunload` are the only events it has to respond to. A transport-specific driver has to deal with *hot-plug*: the device can appear and disappear independently of the module's lifecycle. A USB device can be unplugged in the middle of a read. A SATA disk can be yanked out while the filesystem on it is mounted. An Ethernet cable can be pulled while a TCP connection is open. The driver's attach method runs when a device is physically inserted; its detach method runs when a device is physically removed. The detach may happen while the driver is still in use. Handling this correctly is the third big obstacle every transport-specific driver faces.

The rest of Part 6 is about those three categories of work in three different transports. Chapter 26 teaches USB and serial. Chapter 27 teaches storage. Chapter 28 teaches networking. The matching, the transfer mechanics, and the hot-plug lifecycle look different in each transport, but the three-category structure repeats. That structure is what makes it possible to learn one transport well and then learn the next one quickly.

A useful shorthand: in Parts 2 through 5, you learned how to *be* a Newbus driver. In Part 6, you learn how to *attach* to a bus that has its own ideas about when and how you exist.

26.4.2 The USB Mental Model

USB, the Universal Serial Bus, is a tree-structured, host-controlled, hot-pluggable serial bus. Every one of those adjectives matters, and understanding each of them is the foundation of writing a USB driver.

Tree-structured means that USB devices do not sit on a shared wire like devices on an I2C bus or an old ISA bus. Every USB device has exactly one upstream connection, to a parent hub. The root of the tree is the *root hub*, which is exposed by the USB host controller. Downstream of the root hub are other hubs and devices. A hub has a fixed number of downstream ports; each port can either be empty or connect to exactly one device. The tree is rebuilt on boot and updated every time a device is connected or disconnected. On FreeBSD, `usbconfig` shows this tree; on a fresh boot of a typical desktop you will see something like:

```
ugen0.1: <Intel EHCI root HUB> at usb0, cfg=0 md=HOST spd=HIGH
ugen1.1: <AMD OHCI root HUB> at usb1, cfg=0 md=HOST spd=FULL
ugen0.2: <Some Vendor Hub> at usb0, cfg=0 md=HOST spd=HIGH
ugen0.3: <Some Vendor Mouse> at usb0, cfg=0 md=HOST spd=LOW
```

The tree structure matters to a driver author for two reasons. First, it tells you that when you write a USB driver, your driver's *parent* in the Newbus tree is `uhub`. Every USB device sits under a hub. When you write `DRIVER_MODULE(myfirst_usb, uhub, ...)`, you are telling the kernel “my driver attaches to children of `uhub`,” which is the FreeBSD way of saying “my driver attaches to USB devices.” Second, the tree structure means that enumeration is dynamic. The kernel does not know what devices are on the tree until the tree is walked; a driver is offered each device as it appears, and has to decide whether to claim it.

Host-controlled means that one side of the bus is the master, the *host*, and all other sides are slaves, the *devices*. The host initiates every transfer; devices respond. A USB keyboard does not push keystrokes to the host

whenever a key is pressed; the host polls the keyboard on an *interrupt endpoint* many times per second, and the keyboard replies with “no new keys” or “key ‘A’ has been pressed” in response to each poll. This polling-and-response model has important consequences for a driver. Your driver, running on the host, has to initiate every transfer. A device cannot spontaneously send data; it can only respond when the host asks. What looks from user space like “the driver received data” is always, underneath, “the driver had a pending receive transfer and the host controller notified us that the transfer completed.”

For most of this chapter’s purposes, you are writing *host-mode* drivers: drivers that run on the host side. A FreeBSD system can also be configured as a USB *device*, through the `usb_template(4)` subsystem, and present itself as a keyboard or mass storage device or CDC Ethernet interface to another host. Device-mode drivers are a specialised topic touched on only briefly in Section 5 for testing purposes.

Hot-pluggable means that devices can appear and disappear while the system is running, and the subsystem has to cope. The USB host controller notices when a device is plugged in, a hub’s port status registers tell it so, enumerates the new device by asking it for its descriptors, assigns it an address on the bus, and then offers it to any driver whose match table applies. When a device is unplugged, the host controller notices the port status change and tells the subsystem, which in turn calls the driver’s detach method. The detach method may run at any time, including while the driver is holding a transfer that will now never complete, while user space has the driver’s `/dev` node open, or while the system is under load. Writing a correct detach method is the single hardest part of USB driver development. The chapter returns to this repeatedly.

Serial means that USB is a wire-level serial protocol: bytes flow one after another on a differential pair. The speed of the bus has evolved over the years: low-speed (1.5 Mbps), full-speed (12 Mbps), high-speed (480 Mbps), SuperSpeed (5 Gbps), and faster variants above that. From a driver author’s perspective, the speed is mostly transparent: the host controller and the USB core handle the electrical layer and the packet framing, and your driver works at the level of “here is a buffer, please send it” or “here is a buffer, please fill it.” The speed determines how fast data can move, but the driver code is the same.

With those four adjectives in place, the rest of the USB model falls into shape.

26.4.2.1 Device Classes and What They Mean to a Driver

Every USB device belongs to one or more *classes*, and the class tells the host (and the driver) what kind of device it is. Classes are numerical, defined by the USB Implementers Forum, and the values appear in descriptors. The ones a FreeBSD driver author will see most often include:

- **HID (Human Interface Device)**, class 0x03. Keyboards, mice, joysticks, game controllers, and a long tail of programmable devices that pretend to be keyboards or mice. HID devices present reports through interrupt endpoints; FreeBSD’s HID subsystem handles them mostly generically, though a vendor-specific driver can override.
- **Mass Storage**, class 0x08. USB flash drives, external disks, card readers. These attach through `umass(4)` to the CAM storage framework.
- **Communications (CDC)**, class 0x02, with subclasses for ACM (modem-like serial), ECM (Ethernet), NCM (Ethernet with multi-packet aggregation), and others. CDC ACM devices appear through `ucom(4)` as serial ports. CDC ECM and NCM devices appear through `cdce(4)` as network interfaces.
- **Audio**, class 0x01. Microphones, speakers, audio interfaces. FreeBSD’s audio stack handles these through `uaudio(4)`.
- **Printer**, class 0x07. USB printers. Handled through `ulpt(4)`.

- **Hub**, class 0x09. USB hubs themselves. Handled by the core `uhub(4)` driver.
- **Vendor-specific**, class 0xff. Any device whose functionality does not fit a standard class. Almost every interesting hobby USB device (USB-to-serial bridges, thermometers, relay controllers, programmers, loggers) is in this class.

When you write a USB driver, you often write for a vendor-specific device (class 0xff) and match on vendor/product identifiers. Occasionally you write for a standard-class device that FreeBSD does not yet handle, or for a standard-class device that has quirks requiring a dedicated driver. The class is not usually the match criterion; the vendor/product pair is. But the class tells you what framework, if any, you should integrate with. If the device's class is CDC ACM, the right framework is `ucom`. If the class is HID, the right framework is `hidbus` (new in FreeBSD 14). If the class is 0xff, there is no framework; you write a bespoke driver.

26.4.2.2 Descriptors: The Device's Self-Description

When the host enumerates a new USB device, it asks the device to describe itself. The device responds with a hierarchy of *descriptors*. Descriptors are the single most important USB concept to get clear: they are the USB equivalent of the PCI configuration space, but richer and nested.

The hierarchy is:

Device descriptor

Configuration descriptor [1..N]

Interface descriptor [1..M] (optionally with alternate settings)

Endpoint descriptor [0..E]

A *device descriptor* (`struct usb_device_descriptor` in `/usr/src/sys/dev/usb/usb.h`) describes the device as a whole: its vendor identifier (`idVendor`), its product identifier (`idProduct`), its device class, subclass, and protocol, its maximum packet size on endpoint zero, its release number, and the number of configurations it supports. Most devices have one configuration, but the USB spec allows more (a camera that can run in high-bandwidth or low-bandwidth modes, for example).

A *configuration descriptor* (`struct usb_config_descriptor`) describes one mode of operation: the number of interfaces it contains, whether the device is self-powered or bus-powered, its maximum power draw. When a driver selects a configuration (by calling `usbdevreq_set_config`, though in practice the USB core does this for you), the device's endpoints are activated.

An *interface descriptor* (`struct usb_interface_descriptor`) describes one logical function of the device. A composite device, such as a USB printer with a built-in scanner, has one interface per function. Each interface has its own class, subclass, and protocol. A driver can match on interface class rather than device class; this is common when a device's overall class is "Miscellaneous" or "Composite" but one of its interfaces has a specific class. An interface can have multiple *alternate settings*, which select different endpoint layouts; audio streaming interfaces use alternate settings to offer different bandwidths.

An *endpoint descriptor* (`struct usb_endpoint_descriptor`) describes one data channel. Endpoints have:

- An *address*, which is the endpoint number (0 through 15) combined with a direction bit (IN, meaning from device to host, or OUT, meaning from host to device).
- A *type*, which is one of control, bulk, interrupt, or isochronous.

- A *maximum packet size*, which is the largest single packet the endpoint can handle.
- An *interval*, which for interrupt and isochronous endpoints tells the host how often to poll.

Endpoint zero is special: every device has it, it is always a control endpoint, and it is always bidirectional (one IN half and one OUT half). The USB core uses endpoint zero for enumeration (asking the device for descriptors, setting its address, selecting its configuration). A driver can also use endpoint zero for vendor-specific control requests, though drivers usually access it through helper functions rather than setting up a transfer directly.

The descriptor hierarchy matters to a driver because the driver's probe method has access to the descriptors through the struct `usb_attach_arg` it receives, and its match logic often reads fields from them. The struct `usbdev_lookup_info` inside struct `usb_attach_arg` carries the device's identifiers, its class, subclass, and protocol, the current interface's class, subclass, and protocol, and a few other fields. The match table filters on some subset of those; the helper macros `USB_VP(v, p)`, `USB_VPI(v, p, info)`, `USB_IFACE_CLASS(c)`, and similar build entries that match different combinations of fields.

26.4.2.3 The Four Transfer Types

USB defines four transfer types, each suited to a different kind of data movement. A driver picks one or more types for its endpoints, and the choice affects everything about how the driver is structured.

Control transfers are for setup, configuration, and command exchange. Every device supports them on endpoint zero. They have a small, structured format: an eight-byte setup packet (the struct `usb_device_request`) followed by an optional data stage and a status stage. The setup packet specifies what the request is doing: its direction (IN or OUT), its type (standard, class, or vendor), its recipient (device, interface, or endpoint), and four fields (`bRequest`, `wValue`, `wIndex`, `wLength`) whose meaning depends on the request. Standard requests include `GET_DESCRIPTOR`, `SET_CONFIGURATION`, and so on; class and vendor requests are defined by the class specification or the vendor. Control transfers are reliable: the bus protocol guarantees delivery or returns a specific error. They are also relatively slow, because the bus allocates only a small share of its bandwidth to them.

Bulk transfers are for large, reliable, non-time-critical data. A USB flash drive uses bulk transfers for the actual data. A printer uses bulk OUT for the print stream. A USB-to-serial bridge uses bulk IN and bulk OUT for the two directions of the serial stream. Bulk transfers are reliable (errors are retried by the bus hardware), but they have no guaranteed timing: they use whatever bandwidth is left after control, interrupt, and isochronous traffic has been scheduled. In practice, on a lightly-loaded bus, bulk transfers are very fast. On a heavily-loaded bus, they can stall for milliseconds at a time. Bulk endpoints are the most common endpoint type for device-to-host or host-to-device streaming of data where latency is not critical.

Interrupt transfers are for small, time-sensitive data. The name is misleading: there are no hardware interrupts here. The “interrupt” refers to the fact that the device needs to get the host's attention periodically, and the host polls the endpoint at a configurable interval to see whether there is new data. A USB keyboard uses interrupt transfers to deliver keystrokes; a USB mouse uses them for movement reports; a thermometer uses them to deliver periodic readings. Interrupt endpoints have an `interval` field that tells the host how often to poll (in milliseconds for low- and full-speed devices, in microframes for high-speed). A driver that wants to know about input as it happens sets up an interrupt-IN transfer, submits it, and the USB core arranges the polling. When data arrives, the driver's callback fires.

Isochronous transfers are for streaming data with guaranteed bandwidth but no error recovery. USB audio and USB video use isochronous endpoints. The bus reserves a fixed share of each frame for isochronous traffic, so

the bandwidth is predictable, but transfers are not retried on error; if a packet is corrupted, it is lost. This trade-off makes sense for audio and video, where a dropped sample is better than a stall. Isochronous transfers are the most complex to program because they typically operate on many small frames per transfer; the `struct usb_xfer` machinery supports up to thousands of frames per transfer. Chapter 26 introduces isochronous transfers at the conceptual level and does not develop them further; real isochronous drivers (audio, video) are beyond the chapter's scope.

A typical vendor-specific USB device that a hobbyist or a driver-development learner will write code for looks like this: a vendor/product identifier, one vendor-specific interface, one bulk-IN endpoint, one bulk-OUT endpoint, and possibly an interrupt-IN endpoint for status events. That is the shape of the worked example in Sections 2 and 3.

26.4.2.4 The USB Hot-Plug Lifecycle

The hot-plug lifecycle is the sequence of events that happens when a USB device is inserted, in use, and removed. Writing a driver that handles this lifecycle correctly is the most important single discipline in USB driver development.

When a device is inserted, the host controller notices a port status change. It waits for the device to stabilise, then resets the port and assigns the device a temporary address of zero. It sends `GET_DESCRIPTOR` to endpoint zero on address zero, retrieves the device descriptor, and then assigns the device a unique address with `SET_ADDRESS`. All subsequent communication uses the new address. The host sends `GET_DESCRIPTOR` for the full configuration descriptor (including interfaces and endpoints), chooses a configuration, and sends `SET_CONFIGURATION`. At that point the device's endpoints are active and the USB subsystem offers the device to every registered driver in turn by calling each driver's probe method. The first driver to claim the device by returning a non-error code from probe wins; the subsystem then calls that driver's `attach` method.

During normal operation, the driver submits transfers to its endpoints, the host controller schedules them on the bus, and the callbacks fire on completion. This is the steady state Chapter 26's code examples operate in.

When the device is removed, the host controller notices another port status change. It does not wait; the electrical signal is gone immediately. The subsystem cancels any outstanding transfers on the device's endpoints (they complete in the callback with `USB_ERR_CANCELLED`), and then it calls the driver's `detach` method. The `detach` method has to release every resource the `attach` method acquired, including any `/dev` nodes it created, any locks, any buffers, and any transfers. It has to do this in the face of the fact that other threads may be in the middle of calling into the driver through those resources. A read in progress must be woken up and returned with an error. An `ioctl` in progress must be allowed to finish or interrupted. A callback that has just fired with `USB_ERR_CANCELLED` must not try to re-submit.

The hot-plug lifecycle is why USB drivers cannot be written the way pseudo-drivers are written. In a pseudo-driver, the module lifecycle (`kldload/kldunload`) is the only lifecycle; nothing unexpected happens. In a USB driver, the device lifecycle is separate from the module lifecycle and is driven by physical events. A user can unplug the device while a user-space process is blocked in `read()` on the driver's `/dev` node. The driver must wake that process up and return an error. A well-written USB driver treats this as the normal case, not the edge case.

Section 2 will walk through the structure of a USB driver that handles this correctly. For now, keep the lifecycle in mind: probe, attach, steady-state transfers, detach. Every USB driver has that sequence.

26.4.2.5 USB Speeds and What They Imply

USB has gone through several speed generations, and each matters to a driver writer in different ways. Low-speed (1.5 Mbps) was the original USB 1.0 speed, mostly used by keyboards and mice. Full-speed (12 Mbps) was USB 1.1, used by printers, early cameras, and mass-storage devices. High-speed (480 Mbps) was USB 2.0, which became the dominant speed for most devices in the 2000s. SuperSpeed (5 Gbps) was USB 3.0, which added a separate physical layer for high-throughput applications. SuperSpeed+ (10 Gbps and 20 Gbps) came with USB 3.1 and 3.2. USB 4.0 reuses the Thunderbolt physical layer and supports 40 Gbps.

For most driver writing, only three differences between these speeds matter:

Maximum packet size. Low-speed endpoints have a maximum packet size of 8 bytes. Full-speed goes up to 64 bytes. High-speed bulk endpoints go up to 512 bytes. SuperSpeed bulk endpoints go up to 1024 bytes with burst support. Your buffer sizes in the transfer configuration should match the endpoint's speed; using a 512-byte buffer on a full-speed bulk endpoint wastes memory because only 64 bytes fit in each packet.

Isochronous bandwidth. Isochronous transfers reserve bandwidth at a specific speed. A device that asks for 1 MB/s of isochronous bandwidth can only be supported on a host controller that can provide it; on slower hosts, the device must negotiate a lower rate or fail. This is why some USB audio devices work on one port but not another.

Endpoint polling interval. Interrupt endpoints are polled at a specific interval encoded in the descriptor's `bInterval` field. The units are milliseconds at low/full speed and "125 microsecond microframes" at high-/SuperSpeed. The framework handles the math; your driver just declares the logical polling interval via the endpoint descriptor and the framework does the right thing.

For the drivers we write in this chapter (`myfirst_usb` and the UART bridges like FTDI), speed does not affect the code structure. A bulk-IN channel's callback is the same whether it runs at 12 Mbps or 5 Gbps. The differences are in the numbers, not the flow.

26.4.2.6 Endpoints, FIFOs, and Flow Control

A USB endpoint is logically an I/O queue at one end of a pipe. On the device side, an endpoint corresponds to a hardware FIFO in the chip. On the host side, the endpoint is a framework abstraction. Between them, USB packets flow under the control of the USB protocol itself, which handles retransmission, sequencing, and error detection.

The host cannot be told "the device is full" the way you might expect on a traditional serial link. Instead, when a device cannot accept more data (because its FIFO is full), it returns a NAK handshake. NAK means "try again later." The host will keep retrying, at the protocol level, until either the device accepts the data (returns ACK) or some higher-level timeout fires. This is called NAK-limiting or bus throttling, and it happens invisibly to the driver: the framework sees the final ACK and delivers a successful completion.

Similarly, when the device has no data to send (for a bulk-IN or interrupt-IN transfer), it returns NAK to the IN token, and the host polls again. From the driver's perspective, the transfer is simply "pending" until the device has something to say.

This NAK mechanism is how USB handles flow control at the protocol level. Your driver does not need to implement its own throttling logic for bulk and interrupt channels; the USB protocol does it. Where flow control

does come into play is in higher-level protocols, where the device might want to signal a logical end-of-message or a temporary unavailability. Those signals are protocol-specific and not part of USB itself.

26.4.2.7 Descriptors In Depth

USB descriptors are the self-describing mechanism by which a device tells the host what it is and how to talk to it. We introduced them briefly earlier; here is a more complete picture.

The device descriptor is the root. It contains the device's vendor ID, product ID, USB specification version, device class/subclass/protocol (for devices that declare themselves at the device level rather than the interface level), maximum packet size for endpoint zero, and the number of configurations.

Configuration descriptors describe complete configurations. A configuration is a set of interfaces that work together. Most devices have one configuration; some have multiple to support different modes of operation (e.g., a device that can be either a printer or a scanner, selected by configuration).

Interface descriptors describe functional subsets of the device. Each interface has a class, subclass, and protocol that tells the host what kind of driver to use. A multi-function device has multiple interface descriptors in the same configuration. Additionally, an interface can have alternate settings: different sets of endpoints selectable on the fly for things like “low bandwidth mode” vs “high bandwidth mode”.

Endpoint descriptors describe individual endpoints within an interface. Each has an address (with direction bit), a transfer type, a maximum packet size, and an interval (for interrupt and isochronous endpoints).

String descriptors hold human-readable strings: the manufacturer name, the product name, the serial number. These are optional; their presence is indicated by nonzero string indices in the other descriptors.

Class-specific descriptors extend the standard descriptors with class-specific metadata. HID devices have a report descriptor that describes the format of the reports they send. Audio devices have descriptors for audio controls. Mass-storage devices have descriptors for interface subclasses.

The USB framework parses all of this at enumeration time and exposes the parsed data to drivers through the `struct usb_attach_arg`. Your driver does not have to read descriptors itself; it queries the framework for the information it needs. When the chapter says “the interface's `bInterfaceClass`”, what is meant is “the `bInterfaceClass` field of the interface descriptor the framework parsed and cached for us.”

`usbconfig -d ugenN.M dump_all_config_desc` is how you see the parsed descriptors from userland. Run that command on a few devices you own and note how the descriptors look. You will see that even simple devices like a mouse have a nontrivial descriptor tree: typically one device descriptor, one configuration descriptor, one interface descriptor (with `class=HID`), and one or two endpoint descriptors (for the HID report input and maybe an output).

26.4.2.8 Request-Response Over USB

The USB control transfer type supports a request-response pattern between host and device. A control transfer consists of three phases: a setup stage where the host sends an 8-byte setup packet describing the request, an optional data stage where either the host sends data or the device returns data, and a status stage where the recipient acknowledges the operation.

The setup packet has five fields:

- `bmRequestType`: describes the direction (in or out), the type of request (standard, class, or vendor), and the recipient (device, interface, endpoint, or other).
- `bRequest`: the request number. Standard requests have well-known numbers (`GET_DESCRIPTOR` = 6, `SET_ADDRESS` = 5, and so on). Class and vendor requests have class-specific or vendor-specific meanings.
- `wValue`: a 16-bit parameter, often used to specify a descriptor index or a value to set.
- `wIndex`: another 16-bit parameter, often used to specify an interface or endpoint.
- `wLength`: the number of bytes in the data stage (zero if there is no data stage).

Every USB device must support a small set of standard requests: `GET_DESCRIPTOR`, `SET_ADDRESS`, `SET_CONFIGURATION`, and a few others. The framework handles all of these at enumeration time. Your driver may also issue vendor-specific requests to configure the device in ways the standard does not define.

For example, the FTDI driver issues vendor-specific requests like `FTDI_SIO_SET_BAUD_RATE`, `FTDI_SIO_SET_LINE_CTRL`, and `FTDI_SIO_MODEM_CTRL` to program the chip. These requests are documented in FTDI's application notes; they are not part of USB itself, but they work over the USB control-transfer mechanism.

When your driver needs to issue a vendor-specific control request, the pattern is the one we showed in Section 3: construct the setup packet, copy it into frame zero of a control transfer, copy any data into frame one (for data-stage requests), and submit. The framework handles the three phases and calls your callback when the transfer completes.

26.4.3 The Serial Mental Model

The serial side of Chapter 26 is about a much older and much simpler protocol than USB. Serial communication over a UART is one of the oldest ways two computers can talk to each other, and its simplicity is both its strength and its limitation. A reader coming to UART after USB will find the protocol almost trivially small. But the integration with the rest of the operating system, the tty discipline, baud rate management, parity, flow control, and the two-worlds split between `uart(4)` and `ucom(4)`, is where most of the actual work lives.

26.4.3.1 The UART as a Piece of Hardware

A UART is a *Universal Asynchronous Receiver/Transmitter*: a chip that converts bytes into a serial bit stream on a wire and back again. The classical UART has two pins for data (TX and RX), two pins for flow control (RTS and CTS), four pins for modem status (DTR, DSR, DCD, RI), a ground pin, and occasionally a pin for a second “ring” signal that most modern equipment ignores. On a classic PC, the serial port has a nine-pin or twenty-five-pin D-subminiature connector and operates at RS-232 voltage levels (typically +/- 12 V). Modern embedded UARTs usually operate at 3.3 V or 1.8 V logic levels; a level converter chip sits between the UART and the RS-232 connector if a compatible port is needed.

Inside the UART, the core is a shift register. When the driver writes a byte to the UART's transmit register, the UART adds a start bit, shifts the byte out bit by bit at the configured baud rate, adds an optional parity bit, and then adds one or two stop bits. When a receiving UART detects a falling edge (the start bit), it samples the line at the middle of each bit time, assembles the bits into a byte, checks the parity, verifies the stop bit, and then stores the byte in its receive register. If any of those steps fails (the parity does not match, the stop bit is wrong, the framing is off), the UART notes a framing error, a parity error, or a break condition in its status register.

On most modern UARTs, the single receive and transmit registers are backed by small first-in-first-out buffers (FIFOs). The 16550A UART, still the de facto standard, has a 16-byte FIFO on each side. A driver that programs the FIFO with an appropriate “trigger level” can let the hardware buffer incoming bytes and raise an interrupt only when the FIFO passes the trigger level. This is the difference between “one interrupt per byte” (slow) and “one interrupt per trigger level” (fast). The 16550A’s FIFO is a big part of why this chip became the universal PC standard.

The UART’s speed is controlled by a *baud rate divisor*: the UART has an input clock (often 1.8432 MHz on classic PC hardware), and the baud rate is the clock divided by 16 times the divisor. A divisor of 1 with a 1.8432 MHz clock gives 115200 baud. A divisor of 12 gives 9600 baud. The FreeBSD ns8250 driver computes the divisor from the requested baud rate and programs it into the UART’s divisor-latch registers. Section 4 walks through this code.

RS-232 framing is the full protocol: start bit (one), data bits (five, six, seven, or eight), optional parity bit (none, odd, even, mark, or space), stop bit (one or two). A typical modern configuration is “8N1”: eight data bits, no parity, one stop bit. An older configuration sometimes seen on industrial equipment is “7E1”: seven data bits, even parity, one stop bit. The driver programs the UART’s line control register to select the framing; `struct termios` carries the configuration from user space.

26.4.3.2 Flow Control

The UART can transmit faster than the receiver can read if the receiver’s code is slow or is doing other work. *Flow control* is how the receiver tells the transmitter to pause. Two mechanisms exist.

Hardware flow control uses two extra wires: *RTS* (Request To Send) from the receiver, and *CTS* (Clear To Send) from the transmitter’s perspective (it is the wire the other side drives). When the receiver’s buffer is filling up, it deasserts RTS. The transmitter, seeing CTS deasserted, stops transmitting. When the buffer empties, the receiver reasserts RTS, CTS asserts on the other side, and transmission resumes. Hardware flow control is reliable and requires no software overhead on either side; it is the default choice when the hardware supports it.

Software flow control, also called XON/XOFF, uses two in-band bytes: XOFF (traditionally ASCII DC3, 0x13) to pause transmission, and XON (ASCII DC1, 0x11) to resume. The receiver sends XOFF when it is almost full and XON when it has room again. This mechanism works over a three-wire connection (TX, RX, ground) with no extra pins, at the cost of reserving two byte values for control use. If you are sending binary data that may contain 0x11 or 0x13, you cannot use software flow control; hardware flow control is the only option.

FreeBSD’s tty discipline handles software flow control entirely in software, at the line-discipline layer, with no involvement from the UART driver. Hardware flow control is partly in the driver (the driver programs the UART’s automatic RTS/CTS feature if the chip supports it) and partly in the tty layer. A driver author should know which flow control method the tty layer has selected; the `CRTSCTS` flag in `struct termios` signals hardware flow control.

26.4.3.3 /dev/ttyuN and /dev/cuauN: A FreeBSD-Specific Quirk

The FreeBSD tty layer creates two device nodes per serial port. The *callin* node is `/dev/ttyuN` (where N is the port number, 0 for the first port). The *callout* node is `/dev/cuauN`. The distinction is historical, from the days of dial-up modems, and remains useful.

A process opening `/dev/ttyuN` is saying “I want to answer an incoming call”: the open blocks until the modem raises DCD (Data Carrier Detect). Once DCD is up, the open completes. When DCD drops, the open process receives SIGHUP. The node is for incoming connections.

A process opening `/dev/cuauN` is saying “I want to make an outgoing call”: the open succeeds immediately, without blocking on DCD. The process can then dial out or, on non-modem uses, simply talk to the serial port. The node is for outgoing connections, and more generally for any use that does not require modem semantics.

In modern use, when a serial port is connected to something that is not a modem (a microcontroller, a console, a GPS receiver), the right node to open is almost always `/dev/cuau0`. Opening `/dev/ttyu0` on a non-modem port will usually hang, because DCD is never asserted. The distinction is FreeBSD-specific; Linux has no callout nodes and uses `/dev/ttyS0` or `/dev/ttyUSB0` for everything.

The chapter’s labs will use `/dev/cuau0` and the simulated pair `/dev/nmdm0A`/`/dev/nmdm0B` for serial exercises. The callin nodes are not used.

26.4.3.4 Two Worlds: `uart(4)` and `ucom(4)`

FreeBSD separates real UART hardware from USB-to-serial bridges into two distinct subsystems. The separation is not visible from user space (a USB serial adapter and a built-in serial port both appear as tty devices), but it is very visible from inside the kernel, and a driver author must not confuse the two.

`uart(4)` is the subsystem for real UARTs. Its scope includes the built-in serial port on a PC motherboard, PCI serial cards, the PrimeCell PL011 found on ARM embedded boards, the embedded SoC UARTs on i.MX, Marvell, Qualcomm, Broadcom, and Allwinner platforms, and so on. The `uart` subsystem lives in `/usr/src/sys/dev/uart/`. Its core code is in `uart_core.c` and `uart_tty.c`. Its canonical hardware driver is `uart_dev_ns8250.c`. A driver that attaches to a real UART writes a `uart_class` and a small set of `uart_ops`, and the subsystem handles everything else. The `/dev` nodes that `uart(4)` creates are called `ttyu0`, `ttyu1`, and so on (callin) and `cuau0`, `cuau1`, and so on (callout).

`ucom(4)` is the framework for USB-to-serial bridges: FTDI, Prolific, Silicon Labs, WCH, and similar. Its scope is *not* a UART at all; it is a USB device whose endpoints happen to behave like a serial port. The `ucom` framework lives in `/usr/src/sys/dev/usb/serial/`. Its header is `usb_serial.h`. Its body is `usb_serial.c`. A USB-to-serial driver writes USB probe, attach, and detach methods as in any other USB driver, and then registers a `struct ucom_callback` with the framework. The callback has entries for “open”, “close”, “set line parameters”, “start reading”, “stop reading”, “start writing”, and so on. The framework creates the `/dev` node (called `ttyu0`, `ttyu1` for callin, `cuau0`, `cuau1` for callout, note the capital U) and runs the tty discipline on top of the driver’s USB transfers.

The two worlds never mix. `uart(4)` is for hardware that is physically a UART. `ucom(4)` is for USB devices that behave like a UART. A USB-to-serial adapter is a `ucom` driver, not a `uart` driver. A PCI serial card is a `uart` driver (specifically, a shim in `uart_bus_pci.c`), not a `ucom` driver. The user-space interface is similar (both produce `cu*` device nodes), but the kernel code is entirely disjoint.

A historical note that sometimes confuses readers: FreeBSD once had a separate `sio(4)` driver for 16550-family UARTs. `sio(4)` was retired years ago and is not present in FreeBSD 14.3. If you see references to `sio` in older documentation, translate them mentally to `uart(4)`. Do not try to find or extend `sio`; it is gone.

26.4.3.5 What termios Carries, and Where It Goes

`struct termios` is the user-space structure that configures a tty. It has five fields: `c_iflag` (input flags), `c_oflag` (output flags), `c_cflag` (control flags), `c_lflag` (local flags), `c_cc` (control characters), and two speed fields `c_ispeed` and `c_ospeed`. The fields are manipulated with `tcgetattr(3)`, `tcsetattr(3)`, and the shell command `stty(1)`.

A UART driver cares almost exclusively about `c_cflag` and the speed fields. `c_cflag` carries:

- `CSIZE`: the character size (CS5, CS6, CS7, CS8).
- `CSTOPB`: if set, two stop bits; if clear, one.
- `PARENB`: if set, parity is enabled; the type depends on `PARODD`.
- `PARODD`: if set with `PARENB`, odd parity; if clear with `PARENB`, even parity.
- `CRTSCTS`: hardware flow control.
- `CLOCAL`: ignore modem status lines; treat the link as local.
- `CREAD`: enable the receiver.

When user space calls `tcsetattr`, the tty layer checks the request, invokes the driver's `param` method (via the `tsw_param` callback in `ttydevsw`), and the driver translates the `termios` fields into hardware register settings. The `uart_tty.c` bridge code walks through this in full and is the best place to see the translation happen.

`c_iflag`, `c_oflag`, and `c_lflag` are mostly handled by the tty line discipline, not by the driver. They control things like whether the line discipline maps CR to LF, whether echo is enabled, whether canonical mode is active, and so on. A UART driver does not need to know any of that; the tty layer handles it.

26.4.3.6 Flow Control at the Multiple Layers of a TTY

Flow control sounds like a single concept, but in practice there are several independent layers that can each throttle the data flow. Understanding the layers helps debug situations where data is mysteriously not flowing.

The lowest layer is electrical. On a real RS-232 line, flow control signals (RTS, CTS, DTR, DSR) are physical pins on the connector. The remote side's transmitter only sends data when its CTS pin is asserted. The local side asserts the RTS pin to tell the remote it is ready to receive. For this to work, the cable must pass RTS and CTS through correctly, and both ends must have flow control configured consistently.

The next layer is in the UART chip itself. Some 16650 and later UARTs have automatic flow control: if configured, the chip itself monitors CTS and pauses the transmitter without driver involvement. The `CRTSCTS` flag in `c_cflag` enables this.

The next layer is in the UART framework's ring buffers. When the RX ring fills past a high-water mark, the framework deasserts RTS (if flow control is enabled) to tell the remote side to pause. When it drains below a low-water mark, RTS is reasserted.

The next layer is the tty line discipline, which has its own input and output queues. The line discipline can also generate XON/XOFF bytes (0x11 and 0x13) if `IXON` and `IXOFF` are set in `c_iflag`. These are software flow control signals.

The highest layer is the userland program's read loop. If the program is slow at consuming data, bytes accumulate at every layer below it.

When debugging flow-control issues, check each layer. Use `stty -a -f /dev/cuau0` to see what `c_cflag` and `c_iflag` have active. Use `comcontrol /dev/cuau0` to see the current modem signals. Use a multimeter or oscilloscope on the physical signals if you can. Work down the layers until you find the one that is actually blocking the flow.

26.4.3.7 Why Baud Rate Errors Are Insidious

A common class of serial bug is a baud-rate mismatch that almost works. Suppose one side is running at 115200 and the other at 114400 (which is what you get from a slightly-off crystal). Most bytes will come through, but a few will be corrupted. The exact error rate depends on the bit pattern. Long runs of one polarity drift further than alternating patterns.

Even worse, the error rate depends on the byte being sent. ASCII printable characters are in the range 0x20 to 0x7e, where the bits are well-distributed. Non-printable characters like 0xff or 0x00 are more likely to suffer bit errors because they present long runs of one polarity.

If you find your serial driver “mostly works” but drops or corrupts a few bytes out of thousands, suspect a baud-rate mismatch before suspecting a logic bug in your driver. Compare the actual divisor the chip is using against the expected divisor. If they differ, the baud rate is not what you asked for.

The 16550 uses a clock source (usually 1.8432 MHz) divided by a 16-bit divisor to produce 16 times the baud rate. For 115200, the divisor is $(1843200 / (115200 * 16)) = 1$. For 9600, it is 12. For arbitrary rates, the divisor may not be an integer, and the closest integer produces a rounded rate. A rate of 115200 requested from a 24 MHz clock would produce a divisor of $(24000000 / (115200 * 16)) = 13.02$, rounding to 13, giving an actual rate of $(24000000 / (13 * 16)) = 115384$, which is 0.16% off. Standard tolerance for serial communication is 2-3%, so 0.16% is fine.

When you configure a UART for a nonstandard baud rate, check whether the rate can be represented exactly. If not, test with actual data exchange, not just a loopback check.

26.4.3.8 Historical Note on Minor Numbers

Older FreeBSD versions encoded a lot of information into the minor numbers of serial device files. Different minor numbers for the “callin” side vs the “callout” side, for hardware-flow vs software-flow, and for various lock states. This encoding is largely gone in modern FreeBSD; the distinctions are now handled by separate device nodes with different names (`ttyu` vs `cuau`, with suffixes for lock and init states). If you see odd minor-number manipulation in old code, know that modern code does not need it.

26.4.3.9 Wrapping Up Section 1

Section 1 has established the two mental models Chapter 26 depends on. The USB model is a tree-structured, host-controlled, hot-pluggable serial bus with four transfer types, a rich descriptor hierarchy, and a lifecycle in which physical events drive kernel events. The serial model is a simple shift-register hardware protocol with baud rate, parity, stop bits, and optional flow control, integrated into FreeBSD through a subsystem split between `uart(4)` for real UARTs and `ucom(4)` for USB-to-serial bridges, and exposed to user space through the `tty` discipline and device nodes like `/dev/cuau0`.

Before moving on, spend a few minutes with `usbconfig` on a real system. The vocabulary you have just learned is easier to keep straight once you have seen a real USB device's descriptors with your own eyes.

26.4.4 Exercise: Use `usbconfig` and `dmesg` to Explore USB Devices on Your System

This exercise is a short hands-on checkpoint that grounds Section 1's vocabulary in a device you can see. Perform it on your lab VM (or on any FreeBSD 14.3 system with at least one USB device connected). It takes about fifteen minutes.

Step 1. Inventory. Run `usbconfig` with no arguments:

```
$ usbconfig
ugen0.1: <Intel EHCI root HUB> at usb0, cfg=0 md=HOST spd=HIGH (0mA)
ugen0.2: <Generic Storage> at usb0, cfg=0 md=HOST spd=HIGH (500mA)
ugen0.3: <Logitech USB Mouse> at usb0, cfg=0 md=HOST spd=LOW (98mA)
```

The first line is the root hub. Each other line is a device. Read the format: `ugenN.M` where `N` is the bus number and `M` is the device number; the description in angle brackets is the device's string; `cfg` is the active configuration; `md` is the mode (HOST or DEVICE); `spd` is the bus speed (LOW, FULL, HIGH, SUPER); the parenthesised current is the maximum bus-supplied power draw.

Step 2. Dump a device's descriptors. Pick one of the non-root-hub devices and dump its device descriptor:

```
$ usbconfig -d ugen0.2 dump_device_desc

ugen0.2: <Generic Storage> at usb0, cfg=0 md=HOST spd=HIGH (500mA)

bLength = 0x0012
bDescriptorType = 0x0001
bcdUSB = 0x0200
bDeviceClass = 0x0000 <Probed by interface class>
bDeviceSubClass = 0x0000
bDeviceProtocol = 0x0000
bMaxPacketSize0 = 0x0040
idVendor = 0x13fe
idProduct = 0x6300
bcdDevice = 0x0112
iManufacturer = 0x0001 <Generic>
iProduct = 0x0002 <Storage>
iSerialNumber = 0x0003 <0123456789ABCDE>
bNumConfigurations = 0x0001
```

Read each field. Notice that `bDeviceClass` is zero: that is the USB convention for “the class is defined per interface, not at the device level.” For this device, the interface class will be Mass Storage (0x08).

Step 3. Dump the active configuration. Now dump the configuration descriptor, which includes the interfaces and endpoints:

```
$ usbconfig -d ugen0.2 dump_curr_config_desc

ugen0.2: <Generic Storage> at usb0, cfg=0 md=HOST spd=HIGH (500mA)

Configuration index 0

    bLength = 0x0009
    bDescriptorType = 0x0002
    wTotalLength = 0x0020
    bNumInterface = 0x0001
    bConfigurationValue = 0x0001
    iConfiguration = 0x0000 <no string>
    bmAttributes = 0x0080
    bMaxPower = 0x00fa

Interface 0
    bLength = 0x0009
    bDescriptorType = 0x0004
    bInterfaceNumber = 0x0000
    bAlternateSetting = 0x0000
    bNumEndpoints = 0x0002
    bInterfaceClass = 0x0008 <Mass storage>
    bInterfaceSubClass = 0x0006 <SCSI>
    bInterfaceProtocol = 0x0050 <Bulk only>
    iInterface = 0x0000 <no string>

Endpoint 0
    bLength = 0x0007
    bDescriptorType = 0x0005
    bEndpointAddress = 0x0081 <IN>
    bmAttributes = 0x0002 <BULK>
    wMaxPacketSize = 0x0200
    bInterval = 0x0000

Endpoint 1
    bLength = 0x0007
    bDescriptorType = 0x0005
    bEndpointAddress = 0x0002 <OUT>
    bmAttributes = 0x0002 <BULK>
    wMaxPacketSize = 0x0200
    bInterval = 0x0000
```

Every field in Section 1's vocabulary is right there. The interface class is 0x08 (Mass Storage). The subclass is 0x06 (SCSI). The protocol is 0x50 (Bulk-only Transport). There are two endpoints. Endpoint 0 has address

0x81 (the high bit indicates IN direction, the low five bits are the endpoint number, 1). Endpoint 1 has address 0x02 (the high bit is clear, meaning OUT; the endpoint number is 2). Both endpoints are bulk. Both have a maximum packet size of $0x0200 = 512$ bytes. The interval is zero because bulk endpoints do not use it.

Step 4. Match this against dmesg. Run `dmesg | grep -A 3 ugen0.2` (or look at the last boot's output for the matching device). You should see a line like:

```
ugen0.2: <Generic Storage> at usb0
umass0 on uhub0
umass0: <Generic Storage, class 0/0, rev 2.00/1.12, addr 2> on usb0
```

This is the same information, formatted by the kernel's own logging. The driver that attached is `umass`, which is FreeBSD's USB mass storage driver, and it attached to the Mass Storage interface class.

Step 5. Try `usbconfig -d ugen0.3 dump_all_config_desc` on another device. A mouse, a keyboard, or a flash drive will all work. Compare the endpoint types: a mouse has one interrupt-IN endpoint; a flash drive has one bulk-IN and one bulk-OUT; a keyboard has one interrupt-IN. The pattern holds.

If you want a small additional exercise, write down the vendor and product identifiers of one of your devices. In Section 2 you will be asked to put vendor and product identifiers into a match table; using ones you can see now is concrete.

26.4.5 Wrapping Up Section 1

Section 1 has done four things. It established the mental model of a transport: the protocol plus the lifecycle, plus the three broad categories of work (matching, transfer mechanics, hot-plug lifecycle) that a transport-specific driver has to add to its Newbus foundation. It built the USB model: host and device, hubs and ports, classes, descriptors with their nested structure, the four transfer types, and the hot-plug lifecycle. It built the serial model: the UART as a shift register with a baud generator, RS-232 framing, baud rate and parity and stop bits, hardware and software flow control, the FreeBSD-specific callin and callout node distinction, the two-worlds split between `uart(4)` and `ucom(4)`, and the role of `struct termios`. And it anchored the vocabulary in a concrete exercise that reads descriptors off a real USB device with `usbconfig`.

From here, the chapter turns to code. Section 2 builds a USB driver skeleton: probe, attach, detach, match table, registration macros. Section 3 makes that driver do real work by adding transfers. Section 4 turns to the serial side, walks through the `uart(4)` subsystem with a real driver as the guide, and explains where `ucom(4)` fits in. Section 5 brings the material back to the lab and teaches how to test USB and serial drivers without physical hardware. Each section builds on the mental models just established. If a later paragraph refers to a descriptor or a transfer type and the term does not feel immediate, return to Section 1 for a quick refresher before continuing.

26.5 Section 2: Writing a USB Device Driver

26.5.1 Moving from Concepts to Code

Section 1 built a mental picture of USB: a host that talks to devices through a tree of hubs, devices that describe themselves with nested descriptors, four transfer types that cover every conceivable traffic pattern, and a hot-

plug lifecycle that drivers must respect because USB devices appear and disappear at any moment. Section 2 turns those concepts into a real driver skeleton. By the end of this section, you will have a USB driver that compiles, loads, attaches to a matching device, and detaches cleanly when the device is unplugged. It will not yet perform data transfers; that is the job of Section 3. But the scaffolding you build here is the same scaffolding every FreeBSD USB driver uses, from the tiniest notification LED to the most complex mass-storage controller.

The discipline you learned in Chapter 25 carries forward unchanged. Every resource must have an owner. Every successful allocation in `attach` must be paired with an explicit release in `detach`. Every failure path must leave the system in a clean state. The labelled-goto cleanup chain, the `errno`-returning helper functions, the softc-based resource tracking, the rate-limited logging: all of it still applies. What changes is the set of resources you manage. Instead of bus resources allocated through Newbus and a character device created through `make_dev`, you will manage USB transfer objects allocated through the USB stack and, optionally, a `/dev` entry created through the `usb_fifo` framework. The shape of the code stays the same. Only the specific calls change.

This section moves from the outside in. It begins by explaining where a USB driver sits inside the FreeBSD USB subsystem, because placing the driver in its correct environment is a prerequisite for understanding every call that follows. It then covers the match table, which is how a USB driver declares which devices it wants. It walks through `probe` and `attach`, the two halves of the driver's entry point into the world. It covers the softc layout, which is where the driver keeps its per-device state. It presents the cleanup chain, which is how the driver unwinds its own work when `detach` is called. And it ends with the registration macros that bind the driver to the kernel module system.

Along the way, the chapter uses `uled.c` as a recurring reference. That is a real FreeBSD driver, about three hundred lines long, located at `/usr/src/sys/dev/usb/misc/uled.c`. It is short enough to read end to end in a single sitting and rich enough to show every piece of machinery a USB driver needs. If you want to ground every idea in this section against real code, open that file now in another window and keep it open. Every time the chapter references a pattern, you will be able to see the pattern in a working driver.

26.5.2 Where a USB Driver Sits in the FreeBSD Tree

FreeBSD's USB subsystem lives under `/usr/src/sys/dev/usb/`. That directory contains everything from the host controller drivers at the bottom (`controller/ehci.c`, `controller/xhci.c`, and so on) to the class drivers higher up (`net/if_cdce.c`, `wlan/if_rum.c`, `input/ukbd.c`), to serial drivers (`serial/uftdi.c`, `serial/uplcom.c`), to generic framework code (`usb_device.c`, `usb_transfer.c`, `usb_request.c`). When a new driver is added to the tree, it goes into one of these subdirectories according to its role. A driver for a blinking-LED gadget belongs under `misc/`. A driver for a network adapter belongs under `net/`. A driver for a serial adapter belongs under `serial/`. For your own work, you will not add files to `/usr/src/sys/dev/usb/` directly; you will build out-of-tree modules in your own workshop directory, the same way Chapter 25 did. The directory layout matters for reading the source, not for writing it.

Every FreeBSD USB driver sits somewhere in a small vertical stack. At the bottom is the host controller driver, which actually talks to the silicon. Above that is the USB framework, which handles descriptor parsing, device enumeration, transfer scheduling, hub routing, and the generic machinery every device needs. Above the framework are the class drivers, which you will write. A class driver attaches to a USB interface, not to the bus directly. This is the most important architectural point in the chapter.

In the Newbus tree, the attachment relationship looks like this:

```
nexus0
└─ pci0
    └─ ehci0 (or xhci0, depending on the host controller)
        └─ usb0
            └─ uhub0 (the root hub)
                └─ uhub1 (a downstream hub, if present)
                    └─ [class driver]
```

The driver you will write attaches to `uhub`, not to `usb0`, not to `ehci`, and not to `pci`. The USB framework walks the device descriptors, creates a child for each interface, and offers those children to class drivers through the newbus probe mechanism. When your driver's probe routine is called, it is being asked: "here is an interface; is it yours?" The match table in your driver is how you answer that question.

There is one subtle point to absorb. A USB device can expose multiple interfaces simultaneously. A multi-function peripheral (say, a USB audio device with a headset and a microphone on the same silicon) exposes one interface for playback and another for capture. FreeBSD gives each interface its own newbus child, and each child can be claimed by a different driver. This is why USB drivers attach at the interface level: it lets the framework route interfaces independently. Your driver should not assume the device has only one interface. When you write the match table, you write it against a specific interface, identified by its class, subclass, protocol, or by its vendor/product pair plus an optional interface number.

26.5.3 The Match Table: Telling the Kernel Which Devices Are Yours

A USB driver advertises which devices it will accept through an array of `STRUCT_USB_HOST_ID` entries. This is analogous to the PCI match table from Chapter 23, but with USB-specific fields. The authoritative definition lives in `/usr/src/sys/dev/usb/usbdi.h`. Each entry specifies one or more of the following: a vendor ID, a product ID, a device class/subclass/protocol triple, an interface class/subclass/protocol triple, or a manufacturer-defined `bcdDevice` range. You can match broadly (any device that advertises interface class `0x03`, which is HID) or narrowly (the single device with vendor `0x0403` and product `0x6001`, which is an FTDI FT232). Most drivers match narrowly, because most real devices have driver-specific quirks that apply only to particular hardware revisions.

The framework provides convenience macros to build match entries without having to initialize each field by hand. The most common are `USB_VPI(vendor, product, info)` for vendor/product pairs with an optional driver-specific information field, and the more verbose form where you fill in `mf_l`, `pf_l`, `dc_l`, `dcs_l`, `dcp_l`, `ic_l`, `ics_l`, `icpl` flags to indicate which fields are significant. For clarity and maintainability, drivers written today tend to use the compact macros whenever they are applicable.

Here is how `uled.c` declares its match table. The source is in `/usr/src/sys/dev/usb/misc/uled.c`:

```
static const STRUCT_USB_HOST_ID uled_devs[] = {
    {USB_VPI(USB_VENDOR_DREAMCHEEKY, USB_PRODUCT_DREAMCHEEKY_WEBMAIL_NOTIFIER, 0)},
    {USB_VPI(USB_VENDOR_RISO_KAGAKU, USB_PRODUCT_RISO_KAGAKU_WEBMAIL_NOTIFIER, 0)},
};
```

Two entries, each naming a specific vendor/product pair. The third argument to `USB_VPI` is an unsigned integer that the driver can use to distinguish variants at probe time; `uled` sets it to zero because both devices behave the same way. The vendor and product symbolic names resolve to numeric identifiers defined in `/usr/src/sys/dev/usb/usbdevs.h`, which is a large table generated from `/usr/src/sys/dev/usb/usbdevs`. Adding a new match entry for your own development hardware often means adding a line to `usbdevs` and regenerating the header, or bypassing the symbolic names entirely and writing the hexadecimal values directly in the match table.

For your own out-of-tree driver, you do not need to touch `usbdevs` at all. You can write:

```
static const STRUCT_USB_HOST_ID myfirst_usb_devs[] = {
    {USB_VPI(0x16c0, 0x05dc, 0)}, /* VOTI / generic test VID/PID */
};
```

The numeric form is perfectly acceptable. Use it when you are prototyping against a specific device and do not yet want to propose additions to the upstream `usbdevs` file.

One important detail about match tables: the `STRUCT_USB_HOST_ID` type includes a flag byte that records which fields are meaningful. When you use `USB_VPI`, the macro fills in those flags for you. If you hand-build an entry with literal braces, you must also fill in the flags yourself, because a zero flag byte means “match anything,” and you rarely want that. Prefer the macros.

The match table is plain data. It does not allocate memory, it does not touch hardware, and it does not depend on any per-device state. It is loaded into the kernel along with the module and used by the framework every time a new USB device is enumerated.

26.5.4 The probe Method

The USB framework calls a driver’s probe method once per interface when a matching-like candidate is presented. The goal of probe is to answer a single question: “Should this driver attach to this interface?” The method must not touch hardware. It must not allocate resources. It must not sleep. All it does is look at the USB attach argument, compare it against the match table, and return either a bus-probe value (indicating a match, with an associated priority) or `ENXIO` (indicating that this driver does not want this interface).

The attach argument lives in a structure called `struct usb_attach_arg`, defined in `/usr/src/sys/dev/usb/usbdi.h`. It carries the vendor ID, the product ID, the device descriptor, the interface descriptor, and a handful of helper fields. Newbus lets a driver retrieve it through `device_get_ivars(dev)`. For USB drivers, the framework provides a wrapper called `usb_lookup_id_by_uaa` that takes a match table and an attach argument and returns zero on a match or a nonzero `errno` on a miss. This wrapper encapsulates every case the driver needs to handle: vendor/product matching, class/subclass/protocol matching, the flag-byte logic, and the interface-level dispatch.

A complete probe method for our running example looks like this:

```
static int
myfirst_usb_probe(device_t dev)
{
```

```
struct usb_attach_arg *uaa = device_get_ivars(dev);

if (uaa->usb_mode != USB_MODE_HOST)
    return (ENXIO);

if (uaa->info.bConfigIndex != 0)
    return (ENXIO);

if (uaa->info.bInterfaceIndex != 0)
    return (ENXIO);

return (usbd_lookup_id_by_uaa(myfirst_usb_devs,
    sizeof(myfirst_usb_devs), uaa));
}
```

The three guard clauses at the top of the function are worth explaining in detail, because they reflect standard USB-driver hygiene.

The first guard rejects the case where the USB stack is acting as a device rather than a host. FreeBSD's USB stack can operate in USB-on-the-Go device mode, where the machine itself appears as a USB peripheral to some other host. Most drivers are host-side drivers and have no meaningful behavior in device mode, so they reject it immediately.

The second guard rejects configurations other than index zero. USB devices can expose multiple configurations, and a driver usually targets one specific configuration. Restricting probe to configuration index zero keeps the logic simple for the common case.

The third guard rejects interfaces other than index zero. If the device has multiple interfaces and you are writing a driver for the first one, this clause is what ensures the framework does not offer you the other interfaces by mistake.

After the guards, the call to `usbd_lookup_id_by_uaa` does the real matching work. If the device's vendor, product, class, subclass, or protocol matches any entry in the table, the function returns zero, and the probe method returns zero, which the USB framework interprets as "this driver wants this device." Returning `ENXIO` tells the framework to try another candidate driver. If no candidate wants the device, it ends up attached to `ugen`, the generic USB driver, which exposes raw descriptors and transfers through `/dev/ugenN.M` nodes but provides no device-specific behavior.

A subtle point worth noting: `probe` returns zero for a match rather than a positive bus-probe value. Other FreeBSD bus frameworks use positive values like `BUS_PROBE_DEFAULT` to indicate a priority, but for USB the convention is zero for match and a nonzero `errno` for non-match. The framework handles priority through the dispatch order rather than through probe return values.

26.5.5 The attach Method

Once `probe` reports a match, the framework calls `attach`. This is where the driver does real work: allocate its `softc`, record the parent device pointer, lock the interface, set up transfer channels (covered in Section 3),

create a /dev entry if the driver is user-facing, and log a short informational message. Every allocation and registration in attach has to be paired with a symmetric release in detach, and because any step can fail, the function must have a clear cleanup path from every failure point.

A minimal attach method looks like this:

```
static int
myfirst_usb_attach(device_t dev)
{
    struct usb_attach_arg *uaa = device_get_ivars(dev);
    struct myfirst_usb_softc *sc = device_get_softc(dev);
    int error;

    device_set_usb_desc(dev);

    mtx_init(&sc->sc_mtx, "myfirst_usb", NULL, MTX_DEF);

    sc->sc_udev = uaa->device;
    sc->sc_iface_index = uaa->info.bIfaceIndex;

    error = usbd_transfer_setup(uaa->device, &sc->sc_iface_index,
        sc->sc_xfer, myfirst_usb_config, MYFIRST_USB_N_XFER,
        sc, &sc->sc_mtx);
    if (error != 0) {
        device_printf(dev, "usbd_transfer_setup failed: %d\n", error);
        goto fail_mtx;
    }

    sc->sc_dev = make_dev(&myfirst_usb_cdevsw, device_get_unit(dev),
        UID_ROOT, GID_WHEEL, 0644, "myfirst_usb%d", device_get_unit(dev));
    if (sc->sc_dev == NULL) {
        device_printf(dev, "make_dev failed\n");
        error = ENOMEM;
        goto fail_xfer;
    }
    sc->sc_dev->si_drv1 = sc;

    device_printf(dev, "attached\n");
    return (0);

fail_xfer:
    usbd_transfer_unsetup(sc->sc_xfer, MYFIRST_USB_N_XFER);
fail_mtx:
    mtx_destroy(&sc->sc_mtx);
    return (error);
}
```

```
}

```

Read through this function top to bottom. Each block does one thing.

The call to `device_set_usb_desc` fills in the Newbus device description string from the USB descriptors. After this call, `device_printf` messages will include the manufacturer and product strings read from the device itself, which makes logs much more informative.

The call to `mtx_init` creates a mutex that will protect the per-device state. Every USB transfer callback runs under this mutex (the framework takes it for you around the callback), so everything the callback touches must be serialised by it. Chapter 25 introduced mutexes; the usage here is the same.

The two `sc->sc_` assignments cache two pointers that the rest of the driver will need. `sc->sc_udev` is the `struct usb_device *` that the driver uses when issuing USB requests. `sc->sc_iface_index` identifies the interface index this driver attached to, so later transfer-setup calls target the right interface.

The call to `usbd_transfer_setup` is the biggest single operation in `attach`. It allocates and configures all the transfer objects the driver will use, based on a configuration array (`myfirst_usb_config`) that Section 3 will examine in detail. If this call fails, the driver has not yet allocated anything except the mutex, so the cleanup path goes to `fail_mtx` and destroys the mutex.

The call to `make_dev` creates the user-visible `/dev` node. The Chapter 25 pattern applies here: set `si_drv1` on the `cdev` so that the `cdevsw` handlers can retrieve the `softc` through `dev->si_drv1`. If this call fails, the cleanup path goes to `fail_xfer`, which also runs the `unsetup` for the transfers before destroying the mutex.

The return (0) on the happy path is the contract with the framework: a zero return means the device is attached and the driver is ready.

The two labels at the bottom implement the labelled-goto cleanup chain from Chapter 25. Each label corresponds to the state the driver has reached at the time the failure happened, and the cleanup fall-through runs exactly the teardown steps needed to undo the work done so far. When you read a FreeBSD driver and see this pattern, you are looking at the same discipline you practised in Chapter 25 applied to a new set of resources.

One important detail about the USB framework that Chapter 25 did not need to cover: if you look at `uled.c` or any other real USB driver, you will sometimes see `usbd_transfer_setup` accept a pointer to the interface index rather than an integer. The framework can modify that pointer in the case of virtual or multiplexed interfaces; pass it by address, not by value. The skeleton above does this correctly.

26.5.6 The Softc: Per-Device State

A USB driver's `softc` is a plain C structure stored as the Newbus driver data for each attached device. It is allocated automatically by the framework based on the size declared in the driver descriptor, and it is the place where all per-device mutable state lives. For our running example, the `softc` looks like this:

```
struct myfirst_usb_softc {
    struct usb_device *sc_udev;
    struct mtx        sc_mtx;
    struct usb_xfer    *sc_xfer[MYFIRST_USB_N_XFER];
    struct cdev        *sc_dev;
};

```

```
uint8_t      sc_iface_index;
uint8_t      sc_flags;
#define MYFIRST_USB_FLAG_OPEN      0x01
#define MYFIRST_USB_FLAG_DETACHING 0x02
};
```

Let us walk through each member.

`sc_udev` is the opaque pointer the USB framework uses to identify the device. Every USB call that acts on the device takes this pointer.

`sc_mtx` is the per-device mutex that protects the softc itself and any shared state the driver cares about. The mutex must be acquired before touching any field that a transfer callback might also touch, and the transfer callback always runs with this mutex held (the framework handles the locking for you when it invokes the callback).

`sc_xfer[]` is an array of transfer objects, one per channel the driver uses. Its size is a compile-time constant. Section 3 will discuss how each entry in this array is set up by the configuration array passed to `usbd_transfer_setup`.

`sc_dev` is the character device entry, if the driver exposes a user-facing node. For drivers that do not expose a `/dev` node (some drivers only export data through `sysctl` or `devctl` events), this field can be omitted.

`sc_iface_index` records which interface on the USB device this driver attached to. It is used by transfer setup and, in multi-interface drivers, as a discriminator in logging.

`sc_flags` is a bit vector for driver-private state. Two flags are declared here: `MYFIRST_USB_FLAG_OPEN` is set while a userland process holds the device open, and `MYFIRST_USB_FLAG_DETACHING` is set at the start of detach so that any concurrent I/O path can see that it must abort quickly. This is an application of a standard pattern: setting a flag under the mutex at the start of detach, so anyone else who wakes up sees it and bails out.

Real drivers often have many more fields: per-transfer buffers, request queues, callback-to-callback state machines, timers, and so on. You add to the softc as the driver grows. The guiding principle is that any state that persists between function calls, and is not global to the module, belongs in the softc.

26.5.7 The detach Method

When a device is unplugged, when the module is unloaded, or when userspace uses `devctl detach`, the framework calls the driver's detach method. The driver's job is to release every resource it allocated in `attach`, cancel any in-flight work, make sure no callback is running, and return zero. If `detach` returns an error, the framework treats the device as still attached, which can create problems if the hardware has already physically vanished. Most drivers return zero unconditionally, or only return an error in very specific "device busy" cases where the driver implements its own reference counting for userspace handles.

The detach method for our running example is the symmetric cleanup of the attach method:

```
static int
myfirst_usb_detach(device_t dev)
{
    struct myfirst_usb_softc *sc = device_get_softc(dev);

    mtx_lock(&sc->sc_mtx);
    sc->sc_flags |= MYFIRST_USB_FLAG_DETACHING;
    mtx_unlock(&sc->sc_mtx);

    if (sc->sc_dev != NULL) {
        destroy_dev(sc->sc_dev);
        sc->sc_dev = NULL;
    }

    usbd_transfer_unsetup(sc->sc_xfer, MYFIRST_USB_N_XFER);

    mtx_destroy(&sc->sc_mtx);

    return (0);
}
```

The first block sets the detaching flag under the mutex. If another thread is about to take the mutex and start a new transfer, it will see the flag and refuse. The `destroy_dev` call removes the `/dev` entry; after it returns, no new open calls can arrive. The `usbd_transfer_unsetup` call cancels any in-flight transfers and waits for their callbacks to complete; after it returns, no transfer callback can still be running. With no new openers and no running callbacks, it is safe to destroy the mutex.

There is a subtlety here that new kernel programmers sometimes stumble over: the order matters. Destroying the `/dev` entry before unwinding the transfers ensures that no new user operation can start, but it does not stop the transfers that were already running when detach was called. That is `usbd_transfer_unsetup`'s job. Both steps are necessary, and the order (cdev first, then transfers, then mutex) is the right one because each later step depends on no new work arriving during it.

One further point about detach and concurrency. The framework guarantees that no probe, attach, or detach runs concurrently with another probe, attach, or detach on the same device. But transfer callbacks run on their own path, and they can be in progress at the exact moment detach is called. The combination of the detaching flag and `usbd_transfer_unsetup` is what makes this safe. If you add new resources to your driver, you must add symmetric cleanup that accounts for this concurrency.

26.5.8 Registration Macros

Every FreeBSD driver needs to register itself with the kernel so that the kernel knows when to call its probe, attach, and detach routines. USB drivers use a small set of macros that bind everything together into a kernel module. The macros go at the bottom of the driver file and look intimidating at first but are entirely mechanical once you know what each line does.

```
static device_method_t myfirst_usb_methods[] = {
    DEVMETHOD(device_probe, myfirst_usb_probe),
    DEVMETHOD(device_attach, myfirst_usb_attach),
    DEVMETHOD(device_detach, myfirst_usb_detach),
    DEVMETHOD_END
};

static driver_t myfirst_usb_driver = {
    .name      = "myfirst_usb",
    .methods   = myfirst_usb_methods,
    .size      = sizeof(struct myfirst_usb_softc),
};

DRIVER_MODULE(myfirst_usb, uhub, myfirst_usb_driver, NULL, NULL);
MODULE_DEPEND(myfirst_usb, usb, 1, 1, 1);
MODULE_VERSION(myfirst_usb, 1);
USB_PNP_HOST_INFO(myfirst_usb_devs);
```

Let us read each block.

The `device_method_t` array lists the methods the driver supplies. For a USB driver that does not implement extra newbus children, the three entries shown are sufficient: `probe`, `attach`, `detach`. More complex drivers might add `device_suspend`, `device_resume`, or `device_shutdown`, but for the vast majority of USB drivers the three basic entries are all that is needed. `DEVMETHOD_END` terminates the array; the framework requires it.

The `driver_t` structure binds the methods array to a human-readable name and declares the `softc` size. The name is used in kernel logs and by `devctl`. The `softc` size tells Newbus how much memory to allocate per device.

The `DRIVER_MODULE` macro registers the driver with the kernel. The arguments are, in order: the module name, the parent bus name (always `uhub` for USB class drivers), the driver structure, and two optional hooks for events. The event hooks are rarely needed and are usually `NULL`.

The `MODULE_DEPEND` macro declares that this module needs `usb` to be loaded first. The three numbers are the minimum, preferred, and maximum compatible versions of the `usb` module. For most drivers, `1, 1, 1` is correct: the USB framework has versioned its interface at 1 for a long time, and it would be unusual to require anything else.

The `MODULE_VERSION` macro declares this module's own version number. Other modules that want to depend on `myfirst_usb` would reference the number you declare here.

The `USB_PNP_HOST_INFO` macro is the last piece. It exports the match table into a format the `devd(8)` daemon can read, so that when a matching USB device is plugged in, userspace can auto-load the module. This macro is a relatively recent addition to FreeBSD; older drivers may not have it. Including it is strongly recommended for any driver that wants to participate in FreeBSD's USB plug-and-play system.

Together, these five declarations turn your driver file into a loadable kernel module. Once the file is compiled with a `Makefile` that uses `bsd.kmod.mk`, running `kldload myfirst_usb.ko` will bind the driver to the kernel, and any matching device plugged in afterwards will trigger your `probe` and `attach` routines.

26.5.9 The Hot-Plug Lifecycle, Revisited in Code

Section 1 introduced the hot-plug lifecycle at the level of mental model: a device appears, the framework enumerates it, your driver attaches, userland interacts with it, the device disappears, the framework calls detach, your driver cleans up. With the code in front of you, that narrative now has a concrete sequence:

1. The user plugs in a matching device.
2. The USB framework enumerates the device, reads all its descriptors, and decides which interfaces to offer to which drivers.
3. For each interface that matches your driver's match table, the framework creates a Newbus child and calls your probe method.
4. Your probe method returns zero.
5. The framework calls your attach method. You initialise the softc, set up transfers, create the /dev node, and return zero.
6. Userland opens the /dev node and begins issuing I/O. The transfer callbacks from Section 3 start running.
7. The user unplugs the device.
8. The framework calls your detach method. You set the detaching flag, destroy the /dev node, call `usbd_transfer_unsetup` to cancel all in-flight transfers and wait for callbacks to finish, destroy the mutex, and return zero.
9. The framework deallocates the softc and removes the Newbus child.

At every step, the framework handles the parts you do not have to write yourself. Your responsibility is narrow: react correctly to probe, attach, and detach, and run transfer callbacks that respect the state machine. The machinery around you handles enumeration, bus arbitration, transfer scheduling, hub routing, and the dozens of corner cases that USB layer imposes.

The lifecycle has one more subtle quirk that is worth naming. Between the user unplugging the device and the framework calling detach, there is a brief window in which any in-flight transfer sees a special error: `USB_ERR_CANCELLED`. The transfer framework itself generates this error when it tears down the transfers in response to the disconnect. Section 3 will explain how to handle this error in the callback state machine. For now, know that it exists and that it is the driver's normal signal that the device is going away.

26.5.10 Wrapping Up Section 2

Section 2 has given you a complete USB driver skeleton. The skeleton does not yet move data; that is Section 3's topic. But every other part of the driver is in place: the match table, the probe method, the attach method, the softc, the detach method, and the registration macros. You have seen how the USB framework routes a newly enumerated device through your probe routine, how your attach routine takes ownership and sets up state, how the driver integrates with Newbus through `device_get_ivars` and `device_get_softc`, and how the detach routine walks the allocation steps in reverse to leave the system clean.

Two themes from Chapter 25 have extended naturally into USB territory. First, the labelled-goto cleanup chain. Every resource you acquire has its own label, and every failure path falls through exactly the right sequence of teardown calls. When you compare `myfirst_usb_attach` above with the attach functions in `uled.c`, `ugold.c`, or `uftdi.c`, you will see the same pattern repeated. Second, the discipline of single-source-of-truth state in the softc. Every field has one owner, one lifecycle, and one clear place where it is initialised and destroyed. These habits are what make a driver readable, portable, and maintainable.

Section 3 will now give this skeleton a voice. Transfer channels will be declared in a configuration array. The USB framework will allocate the underlying buffers and schedule the transactions. A callback will wake up each time a transfer completes or needs more data, and it will use a three-state state machine to decide what to do. The same discipline you just learned will apply, but the new concern is the data pipeline itself: how bytes move between the driver and the device.

26.5.11 Reading `uled.c` As a Complete Example

Before moving into transfers, it is worth pausing to read the canonical small-driver example end to end. The file `/usr/src/sys/dev/usb/misc/uled.c` is approximately three hundred lines of C that implements a driver for the Dream Cheeky and Riso Kagaku USB webmail notifier LEDs: small USB gadgets with three coloured LEDs that a host program can light up. The driver is short enough to hold in your head, self-contained, and it exercises every pattern we have discussed.

When you open the file, the first block you encounter is the standard set of header includes. A USB driver pulls in headers from several layers: `sys/param.h`, `sys/systm.h`, `sys/bus.h` for the fundamentals; `sys/module.h` for `MODULE_VERSION` and `MODULE_DEPEND`; the USB headers under `dev/usb/` for the framework; and `usbdevs.h` for the symbolic vendor and product constants. Note that `usbdevs.h` is not a hand-maintained header: it is build-generated from the text file `/usr/src/sys/dev/usb/usbdevs` when the kernel or module is compiled, so the constants it exposes reflect whatever entries the in-tree `usbdevs` file currently lists. `uled.c` also pulls in `sys/conf.h` and friends because it creates a character device.

The second block is the `softc` declaration. `uled` keeps its state in a structure that has the device pointer, a mutex, an array of two transfer pointers (one for control, one for data), a character device pointer, a callback state pointer, and a small “color” byte that records the current LED colour. The `softc` is straightforward: every field is private, every allocation has one place where it is made and one place where it is freed.

The third block is the match table. `uled` supports two vendors (Dream Cheeky and Riso Kagaku) with one product ID each. The `USB_VPI` macro fills in the flag byte for a vendor-plus-product match. The table is two entries, flat and simple.

The fourth block is the transfer configuration array. `uled` declares two channels: a control-out channel used to send `SET_REPORT` requests to the device (which is how the LED colour is actually programmed), and an interrupt-in channel that reads status packets from the LED. The control channel has `type = UE_CONTROL` and a buffer size big enough to hold the setup packet plus the payload. The interrupt channel has `type = UE_INTERRUPT`, `direction = UE_DIR_IN`, and a buffer size that matches the LED’s report size.

The fifth block is the callback functions. The control callback follows the three-state machine you saw in Section 3: in `USB_ST_SETUP`, it constructs a setup packet and an eight-byte HID report payload, submits the transfer, and returns. In `USB_ST_TRANSFERRED`, it wakes any userland writer that was waiting for the colour change to complete. In the default case (errors), it handles cancellation gracefully and retries on other errors.

The interrupt callback is similar but without the setup-packet complication. It reads an eight-byte status report, checks whether it indicates a button press (the Riso Kagaku devices have an optional button), and rearms.

The sixth block is the character-device methods. `uled` exposes a `/dev/uled0` entry that accepts `write(2)` calls with a three-byte payload (red, green, blue). The `d_write` handler copies the three bytes into the `softc`, starts the control transfer, and returns. When the transfer completes, the colour is actually programmed. The `d_read` handler is not implemented (LEDs do not have meaningful state to read), so reads return zero.

The seventh block is the Newbus methods: `probe`, `attach`, `detach`. The `probe` uses `usbd_lookup_id_by_uaa` exactly as shown in Section 2. The `attach` calls `device_set_usb_desc`, initialises the mutex, calls `usbd_transfer_setup` with the configuration array, and creates the character device. The `detach` runs these in reverse.

The eighth block is the registration macros. `DRIVER_MODULE(uled, uhub, ...)`, `MODULE_DEPEND(uled, usb, 1, 1, 1)`, `MODULE_VERSION(uled, 1)`, and `USB_PNP_HOST_INFO(uled_devs)`. Exactly the sequence you learned.

Reading through `uled.c` with the Section 2 vocabulary in hand, the whole file legibly maps onto the patterns you now understand. Every structural choice the driver makes has a name. Every line of code is an instance of a general pattern. This is the kind of clarity that makes FreeBSD drivers readable.

Before continuing to Section 3, we recommend you actually open `uled.c` now and read it. Even if some lines are still obscure, the overall structure will match the mental model you have built. The details will make more sense as you progress through the rest of the chapter, and revisiting this file after finishing the chapter is an excellent way to consolidate the material.

26.6 Section 3: Performing USB Data Transfers

26.6.1 The Transfer Configuration Array

A USB driver declares its transfers up front, at compile time, through a small array of `struct usb_config` entries. Each entry describes one transfer channel: its type (control, bulk, interrupt, or isochronous), its direction (in or out), which endpoint it targets, how big its buffer is, which flags apply, and which callback function to invoke when the transfer completes. The framework reads this array once, during `attach`, when the driver calls `usbd_transfer_setup`. From that point on, each channel behaves like a small state machine that the driver drives through its callback.

The configuration array is declarative. You are not programming the sequence of hardware operations; you are telling the framework what channels your driver will use, and the framework builds the infrastructure to support them. This is an effective abstraction, and it is one of the reasons USB drivers in FreeBSD are usually much shorter than equivalent drivers for buses like PCI that demand direct register manipulation.

For our running example, we will declare three channels. A bulk-IN channel for reading data from the device, a bulk-OUT channel for writing data to the device, and an interrupt-IN channel for receiving asynchronous status events. A real driver for a serial adapter or an LED notifier might use one or two of these; we use three to show the pattern applied to different transfer types.

```
enum {
    MYFIRST_USB_BULK_DT_RD,
    MYFIRST_USB_BULK_DT_WR,
    MYFIRST_USB_INTR_DT_RD,
    MYFIRST_USB_N_XFER,
};

static const struct usb_config myfirst_usb_config[MYFIRST_USB_N_XFER] = {
```

```

[MYFIRST_USB_BULK_DT_RD] = {
    .type      = UE_BULK,
    .endpoint  = UE_ADDR_ANY,
    .direction = UE_DIR_IN,
    .bufsize   = 512,
    .flags     = { .pipe_bof = 1, .short_xfer_ok = 1 },
    .callback  = &myfirst_usb_bulk_read_callback,
},
[MYFIRST_USB_BULK_DT_WR] = {
    .type      = UE_BULK,
    .endpoint  = UE_ADDR_ANY,
    .direction = UE_DIR_OUT,
    .bufsize   = 512,
    .flags     = { .pipe_bof = 1, .force_short_xfer = 0 },
    .callback  = &myfirst_usb_bulk_write_callback,
    .timeout   = 5000,
},
[MYFIRST_USB_INTR_DT_RD] = {
    .type      = UE_INTERRUPT,
    .endpoint  = UE_ADDR_ANY,
    .direction = UE_DIR_IN,
    .bufsize   = 16,
    .flags     = { .pipe_bof = 1, .short_xfer_ok = 1 },
    .callback  = &myfirst_usb_intr_callback,
},
};

```

The enumeration at the top gives each channel a name and defines `MYFIRST_USB_N_XFER` as the total count. This is a common idiom; it keeps the channels symbolically accessible and makes it easy to add a new channel later. `MYFIRST_USB_N_XFER` is what you pass to `usbd_transfer_setup`, to `usbd_transfer_unsetup`, and to the softc's `sc_xfer[]` array declaration.

The array itself uses designated initialisers, which keeps the assignment of each channel to its enumeration index explicit. Let us walk through the fields.

`type` is one of `UE_CONTROL`, `UE_BULK`, `UE_INTERRUPT`, or `UE_ISOCHRONOUS`, from `/usr/src/sys/dev/usb/usb.h`. It has to match the endpoint's type as declared in the USB descriptors. If you say `UE_BULK` but the device has an interrupt endpoint, `usbd_transfer_setup` will fail.

`endpoint` identifies the endpoint number, but in most drivers the special value `UE_ADDR_ANY` is used, which tells the framework to pick any endpoint whose type and direction match. This works because most USB interfaces have only one endpoint of each (type, direction) pair, so “any” is unambiguous. A device with multiple bulk-in endpoints would require explicit endpoint addresses.

`direction` is `UE_DIR_IN` or `UE_DIR_OUT`. Again, this must match the descriptors.

`bufsize` is the size of the buffer the framework allocates for this channel. For bulk transfers, 512 bytes is a common choice because that is the maximum packet size for high-speed bulk endpoints, so a single 512-byte

buffer can hold exactly one packet. Larger buffers are supported, but for most purposes 512 or a small multiple is correct. For interrupt endpoints, the buffer can be smaller because interrupt packets are typically eight, sixteen, or sixty-four bytes.

flags is a bitfield struct (each flag is a one-bit integer). The flags affect how the framework handles short transfers, stalls, timeouts, and pipe behaviour.

- `pipe_bof` (pipe blocked on failure): if the transfer fails, block further transfers on the same pipe until the driver explicitly restarts it. This is usually set for both read and write endpoints.
- `short_xfer_ok`: for incoming transfers, treat a transfer that completed with less data than requested as success rather than error. Setting this is what allows a bulk-IN channel to read responses of variable length from a device.
- `force_short_xfer`: for outgoing transfers, finish the transfer with a short packet even when the data is aligned to a full packet boundary. This is used by some protocols to signal the end of a message.
- Several other flags control more advanced behaviour; for most drivers, `pipe_bof` plus `short_xfer_ok` (on reads) plus possibly `force_short_xfer` (on writes, protocol-dependent) is all that is needed.

callback is the function the framework calls whenever this channel needs attention. The callback is a `usb_callback_t`, which takes a pointer to the struct `usb_xfer` and returns void. All of the channel's state-machine logic lives inside the callback.

timeout (in milliseconds) sets an upper bound on how long a transfer can wait before being forcibly completed with an error. Setting a timeout is useful for write channels, because it prevents a hung device from stalling the driver indefinitely. For read channels, leaving the timeout at zero (meaning "no timeout") is common, because reads are often expected to block waiting for the device to have something to say.

This array, combined with `usbd_transfer_setup`, is all the driver needs to declare its data pipeline. The framework allocates the underlying DMA buffers, sets up the scheduling, and watches the pipes. The driver never has to call into a register or schedule a transaction by hand. It just writes callbacks.

26.6.2 Setting Up and Tearing Down Transfers

In the attach method shown in Section 2, the call to `usbd_transfer_setup` creates the channels from the configuration array:

```
error = usbd_transfer_setup(uaa->device, &sc->sc_iface_index,
    sc->sc_xfer, myfirst_usb_config, MYFIRST_USB_N_XFER,
    sc, &sc->sc_mtx);
```

The arguments are, in order: the USB device pointer, a pointer to the interface index (the framework can update it in certain multi-interface scenarios), the destination array for the created transfer objects, the configuration array, the number of channels, the softc pointer (which is passed into callbacks via `usb_xfer_softc`), and the mutex the framework will hold around each callback.

If this call succeeds, `sc->sc_xfer[]` is populated with pointers to struct `usb_xfer` objects. Each object encapsulates a channel's state. From this point, the driver can submit a transfer on a channel with `usbd_transfer_submit(sc->sc_xfer[i])`, and the framework will, in the fullness of time, call the corresponding callback.

The symmetric teardown, shown in the detach method, is `usbd_transfer_unsetup`:

```
usbd_transfer_unsetup(sc->sc_xfer, MYFIRST_USB_N_XFER);
```

This call does three things, in order. It cancels any in-flight transfer on each channel. It waits for the corresponding callback to run with `USB_ST_ERROR` or `USB_ST_CANCELLED`, so the driver has a chance to clean up any per-transfer state. It frees the framework's internal state for the channel. After `usbd_transfer_unsetup` returns, the `sc_xfer[]` entries are no longer valid, and the associated callback will not be invoked again.

This is the piece of machinery that makes detach safe in the presence of ongoing I/O. You do not need to implement your own “wait for outstanding transfers” logic. The framework provides it, atomically, through this single call.

26.6.3 The Callback State Machine

Every transfer callback follows the same three-state state machine. When the framework invokes the callback, you ask `USB_GET_STATE(xfer)` for the current state, and then you handle it. The three possible states are declared in `/usr/src/sys/dev/usb/usbd.h`:

- `USB_ST_SETUP`: the framework is ready to submit a new transfer on this channel. You should prepare the transfer (set its length, copy data into its buffer, and so on) and call `usbd_transfer_submit`. If you have no work for this channel right now, simply return; the framework will leave the channel idle until something else triggers a submit.
- `USB_ST_TRANSFERRED`: the most recent transfer completed successfully. You should read out the results (copy received data out, decide what to do next) and either return (if the channel should go idle) or fall through to `USB_ST_SETUP` to start another transfer.
- `USB_ST_ERROR`: the most recent transfer failed. You should inspect `usbd_xfer_get_error(xfer)` to see why, handle the error (for most errors, you fall through to `USB_ST_SETUP` to retry after a short delay; for stalls, you issue a clear-stall), and decide whether to continue.

The typical shape of a bulk-read callback looks like this:

```
static void
myfirst_usb_bulk_read_callback(struct usb_xfer *xfer, usb_error_t error)
{
    struct myfirst_usb_softc *sc = usbd_xfer_softc(xfer);
    struct usb_page_cache *pc;
    int actlen;

    usbd_xfer_status(xfer, &actlen, NULL, NULL, NULL);

    switch (USB_GET_STATE(xfer)) {
    case USB_ST_TRANSFERRED:
        pc = usbd_xfer_get_frame(xfer, 0);
        /*
         * Copy actlen bytes from pc into the driver's receive buffer.
         */
    }
```

```

        * This is where you hand the data to userland, to a queue,
        * or to another callback.
        */
        myfirst_usb_deliver_received(sc, pc, actlen);
        /* FALLTHROUGH */
    case USB_ST_SETUP:
tr_setup:
        /*
        * Arm a read for 512 bytes. The actual amount received may
        * be less, because we enabled short_xfer_ok in the config.
        */
        usbd_xfer_set_frame_len(xfer, 0, usbd_xfer_max_len(xfer));
        usbd_transfer_submit(xfer);
        break;

    default: /* USB_ST_ERROR */
        if (error == USB_ERR_CANCELLED) {
            /* The device is going away. Do nothing. */
            break;
        }
        if (error == USB_ERR_STALLED) {
            /* Arm a clear-stall on the control pipe; the framework
            * will call us back in USB_ST_SETUP after the clear
            * completes. */
            usbd_xfer_set_stall(xfer);
        }
        goto tr_setup;
    }
}

```

Let us walk through every piece.

The first line retrieves the softc pointer from the transfer object. This is how the callback gets at the per-device state. It works because the softc was passed to `usbd_transfer_setup`, which stored it inside the transfer object.

The call to `usbd_xfer_status` fills in `actlen`, the number of bytes actually transferred on frame zero. For a read, this is how much data arrived. For a write, it is how much data was sent. The other three parameters (which this example does not use) give the total transfer length, the timeout, and a status flags pointer; most callbacks only need `actlen`.

The switch on `USB_GET_STATE(xfer)` is the state machine. In `USB_ST_TRANSFERRED`, the callback copies the received data out of the USB frame into the driver's own buffer. The helper function `myfirst_usb_deliver_received` (which you would write) could push the data onto a queue, wake a sleeping `read()` on the `/dev` node, or feed a higher-level protocol parser.

The `FALLTHROUGH` after processing the transferred data takes the callback into the `USB_ST_SETUP` branch. This

is the idiomatic pattern for channels that run continuously: every time a read finishes, immediately start another read. If the driver wanted to stop reading after one transfer (say, a one-shot control request), it would return; at the end of `USB_ST_TRANSFERRED` instead of falling through.

In `USB_ST_SETUP`, `usbd_xfer_set_frame_len` sets the length of frame zero to the maximum the channel can handle, and `usbd_transfer_submit` hands the transfer to the framework. The framework will start the actual hardware operation and, when complete, call the callback again with either `USB_ST_TRANSFERRED` or `USB_ST_ERROR`.

The default case is where error handling happens. Two errors get special treatment. `USB_ERR_CANCELLED` is the signal that the transfer is being torn down, typically because the device was unplugged or `usbd_transfer_unsetup` was called. The callback must not resubmit the transfer in this case; if it did, it could race with the teardown and potentially touch memory that is about to be freed. Breaking out of the switch without calling `usbd_transfer_submit` is the correct behaviour.

`USB_ERR_STALLED` is the signal that the endpoint returned a STALL handshake, meaning the device is refusing to accept more data until the host clears the stall. The call to `usbd_xfer_set_stall` schedules a clear-stall operation on the control endpoint. After the clear-stall completes, the framework will call the callback again with `USB_ST_SETUP`, at which point the driver can reissue the transfer. This logic is built into the framework so that every driver gets the same correct behaviour with minimal code.

For any other error, the callback falls through to `tr_setup` and attempts to resubmit the transfer. This is a simple retry policy. A more sophisticated driver might count consecutive errors and give up after a threshold, or it might escalate by calling `usbd_transfer_unsetup` on itself. For many drivers, the default retry loop is sufficient.

26.6.4 The Write Callback

The write callback has the same shape but its `USB_ST_SETUP` branch is more interesting, because it has to decide whether there is any data to write:

```
static void
myfirst_usb_bulk_write_callback(struct usb_xfer *xfer, usb_error_t error)
{
    struct myfirst_usb_softc *sc = usbd_xfer_softc(xfer);
    struct usb_page_cache *pc;
    int actlen;
    unsigned int len;

    usbd_xfer_status(xfer, &actlen, NULL, NULL, NULL);

    switch (USB_GET_STATE(xfer)) {
    case USB_ST_TRANSFERRED:
        /* A previous write finished. Wake any blocked writer. */
        wakeup(&sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]);
        /* FALLTHROUGH */
    case USB_ST_SETUP:
```

```

tr_setup:
    len = myfirst_usb_dequeue_write(sc);
    if (len == 0) {
        /* Nothing to send right now. Leave the channel idle. */
        break;
    }
    pc = usbd_xfer_get_frame(xfer, 0);
    myfirst_usb_copy_write_data(sc, pc, len);
    usbd_xfer_set_frame_len(xfer, 0, len);
    usbd_transfer_submit(xfer);
    break;

default: /* USB_ST_ERROR */
    if (error == USB_ERR_CANCELLED)
        break;
    if (error == USB_ERR_STALLED)
        usbd_xfer_set_stall(xfer);
    goto tr_setup;
}
}

```

The main change is the logic at `tr_setup`. For a read, the driver always wants another read armed, so the callback just sets the frame length and submits. For a write, the driver only submits if there is something to send. The helper `myfirst_usb_dequeue_write` returns the number of bytes pulled from an internal transmit queue; if zero, the callback breaks out of the switch without submitting anything, which leaves the channel idle. When userspace later writes more data into the device, the driver code that handles the `write()` system call queues the bytes and explicitly calls `usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR])`. That call fires an `USB_ST_SETUP` invocation of the callback, which now finds data in the queue and submits it.

This interaction between the userspace I/O path and the transfer state machine is the heart of an interactive USB driver. Reads are self-driving: once armed, they rearm themselves on every completion. Writes are demand-driven: they submit only when data is available and go idle otherwise. Both patterns run inside the same three-state machine; the difference is only in what happens at `USB_ST_SETUP`.

26.6.5 Control Transfers

Control transfers do not typically run on continuously-armed channels; they are usually issued one-shot, either synchronously from a system-call handler or as a one-shot callback triggered by some driver event. The `struct usb_config` for a control channel has `type = UE_CONTROL` and otherwise looks similar to the bulk and interrupt configurations. The buffer size must be at least eight bytes to hold the setup packet, and the callback deals with two frames: frame zero is the setup packet, and frame one is the optional data phase.

The typical one-shot use is to issue a vendor-specific request at driver-load time. The FTDI serial driver, for example, uses control transfers to set the baud rate and line parameters every time the user configures the serial

port. Because the control callback is scheduled by the framework just like any other transfer callback, the code pattern is identical. What differs is the construction of the setup packet in the USB_ST_SETUP branch.

For a control-read transfer, the code looks something like this:

```
case USB_ST_SETUP: {
    struct usb_device_request req;
    req.bmRequestType = UT_READ_VENDOR_DEVICE;
    req.bRequest      = MY_VENDOR_GET_STATUS;
    USETW(req.wValue,  0);
    USETW(req.wIndex,  0);
    USETW(req.wLength, sizeof(sc->sc_status));

    pc = usbd_xfer_get_frame(xfer, 0);
    usbd_copy_in(pc, 0, &req, sizeof(req));

    usbd_xfer_set_frame_len(xfer, 0, sizeof(req));
    usbd_xfer_set_frame_len(xfer, 1, sizeof(sc->sc_status));
    usbd_xfer_set_frames(xfer, 2);
    usbd_transfer_submit(xfer);
    break;
}
```

The USETW macro stores a sixteen-bit value in the request structure in the little-endian byte order USB requires. The usbd_copy_in helper copies from a kernel buffer into a USB frame. The usbd_xfer_set_frame_len and usbd_xfer_set_frames calls tell the framework how many frames the transfer spans and how long each is. For a control-read, frame zero is the setup packet (eight bytes) and frame one is the data phase; the framework transparently handles the status phase at the end.

In the USB_ST_TRANSFERRED branch, the driver reads the response out of frame one:

```
case USB_ST_TRANSFERRED:
    pc = usbd_xfer_get_frame(xfer, 1);
    usbd_copy_out(pc, 0, &sc->sc_status, sizeof(sc->sc_status));
    /* sc->sc_status now holds the device's response. */
    break;
```

Control transfers are the right tool for configuration operations where latency and bandwidth do not matter but correctness and sequencing do. They are the wrong tool for streaming data; use bulk or interrupt transfers for that.

26.6.6 Interrupt Transfers

Interrupt transfers are conceptually the simplest of the four types. An interrupt-IN channel runs a continuous state machine that polls a single endpoint at regular intervals. Each time a packet arrives from the device, the

callback wakes up with `USB_ST_TRANSFERRED`. The driver reads the packet, processes it (often by delivering it to userland), and falls through to rearm.

The callback for our interrupt channel is nearly identical to the bulk-read callback:

```
static void
myfirst_usb_intr_callback(struct usb_xfer *xfer, usb_error_t error)
{
    struct myfirst_usb_softc *sc = usbd_xfer_softc(xfer);
    struct usb_page_cache *pc;
    int actlen;

    usbd_xfer_status(xfer, &actlen, NULL, NULL, NULL);

    switch (USB_GET_STATE(xfer)) {
    case USB_ST_TRANSFERRED:
        pc = usbd_xfer_get_frame(xfer, 0);
        myfirst_usb_handle_interrupt(sc, pc, actlen);
        /* FALLTHROUGH */
    case USB_ST_SETUP:
    tr_setup:
        usbd_xfer_set_frame_len(xfer, 0, usbd_xfer_max_len(xfer));
        usbd_transfer_submit(xfer);
        break;

    default:
        if (error == USB_ERR_CANCELLED)
            break;
        if (error == USB_ERR_STALLED)
            usbd_xfer_set_stall(xfer);
        goto tr_setup;
    }
}
```

The only meaningful difference from the bulk-read callback is that the buffer is smaller (interrupt endpoint packets are typically eight to sixty-four bytes) and the semantics of the data are usually “status update” rather than “stream payload.” A USB HID device, for example, sends a sixty-four-byte report every few milliseconds describing key presses and mouse motions; an interrupt-IN channel polled continuously in this pattern is how the kernel receives those reports.

Interrupt-OUT channels work the same way but in reverse: the callback has to decide whether to send something at each `USB_ST_SETUP`, analogous to the bulk-write pattern.

26.6.7 Frame-Level Operations: What the Framework Gives You

USB transfers are composed of frames. A bulk transfer with a large buffer might be broken into multiple packets by the hardware; the framework hides that detail and presents the transfer as a single operation. A control transfer, on the other hand, has an explicit frame structure (setup, data, status). An isochronous transfer has one frame per scheduled packet. The framework exposes this structure through a small number of helper functions:

- `usbd_xfer_max_len(xfer)` returns the largest total length the channel can transfer in a single submit.
- `usbd_xfer_set_frame_len(xfer, frame, len)` sets the length of a specific frame.
- `usbd_xfer_set_frames(xfer, n)` sets the total number of frames in the transfer.
- `usbd_xfer_get_frame(xfer, frame)` returns a page-cache pointer for a specific frame, which is what you pass to `usbd_copy_in` and `usbd_copy_out`.
- `usbd_xfer_frame_len(xfer, frame)` returns how many bytes were actually transferred in a given frame (for completions).
- `usbd_xfer_max_framelen(xfer)` returns the maximum per-frame length for the channel.

For bulk and interrupt transfers, the vast majority of drivers only touch frame zero. For control transfers, they touch frames zero and one. For isochronous transfers (which we will not cover in this chapter), they loop over many frames. The point is that the framework gives you complete control over the per-frame data layout while hiding the hardware details that would otherwise make transfer scheduling a nightmare.

26.6.8 The `usbd_copy_in` and `usbd_copy_out` Helpers

USB buffers are not plain C buffers. They are allocated by the framework in a way that is addressable by the host controller hardware, which means they often live in DMA-accessible memory pages with platform-specific alignment requirements. The framework wraps these buffers in an opaque struct `usb_page_cache` object, and the driver accesses them through two helpers:

- `usbd_copy_in(pc, offset, src, len)` copies `len` bytes from the plain C buffer `src` into the framework-managed buffer at `offset`.
- `usbd_copy_out(pc, offset, dst, len)` copies `len` bytes out of the framework-managed buffer at `offset` into the plain C buffer `dst`.

You never dereference a struct `usb_page_cache *` directly. You never assume it points to a contiguous memory region. You always go through the helpers. This keeps the driver portable across platforms with different DMA constraints, and it is the standard convention throughout `/usr/src/sys/dev/usb/`.

If your driver needs to fill a USB buffer with data from a mbuf chain or from a userland pointer, there are dedicated helpers for that too: `usbd_copy_in_mbuf`, `usbd_copy_from_mbuf`, and the `uiomove` interaction is handled through `usbd_m_copy_in` and related routines. Search the USB framework source for the right helper; there is almost certainly one that matches your need.

26.6.9 Starting, Stopping, and Querying Transfers

Beyond the three callbacks, the driver interacts with transfer channels through a small number of control functions. The important ones are:

- `usbd_transfer_start(xfer)`: ask the framework to schedule a callback invocation in the `USB_ST_SETUP` state, even if the channel has been idle. Used when new data becomes available for a write channel.
- `usbd_transfer_stop(xfer)`: stop the channel. Any in-flight transfer is cancelled and the callback is invoked with `USB_ST_ERROR` (with `USB_ERR_CANCELLED`). No new callbacks happen until the driver calls `usbd_transfer_start` again.
- `usbd_transfer_pending(xfer)`: returns true if a transfer is currently outstanding. Useful for deciding whether to submit a new one or defer.
- `usbd_transfer_drain(xfer)`: blocks until any outstanding transfer completes and the channel is idle. Used in teardown paths that need to wait for in-flight I/O before continuing.

These functions are safe to call while holding the driver's mutex, and in fact most of them require it. The framework documentation and the existing driver code show the expected usage patterns; when in doubt, `grep` for the function name in `/usr/src/sys/dev/usb/` and read how existing drivers use it.

26.6.10 A Worked Example: Echo-Loop over USB

To make the transfer mechanics concrete, consider a small end-to-end scenario. The driver exposes a `/dev/my-first_usb0` entry that accepts writes and returns reads. A user process writes a string to the device; the driver sends those bytes to the USB device through the bulk-OUT channel. The device bounces the bytes back through its bulk-IN endpoint; the driver receives them and hands them to any process currently blocked in a `read()` on the `/dev` node. This is a useful exercise because it exercises both directions of the bulk pipeline and because it has a simple, observable success criterion: the string that goes in is the string that comes out.

The driver needs a small transmit queue and a small receive queue, both protected by the softc mutex. When userspace writes, the `d_write` handler acquires the mutex, copies the bytes into the transmit queue, and calls `usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR])`. When userspace reads, the `d_read` handler acquires the mutex, checks the receive queue; if empty, it sleeps on a channel related to the queue. The write callback, running under the mutex, dequeues bytes and submits the transfer. The read callback, also under the mutex, enqueues received bytes and wakes any blocked reader.

The complete flow from userspace `write("hi")` to userspace `read()` seeing "hi" involves three threads of execution interleaved through the state machines:

1. User thread runs `write()`. Driver enqueues "hi" on the TX queue. Driver calls `usbd_transfer_start`. User thread returns.
2. Framework schedules the TX callback with `USB_ST_SETUP`. Callback dequeues "hi", copies it into frame zero, sets frame length to 2, submits. Callback returns.
3. Hardware performs the bulk-OUT transaction. Device echoes "hi" on bulk-IN.
4. Framework schedules the RX callback with `USB_ST_TRANSFERRED` (because an earlier `USB_ST_SETUP` had armed a read). Callback reads "hi" from frame zero into the RX queue, wakes any blocked reader, falls through to re-arm the read, submits. Callback returns.
5. User thread, if it was blocked in `read()`, wakes up. The `d_read` handler copies "hi" out of the RX queue into userspace. User thread returns.

At each step, the mutex is held exactly where it needs to be, the state machine moves cleanly between `USB_ST_SETUP` and `USB_ST_TRANSFERRED`, and the driver does not have to think about packet boundaries, DMA mappings, or hardware scheduling. The framework handles all of that.

26.6.11 Putting the Whole Echo-Loop Driver Together

To make the echo-loop description concrete, let us walk through a complete skeleton for `myfirst_usb`. What follows is not a copy of the real driver files in `examples/`; it is a narrative presentation of how the pieces fit. The full code is in the `examples` directory.

The driver has one C source file, `myfirst_usb.c`, and a small header `myfirst_usb.h`. The header declares the `softc` structure, the constants for the transfer enumeration, and the prototypes for internal helper functions. The source file contains the match table, the transfer configuration array, the callback functions, the character-device methods, the Newbus probe/attach/detach, and the registration macros.

The `softc` is as we described earlier: a USB device pointer, a mutex, the transfer array, a character device pointer, an interface index, a flags byte, and two internal ring buffers for RX and TX queued data. Each ring buffer is a fixed-size array (say, 4096 bytes) plus head and tail indices, protected by the mutex.

The match table contains one entry:

```
static const STRUCT_USB_HOST_ID myfirst_usb_devs[] = {
    {USB_VPI(0x16c0, 0x05dc, 0)},
};
```

The 0x16c0/0x05dc VID/PID pair is the Van Oosting Technologies Incorporated / OBDEV generic test VID/PID, which is free to use for prototyping.

The transfer configuration array is the three-channel array from Section 3. The callbacks are the bulk-read, bulk-write, and interrupt-read patterns we walked through.

The bulk-read callback's `USB_ST_TRANSFERRED` branch calls a helper:

```
static void
myfirst_usb_rx_enqueue(struct myfirst_usb_softc *sc,
    struct usb_page_cache *pc, int len)
{
    int space;
    unsigned int tail;

    space = MYFIRST_USB_RX_BUFSIZE - sc->sc_rx_count;
    if (space < len)
        len = space; /* drop the excess; a real driver might flow-control */

    tail = (sc->sc_rx_head + sc->sc_rx_count) & (MYFIRST_USB_RX_BUFSIZE - 1);
    if (tail + len > MYFIRST_USB_RX_BUFSIZE) {
        /* wrap-around copy in two pieces */
        usbd_copy_out(pc, 0, &sc->sc_rx_buf[tail], MYFIRST_USB_RX_BUFSIZE - tail);
        usbd_copy_out(pc, MYFIRST_USB_RX_BUFSIZE - tail,
            &sc->sc_rx_buf[0], len - (MYFIRST_USB_RX_BUFSIZE - tail));
    } else {
        usbd_copy_out(pc, 0, &sc->sc_rx_buf[tail], len);
    }
}
```

```

    }
    sc->sc_rx_count += len;

    /* Wake any sleeper. */
    wakeup(&sc->sc_rx_count);
}

```

This is a ring-buffer enqueue with wrap-around handling. The `usb_copy_out` helper is used to move bytes from the USB frame into the ring buffer. If the ring buffer is full, bytes are dropped. A real driver would likely either apply USB-level flow control (stop arming new reads) or grow the buffer; for the lab, dropping is acceptable.

The bulk-write callback's helper to dequeue data is the mirror image:

```

static unsigned int
myfirst_usb_tx_dequeue(struct myfirst_usb_softc *sc,
    struct usb_page_cache *pc, unsigned int max_len)
{
    unsigned int len, head;

    len = sc->sc_tx_count;
    if (len > max_len)
        len = max_len;
    if (len == 0)
        return (0);

    head = sc->sc_tx_head;
    if (head + len > MYFIRST_USB_TX_BUFSIZE) {
        usb_copy_in(pc, 0, &sc->sc_tx_buf[head], MYFIRST_USB_TX_BUFSIZE - head);
        usb_copy_in(pc, MYFIRST_USB_TX_BUFSIZE - head,
            &sc->sc_tx_buf[0], len - (MYFIRST_USB_TX_BUFSIZE - head));
    } else {
        usb_copy_in(pc, 0, &sc->sc_tx_buf[head], len);
    }
    sc->sc_tx_head = (head + len) & (MYFIRST_USB_TX_BUFSIZE - 1);
    sc->sc_tx_count -= len;
    return (len);
}

```

The character-device methods are straightforward. Open checks that the device is not already open, sets the open flag, and arms the read channel:

```

static int
myfirst_usb_open(struct cdev *dev, int flags, int devtype, struct thread *td)

```

```

{
    struct myfirst_usb_softc *sc = dev->si_drv1;

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_flags & MYFIRST_USB_FLAG_OPEN) {
        mtx_unlock(&sc->sc_mtx);
        return (EBUSY);
    }
    sc->sc_flags |= MYFIRST_USB_FLAG_OPEN;
    sc->sc_rx_head = sc->sc_rx_count = 0;
    sc->sc_tx_head = sc->sc_tx_count = 0;
    usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_RD]);
    usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_INTR_DT_RD]);
    mtx_unlock(&sc->sc_mtx);

    return (0);
}

```

Close clears the open flag and stops the read channel:

```

static int
myfirst_usb_close(struct cdev *dev, int flags, int devtype, struct thread *td)
{
    struct myfirst_usb_softc *sc = dev->si_drv1;

    mtx_lock(&sc->sc_mtx);
    usbd_transfer_stop(sc->sc_xfer[MYFIRST_USB_BULK_DT_RD]);
    usbd_transfer_stop(sc->sc_xfer[MYFIRST_USB_INTR_DT_RD]);
    usbd_transfer_stop(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]);
    sc->sc_flags &= ~MYFIRST_USB_FLAG_OPEN;
    mtx_unlock(&sc->sc_mtx);

    return (0);
}

```

Read blocks until data is available, then copies bytes from the ring buffer to userspace:

```

static int
myfirst_usb_read(struct cdev *dev, struct uio *uio, int flags)
{
    struct myfirst_usb_softc *sc = dev->si_drv1;
    unsigned int len;
    char tmp[128];

```

```

int error = 0;

mtx_lock(&sc->sc_mtx);
while (sc->sc_rx_count == 0) {
    if (sc->sc_flags & MYFIRST_USB_FLAG_DETACHING) {
        mtx_unlock(&sc->sc_mtx);
        return (ENXIO);
    }
    if (flags & O_NONBLOCK) {
        mtx_unlock(&sc->sc_mtx);
        return (EAGAIN);
    }
    error = msleep(&sc->sc_rx_count, &sc->sc_mtx,
        PCATCH | PZERO, "myfirstusb", 0);
    if (error != 0) {
        mtx_unlock(&sc->sc_mtx);
        return (error);
    }
}

while (uio->uio_resid > 0 && sc->sc_rx_count > 0) {
    len = min(uio->uio_resid, sc->sc_rx_count);
    len = min(len, sizeof(tmp));
    /* Copy out of ring buffer into tmp (handles wrap-around) */
    myfirst_usb_rx_read_into(sc, tmp, len);
    mtx_unlock(&sc->sc_mtx);
    error = uiomove(tmp, len, uio);
    mtx_lock(&sc->sc_mtx);
    if (error != 0)
        break;
}
mtx_unlock(&sc->sc_mtx);
return (error);
}

```

Notice the pattern: the mutex is held while manipulating the ring buffer, but it is released around the `uiomove` call, because `uiomove` can sleep (to fault in user pages) and sleeping while holding a mutex is forbidden. The mutex is reacquired after `uiomove` returns.

Write is the mirror: copy bytes from user to TX buffer, then kick the write channel:

```

static int
myfirst_usb_write(struct cdev *dev, struct uio *uio, int flags)
{
    struct myfirst_usb_softc *sc = dev->si_drv1;

```

```

unsigned int len, space, tail;
char tmp[128];
int error = 0;

mtx_lock(&sc->sc_mtx);
while (uio->uio_resid > 0) {
    if (sc->sc_flags & MYFIRST_USB_FLAG_DETACHING) {
        error = ENXIO;
        break;
    }
    space = MYFIRST_USB_TX_BUFSIZE - sc->sc_tx_count;
    if (space == 0) {
        /* buffer is full; wait for the write callback to drain it */
        error = msleep(&sc->sc_tx_count, &sc->sc_mtx,
            PCATCH | PZERO, "myfirstusbw", 0);
        if (error != 0)
            break;
        continue;
    }
    len = min(uio->uio_resid, space);
    len = min(len, sizeof(tmp));

    mtx_unlock(&sc->sc_mtx);
    error = uiomove(tmp, len, uio);
    mtx_lock(&sc->sc_mtx);
    if (error != 0)
        break;

    /* Copy tmp into TX ring buffer (handles wrap-around) */
    tail = (sc->sc_tx_head + sc->sc_tx_count) & (MYFIRST_USB_TX_BUFSIZE - 1);
    myfirst_usb_tx_buf_append(sc, tail, tmp, len);
    sc->sc_tx_count += len;
    usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]);
}
mtx_unlock(&sc->sc_mtx);
return (error);
}

```

Two things are worth noticing in write. First, when the TX buffer is full, the write handler sleeps on `sc_tx_count`; the write callback's `USB_ST_TRANSFERRED` branch calls `wakeup(&sc_tx_count)` after draining some bytes, which wakes the sleeping writer. Second, the write handler calls `usbd_transfer_start` on every chunk it enqueues. This is safe (starting an already-running channel is a no-op) and it ensures the write callback is nudged even if the channel had gone idle.

With these four cdev methods and the three transfer callbacks, you have a complete minimum-viable USB echo

driver. The full source is approximately three hundred lines: short enough to fit on a single screen, concrete enough to exercise the real API.

26.6.12 Choosing Between `usb_fifo` and a Custom `cdevsw`

When a USB driver needs to expose a `/dev` entry to userland, FreeBSD offers two approaches. The first is the `usb_fifo` framework, a generic byte-stream abstraction that gives you `/dev/ugenN.M.epM` style nodes with `read`, `write`, `poll`, and a small `ioctl` interface. You declare a `struct usb_fifo_methods` with `open`, `close`, `start-read`, `start-write`, `stop-read`, and `stop-write` callbacks, and the framework handles the `cdev` plumbing and the queueing. This is the path of least resistance; `uhid(4)` and `ucom(4)` both use it.

The second approach is a custom `cdevsw`, the same pattern you practised in Chapter 24. This gives you total control over the user interface at the cost of writing more code. It is appropriate when the driver needs a very specific `ioctl` surface, when the `read/write` semantics do not fit a byte stream (for example, a message-oriented protocol), or when the driver already fits poorly into the `usb_fifo` model.

For the running example we have built, a custom `cdevsw` is the right choice because we wrote the `attach` method that calls `make_dev` and the `detach` method that calls `destroy_dev`, which is exactly what a custom `cdevsw` requires. For a driver that exposes a byte stream (a serial adapter, say), `usb_fifo` is simpler. When you write your next USB driver, look at both options and pick the one whose interface matches your problem.

26.6.13 Error Handling and Retry Policy

The retry loop that our bulk-read callback uses, “on any error, rearm and try again,” is a reasonable default for robust drivers. But it is not the only policy, and sometimes it is the wrong one.

For a device that might genuinely go away mid-transfer (a USB adapter whose physical connection has been removed before the framework has had a chance to notice), rearming indefinitely is a waste; the transfers will keep failing until `detach` is called. Adding a small retry counter and giving up after, say, five consecutive errors, keeps the log from filling with noise.

For a device that implements a strict request-response protocol, an error might invalidate the entire session. In that case, the callback should not rearm; instead, it should mark the driver as “in error” and let the user close and reopen the device to reset.

For a device that supports stall-and-clear as a normal flow-control mechanism, the `usbdxfer_set_stall` path is in the happy path, not the error path. Some class protocols use stalls to signal “I am not ready right now”; the framework’s automatic clear-stall machinery handles this transparently.

Your choice of retry policy should match the real behaviour of the device you are writing for. When in doubt, start with the simple “rearm on error” default, observe what happens when you plug and unplug the device repeatedly, and refine from there.

26.6.14 Timeouts and Their Consequences

A timeout on a USB transfer is not just a safety net against hardware stalls; it is an explicit statement about how long the driver is willing to wait for an operation to complete before treating it as a failure. Choosing a timeout is

a design decision that interacts with many other parts of the driver, and getting it right requires thinking through several scenarios.

The configuration field `timeout` in `struct usb_config` is measured in milliseconds. A value of zero means “no timeout”; the transfer will wait indefinitely. A positive value means “if the transfer has not completed after this many milliseconds, cancel it and deliver a timeout error to the callback.”

For a read channel on a bulk endpoint, the usual choice is zero. Reads on bulk channels are waiting for the device to have something to say, and if the device is silent for minutes, that is not necessarily an error. A timeout would force the driver to rearm the read every few seconds, which wastes time and produces noise in the log.

For a write channel, the usual choice is a modest positive value like 5000 (five seconds). If the device fails to drain its FIFO in that time, something is wrong; rather than block an indefinite-length write, the driver returns an error to userland, which can retry if it wishes.

For an interrupt-IN channel polling for status updates, the usual choice is either zero (like a bulk read) or a timeout that matches the expected polling interval from the endpoint descriptor’s `bInterval` field. Matching `bInterval` gives the driver an explicit “I should have heard from the device by now” signal.

For a control transfer, timeouts matter most, because control transfers are how the driver configures the device, and a device that does not respond to configuration is wedged. A timeout of 500 to 2000 milliseconds is common. If the device does not respond to a configuration request in a few seconds, the driver should assume something is wrong.

What happens when a timeout fires? The framework calls the callback with `USB_ERR_TIMEOUT` as the error. The callback typically treats this as a transient failure and rearms (for repeating channels) or returns an error to the caller (for one-shot operations). A repeating read channel that keeps timing out is probably talking to a device that is not responding; after a few consecutive timeouts, it may be worth escalating by calling `usbd_transfer_unsetup` or by logging a more visible warning.

One subtle interaction is worth mentioning: if the transfer has a timeout and the driver also sets `pipe_bof` (pipe blocked on failure), a timeout will block the pipe until the driver explicitly clears the block. This is usually what you want, because the pipe may be in an inconsistent state, and clearing the block (by submitting a fresh setup, or by calling `usbd_transfer_start`) is a good point to log what happened and decide what to do next.

26.6.15 What Goes Wrong When Transfer Setup Fails

The `usbd_transfer_setup` call can fail for several reasons. Understanding each is useful both for debugging your own driver and for reading the FreeBSD source when you encounter failures.

Endpoint mismatch. If the configuration array asks for an endpoint with a specific type/direction pair that does not exist on the interface, the call fails with `USB_ERR_NO_PIPE`. This usually means the match table matched a device that has a different descriptor layout than the driver expected; it is a bug in the driver.

Unsupported transfer type. If the configuration specifies `UE_ISOCHRONOUS` on a host controller that does not support isochronous transfers, or if the bandwidth reservation cannot be satisfied, the call fails. Isochronous is the most complex transfer type and the most likely to have platform-specific limitations.

Out of memory. The framework allocates DMA-capable buffers for the channels. If memory is low, the allocation fails. This is rare on modern systems but can happen on embedded platforms with tight memory budgets.

Missing or invalid attributes. If the configuration has a buffer size of zero, or a negative frame count, or an invalid flag combination, the call fails. Check the configuration against the declarations in `/usr/src/sys/dev/usb/usbdi.h`.

Power management states. If the device has been suspended or is in a low-power state, some transfer setup requests will fail. This is mainly relevant for drivers that handle USB selective suspend.

When `usb_transfer_setup` fails, the error code is an `usb_error_t` value, not a standard `errno`. The definitions are in `/usr/src/sys/dev/usb/usbdi.h`. The function `usb_errstr` converts an error code to a printable string; use it in your `device_printf` to make diagnostic messages informative.

26.6.16 A Detail About `pipe_bof`

We mentioned `pipe_bof` (pipe blocked on failure) as a flag in the transfer configuration, but the motivation for it deserves a closer look. USB endpoints are conceptually single-threaded from the device's perspective. When the host submits a bulk-OUT packet, the device must process that packet before accepting another. If the packet fails, the device may be in an indeterminate state, and the next packet should not be sent until the driver has had a chance to resynchronise.

`pipe_bof` tells the framework to pause the pipe when a transfer fails. The next `usb_transfer_submit` will not actually start a hardware operation; instead, the framework waits until the driver explicitly calls `usb_transfer_start` on the channel, which acts as a “resume” signal. This lets the driver do a clear-stall or otherwise resynchronise before the next transfer begins.

Without `pipe_bof`, the framework would immediately submit the next transfer after a failure, which might run into the same failure before the driver has had a chance to react.

Setting `pipe_bof = 1` is the safe default for most drivers. Clearing it is appropriate for drivers that want to keep a pipeline full even through occasional errors (for example, audio drivers where a brief glitch is preferable to a synchronous resynchronisation).

26.6.17 `short_xfer_ok` and Data-Length Semantics

The `short_xfer_ok` flag is another configuration option whose meaning is worth spelling out. USB bulk transfers do not have an inherent end-of-message marker. If the host has a buffer of 512 bytes and the device only has 100 bytes to send, what should happen? There are two possible answers.

With `short_xfer_ok` clear (the default), a transfer that completes with less data than requested is treated as an error. The framework delivers `USB_ERR_SHORT_XFER` to the callback, and the driver must decide whether to retry, ignore, or escalate.

With `short_xfer_ok` set, a short transfer is treated as success. The callback gets `USB_ST_TRANSFERRED` with `act_len` set to the actual number of bytes received. This is almost always what you want for bulk-IN on message-oriented protocols, where the device decides how much data to send.

There is a corresponding flag for outgoing transfers: `force_short_xfer`. If set, a transfer whose data happens to be an exact multiple of the endpoint's maximum packet size will be padded with a zero-length packet at the end to signal “end of message.” USB treats a zero-length packet as a valid transaction, and many protocols use it as an explicit boundary marker. The FTDI driver sets this flag on its write channel, for example, because the FTDI protocol expects a trailing short packet.

Knowing which flag is appropriate requires knowing the protocol the device implements. When you write a driver for a device documented with a public protocol specification, check the specification for how it handles boundaries. When you write a driver for a poorly-documented device, set `short_xfer_ok` on reads (you can always count the bytes), and test both settings of `force_short_xfer` on writes to see which the device accepts.

26.6.18 Locking Rules Around Transfers

The USB framework imposes two locking rules that are essential to get right.

First, the mutex you pass to `usbd_transfer_setup` is held by the framework around every invocation of the callback. You do not need to acquire it inside the callback; it is already held. You also must not release it inside the callback; doing so breaks the framework's assumption and can cause random failures.

Second, every call from driver code (not from the callback) to one of `usbd_transfer_start`, `usbd_transfer_stop`, `usbd_transfer_submit`, `usbd_transfer_drain`, and `usbd_transfer_pending` must be made with the mutex held. This is because these functions read and write fields inside the transfer object that the callback also touches, and the mutex is what serialises access.

Practically, this means most driver code that interacts with transfers looks like:

```
mtx_lock(&sc->sc_mtx);
usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]);
mtx_unlock(&sc->sc_mtx);
```

or in longer critical sections:

```
mtx_lock(&sc->sc_mtx);
/* enqueue data */
enqueue(sc, data, len);
/* nudge the channel if it is idle */
if (!usbd_transfer_pending(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]))
    usbd_transfer_start(sc->sc_xfer[MYFIRST_USB_BULK_DT_WR]);
mtx_unlock(&sc->sc_mtx);
```

Drivers that violate these rules occasionally appear to work but fail intermittently on load, under heavy I/O, or during detach. Getting the locking right from the start saves many hours of debugging later.

26.6.19 Wrapping Up Section 3

Section 3 has shown how data flows through a USB driver. A configuration array declares the channels, `usbd_transfer_setup` allocates them, the callbacks drive them through the three-state machine, and `usbd_transfer_unsetup` tears them down. The framework abstracts away the hardware details: DMA buffers, frame scheduling, endpoint arbitration, stall handling. The driver's job is to write callbacks that handle completion and to arrange the flow of data through the callbacks.

Three themes are worth carrying forward. First, the three-state state machine (`USB_ST_SETUP`, `USB_ST_TRANSFERRED`, `USB_ST_ERROR`) is the same in every channel, regardless of transfer type. Learning to read a USB callback means learning to parse this state machine; once you know it, every callback in every USB driver in the tree is legible. Second, the `usb_page_cache` abstraction is the only safe way to move data into and out of USB buffers. Never bypass `usbd_copy_in` and `usbd_copy_out`. Third, the locking discipline around `usbd_transfer_start`, `_stop`, and `_submit` is not optional; every call from driver code must be made under the mutex.

With Sections 1 through 3 in hand, you have a complete mental model of USB driver writing: the concepts, the skeleton, and the data pipeline. Section 4 now shifts to the serial side of Part 6. The UART subsystem is older, simpler in some ways, more constrained in others, and its idioms are different from USB's. But many of the same habits carry over: match against what you support, attach in phases that can be cleanly reversed, drive the hardware through a state machine, and respect the locking.

Take a breath. We have now worked through the USB half of the chapter: the host and device roles, the descriptor tree, the four transfer types, the probe/attach/detach skeleton, and the three-state `USB_ST_SETUP/USB_ST_TRANSFERRED/USB_ST_ERROR` callback machine that every USB driver runs. The rest of the chapter turns to the serial side: the `uart(4)` framework with its `ns8250` reference driver, integration with the TTY layer and `termios`, the `ucom(4)` bridge used by USB-to-serial adapters, and the tools and labs that let you test both kinds of drivers without real hardware. If you want to close the book and come back, this is a natural pause.

26.7 Section 4: Writing a Serial UART Driver

26.7.1 From USB to UART: A Shift of Landscape

Sections 2 and 3 gave you a complete USB driver. The framework there was modern in every sense: hot-plug, DMA-aware, message-oriented, richly abstracted. Section 4 now turns to `uart(4)`, FreeBSD's framework for driving Universal Asynchronous Receiver/Transmitters. The landscape is different. Many UART chips are older than USB itself, and the framework's design reflects that. There is no hot-plug (a serial port is usually soldered to the board). There is no DMA for most parts (the chip has a small FIFO you poll or an interrupt you handle). There is no descriptor hierarchy (the chip does not advertise its capabilities; you know what you built against). And there is no notion of transfer channels; there is just the port, into which bytes go and out of which bytes come.

What the framework does provide is a disciplined split of responsibilities between three layers. At the bottom sits your driver, which knows how the chip's registers work, how its interrupts fire, how its FIFOs behave, and what platform-specific resources (IRQ line, I/O port range, clock source) it needs. In the middle sits the `uart(4)` framework itself, which handles registration, baud-rate configuration calculations, buffering, TTY integration, and the scheduling of read and write work. At the top sits the TTY layer, which presents the port to userland as `/dev/ttyuN` and `/dev/cuauN` and handles terminal semantics: line editing, signal generation, control characters, and the vast vocabulary of `termios` knobs that `stty(1)` exposes.

You do not write the TTY layer. You do not write most of the `uart(4)` framework. Your job, when you write a UART driver, is to implement a small set of hardware-specific methods that the framework calls when it needs to do something at the register level. The framework then wires those methods into the rest of the kernel's serial machinery for free.

This section walks through that wiring. It covers the layout of the `uart(4)` framework, the structures and methods you have to fill in, the canonical `ns8250` driver as a concrete reference, and the integration with the TTY layer. It ends with the related `ucom(4)` framework, which is how USB-to-serial bridges expose themselves to userland using the same TTY interface as a real UART.

26.7.2 Where the `uart(4)` Framework Lives

The framework itself lives in `/usr/src/sys/dev/uart/`. If you list that directory, you see a handful of framework files and a family of hardware-specific drivers.

The framework files are:

- `/usr/src/sys/dev/uart/uart.h`: the top-level header that defines the framework's public API.
- `/usr/src/sys/dev/uart/uart_bus.h`: the structures for newbus integration and the per-port softc.
- `/usr/src/sys/dev/uart/uart_core.c`: the attachment logic, the interrupt dispatcher, the polling loop, the link between `uart(4)` and `tty(4)`.
- `/usr/src/sys/dev/uart/uart_tty.c`: the `ttydevsw` implementation that maps `uart(4)` operations onto `tty(4)` operations.
- `/usr/src/sys/dev/uart/uart_cpu.h`, `uart_dev_*.c`: platform glue and console registration.

The hardware-specific drivers are files of the form `uart_dev_NAME.c` and occasionally `uart_dev_NAME.h`. The most important of these is `uart_dev_ns8250.c`, which implements the `ns8250` family (including the 16450, 16550, 16550A, 16650, 16750, and many compatibles). Because the 16550A is effectively the standard UART for PC-style serial ports, this one driver handles the majority of actual serial hardware in the world. When you want to learn how a real FreeBSD UART driver looks, this is the file to open.

Other drivers in the directory handle chips that are not 16550-compatible: the Intel MID variant, the PL011 ARM UART used on Raspberry Pi and other ARM boards, the NXP i.MX UART, the Sun Microsystems Z8530, and so on. Each one follows the same pattern: fill in a `struct uart_class` and a `struct uart_ops`, register with the framework, and implement the hardware access methods.

26.7.3 The `uart_class` Structure

Every UART driver begins by declaring a `struct uart_class`, which is the hardware descriptor that the framework uses to identify the chip family. The definition lives in `/usr/src/sys/dev/uart/uart_bus.h`. The structure looks like this (paraphrased; the real declaration has a few more fields):

```
struct uart_class {
    KOBJ_CLASS_FIELDS;
    struct uart_ops *uc_ops;
    u_int          uc_range;
    u_int          uc_rclk;
    u_int          uc_rshift;
};
```

The `KOBJ_CLASS_FIELDS` macro pulls in the `kobj` machinery that Chapter 23 introduced (in the context of Newbus). A `uart_class` is, at the kernel's abstract-object level, a `kobj` class whose instances are `uart_softc`.

This is how the framework can call into driver-specific methods without needing an `if` ladder: the method dispatch is done by `kobj` lookup.

`uc_ops` is a pointer to the operations structure (coming next), which lists the chip-specific methods.

`uc_range` is how many bytes of register address space the chip uses. For an ns16550-compatible UART, this is 8.

`uc_rclk` is the reference clock frequency in hertz. The framework uses this to compute baud-rate divisors. For a PC-style UART, the reference clock is usually 1,843,200 hertz (a specific multiple of the standard baud rates).

`uc_rshift` is the register address shift. On some buses, UART registers are spaced at intervals other than one byte (for example, every four bytes on some memory-mapped designs). A shift of zero means tight packing; a shift of two means each logical register occupies four bytes of address space.

For our running example, the class declaration looks like this:

```
static struct uart_class myfirst_uart_class = {
    "myfirst_uart class",
    myfirst_uart_methods,
    sizeof(struct myfirst_uart_softc),
    .uc_ops    = &myfirst_uart_ops,
    .uc_range  = 8,
    .uc_rclk   = 1843200,
    .uc_rshift = 0,
};
```

The first three positional arguments are the `KOBJ_CLASS_FIELDS` entries: a name, a method table, and a per-instance size. The named fields are the UART-specific ones. For a driver targeting 16550-compatible chips, these values are the conventional defaults.

26.7.4 The `uart_ops` Structure

The `struct uart_ops` is where the real hardware-specific code lives. It is a table of function pointers that the framework calls at specific moments. The definition lives in `/usr/src/sys/dev/uart/uart_cpu.h`:

```
struct uart_ops {
    int  (*probe)(struct uart_bas *);
    void (*init)(struct uart_bas *, int, int, int, int);
    void (*term)(struct uart_bas *);
    void (*putc)(struct uart_bas *, int);
    int  (*rxready)(struct uart_bas *);
    int  (*getc)(struct uart_bas *, struct mtx *);
};
```

Each operation takes a `struct uart_bas *` as its first argument. The “bas” stands for “bus address space”; it is the framework’s abstraction for access to the chip’s registers. A driver does not know or care whether the chip

is in I/O space or in memory-mapped space; it just calls `uart_getreg(bas, offset)` and `uart_setreg(bas, offset, value)` (declared in `/usr/src/sys/dev/uart/uart.h`), and the framework routes the access correctly.

Let us go through the six operations in turn.

`probe` is called when the framework needs to know whether a chip of this class is present at a given address. The driver typically pokes a register, reads it back, and returns zero if the readback matches (suggesting the chip is really there) or a nonzero `errno` otherwise. For an `ns16550`, the probe writes a test pattern to the scratch register and reads it back.

`init` is called to initialise the chip to a known state. The arguments after the `bas` are `baudrate`, `databits`, `stopbits`, and `parity`. The driver computes the divisor, writes the divisor-latch-access bit, writes the divisor, clears the divisor-latch, sets the line control register for the requested data/stop/parity configuration, enables the FIFOs, and enables the chip's interrupts. The exact register sequence for a 16550 is several dozen lines of code and is documented in the chip's data sheet.

`term` is called to shut down the chip. It typically disables interrupts, flushes the FIFOs, and leaves the chip in a safe state.

`putc` sends a single character. This is used by the low-level console path and by polling-based diagnostic output. The driver busy-waits on the transmitter-holding-register-empty flag, then writes the byte to the transmit register.

`rxready` returns nonzero if at least one byte is available to read. The driver reads the line status register and checks the data-ready bit.

`getc` reads a single character. Used by the low-level console for input. The driver busy-waits on the data-ready flag (or the caller ensures `rxready` just returned true), then reads the receive register.

These six methods are the entire hardware-specific surface for a UART driver at the low level. Everything else (interrupt handling, buffering, TTY integration, hot-plug of PCIe UARTs, console selection) is provided by the framework. A new UART driver is, in effect, a six-function implementation plus a handful of declarations.

26.7.5 A Closer Look at ns8250

The `ns8250` driver at `/usr/src/sys/dev/uart/uart_dev_ns8250.c` is the best place to see these methods concretely. It is a mature, production-grade driver that handles every variant of the 8250/16450/16550/16550A family. The register definitions it uses (from `/usr/src/sys/dev/ic/ns16550.h`) are the same ones every UART-related header in the PC world uses. When you read this driver, you are reading, in effect, the reference implementation of a 16550 driver for FreeBSD.

The put-character implementation is instructive for its simplicity:

```
static void
ns8250_putc(struct uart_bas *bas, int c)
{
    int limit;

    limit = 250000;
```

```
while ((uart_getreg(bas, REG_LSR) & LSR_THRE) == 0 && --limit)
    DELAY(4);
uart_setreg(bas, REG_DATA, c);
uart_barrier(bas);
limit = 250000;
while ((uart_getreg(bas, REG_LSR) & LSR_TEMT) == 0 && --limit)
    DELAY(4);
}
```

The loop polls the line status register (LSR) for the transmitter-holding-register-empty (THRE) flag. When it is set, the transmit holding register is ready to accept a byte. The driver writes the byte to the data register (REG_DATA) and then polls again for the transmitter-empty (TEMT) flag to ensure the byte has been shifted out before returning.

The `uart_barrier` call is a memory barrier that ensures the write to the data register is visible to the hardware before subsequent reads. On platforms with weak memory ordering, missing this barrier would cause intermittent data loss.

The `DELAY(4)` yields four microseconds per iteration, and the `limit` counter is 250,000. Together, they give a one-second timeout before the loop gives up. For a real UART, 250,000 iterations is a cap that should never be reached in normal operation; it is a safety net for the pathological case where the chip is in an unexpected state.

The probe is equally direct:

```
static int
ns8250_probe(struct uart_bas *bas)
{
    u_char val;

    /* Check known 0 bits that don't depend on DLAB. */
    val = uart_getreg(bas, REG_IIR);
    if (val & 0x30)
        return (ENXIO);
    return (0);
}
```

Bits 4 and 5 of the Interrupt Identification Register (IIR) are defined as always-zero for every variant of the 16550 family. If those bits read as one, this is not a real 16550 register, and the probe rejects the address.

You could read the whole driver in an afternoon. What you would come away with is a clear mental model: the methods are narrow, the framework is large, and the real engineering is in handling the quirks of specific chip revisions (a FIFO bug in the 16550 predecessor, an erratum in some PC chipsets, a signal-detect issue on certain Oxford devices). A new UART driver for a well-behaved chip is genuinely a small file.

26.7.6 The `uart_softc` and How the Framework Uses It

Each instance of a UART driver has a struct `uart_softc`, defined in `/usr/src/sys/dev/uart/uart_bus.h`. The framework allocates one per attached port. Its important fields include a pointer to the `uart_bas` that describes the port's register layout, the I/O resources (the IRQ, the memory range or I/O port range), the TTY device attached to this port, the current line parameters, and two byte buffers (RX and TX) that the framework uses internally. The driver does not usually allocate its own `softc`; it uses the framework's `uart_softc`, with the hardware-specific extensions added through `kobj` class inheritance.

When the framework receives an interrupt from a UART, it calls a framework-internal function that reads the interrupt-identification register, decides what kind of work the chip has requested (transmit-ready, receive-data-available, line-status, modem-status), and dispatches to the appropriate handler. The handlers pull data out of the chip's RX FIFO into the framework's RX ring buffer, or push data from the framework's TX ring buffer into the chip's TX FIFO, or update state variables in response to modem-signal changes. The interrupt handler returns, and the TTY layer consumes the ring buffers at its own pace through the framework's `put-character` and `get-character` paths.

This is why the driver's `uart_ops` table is so small. The high-volume work (moving bytes between the chip and the ring buffers) is handled by shared framework code that reads the chip's registers through `uart_getreg` and `uart_setreg`. The driver only needs to expose the low-level primitives; the composition is done for it.

26.7.7 Integration with the TTY Layer

Above the `uart(4)` framework sits the TTY layer, defined in `/usr/src/sys/kern/tty.c` and friends. A UART port in FreeBSD appears to userland as two `/dev` nodes:

- `/dev/ttyuN`: the callin node. Opening it blocks until a carrier detect signal is asserted (which models an incoming call on a modem). It is used for devices that answer, not initiate, connections.
- `/dev/cuaun`: the callout node. Opening it does not wait for carrier detect. It is used for devices that initiate connections, or for developers who want to talk to a serial port without pretending it is a modem.

The distinction is historical, dating from the era when serial ports were genuinely connected to analog modems with separate “someone is calling” and “I am initiating a call” semantics. FreeBSD preserves the distinction because some embedded and industrial workflows still rely on it, and because the implementation cost is minimal once the TTY layer's “two sides of the same port” pattern is in place.

The TTY layer calls into the `uart(4)` framework through a `ttysw` structure whose methods map neatly onto UART operations. The important entries include:

- `tsw_open`: called when userland opens the port. The framework enables interrupts, powers on the chip, and applies the default `termios`.
- `tsw_close`: called when the last userland reference is released. The framework drains the TX buffer, disables interrupts (unless the port is also a console), and puts the chip in an idle state.
- `tsw_ioctl`: called for `ioctls` the TTY layer does not handle itself. Most UART-specific `ioctls` are handled by the framework.
- `tsw_param`: called when `termios` changes. The framework reprograms the chip's baud rate, data bits, stop bits, parity, and flow control.

- `tsw_outwakeup`: called when there is new data to transmit. The framework enables the transmit-ready interrupt if it was disabled; on the next IRQ, the framework pushes bytes from the ring buffer into the chip.

You do not usually have to write any of these. The framework in `uart_tty.c` implements them once for every UART driver. Your driver's only contribution is the six methods in `uart_ops`.

26.7.8 The termios Interface in Practice

When a user runs `stty 115200` on a serial port, the following chain of calls happens:

1. `stty(1)` opens the port and issues a `TIOCSETA` ioctl carrying the new `struct termios`.
2. The kernel TTY layer receives the ioctl and updates its internal copy of the port's `termios`.
3. The TTY layer calls `tsw_param` on the port's `ttydevsw`, passing the new `termios`.
4. The `uart(4)` framework's `uart_param` implementation looks at the `termios` fields (`c_ispeed`, `c_ospeed`, `c_cflag` with its `CSIZE`, `CSTOPB`, `PARENB`, `PARODD`, `CRTSCTS` sub-bits) and calls the driver's `init` method with the corresponding raw values.
5. The driver's `init` method computes the divisor, writes the line-control register, reconfigures the FIFO, and returns.

None of this requires the driver to know about `termios`. The translation from `termios` bits to raw integers is done by the framework. The driver sees only the raw values: baudrate in bits per second, databits (usually 5 through 8), stopbits (1 or 2), and a parity code.

This separation is what lets FreeBSD run the same `uart(4)` framework on top of radically different chips. A 16550 driver and a PL011 driver both implement the same six `uart_ops` methods. The `termios`-to-raw translation happens once, in framework code, for every chip family.

26.7.9 Flow Control at the Register Level

Hardware flow control is typically driven by two signals on the UART: CTS (clear to send) and RTS (request to send). When CTS is asserted by the remote side, it is telling the local transmitter "I am ready for more data." When the local side asserts RTS, it is telling the remote transmitter the same thing. When either signal is not asserted, the corresponding transmitter pauses.

In a 16550, RTS is driven by a bit in the modem control register (MCR), and CTS is read from a bit in the modem status register (MSR). The framework exposes flow control through `termios` (`CRTSCTS` flag), through ioctls (`TIOCMGET`, `TIOCMSET`, `TIOCMBS`, `TIOCMBSIC`), and through automatic responses to FIFO fill levels.

When the receive FIFO fills past a threshold, the driver deasserts RTS to ask the remote side to stop transmitting. When the FIFO drains below a different threshold, the driver reasserts RTS. When the modem-status-interrupt fires because CTS changed, the interrupt handler enables or disables the transmit path accordingly. All of this is framework logic; the driver only exposes the register-level primitives.

Software flow control (XON/XOFF) is handled entirely in the TTY layer, by inserting and interpreting the XON (0x11) and XOFF (0x13) bytes in the data stream. The UART driver has no role in it.

26.7.10 The Interrupt Handler Path in Detail

Beyond the six `uart_ops` methods, a real UART driver usually implements an interrupt handler. The framework provides a generic one in `uart_core.c` that works for the vast majority of chips, but the driver can supply its own for chips with unusual behaviour. To understand what the framework's generic handler does, and when you might want to override it, it helps to trace the handler's path.

When the hardware interrupt fires, the framework's ISR reads the interrupt identification register (IIR) through `uart_getreg`. The IIR encodes which of four conditions triggered the interrupt: line-status (a framing error or overrun occurred), received-data-available (at least one byte is in the receive FIFO), transmitter-holding-register-empty (the TX FIFO wants more data), or modem-status (a modem signal changed state).

For line-status interrupts, the framework logs a warning (or increments a counter) and continues.

For received-data-available, the framework reads bytes out of the chip's RX FIFO one at a time, pushing each into the driver's internal RX ring buffer. The loop continues until the receive-data-available flag clears. Once the ring buffer has bytes, the framework signals the TTY layer's input path, which will pull bytes out as the consumer is ready.

For transmitter-holding-register-empty, the framework pulls bytes out of its internal TX ring buffer and pushes them into the chip's TX FIFO one at a time. The loop continues until the TX FIFO is full or the ring buffer is empty. Once the ring buffer is empty, the framework disables the transmit interrupt so the chip does not keep firing; the next `tsw_outwakeup` call (from the TTY layer, when there is new data) will reenable it.

For modem-status changes, the framework updates its internal modem-signal state and signals the TTY layer if the change is significant (for example, CTS deassertion when hardware flow control is enabled).

This is all done in interrupt context with the driver's mutex held. The mutex is a spin mutex (`MTX_SPIN`) for UART drivers, because taking a sleepable mutex in an interrupt handler is forbidden. The framework's helpers know this and use appropriate primitives.

When might a driver want to override the generic handler? Three situations come to mind.

First, if the chip has unusual FIFO semantics. Some chips do not clear their interrupt identification registers in the obvious way; you have to drain the FIFO completely, or you have to read a specific register to acknowledge. If your chip's data sheet describes such a quirk, you override the handler with chip-specific logic.

Second, if the chip has DMA support you want to use. The framework's generic handler is PIO (programmed I/O): one byte per register access. A chip with a DMA engine could move many bytes per interrupt, significantly reducing CPU overhead at high baud rates. Implementing DMA requires chip-specific code.

Third, if the chip has hardware timestamping or other advanced features. Some embedded UARTs can timestamp individual received bytes with microsecond precision, which is invaluable for industrial protocols. The framework does not know about this, so the driver must implement it.

For typical hardware, the generic handler is correct and performant. Do not override it without a specific reason.

26.7.11 The TX and RX Ring Buffers

The `uart(4)` framework keeps two ring buffers inside each port's `softc`. These are separate from any buffering on the chip itself: even if the chip has a 64-byte FIFO, the framework has its own ring buffers of some

configurable size (typically 4 KB for each direction) that sit between the chip and the TTY layer.

The purpose of these ring buffers is to absorb bursts. Suppose the consumer of data is slow (a busy userland process), and the producer (the remote serial device) is pushing data at 115200 baud. Without a ring buffer, the chip's 64-byte FIFO would fill up in about 6 milliseconds, and bytes would be lost. With a 4 KB ring buffer, the buffer can absorb a 350-millisecond burst at 115200 baud, which is enough for userland to catch up in almost every realistic scenario.

The sizes of these ring buffers are not generally configurable per-driver; they are baked into the framework. The ring buffer implementation is in `uart_core.c` and uses the same kind of head/tail pointer arithmetic as the ring buffers in our USB echo driver.

When the TTY layer asks for bytes (through `ttydisc_rint`), the framework moves bytes out of the RX ring into the TTY layer's own input queue, which has its own buffering and line-discipline processing (canonical mode, echo, signal generation, and so on). When userland writes bytes, they arrive at the framework's `tsw_outwakeup` path and are moved into the TX ring; the framework's transmit-empty interrupt handler pushes them from the ring into the chip.

This arrangement has a nice property: the driver, the framework, and the TTY layer are all loosely coupled. The driver only knows about the chip. The framework only knows about registers and ring buffers. The TTY layer only knows about buffering and line discipline. Each layer can be tested and reasoned about independently.

26.7.12 Debugging Serial Drivers

When a serial driver does not work, the symptoms can be confusing. Bytes go in, bytes come out, but the two do not match. The clock ticks, but the characters look like gibberish. The port opens, but writes return zero bytes. This section lists the diagnostic techniques that help.

Log aggressively at attach. Use `device_printf(dev, "attached at %x, IRQ %d\n", ...)` to verify the address and IRQ your driver ended up with. If the address is wrong, no I/O will work; if the IRQ is wrong, no interrupts will fire. Attach messages are the first line of defence.

Use `sysctl dev.uart.0.*` to inspect port state. The `uart(4)` framework exports many per-port knobs and statistics through `sysctl`. Reading them shows the current baud rate, the number of bytes transmitted, the number of overruns, the modem signal state, and more. If `tx` is incrementing but `rx` is not, the transmitter works but the receiver does not; if both are zero, nothing is happening at all.

Probe the hardware with `kgdb`. If you have a kernel crash dump or the ability to attach a kernel debugger, you can inspect the `uart_softc` directly and read its register values. This is invaluable when the chip is in a confused state that the software abstraction hides.

Compare against a working driver. If your modification broke something, bisect the change against the upstream `ns8250.c`. The difference will be small, and once you identify it, the fix is usually clear.

Use `dd` for small, repeatable tests. Instead of `cu` for debugging, use `dd if=/dev/zero of=/dev/cuau0 bs=1 count=100` to write exactly 100 bytes. Then `dd if=/dev/cuau0 of=output.bin bs=1 count=100` to read exactly 100 bytes (with a suitable timeout or a second open). This isolates timing and character-encoding issues that interactive `cu` might mask.

Check the hardware flow control pins. Many flow-control bugs are hardware, not software. Use a break-out board, a multimeter, or an oscilloscope to verify that DTR, RTS, CTS, and DSR are at the voltages you expect.

If one is stuck floating, the chip's behaviour is undefined.

Compare behaviour under `nmdm(4)`. If your userland tool works with `nmdm(4)` but not with your driver, the bug is in the driver. If it fails with both, the bug is in the tool.

These techniques apply equally to `uart(4)` drivers and `ucom(4)` drivers. The difference is that `uart(4)` problems often come down to register manipulation (did you set the divisor correctly?), while `ucom(4)` problems often come down to USB transfers (did the control transfer to set the baud rate actually succeed?). The debugging tools (USB: `usbconfig`, transfer statistics; UART: `sysctl`, chip registers) are different, but the investigative mindset is the same.

26.7.13 Writing a UART Driver Yourself

Putting the pieces together, a minimal UART driver for an imaginary register-compatible chip would be organised like this:

1. Define register offsets and bit positions in a local header.
2. Implement the six `uart_ops` methods: `probe`, `init`, `term`, `putc`, `rxready`, `getc`.
3. Declare a `struct uart_ops` initialised with those six methods.
4. Declare a `struct uart_class` initialised with the ops and the hardware parameters (range, reference clock, register shift).
5. Implement the interrupt handler if the chip needs more than the framework's default dispatch.
6. Register the driver with Newbus using the standard macros.

Most new UART drivers in the tree are small. Oxford single-port PCIe UARTs, for example, are a few hundred lines because they are fundamentally 16550-compatible and only need a thin layer of PCI-specific attach code. Complex ones like the Z8530 are larger because the chip has a more complicated programming model; the driver size tracks the chip's complexity, not the framework's.

26.7.14 Looking at `myfirst_uart.c` in Skeleton Form

For our running example, the skeleton of a minimal UART driver looks like this:

```
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/bus.h>
#include <sys/module.h>
#include <sys/kernel.h>

#include <dev/uart/uart.h>
#include <dev/uart/uart_cpu.h>
#include <dev/uart/uart_bus.h>

#include "uart_if.h"

static int    myfirst_uart_probe(struct uart_bas *);
```

```

static void myfirst_uart_init(struct uart_bas *, int, int, int, int);
static void myfirst_uart_term(struct uart_bas *);
static void myfirst_uart_putc(struct uart_bas *, int);
static int myfirst_uart_rxready(struct uart_bas *);
static int myfirst_uart_getc(struct uart_bas *, struct mtx *);

static struct uart_ops myfirst_uart_ops = {
    .probe    = myfirst_uart_probe,
    .init     = myfirst_uart_init,
    .term     = myfirst_uart_term,
    .putc     = myfirst_uart_putc,
    .rxready  = myfirst_uart_rxready,
    .getc     = myfirst_uart_getc,
};

struct myfirst_uart_softc {
    struct uart_softc base;
    /* any chip-specific state would go here */
};

static kobj_method_t myfirst_uart_methods[] = {
    /* Most methods inherit from the framework. */
    { 0, 0 }
};

struct uart_class myfirst_uart_class = {
    "myfirst_uart class",
    myfirst_uart_methods,
    sizeof(struct myfirst_uart_softc),
    .uc_ops    = &myfirst_uart_ops,
    .uc_range  = 8,
    .uc_rclk   = 1843200,
    .uc_rshift = 0,
};

```

The inclusion of `uart_if.h` is notable: that header is generated at build time by the `kobj` machinery from the interface definition in `/usr/src/sys/dev/uart/uart_if.m`. It declares the method prototypes that the framework expects drivers to implement. When you write a new driver, you depend on this header.

The six methods themselves are straightforward once you have the chip's programming manual open. `init` computes the divisor from `uc_rclk` and the baud rate, writes the line control register for the databits/stopbits/parity combination, enables FIFOs, and sets the interrupt enable register to the desired mask. `term` inverts `init`. `putc`, `getc`, and `rxready` each do a single-register access plus a spin on the status register.

A complete implementation of all six methods for a 16550-compatible chip is about three hundred lines. For a chip with quirks, it might grow to five hundred or more. The `ns8250` driver is longer than most because it

handles errata and variant detection for dozens of real chips, but the core logic of its six methods is still the standard pattern.

26.7.15 The ucom(4) Framework: USB-to-Serial Bridges

Not every serial port is a real UART on the system bus. Many are USB adapters: a PL2303, a CP2102, an FTDI FT232, a CH340G. These chips expose a serial port over USB, and FreeBSD's approach to supporting them is a small framework called ucom(4). It lives in `/usr/src/sys/dev/usb/serial/`, alongside the drivers for each chip family.

ucom(4) is distinct from uart(4). It does not use `uart_ops`, it does not use `uart_bas`, and it does not use the ring buffers inside `uart_core.c`. What it does is provide a TTY abstraction on top of USB transfers. A ucom(4) client declares itself through a struct `ucom_callback`:

```
struct ucom_callback {
    void (*ucom_cfg_get_status)(struct ucom_softc *, uint8_t *, uint8_t *);
    void (*ucom_cfg_set_dtr)(struct ucom_softc *, uint8_t);
    void (*ucom_cfg_set_rts)(struct ucom_softc *, uint8_t);
    void (*ucom_cfg_set_break)(struct ucom_softc *, uint8_t);
    void (*ucom_cfg_set_ring)(struct ucom_softc *, uint8_t);
    void (*ucom_cfg_param)(struct ucom_softc *, struct termios *);
    void (*ucom_cfg_open)(struct ucom_softc *);
    void (*ucom_cfg_close)(struct ucom_softc *);
    int (*ucom_pre_open)(struct ucom_softc *);
    int (*ucom_pre_param)(struct ucom_softc *, struct termios *);
    int (*ucom_ioctl)(struct ucom_softc *, uint32_t, caddr_t, int,
                     struct thread *);
    void (*ucom_start_read)(struct ucom_softc *);
    void (*ucom_stop_read)(struct ucom_softc *);
    void (*ucom_start_write)(struct ucom_softc *);
    void (*ucom_stop_write)(struct ucom_softc *);
    void (*ucom_tty_name)(struct ucom_softc *, char *pbuf, uint16_t buflen,
                          uint16_t unit, uint16_t subunit);
    void (*ucom_poll)(struct ucom_softc *);
    void (*ucom_free)(struct ucom_softc *);
};
```

The methods divide into three groups. Configuration methods (names prefixed with `ucom_cfg_`) are called to change the state of the underlying chip: set DTR, set RTS, change the baud rate, and so on. These methods run in the framework's configuration thread, which is designed for making synchronous USB control requests. Flow methods (`ucom_start_read`, `ucom_start_write`, `ucom_stop_read`, `ucom_stop_write`) are called to enable or disable the data path on the underlying USB channels. The pre-methods (`ucom_pre_open`, `ucom_pre_param`) run on the caller's context before the framework schedules a configuration task, which is where a driver validates userland-supplied arguments and returns an `errno` if they are unacceptable. The `ucom_ioctl` method translates chip-specific userland ioctls that the framework does not handle into USB requests.

A USB-to-serial driver's job is to implement these callbacks in terms of USB transfers. When `ucom_cfg_param` is called with a new baud rate, the driver issues a vendor-specific control transfer that programs the chip's baud-rate register. When `ucom_start_read` is called, the driver starts a bulk-IN channel that delivers incoming bytes. When `ucom_start_write` is called, the driver starts a bulk-OUT channel that flushes outgoing bytes.

The FTDI driver at `/usr/src/sys/dev/usb/serial/uftdi.c` is the concrete reference. Its `ucom_cfg_param` implementation translates the `termios` fields into the FTDI's proprietary baud-rate divisor format (which is weird, because FTDI chips use a sub-integer divisor scheme that is almost but not quite standard 16550) and issues a control transfer to `bRequest = FTDI_SIO_SET_BAUD_RATE`. Its `ucom_start_read` starts the bulk-IN channel that reads from the FTDI's RX FIFO. Its `ucom_start_write` starts the bulk-OUT channel that writes to the FTDI's TX FIFO.

From userland's perspective, a `ucom(4)` device looks identical to a `uart(4)` device. Both appear as `/dev/ttyuN` and `/dev/cuaN`. Both respond to `stty`, `cu`, `tip`, `minicom`, and every other serial tool. Both support the same `termios` flags. The distinction only matters to a driver writer.

26.7.16 Reading `uftdi.c` As a Complete Example

FTDI chips (FT232R, FT232H, FT2232H, and many others) are the most widely deployed USB-to-serial chips in the embedded world. If you ever work with microcontrollers, evaluation boards, 3D printers, or industrial sensors, you will encounter FTDI hardware. FreeBSD has supported FTDI since 4.x, and the current driver lives in `/usr/src/sys/dev/usb/serial/uftdi.c`. At roughly three thousand lines, it is not short, but most of that length is devoted to the large match table (FTDI products are legion) and to chip-variant quirks (every few years FTDI adds a new FIFO size, a new baud-rate divisor scheme, or a new register). The pedagogically interesting core is a few hundred lines, and reading it is a direct reward for the conceptual work of Section 4.

When you open the file, the first thing to notice is the enormous match table. FTDI assigns OEM-specific USB IDs to their customers, so the match table includes not just FTDI's own VID/PID pairs but also hundreds of VIDs and PIDs from companies that embed FTDI chips in their products. Sparkfun, Pololu, Olimex, Adafruit, various industrial vendors: every one has at least one entry in the `uftdi` match table. The `STRUCT_USB_HOST_ID` array is a few hundred entries long, grouped with comments indicating which product family each cluster belongs to.

The `softc` comes next. An FTDI `softc` includes the USB device pointer, a mutex, the transfer array for the bulk-IN and bulk-OUT channels (FTDI devices use bulk for data, not interrupt), a `struct ucom_super_softc` for the `ucom(4)` layer, a `struct ucom_softc` for the per-port state, and FTDI-specific fields: the current baud-rate divisor, the current line control register contents, the current modem control register contents, and a few flags for the variant family (FT232, FT2232, FT232H, and so on). Each variant requires slightly different code for some operations, so the driver keeps a variant identifier in the `softc` and branches on it in the operations that differ.

The transfer configuration array is where the FTDI driver's interaction with the USB framework is declared. It declares two channels: `UFTDI_BULK_DT_RD` for incoming data and `UFTDI_BULK_DT_WR` for outgoing. Each is a `UE_BULK` transfer with a moderate buffer size (the FTDI default is 64 bytes for low-speed and 512 bytes for full-speed, and the driver picks the right size at attach based on the chip variant). The callbacks are `uftdi_read_callback` and `uftdi_write_callback`, and they follow the three-state pattern exactly as described in Section 3.

The `ucom_callback` structure is the next important block. It wires the FTDI driver into the `ucom(4)` framework. The methods it provides include `uftdi_cfg_param` (called when the baud rate or byte format

changes), `uftdi_cfg_set_dtr` (called to assert or deassert DTR), `uftdi_cfg_set_rts` (same for RTS), `uftdi_cfg_open` and `uftdi_cfg_close` (called when a userland process opens or closes the device), and `uftdi_start_read`, `uftdi_start_write`, `uftdi_stop_read`, `uftdi_stop_write` (called to enable or disable the data channels). Each configuration method translates a high-level operation into a USB control transfer to the FTDI chip.

The baud-rate programming is one of the most instructive parts of the driver, because FTDI chips use a peculiar divisor scheme. Rather than the clean integer divisors a 16550 UART uses, FTDI supports a fractional divisor where the numerator is an integer and the denominator is computed from two bits that select one-eighth, one-quarter, three-eighths, one-half, or five-eighths. The function `uftdi_encode_baudrate` takes a requested baud rate and the chip's reference clock and computes the closest valid divisor. It handles the edge cases (very low baud rates, very high baud rates on newer chips, standard rates like 115200 which are exactly representable, nonstandard rates like 31250 used by MIDI). The resulting sixteen-bit value is passed to `uftdi_set_baudrate`, which issues a control transfer to the FTDI's baud-rate register.

The line control register (data bits, stop bits, parity) is programmed through a similar sequence: the `termios` structure arrives at `uftdi_cfg_param`, the driver extracts the relevant bits, encodes them into the FTDI's line-control format, and issues a control transfer.

The modem control signals (DTR, RTS) are programmed through `uftdi_cfg_set_dtr` and `uftdi_cfg_set_rts`. These are the simplest transfers: a control-out with no payload, which the chip interprets as “set DTR to X” or “set RTS to Y.”

The data path is in the two callbacks. `uftdi_read_callback` handles the bulk-IN channel. On `USB_ST_TRANSFERRED`, it extracts the received bytes from the USB frame (ignoring the first two bytes, which are FTDI status bytes) and feeds them into the `ucom(4)` layer for delivery to userland. On `USB_ST_SETUP`, it rearms the read for another buffer. `uftdi_write_callback` handles the bulk-OUT channel. On `USB_ST_SETUP`, it asks the `ucom(4)` layer for more data, copies it into a USB frame, and submits the transfer. On `USB_ST_TRANSFERRED`, it rearms to check for more data.

Reading through `uftdi.c` with Section 4 vocabulary in hand, you can see how the entire `ucom(4)` framework pattern is instantiated for a specific chip. The FTDI-specific logic (baud-rate encoding, line-control encoding, modem-control setting) is isolated into helper functions. The framework integration is handled by the `ucom_callback` structure. The data flow is handled by the two bulk transfers. If you were writing a driver for a different USB-to-serial chip, you would copy this structure and change the chip-specific parts.

The existence of this driver explains something that might otherwise be puzzling. Why did FreeBSD add `ucom(4)` as a separate framework rather than as part of `uart(4)`? Because the entire data-path machinery of a `uart(4)` driver (interrupt handlers, ring buffers, register accesses) has no analogue in a USB-to-serial world. The FTDI chip's “FIFO” is an on-chip buffer that the driver cannot directly access; it can only send bulk packets to the chip and receive them back. The `uart(4)` machinery would be unused overhead. By having `ucom(4)` as a separate framework with its own data-path abstractions, FreeBSD can make a USB-to-serial driver like `uftdi` weigh just a few hundred lines of core logic rather than wrap an unnecessary layer of 16550 emulation.

When you finish reading `uftdi.c`, open up `lcom.c` (the Prolific PL2303 driver) and `uslcom.c` (the Silicon Labs CP210x driver) in sequence. They follow the same structure with different chip-specific details. After reading all three, you will have a working understanding of how a USB-to-serial driver is organised in FreeBSD, and you will be ready to write one for any chip you encounter.

26.7.17 Choosing Between `uart(4)` and `ucom(4)`

The choice is mechanical. If the chip sits on the system bus (PCI, ISA, a platform I/O port, a memory-mapped SoC peripheral), you write a `uart(4)` driver. If the chip sits on USB and exposes a serial interface, you write a `ucom(4)` driver.

The two frameworks do not mix. You cannot take a `uart(4)` driver and plug it into USB, and you cannot take a `ucom(4)` driver and attach it to PCIe. They are independent implementations of the same user-visible abstraction (a TTY port), but with very different internals.

Beginners sometimes ask why the two frameworks exist at all, instead of a unified serial framework with a pluggable transport layer. The answer is historical: `uart(4)` was rewritten in its modern form in the early 2000s to replace the older `sio(4)` driver, and at that time USB serial support was a set of ad-hoc drivers. When USB serial support was unified, the natural approach was to add a thin TTY-integration layer (`ucom(4)`) rather than retrofit `uart(4)`. The two are now independent because decoupling them has been stable and useful. A unification effort would be a significant project with modest payoff.

For your purposes as a beginning driver writer, the rule is simple. If you are writing a driver for a chip that lives on your motherboard's serial ports or on a PCIe card, use `uart(4)`. If you are writing a driver for a USB dongle that pretends to be a serial port, use `ucom(4)`. The reference drivers for each case (`ns8250` for `uart(4)`, `uftdi` for `ucom(4)`) are the right places to learn the details.

26.7.18 Differences Between Chip Variants

Working with real UART hardware quickly teaches you that “16550-compatible” is a spectrum, not a fixed specification. Here are the variants you are most likely to encounter and the differences that matter.

8250. The original, from the late 1970s. Has no FIFO; every received byte must be collected by the CPU before the next arrives. Software for 16550A will usually work, with reduced performance.

16450. Like 8250 but with some register improvements and slightly more reliable behaviour. Still no FIFO.

16550. Introduced a 16-byte FIFO, but the original 16550 had buggy FIFO behaviour. Software should detect this and refuse to use the FIFO in the bad case.

16550A. Fixed the FIFO bugs. This is the canonical “16550” that every PC serial driver targets. Reliable, widely compatible.

16550AF. Further revisions for clocking and margin. For software purposes, identical to 16550A.

16650. Extended the FIFO to 32 bytes and added automatic hardware flow control. Mostly 16550A-compatible.

16750. Extended the FIFO to 64 bytes. Some chips with this label also have additional autobaud and high-speed modes. Software must decide whether to enable the extended FIFO.

16950 (Oxford Semiconductor). A 128-byte FIFO, additional flow-control features, and support for unusual baud rates through a modified divisor scheme. Often seen on high-performance PCIe serial cards.

UART-compatible SoC controllers. Many embedded processors have built-in UARTs that are register-compatible with 16550 but with quirks: some have different clock rates, some have different register offsets, some have DMA support, some have different interrupt semantics. The `ns8250` driver in FreeBSD probes for these variants during attach and adjusts its behaviour accordingly.

The `ns8250` driver's probe logic reads several registers to determine which variant is present. It checks the IIR bits we saw earlier, reads the FIFO control register to see what FIFO size is reported, checks for 16650/16750/16950 identification markers, and records the result in a variant field in the `softc`. The body of the driver then branches on this field at a few places where the variants differ.

When you write a driver for a new UART, decide upfront whether you want to target a single variant or a family. Targeting a single variant is simpler but limits the hardware you can support. Targeting a family requires variant detection logic like `ns8250`'s.

26.7.19 The Console Path

FreeBSD can use a serial port as the console. This is especially useful for embedded systems that do not have a display, for servers that do not have a keyboard and monitor, and for kernel debugging (so that `printf` output goes somewhere visible even when the display driver is broken).

The console path is tightly integrated with `uart(4)`. A UART that is designated as the console is probed early in boot, before most of the kernel is initialised. The console's `putc` and `getc` methods are used to emit boot messages and to read boot-time keyboard input. Only after the full kernel is up does the UART get attached to the TTY layer in the normal way.

Two mechanisms select which port is the console. The boot loader can set a variable (typically `console=comconsole`) in the environment, which the kernel reads at startup. Alternatively, the kernel can be configured at build time with a specific port as the console (via options `UART_EARLY_CONSOLE` in a kernel configuration file).

When a port is the console, it stays active across driver unload and detach. You cannot unload `uart` or disable the console port without losing console output. This constraint is enforced in the `uart(4)` framework and is usually invisible to driver writers (you do not need to special-case the console port), but it is worth knowing about in case you see console-related oddities during testing.

26.7.20 Comparing UART Drivers Across Architectures

One of FreeBSD's strengths is that the same `uart(4)` framework works across multiple architectures. An `x86_64` laptop with a 16550 on a PCIe card, an `aarch64` Raspberry Pi with a PL011 on-chip UART, and a `riscv64` development board with a SiFive-specific UART all expose the same TTY interface to userland. Only the driver differs.

Here is a quick survey of the UART drivers in FreeBSD 14.3:

- `uart_dev_ns8250.c`: the 16550 family for `x86` and many other platforms.
- `uart_dev_pl011.c`: the ARM PrimeCell PL011 UART, used on Raspberry Pi and many ARM SoCs.
- `uart_dev_imx.c`: the NXP i.MX UART, used on i.MX-based ARM boards.
- `uart_dev_z8530.c`: the Zilog Z8530, historically used on SPARC workstations.
- `uart_dev_ti8250.c`: a TI variant of the 16550 with additional features.
- `uart_dev_pl011.c` (sbsa variant): the SBSA-standardised ARM UART for server-class ARM hardware.
- `uart_dev_snps.c`: the Synopsys DesignWare UART, used on many RISC-V boards.

Open any two of these and compare their `uart_ops` implementations side by side. The structure is identical: six methods, each pointing at a function that reads or writes chip-specific registers. The chip-specific details differ, but the framework's API is the same.

This is the payoff of the layered design. A new UART driver is a contained project: a few hundred lines of code, reusing all the buffering and TTY integration from the framework. If FreeBSD had to reimplement buffering for every UART, the system would be much larger and much harder to verify.

26.7.21 What About the USB CDC ACM Standard?

USB has a standard class for serial devices, called CDC ACM (Communication Device Class, Abstract Control Model). Chips that implement CDC ACM advertise themselves with a specific class/subclass/protocol triple at the interface level, and they can be driven by a single generic driver rather than a vendor-specific one. FreeBSD's generic CDC ACM driver is `u3g.c` in `/usr/src/sys/dev/usb/serial/`, and it is also built on top of `ucom(4)`.

Many modern USB serial chips implement CDC ACM, so the generic driver just works for them without a vendor-specific file. Others (like FTDI) use proprietary protocols that require a vendor-specific driver. The class/subclass/protocol triple in the interface descriptor is what tells you which case you are in; `usbconfig -d ugenN.M dump_all_config_desc` will show it.

When you are shopping for a USB serial adapter for development work, prefer chips that implement CDC ACM. They are cheaper, more portable, and do not require proprietary drivers. FTDI chips are historically dominant in embedded development because of their reliability, and FreeBSD supports them well, but a modern CP2102 or CH340G running in CDC ACM mode is equally usable.

26.7.22 Wrapping Up Section 4

Section 4 has given you a complete picture of how serial drivers work in FreeBSD. You have seen the layering: `uart(4)` at the framework level, `ttydevsw` at the TTY integration level, `uart_ops` at the hardware level. You have seen the distinction between `uart(4)` for bus-attached UARTs and `ucom(4)` for USB-to-serial bridges, and the practical rule for deciding which to use. You have seen, at a high level, the six hardware methods a UART driver implements, the configuration callbacks a USB-to-serial driver implements, and how the TTY layer sits on top of both with one uniform interface to userland.

The level of depth in this section is necessarily lighter than the USB-side sections, because serial drivers in FreeBSD are more specialised than USB drivers and you are more likely to read an existing one (or modify one) than to write a brand-new one from scratch. If you do find yourself writing a new UART driver for a custom board, the path is clear: open `ns8250` in one window, open your chip's data sheet in another, and write the six methods one by one.

Two key takeaways frame Section 5. First, testing serial drivers does not require real hardware. FreeBSD ships a `nmdm(4)` null-modem driver that creates pairs of virtual TTYs you can wire together, letting you exercise `termios` changes, flow control, and data flow without plugging in anything. Second, testing USB drivers without hardware is harder but not impossible: you can use QEMU with USB redirection to test against real devices through a VM, or you can use FreeBSD's USB gadget mode to make one machine present itself as a USB device to another. Section 5 covers both. The goal is to enable a development loop that does not depend on cable-handling and on plugging things in and out.

26.8 Section 5: Testing USB and Serial Drivers Without Real Hardware

26.8.1 Why This Section Exists

A beginning driver writer often gets stuck at the same obstacle. They write a driver, compile it, want to try it, and discover they do not have the hardware, the hardware is behaving badly, the hardware is on the wrong machine, or the iteration loop of “change code, plug it in, see what happens, unplug it, change code again” is painfully slow and unreliable. Section 5 addresses this directly. FreeBSD provides several mechanisms that let you exercise driver code paths without physical hardware, and knowing these mechanisms will save you hours of frustration.

The goal is not to pretend hardware is present when it is not. The goal is to give you tools that cover the parts of driver development where hardware is incidental, so that when you do plug in real hardware, you already know your code path logic is correct and you are only validating the physical interaction. Debugging a register-level quirk is faster when you know that your locking, your state machines, and your user interface are already sound.

This section covers four such mechanisms: the `nmdm(4)` null-modem driver for serial testing, basic userland tools for exercising TTYs (`cu`, `tip`, `stty`, `comcontrol`), QEMU with USB redirection for USB driver testing, and FreeBSD’s USB gadget mode for presenting one machine as a USB device to another. It ends with a short discussion of techniques that do not require any special tooling: unit tests at the functional layer, logging discipline, and assertion-driven development.

26.8.2 The `nmdm(4)` Null-Modem Driver

`nmdm(4)` is a kernel module that creates pairs of linked virtual TTYs. When you write to one side, it comes out the other side, exactly as if you had connected two real serial ports with a null-modem cable. The driver is in `/usr/src/sys/dev/nmdm/nmdm.c`, and it is loaded with:

```
# kldload nmdm
```

Once loaded, you can instantiate pairs on demand simply by opening them. Run:

```
# cu -l /dev/nmdm0A
```

This opens the A side of pair 0. On another terminal, run:

```
# cu -l /dev/nmdm0B
```

Whatever you type into one `cu` session will appear in the other. You have now created a pair of virtual TTYs, with no hardware involved. You can change baud rates with `stty` and the change will be noticed on both sides. You can assert DTR and CTS through `ioctl`s and see the effect on the other side.

The utility of `nmdm(4)` for driver development is twofold. First, if you are writing a TTY-layer user (say, a driver that spawns a shell on a virtual TTY, or a userland program that implements a protocol over a TTY), you

can test it end-to-end against `nmdm(4)` without any hardware. Second, if you are writing a `ucom(4)` or `uart(4)` driver, you can compare its behaviour to `nmdm(4)`'s behaviour by running the same userland test against both. If your driver misbehaves where `nmdm(4)` does not, the bug is in your driver; if both misbehave, the bug is probably in your userland test.

A small caveat: `nmdm(4)` does not simulate baud rate delays. Whatever you write comes out the other side at memory speed. This is usually what you want (you do not want to wait through a real 9600-baud transmission for a hundred-kilobyte test payload), but it does mean that timing-sensitive protocols cannot be tested with `nmdm(4)` alone.

26.8.3 The `cu(1)`, `tip(1)`, and `stty(1)` Toolbox

Whether you are using `nmdm(4)`, a real UART, or a USB-to-serial dongle, the userland tools you use to interact with a TTY are the same. The most important three are `cu(1)`, `tip(1)`, and `stty(1)`.

`cu` is the classic “call up” program. It opens a TTY, puts the terminal into raw mode, and lets you type bytes to the port and see bytes coming back. To open a port at a specific baud rate:

```
# cu -l /dev/cuau0 -s 115200
```

The `-l` argument specifies the device, and `-s` specifies the baud rate. `cu` supports a handful of escape sequences (all starting with `~`) for exiting, sending files, and similar operations; `~.` is the standard “exit” escape and `~?` lists the others.

`tip` is a related tool with similar semantics but a different configuration mechanism. `tip` reads `/etc/remote` for named connection entries and can take a name argument rather than a device path. For most purposes, `cu` and `tip` are interchangeable; `cu` is more convenient for one-off use.

`stty` prints or changes the termios parameters of a TTY. Run `stty -a -f /dev/ttyu0` to see every termios flag on the port. Run `stty 115200 -f /dev/ttyu0` to set the baud rate. Run `stty cs8 -parenb -cstopb -f /dev/ttyu0` to set eight data bits, no parity, one stop bit (the most common configuration in modern embedded work). The manual page is extensive, and the flags map almost directly onto the bits of `c_cflag`, `c_iflag`, `c_lflag`, and `c_oflag` in the `termios` struct.

Using these three tools together gives you a flexible way to poke at your driver from userland. You can change settings with `stty`, open the port with `cu`, send and receive bytes, close the port, check the state with `stty` again, and repeat. If your driver's `tsw_param` implementation has a bug, `stty` will expose it: the settings you set will not read back correctly, or the port will behave differently than requested.

26.8.4 The `comcontrol(8)` Utility

`comcontrol` is a specialised utility for serial ports. It sets port-specific parameters that are not exposed through `termios`. The two most important are the `drainwait` and the `specific-RS-485` options. For beginner driver testing, the more common use is inspecting port state: `comcontrol /dev/ttyu0` shows the current modem signals (DTR, RTS, CTS, DSR, CD, RI) and the current `drainwait`. You can also set the signals:

```
# comcontrol /dev/ttyu0 dtr rts
```

sets DTR and RTS. This is useful for testing flow-control handling without writing a custom program.

26.8.5 The `usbconfig(8)` Utility

On the USB side, `usbconfig(8)` is the Swiss Army knife. You used it at the end of Section 1 to inspect a device's descriptors. Several other subcommands are useful during driver development:

- `usbconfig list`: list all attached USB devices.
- `usbconfig -d ugenN.M dump_all_config_desc`: print every descriptor for a device.
- `usbconfig -d ugenN.M dump_device_quirks`: print any quirks applied by the USB framework.
- `usbconfig -d ugenN.M dump_stats`: print per-transfer statistics.
- `usbconfig -d ugenN.M suspend`: put the device into the USB suspend state.
- `usbconfig -d ugenN.M resume`: wake it up.
- `usbconfig -d ugenN.M reset`: physically reset the device.

The `reset` command is particularly useful during development. A driver under test can easily leave a device in a confused state; `usbconfig reset` puts the device back to the just-plugged-in condition without requiring a physical unplug.

26.8.6 Testing USB Drivers with QEMU

QEMU, the generic CPU emulator, has strong USB support. You can run a FreeBSD guest inside QEMU and redirect real host USB devices into the guest. This is the single most useful technique for USB driver development, because it lets you test against real hardware while retaining all the iteration speed of working inside a VM.

On a FreeBSD host, install QEMU from ports:

```
# pkg install qemu
```

Install a FreeBSD guest image into a disk file (the mechanics are covered in Chapter 4 and Appendix A). When you boot the guest, add USB redirection options:

```
qemu-system-x86_64 \  
-drive file=freebsd.img,format=raw \  
-m 1024 \  
-device nec-usb-xhci,id=xhci \  
-device usb-host,bus=xhci.0,vendorid=0x0403,productid=0x6001
```

The `-device nec-usb-xhci` line adds a USB 3.0 controller to the guest. The `-device usb-host` line attaches a specific USB device from the host (identified by vendor and product) to that controller. When the guest boots, the device appears on the guest's USB bus and can be enumerated by the guest's kernel.

This setup gives you the full iteration loop inside the VM. You can load your driver, unload it, reload a rebuilt version, all without physically handling any cables. You can use serial console or networking to interact with the VM. You can snapshot the VM state before a risky test and revert if the test panics.

The main limitation is USB isochronous support, which is less stable across emulators. For bulk, interrupt, and control transfers (the three types most drivers use), QEMU USB redirection is reliable enough to be your primary development environment.

26.8.7 FreeBSD USB Gadget Mode

If QEMU is not available and you have two FreeBSD machines, there is another option: `usb_template(4)` and the dual-role USB support on some hardware let you make one machine present itself as a USB device to another. The host machine sees a normal USB peripheral; the gadget machine is actually running the device side of the USB protocol.

This is an advanced topic and the hardware support is variable. On x86 platforms with USB-on-the-Go-capable chipsets, on some ARM boards, and on specific embedded configurations, the setup works. On most desktop hardware, it does not. The gory details are in `/usr/src/sys/dev/usb/template/` and in the `usb_template(4)` manual page.

If you have the hardware to use this technique, it is the closest thing to a full end-to-end USB driver test without physical peripherals. If you do not, do not pursue it for a learning project; use QEMU instead.

26.8.8 Techniques That Do Not Require Special Tooling

Beyond the frameworks above, there are several techniques that rely only on good driver design.

First, design your driver so that the hardware-independent parts can be unit-tested in userland. If your driver has a protocol parser, a state machine, or a checksum calculator, factor those into functions that take plain C buffers and return plain C results. You can then compile those functions into a userland test program and run them against known inputs. This catches many bugs before they reach the kernel.

Second, log aggressively during development and quietly in production. The `DLOG_RL` macro from Chapter 25 is your friend: it lets you emit frequent diagnostic messages during development, with a `sysctl` to suppress them in production. Rate-limiting prevents log storms if something goes wrong.

Third, use assertions for invariants. `KASSERT(cond, ("message", args...))` will panic the kernel if `cond` is false, but only in `INVARIANTS` kernels. You can run your driver in an `INVARIANTS` kernel during development and in a production kernel later, without changing the code. The Chapter 20 discussion of `INVARIANTS` is the reference.

Fourth, be rigorous about concurrency testing. Use `INVARIANTS` plus `WITNESS` (which tracks lock ordering) during development. If your driver has a locking bug that almost always works but occasionally deadlocks, `WITNESS` will catch it on the first occurrence.

Fifth, write a simple userland client for your driver and use it as part of your development loop. Even a ten-line program that opens the device, writes a known string, reads a known response, and checks the result is enormously useful. You can run it in a loop during stress testing, you can run it with `ktrace -f cmd` to get a trace of system calls, and you can run it under a debugger if something surprises you.

26.8.9 A Walkthrough of QEMU USB Redirection

QEMU's USB support is the single most useful tool for USB driver development, so a more detailed walkthrough is in order. Suppose you want to develop a driver for a specific FT232 adapter. Your host is a FreeBSD 14.3 machine, and you want to run your driver on a guest FreeBSD 14.3 VM inside QEMU.

First, install QEMU and create a guest disk image:

```
# pkg install qemu
# truncate -s 16G guest.img
```

Install FreeBSD into the image. The exact procedure is covered in Appendix A, but the short version is: boot a FreeBSD installer ISO as the CD-ROM, install onto the disk image, reboot.

Once the guest is installed, locate the host USB device you want to redirect. Plug in the FT232 and note the vendor and product IDs from `usbconfig list`:

```
ugen0.3: <FTDI FT232R USB UART> at usb0
```

`usbconfig -d ugen0.3 dump_device_desc` will show `idVendor = 0x0403` and `idProduct = 0x6001`.

Now start QEMU with USB redirection:

```
qemu-system-x86_64 \
  -enable-kvm \
  -cpu host \
  -m 2048 \
  -drive file=guest.img,format=raw \
  -device nec-usb-xhci,id=xhci \
  -device usb-host,bus=xhci.0,vendorid=0x0403,productid=0x6001 \
  -net user -net nic
```

The `-device nec-usb-xhci` line adds a USB 3.0 controller to the VM. The `-device usb-host` line redirects the matching host device into the VM. When the VM boots, the FT232 will appear as if it were plugged directly into the VM's USB port.

Inside the VM, run `dmesg` and look for the USB attach:

```
uhub0: 4 ports with 4 removable, self powered
uftdi0 on usb0
uftdi0: <FTDI FT232R USB UART, class 255/0, rev 2.00/6.00, addr 2> on usb0
```

Your driver (whether `uftdi` or your own work-in-progress) will see a real FT232 with real descriptors, real transfer behaviour, and real quirks. You can unload and reload your driver inside the VM without disconnecting anything; you can run kernel with `INVARIANTS` and `WITNESS` without worrying about host-side impact; you can snapshot the VM and revert if a test goes badly.

A few subtleties to be aware of with USB redirection:

- Only one consumer can claim a USB device at a time. If you redirect a device into a VM, the host loses access to it until the VM releases it. This matters if you are redirecting something like a USB keyboard or mouse; choose a spare device for development.
- USB isochronous transfers have some quirks in QEMU. They work, but timing can be slightly off. For most driver development, you will be working with bulk, interrupt, and control transfers, so this is rarely a concern.
- Some host controllers (particularly xHCI) can reset under heavy I/O. If your driver behaves strangely under stress testing, try with a different `-device` type (`uhci`, `ehci`, `xhci`) to see whether the issue is in your driver or in the emulated controller.
- USB 3.0 SuperSpeed transfers are more reliable with `-device nec-usb-xhci`. Older `-usb` flag-based controllers are limited to USB 2.0.

When the VM is running, the iteration cycle becomes: edit code on the host, copy to the VM (or mount a shared directory), build inside the VM, load, test, reload, repeat. A Makefile with a `test`: target that does all of this can cut iteration time to tens of seconds.

26.8.10 Using devd(8) During Development

`devd(8)` is FreeBSD's device-event daemon. It reacts to kernel notifications about device attach and detach and can run configured commands in response. During driver development, `devd` is useful in two ways.

First, it can auto-load your module when a matching device is plugged in. If your module is in `/boot/modules/` and your `USB_PNP_HOST_INFO` is set, `devd` will run `kldload` automatically when it sees a device that would match.

Second, it can run diagnostic commands on attach. A `/etc/devd.conf` entry like:

```
attach 100 {
    device-name "myfirst_usb[0-9]+";
    action "logger -t myfirst-usb 'device attached: $device-name'";
};
```

will write a log line every time a `myfirst_usb` device attaches. For more elaborate diagnostics, you can invoke your own shell script that dumps state, starts userland consumers, or sends notifications.

During development, a useful pattern is to have `devd` open a `cu` session to a newly attached `ucom` device, so you can exercise the driver the moment it attaches:

```
attach 100 {
    device-name "cuaU[0-9]+";
    action "setsid screen -dmS usb-serial cu -l /dev/$device-name -s 9600";
};
```

This runs the test in a detached screen session, which you can later attach to with `screen -r usb-serial`.

26.8.11 Writing a Simple Userland Test Harness

Most driver bugs are exposed by actually running the driver against userland. Even a short test program catches more bugs than reading the driver's code carefully. For our echo driver, a minimal test program looks like:

```
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

int
main(int argc, char **argv)
{
    int fd;
    const char *msg = "hello";
    char buf[64];
    int n;

    fd = open("/dev/myfirst_usb0", O_RDWR);
    if (fd < 0) {
        perror("open");
        return (1);
    }

    if (write(fd, msg, strlen(msg)) != (ssize_t)strlen(msg)) {
        perror("write");
        close(fd);
        return (1);
    }

    n = read(fd, buf, sizeof(buf) - 1);
    if (n < 0) {
        perror("read");
        close(fd);
        return (1);
    }
    buf[n] = '\0';
    printf("got %d bytes: %s\n", n, buf);

    close(fd);
    return (0);
}
```

Compile with `cc -o lab03-test lab03-test.c`. Run with `./lab03-test`. The expected output is “got 5

bytes: hello”.

Extensions to this test harness that catch more bugs:

- Loop the open/write/read/close cycle a thousand times. Memory leaks and resource leaks show up after a few hundred iterations.
- Fork multiple processes and have them all read/write concurrently. Race conditions manifest as random data corruption or deadlocks.
- Intentionally kill the test process mid-transfer. Driver-side state machines sometimes get confused when a userland consumer disappears unexpectedly.
- Send random-length writes (1 byte, 10 bytes, 100 bytes, 1 KB, 10 KB). Edge cases around short and long transfers are where many subtle bugs live.

Build these extensions incrementally. Each one will probably reveal a bug the previous version did not; each bug you fix will make your driver more robust.

26.8.12 Logging Patterns for Development

During development, you want verbose logging. In production, you want silence. The pattern from Chapter 25 (DLOG_RL with a sysctl to control verbosity) carries over unchanged to USB and UART drivers. Define a rate-limited logging macro that compiles to a no-op in production builds, and sprinkle it through every branch that might be interesting during debugging:

```
#ifdef MYFIRST_USB_DEBUG
#define DLOG(sc, fmt, ...) \
    do { \
        if (myfirst_usb_debug) \
            device_printf((sc)->sc_dev, fmt "\n", ##__VA_ARGS__); \
    } while (0)
#else
#define DLOG(sc, fmt, ...) ((void)0)
#endif
```

Then in the callback:

```
case USB_ST_TRANSFERRED:
    DLOG(sc, "bulk read completed, actlen=%d", actlen);
    ...
```

Control myfirst_usb_debug through a sysctl:

```
static int myfirst_usb_debug = 0;
SYSCTL_INT(_hw_myfirst_usb, OID_AUTO, debug, CTLFLAG_RWTUN,
    &myfirst_usb_debug, 0, "Enable debug logging");
```

Now you can turn logging on and off at runtime with `sysctl hw.myfirst_usb.debug=1`. During development, turn it on. During stress tests, turn it off (logging rate-limiting helps, but zero logging is even cheaper). During post-mortem analysis of a bug, turn it on and reproduce.

26.8.13 A Test-Driven Workflow for Chapter 26

For the hands-on labs coming in the next section, a good workflow looks like this:

1. Write the driver code.
2. Compile it. Fix build errors.
3. Load it in a test VM. Observe `dmesg` for attach failures.
4. Run a small userland client that exercises the driver's I/O paths.
5. Unload. Make a change. Go back to step 2.
6. Once the driver behaves well in the VM, test it on real hardware as a sanity check.

Most of the time spent on this loop is in steps 1 through 4. Real hardware testing in step 6 is a validation step, not an iteration step. If you try to iterate on real hardware, you will waste time on plug-unplug cycles and on recovering from accidental misconfigurations; the VM saves you this.

A fresh install of FreeBSD in a small VM, configured to boot quickly and to have your driver's build directory mounted as a shared filesystem, is a highly productive development environment. Spending half a day to set one up pays back many times over in the days that follow.

26.8.14 Wrapping Up Section 5

Section 5 has given you the tools to develop USB and serial drivers without being tied to specific physical hardware. `nmdm(4)` covers the serial-port side for any test that does not need a real modem. QEMU USB redirection covers the USB side for nearly any driver you might write. The `cu`, `tip`, `stty`, `comcontrol`, and `usbconfig` utilities give you the userland tools to exercise driver code paths by hand. And the general techniques, from factoring hardware-independent code into userland-testable functions to using `INVARIANTS` and `WITNESS` for kernel-time correctness checking, work regardless of what transport you are writing for.

Having reached the end of Section 5, you have everything you need to start writing real USB and serial drivers for FreeBSD 14.3. The conceptual models, the code skeletons, the transfer mechanics, the TTY integration, and the testing environment are all in place. What remains is practice, which is the purpose of the next section.

26.9 Common Patterns Across Transport Drivers

Now that we have walked through USB and serial in detail, it is worth stepping back and noting the patterns that recur. These patterns appear in network drivers (Chapter 28), block drivers (Chapter 27), and most other transport-specific drivers in FreeBSD. Recognising them saves time when you read a new driver.

26.9.1 Pattern 1: Match Table, Probe, Attach, Detach

Every transport driver begins with a match table describing which devices it supports. Every transport driver has a probe method that tests a candidate against the match table and returns zero or `ENXIO`. Every transport

driver has an attach method that takes ownership of a matched device and allocates all per-device state. Every transport driver has a detach method that releases everything the attach method allocated, in reverse order.

The specifics vary. USB match tables use `STRUCT_USB_HOST_ID`. PCI match tables use `pcidev(9)` entries. ISA match tables use resource descriptions. The content differs, but the structure is identical.

When you read a new driver, the first thing to find is the match table. It tells you what hardware the driver supports. The second thing to find is the attach method. It tells you what resources the driver owns. The third thing to find is the detach method. It tells you the shape of the driver's resource hierarchy.

26.9.2 Pattern 2: Softc As The Single Source of Per-Device State

Every transport driver has a per-device softc. Every piece of mutable state lives in the softc. No global variables are used to hold per-device state (global configuration like module flags is fine). This pattern keeps multi-device drivers correct without surprise.

The softc's size is declared in the driver structure. The framework allocates and frees the softc automatically. The driver accesses it through `device_get_softc(dev)` inside Newbus methods and through whatever framework helper (like `usbd_xfer_softc`) is appropriate in callbacks.

Adding a new feature to a driver often means adding a new field to the softc, a new initialisation step in attach, a new cleanup step in detach, and whatever code uses the field in between. When you structure changes this way, you rarely forget to clean things up, because the shape of the change makes the cleanup step obvious.

26.9.3 Pattern 3: Labelled-Goto Cleanup Chain

When an attach method has to allocate several resources, each allocation has a failure path that unwinds all previous allocations. The labelled-goto chain from Chapter 25 implements this uniformly. Every resource has a label corresponding to "the state where this resource has been successfully allocated." A failure at any point jumps to the label for the state just before, which cleans up in reverse order.

This pattern is not aesthetically pleasing to some programmers (C's goto has a bad reputation), but it is pragmatically the cleanest way to handle an arbitrary number of cleanup steps in C. Alternatives like wrapping each resource in a separate function with its own cleanup are often more verbose. Alternatives like setting a flag per resource and testing it in a common cleanup routine add error-prone state management.

Whatever you think of goto, FreeBSD drivers use the labelled-goto pattern, and new drivers are expected to follow the convention.

26.9.4 Pattern 4: Frameworks Hide Transport Details

Each transport has a framework that hides transport-specific details behind a uniform API. The USB framework hides DMA buffer management behind `usb_page_cache` and `usbd_copy_in/out`. The UART framework hides interrupt dispatching behind `uart_ops`. The network framework (Chapter 28) will hide packet buffer management behind `mbufs` and `ifnet(9)`.

The value of these frameworks is that drivers become smaller and more portable. A 200-line UART driver that supports dozens of chip variants would be impossible without the framework. A 500-line USB driver that supports a complex protocol like USB audio would likewise be out of reach.

When you read a new driver, the parts you find most dense are usually the chip-specific logic. The parts that seem almost absent (the transfer scheduling, the buffer management, the TTY integration) are where the framework is doing its work.

26.9.5 Pattern 5: Callbacks with State Machines

The USB callback's three-state machine (`USB_ST_SETUP`, `USB_ST_TRANSFERRED`, `USB_ST_ERROR`) is the canonical example, but similar patterns appear in other transport drivers. A network driver's transmit completion callback has a similar structure. A block driver's request completion callback is similar. The framework calls the driver back at well-defined moments, and the driver uses a state machine to decide what to do.

Learning to read these state machines is learning a universal driver-reading skill. The specific states differ from framework to framework, but the pattern is recognisable.

26.9.6 Pattern 6: Mutexes and Wakeups

Every driver protects its softc with a mutex. Userland-facing code (read, write, ioctl) takes the mutex while manipulating softc fields. Callback code runs with the mutex held (the framework acquires it before calling). Userland code releases the mutex before sleeping and reacquires it after waking. Wakeup calls from callbacks release any sleeper waiting on the relevant channel.

The specifics vary by transport, but the pattern is universal. Modern FreeBSD drivers are uniformly multi-threaded and multi-CPU safe, which requires disciplined locking.

26.9.7 Pattern 7: Errno-Returning Helpers

Chapter 25 introduced the errno-returning helper function pattern: every internal function returns an integer errno (zero for success, nonzero for failure). Callers check the return value and propagate failure up through the stack. The attach method accumulates successful helpers in the labelled-goto chain; each helper's failure triggers the cleanup corresponding to its position.

This pattern requires discipline. Every helper must be consistent; no helper can return a "success value" that varies in meaning, and no helper can use global state to communicate failure. When followed rigorously, the pattern produces drivers where the control flow is legible and the error paths are easy to audit.

26.9.8 Pattern 8: Version Declarations and Module Dependencies

Every driver module declares its own version with `MODULE_VERSION`. Every driver module declares its dependencies with `MODULE_DEPEND`. Dependencies are versioned ranges (minimum, preferred, maximum), which allows parallel development of framework and driver to proceed without lockstep releases.

When a new major version of a framework is released with breaking API changes, the version range in `MODULE_DEPEND` is how a driver expresses "I work with framework v1 or v2, but not v3." The kernel module loader refuses to load a driver whose dependencies cannot be satisfied, which prevents many classes of silent breakage.

26.9.9 Pattern 9: Cross-Framework Layering

Some drivers sit on top of multiple frameworks. A USB-to-Ethernet driver sits on top of `usbdi(9)` (for USB transfers) and `ifnet(9)` (for network interface semantics). A USB-to-serial driver sits on top of `usbdi(9)` and `ucom(4)`. A USB mass-storage driver sits on top of `usbdi(9)` and CAM.

When you write a cross-framework driver, the structure is: you write callbacks for each framework, and you orchestrate the interaction between them in your driver's helper code. The framework on top of which you sit defines how userland sees your driver. The framework below handles the transport.

Reading `uftdi.c` showed you this pattern: the driver is a USB driver (it uses `usbdi(9)`) and a serial driver (it uses `ucom(4)`), and the orchestration between the two is the heart of the file.

26.9.10 Pattern 10: Early Attach Deferral

Some drivers cannot finish their attach work synchronously. For example, a driver might need to read a configuration EEPROM that takes a few hundred milliseconds, or it might need to wait for a PHY to autonegotiate a link. These drivers use a deferred-attach pattern: the Newbus attach method queues a taskqueue task that does the slow work, then returns quickly.

This pattern keeps the system boot fast (no single driver holds up boot by taking a long time in attach) and lets drivers do their work asynchronously. The caller must be aware that attach “finishing” does not mean the device is fully usable; a separate “ready” state has to be polled or signalled.

For USB and UART drivers, attach is usually fast enough that deferral is not needed. For more complex drivers (network cards in particular), deferral is common. Chapter 28 will show an example.

26.9.11 Pattern 11: Separate Data Path and Control Path

In every transport driver, two conceptual paths exist: the control path (configuration, state changes, error recovery) and the data path (the actual bytes moving through the device). Most drivers structure these as separate code paths, sometimes with separate locking.

The control path is low-bandwidth and infrequent. It can afford heavy locking and synchronous calls. The data path is high-bandwidth and continuous. It must be optimised for throughput: minimal locking, no synchronous calls, efficient buffer management.

The USB framework keeps them naturally separate: configuration through `usbd_transfer_setup` and control transfers; data through bulk and interrupt transfers. The UART framework likewise: configuration through `tsw_param`; data through the interrupt handler and ring buffers. Network drivers have the most pronounced separation: configuration through `ioctl`s; data through the TX and RX queues.

Reading a new driver, knowing this separation exists helps you parse what each code block is doing. A function with extensive locking and error handling is probably control path. A function with short, tight code and careful buffer management is probably data path.

26.9.12 Pattern 12: Reference Drivers

Every transport in FreeBSD has one or two “canonical” reference drivers that illustrate the patterns correctly and thoroughly. For USB, `uled.c` and `uftdi.c` are the references. For UART, `uart_dev_ns8250.c` is the reference. For networking, `em` (Intel Ethernet) and `rl` (Realtek) are the references. For block devices, `da` (direct-access storage) is the reference.

When you need to understand how to write a new driver in an existing transport, the reference driver is the right place to start. Do not try to understand the framework from its code alone; that is too abstract. Start from a working driver and let it ground your understanding.

26.10 Hands-On Labs

These labs give you a chance to turn the reading into muscle memory. Each lab is designed to fit in a single sitting, ideally under an hour. They assume a FreeBSD 14.3 lab environment (either on physical hardware or inside a virtual machine), root access, and a working build environment as described in Chapter 3. The companion files for every lab in this chapter are available under `examples/part-06/ch26-usb-serial/` in the book’s repository.

The labs build on each other but do not strictly depend on each other. You can skip a lab and come back to it later without losing continuity. The first three labs focus on USB; the last three focus on serial. Each lab has the same structure: a short summary, the steps, expected output, and a “what to watch for” note that highlights the learning goal.

26.10.1 Lab 1: Exploring a USB Device with `usbconfig`

This lab exercises the descriptor vocabulary from Section 1 by inspecting real USB devices on your machine. It does not involve writing any code.

Goal. Read the descriptors of three different USB devices and identify their interface class, the number of endpoints, and the endpoint types.

Requirements. A FreeBSD system with at least three USB devices plugged in. If you only have one machine and few USB ports, a USB hub with a few small peripherals (mouse, keyboard, flash drive) is ideal.

Steps.

1. Run `usbconfig list` as root. Record the `ugenN.M` identifiers of three devices.
2. For each device, run:

```
# usbconfig -d ugenN.M dump_all_config_desc
```

Read through the output. Identify the `bInterfaceClass`, `bInterfaceSubClass`, and `bInterfaceProtocol` for each interface. For each endpoint in each interface, record the `bEndpointAddress` (including direction bit), the `bmAttributes` (including transfer type), and the `wMaxPacketSize`.

3. Build a small table. For each device, write down: vendor ID, product ID, interface class (with name from the USB class list), number of endpoints, and the transfer type of each endpoint.

4. Match your table against `dmesg`. Confirm that the driver that claimed each device makes sense given the interface class you recorded.
5. Optional: repeat the exercise for a device you have not seen before (someone else's keyboard, a USB audio interface, a game controller). The more variety you see, the faster descriptor reading becomes.

Expected output. A filled-in table with at least three rows. The exercise is successful if you can answer, for any device in the table: "What class of driver would handle this?"

What to watch for. Pay attention to devices that expose multiple interfaces. A webcam, for example, often has an audio interface (for the microphone) in addition to its video interface. A multi-function printer might expose a printer interface, a scanner interface, and a mass-storage interface. Noticing these is what trains your eye for the multi-interface logic in the probe method.

26.10.2 Lab 2: Building and Loading the USB Driver Skeleton

This lab walks through building the skeleton driver from Section 2, loading it, and observing its behaviour when a matching device is plugged in.

Goal. Compile and load `myfirst_usb.ko`, and observe its attach and detach messages.

Requirements. The build environment from Chapter 3. The files under `examples/part-06/ch26-usb-serial/lab02-usb-skeleton/`. A USB device whose vendor/product you can match. For development, a VOTI/OBDEV test VID/PID (0x16c0/0x05dc) is free to use; otherwise, pick a cheap prototyping device (like an FT232 breakout board) and adjust the match table to match its IDs.

Steps.

1. Enter the lab directory:

```
# cd examples/part-06/ch26-usb-serial/lab02-usb-skeleton
```

2. Read `myfirst_usb.c` and `myfirst_usb.h`. Identify the match table, the probe method, the attach method, the `softc`, and the detach method. For each, trace how it relates to the Section 2 walkthrough.
3. Build the module:

```
# make
```

You should see `myfirst_usb.ko` created in the build directory.

4. Load the module:

```
# kldload ./myfirst_usb.ko
```

Run `kldstat | grep myfirst_usb` to confirm the module is loaded.

5. Plug in a matching device. Observe `dmesg`. You should see a line like:

```
myfirst_usb0: <Vendor Product> on uhub0
myfirst_usb0: attached
```

If the device does not match, nothing will happen. In that case, open `usbdevs` on the target machine, find the vendor/product of a device you do have, and edit the match table accordingly. Rebuild, reload, and try again.

6. Unplug the device. Observe `dmesg`. You should see the kernel remove the device. Your detach does not log anything explicitly in this minimal skeleton, but you can add a `device_printf(dev, "detached\n")` if you want confirmation.
7. Unload the module:

```
# kldunload myfirst_usb
```

Expected output. Attach messages in `dmesg` when the device is plugged in. Clean unload with no panics when the module is removed.

What to watch for. If `kldload` fails with an error about symbol lookups, you probably forgot a `MODULE_DEPEND` line or misspelled a symbol name. If `attach` is never called but the device is definitely present, the match table is wrong: check the vendor and product IDs in `usbconfig_list` and verify they match what you wrote in `myfirst_usb_devs`. If `attach` is called but fails, check `device_printf` output for the failure reason.

26.10.3 Lab 3: A Bulk Loopback Test

This lab adds the transfer mechanics from Section 3 to the skeleton from Lab 2 and sends a few bytes through a USB device that implements a loopback protocol. It is the first lab that actually moves data.

Goal. Add a bulk-OUT and bulk-IN channel to the driver, write a small userland client that sends a string and reads it back, and observe the roundtrip.

Requirements. A USB device that implements bulk loopback. The simplest such device for development is a USB gadget controller running a loopback program (possible on some ARM boards and on some development kits). If you do not have one, you can substitute a simpler exercise: attach the driver to a USB flash drive, open one of its `ugen` endpoints, and simply armed-submit-complete a single read transfer. The loop will fail (because flash drives do not echo data), but the mechanics of setup and submission will run correctly.

Steps.

1. Copy `lab02-usb-skeleton` to `lab03-bulk-loopback` as a working copy.
2. Add the bulk channels to the driver. Paste the config array from Section 3, the callback functions, and the userland interaction. Make sure the `/dev` entry your driver creates supports `read(2)` and `write(2)`, which are what the lab test program uses.
3. Rebuild and reload the module.
4. Run the userland client:

```
# ./lab03-test
```

which you will find alongside the driver in the lab directory. The program opens `/dev/myfirst_usb0`, writes “hello”, reads up to 16 bytes, and prints them. If loopback works, the output is “hello”.

5. Observe `dmesg` for any stall warnings or error messages.

Expected output. “hello” echoed back. If the remote device does not implement loopback, the read will return after the channel’s timeout with no data, which is also a valid test outcome for the purposes of exercising the state machine.

What to watch for. The most common mistake in this lab is mismatched endpoint directions. Remember: `UE_DIR_IN` means “the host reads from the device” and `UE_DIR_OUT` means “the host writes to the device”. If you swap them, the transfers will fail with stalls. Watch also for missing locking around the userland read/write handlers; if you manipulate the transmit queue without the softc mutex held, you can race with the write callback and see bytes disappear.

26.10.4 Lab 4: A Simulated Serial Driver with `nmdm(4)`

This lab is not about writing a driver; it is about learning the userland half of serial testing. The results will inform how you approach Lab 5 and how you debug any TTY-layer work in the future.

Goal. Create a pair of `nmdm(4)` virtual ports, observe how data flows, and exercise `stty` and `comcontrol` to see how termios and modem signals work.

Requirements. A FreeBSD system. No special hardware.

Steps.

1. Load the `nmdm` module:

```
# kldload nmdm
```

2. In terminal A, open the A side:

```
# cu -l /dev/nmdm0A -s 9600
```

3. In terminal B, open the B side:

```
# cu -l /dev/nmdm0B -s 9600
```

4. Type in terminal A. Observe that the characters appear in terminal B. Type in terminal B; they appear in terminal A.

5. Exit `cu` in both terminals (type `~.`). In a third terminal, run:

```
# stty -a -f /dev/nmdm0A
```

Read through the output. Notice `9600` for the baud rate, `cs8 -parenb -cstopb` for the byte format, and various flags for line discipline.

6. Change the baud rate on one side:

```
# stty 115200 -f /dev/nmdm0A
```

Then open the ports again with `cu -s 115200`. The baud rate change is visible, even though `nmdm(4)` does not actually wait for serialised bits.

7. Run:

```
# comcontrol /dev/ttyu0A
```

...or rather, the equivalent for the `nmdm` character devices. The `nmdm` pairs do not always have `comcontrol`-visible modem signals, depending on the FreeBSD version; if your version does not, skip this step.

Expected output. Text appears on the opposite side. `stty` shows termios flags. You now have a reproducible way to test TTY-layer behaviour on your machine.

What to watch for. The pair identifiers (0, 1, 2...) are implicit and allocated on first open. If you cannot open `/dev/nmdm5A` because nothing has opened `/dev/nmdm4A` yet, this is expected: pairs are created lazily in increasing order. Also note that `cu` uses a lock file in `/var/spool/lock/`; if you kill `cu` abruptly, the lock file may persist and prevent reopens. Delete it manually if you get a “port in use” error.

26.10.5 Lab 5: Talking to a Real USB-to-Serial Adapter

This lab brings real hardware into the loop. You will use a USB-to-serial adapter (an FT232, a CP2102, a CH340G, or anything else FreeBSD supports) and a terminal program to exercise the full path from `ucom(4)` through the TTY layer to userland.

Goal. Plug in a USB-to-serial adapter, verify it attaches, and use `cu` to send data to it (perhaps by looping the TX and RX pins together with a jumper).

Requirements. A USB-to-serial adapter. A jumper wire (if you want to do a hardware loopback) or a second serial device to talk to (a development board, an embedded computer, or an old serial modem).

Steps.

1. Plug in the adapter. Run `dmesg | tail` and confirm it attaches. You should see lines like:

```
uftdi0 on uhub0
uftdi0: <FT232R USB UART, class 0/0, ...> on usb0
```

and a `ucomN: <...>` line just after that.

2. Run `ls -l /dev/cuaU*`. The adapter’s port is usually `/dev/cuaU0` for the first adapter, `/dev/cuaU1` for the second, and so on. (Note the capital-U suffix, which distinguishes USB-provided ports from the real UART ports at `/dev/cua0`.)
3. Put a jumper wire between the TX and RX pins of the adapter. This creates a hardware loopback: whatever the adapter transmits comes back on its own RX line.
4. In one terminal, set the baud rate:

```
# stty 9600 -f /dev/cuaU0
```

5. Open the port with `cu`:

```
# cu -l /dev/cuaU0 -s 9600
```

Type characters. Every character you type should appear twice: once as local echo (if your terminal is echoing), and once as the character coming back through the loopback. Disable the local echo in `cu` if it is confusing; the `stty -echo` will help.

6. Remove the jumper. Type characters. Now they will not come back, because there is nothing connected to RX.
7. Exit `cu` with `~.`. Unplug the adapter. Run `dmesg | tail` and verify clean detach.

Expected output. Characters are echoed back when the jumper is in place and lost when it is not. The `dmesg` shows clean attach and detach.

What to watch for. If the adapter attaches but no `cuau` device appears, the underlying `ucom(4)` instance may have attached but failed to create its TTY. Check `dmesg` for errors. If characters come out garbled, the baud rate is probably wrong: make sure every stage of the path (your terminal, `cu`, `stty`, the adapter, and the far end) is set to the same rate. On older hardware, some USB-to-serial adapters do not reset their internal configuration when you open them; you may need to explicitly set the baud rate with `stty` before `cu` will work correctly.

26.10.6 Lab 6: Observing Hot-Plug Lifecycle

This lab does not require writing any new driver code. It exercises the hot-plug lifecycle we described conceptually in Section 1 and in code in Section 2, using the existing `uhid` or `ukbd` driver as the test subject.

Goal. Plug in and unplug a USB device repeatedly while monitoring kernel logs, observing the full attach/detach sequence.

Requirements. A USB device you can plug and unplug without disrupting your work session. A USB flash drive or a USB mouse are both safe; a USB keyboard is not (because detaching a keyboard in the middle of a session can strand your shell).

Steps.

1. Open a terminal window and run:

```
# tail -f /var/log/messages
```

or, if your system does not log kernel messages to that file:

```
# dmesg -w
```

(The `-w` flag is a FreeBSD 14 addition that streams new kernel messages as they arrive.)

2. Plug in your USB device. Observe the messages. You should see:

- A message from the USB controller about the new device appearing.
- A message from `uhub` about the port powering up.
- A message from the class driver that matched the device (e.g., `ums0` for a mouse, `umass0` for a flash drive).
- Possibly a message from the higher-level subsystem (e.g., `da0` for a mass-storage device).

3. Unplug the device. Observe the messages. You should see:

- A message from `uhub` about the port powering down.
- A detach message from the class driver.

4. Repeat several times. Watch that every attach is matched by a detach. Watch that no message is missed. Watch the timing; the attach sequence can take tens or hundreds of milliseconds because enumeration involves several control transfers.

5. Write a tiny shell loop that records the attach and detach times:

```
# dmesg -w | awk '/ums|umass/ { print systime(), $0 }'
```

(Adjust the regex for the device type you are using.) This gives you a machine-readable log of attach and detach timestamps.

Expected output. Clean attach and detach every time, with no dangling state.

What to watch for. Occasionally you will see a device attach and then immediately detach within a few hundred milliseconds. This usually indicates the device is failing enumeration: either a bad cable, insufficient power, or a buggy device firmware. If it happens consistently with one device, try a different USB port or a powered hub. Also watch for cases where the kernel reports a stall during enumeration; these are rarely harmful but indicate that the enumeration needed multiple tries.

26.10.7 Lab 7: Building a ucom(4) Skeleton from Scratch

This lab is an extended one that combines the USB and serial material from the chapter. You will build a minimal ucom(4) driver skeleton that presents itself as a serial port but is backed by a simple USB device.

Goal. Build a ucom(4) driver skeleton that attaches to a specific USB device, registers with the ucom(4) framework, and provides empty implementations of the key callbacks. The driver will not actually talk to the hardware, but it will exercise the full ucom(4) registration path.

Requirements. The materials from Lab 2 (the USB driver skeleton). A USB device you can match against (for testing, you can use the same VOTI/OBDEV VID/PID as in Lab 2, or any spare USB device whose IDs you can read).

Steps.

1. Start from Lab 2 as a template. Copy the directory to lab07-ucm-skeleton.
2. Modify the softc to include a struct ucom_super_softc and a struct ucom_softc:

```
struct lab07_softc {
    struct ucom_super_softc sc_super_ucm;
    struct ucom_softc      sc_ucm;
    struct usb_device      *sc_udev;
    struct mtx             sc_mtx;
    struct usb_xfer         *sc_xfer[LAB07_N_XFER];
    uint8_t                sc_iface_index;
    uint8_t                sc_flags;
};
```

3. Add a struct ucom_callback with stub implementations:

```
static void lab07_cfg_open(struct ucom_softc *);
static void lab07_cfg_close(struct ucom_softc *);
static int  lab07_pre_param(struct ucom_softc *, struct termios *);
static void lab07_cfg_param(struct ucom_softc *, struct termios *);
static void lab07_cfg_set_dtr(struct ucom_softc *, uint8_t);
static void lab07_cfg_set_rts(struct ucom_softc *, uint8_t);
static void lab07_cfg_set_break(struct ucom_softc *, uint8_t);
static void lab07_start_read(struct ucom_softc *);
```

```

static void lab07_stop_read(struct ucom_softc *);
static void lab07_start_write(struct ucom_softc *);
static void lab07_stop_write(struct ucom_softc *);
static void lab07_free(struct ucom_softc *);

static const struct ucom_callback lab07_callback = {
    .ucm_cfg_open      = &lab07_cfg_open,
    .ucm_cfg_close     = &lab07_cfg_close,
    .ucm_pre_param     = &lab07_pre_param,
    .ucm_cfg_param     = &lab07_cfg_param,
    .ucm_cfg_set_dtr   = &lab07_cfg_set_dtr,
    .ucm_cfg_set_rts   = &lab07_cfg_set_rts,
    .ucm_cfg_set_break = &lab07_cfg_set_break,
    .ucm_start_read    = &lab07_start_read,
    .ucm_stop_read     = &lab07_stop_read,
    .ucm_start_write   = &lab07_start_write,
    .ucm_stop_write    = &lab07_stop_write,
    .ucm_free          = &lab07_free,
};

```

`ucm_pre_param` runs on the caller's context before the configuration task is scheduled; use it to reject unsupported `termios` values by returning a nonzero `errno`. `ucm_cfg_param` runs in the framework's task context and is where you would issue the actual USB control transfer to reprogram the chip.

4. Implement each callback as a no-op for now. Add `device_printf(sc->sc_super_ucm, sc_dev, "%s\n", __func__)` to each so that you can see which callbacks are being invoked.
5. In the attach method, after `usbd_transfer_setup`, call:

```

error = ucom_attach(&sc->sc_super_ucm, &sc->sc_ucm, 1, sc,
    &lab07_callback, &sc->sc_mtx);
if (error != 0) {
    goto fail_xfer;
}

```

6. In the detach method, call `ucm_detach(&sc->sc_super_ucm, &sc->sc_ucm)` before `usbd_transfer_unsetup`.
7. Add `MODULE_DEPEND(lab07, ucom, 1, 1, 1)`; after the existing `MODULE_DEPEND`.
8. Build, load, plug in the device, and observe. In `dmesg`, you should see the driver attach, and you should see a `cuaU0` device appear in `/dev/`.
9. Run `cu -l /dev/cuaU0 -s 9600`. The `cu` command will open the device, which triggers several of the `ucm` callbacks. Watch `dmesg` to see which ones fire. Close `cu` with `~.` and observe more callbacks.
10. Run `stty -a -f /dev/cuaU0`. Observe that the port has default `termios` settings. Run `stty 115200 -f /dev/cuaU0` and observe that `lab07_cfg_param` is called.
11. Unplug the device. Observe clean detach.

Expected output. The driver attaches as a ucom device, creates `/dev/cuaU0`, and responds to configuration ioctls (even though the underlying USB device does not actually do anything). Every callback invocation is visible in `dmesg`.

What to watch for. If the driver attaches but `/dev/cuaU0` does not appear, check that `ucom_attach` succeeded. The return value is an `errno`; a nonzero value means failure. If it failed with `ENOMEM`, you are running out of memory for the TTY allocation. If it failed with `EINVAL`, one of the callback fields is probably null (look at `/usr/src/sys/dev/usb/serial/usb_serial.c` to see which fields are strictly required).

This lab is a building block. A real ucom driver (like `uftdi`) would fill in the callbacks with actual USB transfers to the chip. Starting from an empty skeleton and adding one callback at a time is a good way to build a new driver.

26.10.8 Lab 8: Troubleshooting a Hung TTY Session

This lab is a diagnostic exercise. Given a malfunctioning serial setup, you will use the tools from Section 5 to find the problem.

Goal. Find why a `cu` session does not echo characters back after connecting to an `nmdm(4)` pair that has an unconfigured baud rate on one side.

Steps.

1. Load `nmdm`:

```
# kldload nmdm
```

2. Set different baud rates on the two sides. This is contrived but mimics a real configuration bug:

```
# stty 9600 -f /dev/nmdm0A
# stty 115200 -f /dev/nmdm0B
```

3. Open both sides with `cu`, each with the mismatched rate:

```
(terminal 1) # cu -l /dev/nmdm0A -s 9600
(terminal 2) # cu -l /dev/nmdm0B -s 115200
```

4. Type in terminal 1. You will likely see characters appear in terminal 2, but possibly garbled. Or characters may not appear at all if the `nmdm(4)` driver enforces rate matching strictly.
5. Exit both `cu` sessions.
6. Run `stty -a -f /dev/nmdm0A` and `stty -a -f /dev/nmdm0B`. Find the discrepancy.
7. Fix: set both sides to the same rate. Reopen `cu` and verify that the issue is resolved.

What to watch for. This lab teaches the diagnostic habit of checking both ends of a link. A mismatch at any one end produces problems; finding it requires looking at both. The diagnostic tools (`stty`, `comcontrol`) work from the command line and produce human-readable output. Making use of them is a simple first check before diving into deeper debugging.

26.10.9 Lab 9: Monitoring USB Transfer Statistics

This lab explores the per-channel statistics the USB framework maintains, which can help identify performance issues or hidden errors.

Goal. Use `usbconfig dump_stats` to observe the transfer counts on a busy USB device and identify whether the device is performing as expected.

Steps.

1. Plug in a USB device that you can exercise meaningfully. A USB flash drive is a good choice because you can trigger bulk transfers by copying files.

2. Identify the device:

```
# usbconfig list
```

Note the `ugenN.M` identifier.

3. Dump the baseline statistics:

```
# usbconfig -d ugenN.M dump_stats
```

Record the output.

4. Perform significant I/O to the device. For a flash drive, copy a large file:

```
# cp /usr/src/sys/dev/usb/usb_transfer.c /mnt/usb_mount/
```

5. Dump the statistics again. Compare.

6. Note which counters changed. `xfer_completed` should have increased significantly. `xfer_err` should still be small.

7. Try to deliberately cause errors. Unplug the device mid-transfer. Then plug it back in. Dump the stats on the new `ugenN.M` (a new one is allocated on replug).

What to watch for. The statistics reveal invisible behaviours. A device that is mostly working but occasionally stalling will show `stall_count` nonzero. A device that is dropping transfers will show `xfer_err` climbing. In normal operation, a healthy device shows steady `xfer_completed` growth and zero errors.

If you are developing a driver and the statistics show unexpected errors, that is a clue that something is wrong. The statistics are maintained by the USB framework, not the driver, so they reflect reality regardless of whether the driver notices.

26.11 Challenge Exercises

Challenge exercises stretch your understanding. They are not strictly necessary for progressing to Chapter 27, but each one will deepen your grasp of USB and serial driver work. Take your time. Read relevant FreeBSD source. Write small programs. Expect some challenges to take several hours.

26.11.1 Challenge 1: Add a Third USB Endpoint Type

The skeleton in Section 2 supports bulk transfers. Extend it to also handle an interrupt endpoint. Add a new channel to the `struct usb_config` array with `.type = UE_INTERRUPT`, `.direction = UE_DIR_IN`, and a small buffer (say, sixteen bytes). Implement the callback as a continuous poll, reading a small status packet from the device on every interrupt-IN completion.

Test the change by comparing the behaviour of the three channels. Bulk channels should be quiet most of the time and only submit transfers when the driver has work to do. The interrupt channel should run continuously, quietly consuming interrupt-IN packets whenever the device sends them.

A stretch goal: make the interrupt callback deliver received bytes to the same `/dev` node as the bulk channel. When userspace reads the node, it gets a merged view of bulk-in and interrupt-in data. This is a useful pattern for devices that have both streaming data and asynchronous status events.

26.11.2 Challenge 2: Write a Minimal USB Gadget Driver

The running example is a host-side driver: the FreeBSD machine is the USB host, and the device is the peripheral. Turn the example around by writing a USB gadget driver that makes the FreeBSD machine present itself as a simple device to another host.

This requires USB-on-the-Go hardware, so the challenge is only feasible on specific boards (some ARM development boards support it). The relevant source is in `/usr/src/sys/dev/usb/template/`. Start from `usb_template_cdce.c`, which implements the CDC Ethernet class, and modify it to implement a simpler vendor-specific class with one bulk-OUT endpoint that just swallows whatever the host sends.

This challenge teaches you how the USB framework looks from the other side. Many of the concepts are mirror-imaged: what was a transfer from the host's perspective is a transfer from the device's perspective, but the direction of the bulk arrow is reversed.

26.11.3 Challenge 3: A Custom `termios` Flag Handler

The `termios` structure has many flags, and the `uart(4)` framework handles most of them automatically. Write a small modification to a UART driver (or to a copy of `uart_dev_ns8250.c` in a private build) that makes the driver log a `device_printf` message every time a specific `termios` flag changes value.

Pick, say, `CRTSCTS` (hardware flow control) as the flag to track. Add a log message in the driver's `param` path that prints “`CRTSCTS=on`” or “`CRTSCTS=off`” whenever the flag's new value differs from its old value.

Test the modification by running:

```
# stty crtscts -f /dev/cuau0
# stty -crtscts -f /dev/cuau0
```

Verify that the log messages appear in `dmesg` and that they correspond correctly to the `stty` changes.

This challenge is about understanding exactly where in the call chain the `termios` change arrives at the driver. The answer (in `param`) is documented in the source, but seeing it with your own eyes is different from reading about it.

26.11.4 Challenge 4: Parsing a Small USB Protocol

Pick a USB protocol you are curious about. HID is a good candidate because it is widely documented. CDC ACM is another good choice because it is simple. Pick one, read the specification on usb.org (the public parts), and write a small protocol parser in C that takes a buffer of bytes and prints what they mean.

For HID, the parser would consume reports: input reports, output reports, feature reports. It would look up the device's report descriptor to learn the layout. It would print, for each report, the usage (mouse motion, button press, keyboard scan code) and the value.

For CDC ACM, the parser would consume the AT command set: a small set of commands that terminal programs use to configure modems. It would recognise the commands and report which ones the driver would handle and which would be passed through to the device.

This is not a driver-writing challenge per se; it is a protocol-understanding challenge. Device drivers implement protocols, and being comfortable with protocol specifications is a core skill.

26.11.5 Challenge 5: Robustness Under Load

Take the echo-loop driver from Lab 3 (or a similar driver you have written) and stress-test it. Write a userland program that runs two threads: one constantly writes random bytes to the device, one constantly reads and verifies.

Run the program for an hour. Then run it for a day. Then unplug and replug the device during the run and see whether the program recovers cleanly.

You will probably find bugs. Common ones include: write callback locking issues under concurrent access, races between `close()` and in-flight transfers, memory leaks from buffers that are allocated but never freed on specific error paths, and state machine bugs when a stall arrives at an unexpected moment.

Each bug you find will teach you something about where the driver's contract with its callers is subtle. Fix the bugs. Log what you learned. This is exactly the kind of work that separates a good driver from a merely working one.

26.11.6 Challenge 6: Implement Suspend/Resume Properly

Most USB drivers do not implement suspend and resume handlers. The framework has defaults that work for the common case, but a driver that holds long-term state (a queue of pending commands, a streaming context, a negotiated session) may need to save and restore that state around suspend cycles.

Extend the echo-loop driver with `device_suspend` and `device_resume` methods. In suspend, flush any pending transfers and save a small amount of state. In resume, restore the state and resubmit any pending work.

Test by running the system through a suspend cycle (on a laptop that supports it) while the driver is running. Verify that after resume, the driver continues working correctly and no state was lost.

This challenge teaches the subtleties of suspend/resume, including that hardware may be in a different state after resume than it was before suspend, and that all in-flight state must be reconstructed or abandoned.

26.11.7 Challenge 7: Adding poll(2) Support

Most drivers shown in this chapter support `read(2)` and `write(2)` but not `poll(2)` or `select(2)`. These system calls let userland programs wait for I/O readiness on multiple descriptors at once, which is essential for servers and interactive programs.

Add a `d_poll` method to the echo driver's `cdevsw`. The method should return a bitmask indicating which I/O events are currently possible: `POLLIN` if there is data to read, `POLLOUT` if there is space to write.

The hardest part of adding poll support is the wakeup logic. When a transfer callback adds data to the RX queue, it must call `selwakeup` on the `selinfo` structure the poll mechanism uses. Similarly, when the write callback drains bytes from the TX queue and makes space, it must call `selwakeup` on the write `selinfo`.

This challenge will require reading `/usr/src/sys/kern/sys_generic.c` and `/usr/src/sys/sys/selinfo.h` to understand the `selinfo` mechanism.

26.11.8 Challenge 8: Writing a Character-Counter ioctl

Add an `ioctl` to the echo driver that returns the current TX and RX byte counters. The `ioctl` interface requires you to:

1. Define a magic number and struct for the `ioctl` in a header:

```
struct myfirst_usb_stats {
    uint64_t tx_bytes;
    uint64_t rx_bytes;
};
#define MYFIRST_USB_GET_STATS _IOR('U', 1, struct myfirst_usb_stats)
```

2. Implement a `d_ioctl` method that responds to `MYFIRST_USB_GET_STATS` by copying the counters out to userland.
3. Maintain the counters in the `softc`, incrementing them in the transfer callbacks.
4. Write a userland program that issues the `ioctl` and prints the results.

This challenge teaches the `ioctl` interface, which is the standard way drivers expose non-streaming operations to userland. It also introduces you to the `_IOR`, `_IOW`, and `_IOWR` macros from `<sys/ioccom.h>`.

26.12 Troubleshooting Guide

Despite your best efforts, problems will occur. This section documents the most common classes of problem you will hit while working on USB and serial drivers, with concrete steps to diagnose each.

26.12.1 The Module Will Not Load

Symptom: `kldload myfirst_usb.ko` returns an error, typically with a message about unresolved symbols.

Causes and fixes: - Missing `MODULE_DEPEND` entry. Add `MODULE_DEPEND(myfirst_usb, usb, 1, 1, 1);` to the driver. - Missing `MODULE_DEPEND` on a second module, such as `ucom`. If your driver uses `ucom_attach`, add a dependency on `ucom`. - Compiled against a kernel that does not match the running kernel. Rebuild the module against the currently-running sources. - Kernel symbol table out of date. After kernel upgrade, run `kldxref /boot/kernel` to refresh.

If the error message mentions a specific symbol you did not write (like `ttymcreate` or `cdevsw_open`), look up the missing symbol in the source tree to find out which subsystem it lives in, and add a `MODULE_DEPEND` on that module.

26.12.2 The Driver Loads but Never Attaches

Symptom: `kldstat` shows the driver loaded, but `dmesg` shows no attach message when the device is plugged in.

Causes and fixes: - Match table does not match the device. Compare the vendor and product IDs from `usbconfig list` against your `STRUCT_USB_HOST_ID` entries. - Interface number mismatch. If the device has multiple interfaces and your probe guards against `bInterfaceIndex != 0`, try a different interface. - Probe returns `ENXIO` for some other reason. Add `device_printf(dev, "probe with class=%x subclass=%x\n", uaa->info.bInterfaceClass, uaa->info.bInterfaceSubClass);` at the top of probe temporarily to see what the framework is offering. - Another driver is claiming the device first. Check `dmesg` for other driver attachments; you may need to explicitly unload the competing driver with `kldunload` before yours can bind. Alternatively, give your driver a higher priority through bus-probe return values (applies to PCI-like buses, not USB).

26.12.3 The Driver Attaches but /dev Node Does Not Appear

Symptom: attach message in `dmesg`, but `ls /dev/` shows no corresponding entry.

Causes and fixes: - `make_dev` call failed. Check the return value; if null, handle the error and log it. - Wrong `cdevsw`. Make sure `myfirst_usb_cdevsw` is declared correctly with `d_version = D_VERSION` and valid `d_name`, `d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl` where relevant. - `si_drv1` not set. Although not strictly required for the node to appear, many bugs manifest as “the node appears but `ioctl`s see a NULL softc” because `si_drv1` was not initialised. - Permissions issue. The default 0644 permissions may restrict access; try 0666 temporarily during development.

26.12.4 The Driver Panics on Detach

Symptom: unplugging the device (or unloading the module) causes a kernel panic.

Causes and fixes: - Transfer callback running during detach. You must call `usbd_transfer_unsetup` before destroying the mutex. The framework’s cancellation and wait logic is what makes detach safe. - `/dev` node open when driver unloads. If userspace has the node open, the module cannot unload. Run `fstat | grep myfirst_usb` to see which process holds it, and kill the process or close the file. - Memory freed before all uses complete. If you use deferred work (taskqueue, callout), you must cancel and wait for it before freeing the softc. The `taskqueue_drain` and `callout_drain` functions exist for this. - Softc use-after-free. If you have

code outside the driver that holds a pointer to the `softc`, the `softc` can be freed while that pointer is still dangling. Redesign to avoid external `softc` pointers, or add reference counting.

26.12.5 Transfers Stall

Symptom: bulk transfers appear to succeed at the `submit` call but never complete, or they complete with `USB_ERR_STALLED`.

Causes and fixes: - Wrong endpoint direction. Verify the direction in your `struct usb_config` against the endpoint's `bEndpointAddress` high bit. - Wrong endpoint type. Verify that the `type` field matches the endpoint's `bmAttributes` low bits. - Transfer too large. If you set a frame length larger than the endpoint's `wMaxPacketSize`, the framework will usually slice it into packets, but some devices reject a transfer that exceeds an internal buffer. - Device firmware stall. The remote device is signalling “not ready.” The framework's automatic clear-stall should recover, but a persistent stall usually indicates a protocol error (wrong command, wrong sequence, missing authentication).

26.12.6 Serial Characters Garbled

Symptom: bytes appear on the wire but are wrong or contain extra characters.

Causes and fixes: - Baud rate mismatch. Every stage must agree. Use `stty` to check all stages. - Byte format mismatch. Set databits, parity, and stopbits to match. `stty cs8 -parenb -cstopb` is the most common configuration. - Incorrect `termios` flag handling in the driver. If you modify `uart_dev_ns8250.c` and `breakparam`, the chip will be programmed wrong. Compare against the upstream file. - Flow-control mismatch. If one side has `CRTSCTS` enabled and the other does not, bytes will be lost under load. Set both sides consistently. - Cable issue. A bad cable or a cable with unusual pinouts (some RJ45-to-DB9 cables have nonstandard pinouts) can introduce bit errors. Swap cables to rule this out.

26.12.7 A Process is Stuck in `read(2)` and Will Not Exit

Symptom: a program blocked on the driver's `read()` path will not respond to `Ctrl+C` or `kill`.

Causes and fixes: - Driver `d_read` sleeps without checking for signals. Use `msleep(..., PCATCH, ...)` (with the `PCATCH` flag) so the sleep returns `EINTR` when a signal arrives, and propagate the `errno` back to userspace. - Driver `d_read` holds a non-interruptible lock. Verify that the sleep is on an interruptible condition variable and that the mutex is dropped during the sleep. - Transfer callback is never arming the channel. If your `d_read` waits on a flag that only the read callback sets, and the read callback is never fired, the wait will never complete. Make sure the channel is started on `d_open` or at attach time.

26.12.8 High CPU Usage When Idle

Symptom: the driver consumes significant CPU even when no data is flowing.

Causes and fixes: - Polling-based implementation. If your driver polls a flag in a busy loop, rewrite it to sleep on an event. - Callback firing excessively. The framework should not fire a callback without a state change, but some misconfigured channels can enter a “retry on error” loop that fires the callback as fast as the hardware can

respond. Add a retry counter or a rate-limiter. - Read callback with no work but always rearming. If the device sends zero-byte transfers to signal “I have nothing to say,” make sure your callback handles these gracefully without treating them as normal data.

26.12.9 `usbconfig` Shows the Device but `dmesg` Is Silent

Symptom: `usbconfig list` shows the device, but no driver attach message appears.

Causes and fixes: - Device attached to `ugen` (the generic driver) because no specific driver matched. This is the normal behaviour when there is no matching driver. Check the match tables of the available drivers. `pciconf -lv` will not help here because this is USB, not PCI; the USB equivalent is `usbconfig -d ugenN.M`. `dump_device_desc`. - `devd` is disabled and auto-load is not happening. Enable `devd` by running `service devd onestart`, then plug the device in again. - Module file is not in a loadable path. `kldload` can take a full path (`kldload /path/to/module.ko`), but for automatic loading by `devd`, the module has to be in a directory `devd` is configured to search. `/boot/modules/` is the conventional location for out-of-tree modules on a production system.

26.12.10 Debugging a Deadlock with `WITNESS`

Symptom: the kernel hangs with the CPU stuck in a specific function, and `WITNESS` is enabled.

Causes and fixes: - Lock order violation. `WITNESS` will log the violation on the serial console. Read the log: it will tell you which locks were taken in which order, and where the reverse order was observed. Fix by establishing a consistent lock acquisition order throughout your driver. - Lock held across a sleep. If you hold a mutex and then call a function that sleeps, you can deadlock with any other thread that wants the mutex. Identify the sleeping function (often hidden in an allocation or in a USB transfer wait), and restructure to release the mutex before the sleep. - Lock taken in interrupt context that was first taken outside interrupt context without `MTX_SPIN`. FreeBSD mutexes have two forms: default (`MTX_DEF`) can sleep, spin (`MTX_SPIN`) cannot. Taking a sleep mutex from an interrupt handler is a bug.

Enabling `WITNESS` during development (by building the kernel with options `WITNESS` or by using `GENERIC-NODEBUG`'s `INVARIANTS`-enabled counterpart) catches many of these problems before they appear on a user's machine.

26.12.11 A Driver That Appears Twice for the Same Device

Symptom: `dmesg` shows your driver attaching twice for a single device, creating `myfirst_usb0` and `myfirst_usb1` with the same USB IDs.

Causes and fixes: - The device has two interfaces and the driver is matching both. Check `bIfaceIndex` in the probe method and match only the interface you actually support. - The device has multiple configurations and both are active. This is rare; if so, select the correct configuration explicitly in the attach method. - Another driver is attached to one of the interfaces. This is not a bug; it just means the device is multi-interface and different drivers claim different interfaces. If you see `myfirst_usb0` and `ukbd0` for the same device, the device has both a vendor-specific interface and a HID interface, and the two drivers attach independently.

26.12.12 USB Serial Baud Rate Does Not Take Effect

Symptom: You `stty 115200 -f /dev/cuaU0`, but data exchange happens at a different rate.

Causes and fixes: - The control transfer to program the baud rate failed. Check `dmesg` for error messages from `ucom_cfg_param`. Instrument the driver to log the result of the control transfer. - The chip's divisor encoding is wrong. Different FTDI variants use slightly different divisor formulas; check the variant detection in the driver. - The peer is running at a different rate. As noted earlier in the chapter, both ends must agree. - The cable or adapter is introducing its own rate limitation. Some USB-to-serial adapters silently renegotiate; this is rare but can happen with poor-quality cables.

26.12.13 A Kernel Panic with “Spin lock held too long”

Symptom: The kernel panics with this message, usually during high I/O on the driver.

Causes and fixes: - A UART driver's `uart_ops` method is sleeping or blocking. The six methods in `uart_ops` run with spin locks held (on some paths) and must not sleep, call non-spin-safe functions, or do long loops. Review the offending method for any expensive calls. - The interrupt handler is not draining the interrupt source fast enough. If the handler takes longer than the interrupt rate, interrupts accumulate. Speed up the handler. - Lock contention is causing priority inversion. Reduce the scope of the critical section, or break it up.

26.12.14 A Device Never Completes Enumeration

Symptom: Plugging in a device produces a `dmesg` line or two about enumeration starting, but never a completion message.

Causes and fixes: - The device is violating the USB specification. Some cheap or counterfeit devices have buggy firmware. If possible, try a different device. - Insufficient power. Devices that claim more power than the port can supply will fail to enumerate. Try a powered hub. - Electromagnetic interference. A bad cable or a bad port can cause bit errors during enumeration. Try different cables or ports. - The USB host controller is in a confused state. Try unloading and reloading the host controller driver, or (as a last resort) rebooting.

26.12.15 Diagnostic Checklist When You Are Stuck

When a driver under development is not behaving correctly and you do not know why, walk through this checklist in order. Each step eliminates a large class of possible problems.

1. Compile cleanly with `-Wall -Werror`. Many subtle bugs produce warnings.
2. Load in a kernel built with `INVARIANTS` and `WITNESS`. Any locking or invariant violations will be caught immediately.
3. Enable your driver's debug logging. Run a minimal reproduction scenario and capture the logs.
4. Compare the driver's behaviour against a known-working driver for similar hardware. Diffing behaviour reveals bugs that staring at your own code does not.
5. Simplify the scenario. Write a minimal userland test program. Use a minimal USB device (or an `nmdm` pair for serial). Remove every variable you can.

6. Use `dtrace` on the USB framework functions. `usbd_transfer_submit:entry` and `usbd_transfer_submit:return` probes let you trace exactly which transfers were submitted and what happened to them.
7. Run the driver with `WITNESS_CHECKORDER` enabled. Each time a mutex is taken, the order is verified against the accumulated history.
8. If the issue is intermittent, run under a stress-test harness that generates load for hours. Intermittent bugs become reproducible under sustained load.

This checklist is not exhaustive, but it covers the techniques that find the majority of driver bugs.

26.13 Reading the FreeBSD USB Source Tree: A Guided Tour

The `myfirst_usb` skeleton and the FTDI walkthrough have given you the shape of a USB driver. But the real learning happens when you read existing drivers in the tree. Each one is a small lesson in how to apply the framework to a specific class of device. This section gives you a guided tour of five drivers, ordered from simplest to most representative, and points out what each one teaches.

The pattern we recommend is this. Open each driver's source file next to this section. Read the opening comment block and the structure definitions first; those tell you what the driver is for and what state it maintains. Then trace the lifecycle: match table, probe, attach, detach, registration. Only after the lifecycle is clear should you move on to the data path. This ordering mirrors how the framework itself treats the driver: first as a match candidate, then as an attached driver, and only then as something that moves data.

26.13.1 Tour 1: `uled.c`, the Simplest USB Driver

File: `/usr/src/sys/dev/usb/misc/uled.c`.

Start here. `uled.c` is the Dream Cheeky USB LED driver. It is under 400 lines. It implements a single output (setting the LED colour) through a single control transfer. There is no input, no bulk transfer, no interrupt transfer, no concurrent I/O. Everything about it is minimal, and for that reason everything about it is easy to read.

Key things to study in `uled.c`:

The match table has a single entry: `{USB_VPI(USB_VENDOR_DREAM_CHEEKY, USB_PRODUCT_DREAM_CHEEKY_WEBMAIL_NOTIFICATION), 0}`. This is the minimal match-by-VID/PID idiom. No subclass or protocol filtering; just vendor and product.

The `softc` is tiny. It contains a mutex, the `usb_device` pointer, the `usb_xfer` array, and the LED state. This is the minimum every USB driver needs.

The probe method is two lines: check that the device is in host mode and return the result of `usbd_lookup_id_by_uaa` against the match table. No interface-index check, no complex matching. For a simple device with a single function, this is enough.

The attach method allocates the transfer channel, creates a device-file entry with `make_dev`, and stores the pointers. No complex negotiation; the device is ready after attach returns.

The I/O path is a single control transfer with a fixed setup. The driver sets the frame length, fills in the color bytes with `usbd_copy_in`, and calls `usbd_transfer_submit`. That is it.

Read `uled.c` first. When you have read it once, the rest of the USB subsystem opens up. Every more complex driver is a variation on this pattern.

26.13.2 Tour 2: `ugold.c`, Adding Interrupt Transfers

File: `/usr/src/sys/dev/usb/misc/ugold.c`.

`ugold.c` drives a USB thermometer. It is still very short, under 500 lines, but it introduces interrupt transfers, which are the staple of HID-class devices.

Key things to learn from `ugold.c`:

The device publishes temperature readings periodically via an interrupt endpoint. The driver's job is to listen on that endpoint and deliver the readings to userland via `sysctl`.

The `usb_config` array now has an entry for `UE_INTERRUPT`, with `UE_DIR_IN`. This tells the framework to set up a channel that polls the interrupt endpoint.

The interrupt callback shows the canonical pattern: on `USB_ST_TRANSFERRED`, extract the received bytes with `usbd_copy_out`, parse them, update the `softc`. On `USB_ST_SETUP` (including the initial callback after start), set the frame length and submit. On `USB_ST_ERROR`, decide whether to recover or give up.

The driver exposes readings through `sysctl` nodes created in `attach` and torn down in `detach`. This is a common pattern for devices that produce occasional readings: the interrupt callback writes to `softc` state, and userland reads from `sysctl` when it wants a value.

Compare `ugold.c` to `uled.c` after reading both. The control-transfer-only driver and the interrupt-transfer driver represent the two most common skeleton patterns. Most other USB drivers are composed of variations of these two.

26.13.3 Tour 3: `udbp.c`, Bidirectional Bulk Transfers

File: `/usr/src/sys/dev/usb/misc/udbp.c`.

`udbp.c` is the USB Double Bulk Pipe driver. It exists to test bidirectional bulk data flow between two computers connected by a special USB-to-USB cable. It is about 700 lines and gives you a complete working example of bulk read and bulk write.

Key things to learn from `udbp.c`:

The `usb_config` has two entries: one for `UE_BULK UE_DIR_OUT` (host-to-device) and one for `UE_BULK UE_DIR_IN` (device-to-host). This is the standard bulk-duplex pattern.

Each callback does the same three-state dance. On `USB_ST_SETUP`, set the frame length (or if it is a read, just submit). On `USB_ST_TRANSFERRED`, consume the completed data and re-arm. On `USB_ST_ERROR`, decide the recovery policy.

The driver uses the netgraph framework to integrate with higher layers. This is a choice specific to the Double Bulk Pipe device. For a simple application, you would expose the bulk channels through a character device, as `myfirst_usb` does.

Trace how the softc maintains the state of each direction independently. The receive callback rearms only when a buffer is available. The transmit callback rearms only when there is something to send. The two callbacks coordinate only through shared softc fields (counter of pending operations, queue pointers).

26.13.4 Tour 4: `uplcom.c`, a USB-to-Serial Bridge

File: `/usr/src/sys/dev/usb/serial/uplcom.c`.

`uplcom.c` drives the Prolific PL2303, one of the most common USB-to-serial chips. At around 1400 lines, it is more substantial than the previous three, but every part of it maps directly onto the serial-driver pattern from Section 4 of this chapter.

Key things to learn from `uplcom.c`:

The `ucom_callback` structure fills in every configuration method you would expect a real driver to implement: `ucom_cfg_open`, `ucom_cfg_param`, `ucom_cfg_set_dtr`, `ucom_cfg_set_rts`, `ucom_cfg_set_break`, `ucom_cfg_get_status`, `ucom_cfg_close`. Each of these calls the framework-provided `ucom` primitives after issuing the chip-specific USB control transfer.

Look at `uplcom_cfg_param`. It takes a `termios` structure, extracts the baud rate and framing, and constructs a vendor-specific control transfer to program the chip. This is how a user's `stty 9600` call propagates through the layers: `stty` updates `termios`, the TTY layer calls `ucom_param`, the framework schedules the control transfer, and `uplcom_cfg_param` programs the chip.

Compare `uplcom_cfg_param` with the corresponding function in `uftdi.c`. Both translate a `termios` to a vendor-specific control sequence, but the vendor protocols are entirely different. This illustrates why the framework insists on per-vendor drivers: each chip has its own command set, and the framework's job is only to give each driver a uniform way to be called.

Note how the driver handles reset, modem signals, and break. Each modem-line operation is a separate USB control transfer. The cost of changing, say, DTR is one round-trip to the device, which on a 12 Mbps bus takes about 1 ms. This tells you why line signals change more slowly over USB-to-serial than over a native UART, and why protocols that toggle DTR frequently can behave differently through a USB-to-serial adapter.

26.13.5 Tour 5: `uhid.c`, the Human Interface Device Driver

File: `/usr/src/sys/dev/usb/input/uhid.c`.

`uhid.c` is the generic HID driver. HID stands for Human Interface Device; it covers keyboards, mice, gamepads, touchscreens, and countless vendor-specific devices that conform to the HID class standard. `uhid.c` is roughly 1000 lines.

Key things to learn from `uhid.c`:

The match table uses class-based matching. Instead of listing every VID/PID, the driver matches any device that advertises the HID interface class. `UIFACE_CLASS(UICLASS_HID)` tells the framework to match any HID interface, no matter which vendor made the device.

The driver exposes the device through a character device, not through `ucom` or a networking framework. The character device pattern lets userland programs open `/dev/uhidN` and issue `ioctl` calls to read HID descriptors, read reports, and set feature reports.

The interrupt endpoint delivers HID reports, and the driver hands them up to userland through a ring buffer and read. This is the USB equivalent of a character-device interrupt-driven read loop.

Study how `uhid.c` uses the HID report descriptor to understand what the device is. The descriptor is parsed at attach time, and the driver populates its internal tables from the parse. Every HID device describes itself this way; the driver does not hard-code device semantics.

26.13.6 How to Study a Driver You Have Never Seen

Beyond the tour, you will encounter drivers in the tree that you have never seen. A general-purpose reading strategy helps:

Open the source file and scroll to the bottom. The registration macros are there. They tell you what the driver attaches to (`uhub`, `usb`) and its name (`udbp`, `uhid`). Already you know where the driver fits in the tree.

Scroll back up to the `usb_config` array (or the transfer declarations for non-USB drivers). Each entry is one channel. Count them; look at their types and directions. You now know the shape of the data path.

Look at the probe method. If it matches by VID/PID, the device is vendor-specific. If it matches by class, the driver supports a family of devices. This tells you the scope of the driver.

Look at the attach method. Follow its labelled-goto chain. The labels give you the order of resource allocation: mutex, channels, character device, sysctls, and so on.

Finally, look at the data-path callbacks. Each one is a three-state state machine. Read `USB_ST_TRANSFERRED` first; that is where the actual work happens. Then read `USB_ST_SETUP`; that is the kickoff. Then read `USB_ST_ERROR`; that is the recovery policy.

With this reading order, you can make sense of any USB driver in the tree in about 15 minutes. With practice, you will start to recognise patterns across drivers and know which ones are idiomatic (the ones to copy) and which ones are historical oddities (the ones to understand but not copy).

26.13.7 Where to Go Beyond the Tour

The `/usr/src/sys/dev/usb/` tree has four subdirectories that are worth exploring:

`/usr/src/sys/dev/usb/misc/` contains simple, single-purpose drivers: `uled`, `ugold`, `udbp`. If you are writing a new device-specific driver that does not fit an existing class, read the drivers here to see how small drivers are structured.

`/usr/src/sys/dev/usb/serial/` contains the USB-to-serial bridge drivers: `uftdi`, `uplcom`, `uslcom`, `u3g` (3G modems, which present as serial to userland), `uark`, `uipaq`, `uchcom`. If you are writing a new USB-to-serial driver, start here.

`/usr/src/sys/dev/usb/input/` contains keyboard, mouse, and HID drivers. `ukbd`, `ums`, `uhid`. If you are writing a new input driver, these are the patterns to follow.

`/usr/src/sys/dev/usb/net/` contains USB network drivers: `axge`, `axe`, `cdce`, `ure`, `smc`. These are the drivers that bridge Chapter 26 to Chapter 27, because they combine the USB framework of this chapter with the `ifnet(9)` framework of the next. Reading one of them after finishing Chapter 27 is a productive exercise.

The `/usr/src/sys/dev/uart/` tree has fewer files but each is worth reading:

`/usr/src/sys/dev/uart/uart_core.c` is the framework core. Read this to understand what happens above your driver: how bytes flow in and out, how the TTY layer connects, how interrupts are dispatched.

`/usr/src/sys/dev/uart/uart_dev_ns8250.c` is the canonical reference driver. Read this after the framework core so you can see how a driver plugs in.

`/usr/src/sys/dev/uart/uart_bus_pci.c` shows the PCI bus-attach glue for UARTs. If you ever need to write a UART driver that attaches to PCI, this is your starting point.

Each of these files is small enough to read in one sitting. Reading the source is not homework; it is how you learn a subsystem. Chapter 26 has given you the vocabulary and the mental model; the source is where you apply them.

26.14 Performance Considerations for Transport Drivers

Most of Chapter 26 has focused on correctness: getting a driver to attach, do its work, and detach cleanly. Correctness always comes first. But once your driver works, you will often want to know how fast it is, and whether its performance matches what the transport can sustain. This section gives you a practical frame for thinking about USB and UART performance without turning the chapter into a benchmarking manual.

26.14.1 The USB Bus as a Shared Resource

Every device on a USB bus shares the bus with every other device. The bandwidth is not divided fairly; it is allocated according to USB's scheduling rules. Control and interrupt endpoints get guaranteed periodic service. Bulk endpoints get what is left over, in a fair-share sense. Isochronous endpoints reserve bandwidth up front; if there is not enough, the allocation fails.

For a bulk-transferring driver, the practical upshot is this. Your effective bandwidth is the theoretical link speed (12, 480, 5000 Mbps) minus the overhead of other devices' periodic traffic, minus the USB protocol overhead (roughly 10% on full-speed, less on higher speeds), minus the overhead of short transfers.

The last item is the one you can influence. A transfer of 16 KB is not 16 times more expensive than a transfer of 1 KB; the overhead of initiating and completing a transfer is fixed, and the data-transfer portion is close to linear in size. For high-throughput bulk transfers, use large buffers. The hardware is designed for this; the framework is designed for this; your driver should be designed for this.

For an interrupt-transferring driver, the constraint is different. The interrupt endpoint polls at a fixed interval (configured by the device). The framework delivers a callback whenever the polled transfer completes. The maximum report rate is the endpoint's polling rate. If the device has a 1-ms interval, you get at most 1000 reports per second. Planning for interrupt-driven performance means planning around the polling rate.

26.14.2 Latency: What Costs Microseconds, What Costs Milliseconds

USB is not a low-latency bus. A single control transfer on full-speed USB takes roughly 1 ms round-trip. A single bulk transfer takes roughly 1 ms of framing overhead plus the time to move the data. Interrupt transfers are scheduled at the polling interval, so the minimum latency is the interval itself.

Compare this to native UART, where a character transmission takes roughly 1 ms at 9600 baud, 100 us at 115200 baud, and 10 us at 1 Mbps. A native UART driver can push out a byte in hundreds of microseconds if it is well designed; a USB-to-serial bridge cannot match that, because each byte has to traverse USB first.

For your driver, this means: think about where latency matters for your use case. If you are building a monitoring driver that reports once a second, USB is fine. If you are building an interactive controller where the user can feel each character round-trip, native UART is much better. If you are building a real-time control loop where characters must traverse in tens of microseconds, neither USB nor general-purpose UART is appropriate; you need a dedicated bus with known timing.

26.14.3 When to Rearm: The Classic USB Tradeoff

A key decision in any streaming USB driver is where in the callback to re-arm the transfer. There are two viable patterns:

Rearm after work. In `USB_ST_TRANSFERRED`, do the work (parse the data, hand it up, update state), then rearm. Simple to implement. Has a latency cost: the time between the previous completion and the next submission is the time it took to do the work.

Rearm before work, using multiple buffers. In `USB_ST_TRANSFERRED`, immediately rearm with a fresh buffer, then do the work on the just-completed buffer. This requires multiple frames in the `usb_config` (so the frame-work rotates through a pool of buffers) or two parallel transfer channels. Has near-zero latency between transfers because the hardware always has a buffer ready.

Most drivers in the tree use the first pattern because it is simpler. The second pattern is used in high-throughput drivers where hiding the work latency matters. `ugold.c` is the first pattern; some of the USB Ethernet drivers in `/usr/src/sys/dev/usb/net/` are the second.

26.14.4 Buffer Sizing

For bulk transfers, the buffer size is a knob. Larger buffers amortise the per-transfer overhead, but they also delay the delivery of partial data and increase memory usage. The typical values in the tree are between 1 KB and 64 KB.

For interrupt transfers, the buffer size is usually small (8 to 64 bytes) because the endpoint itself limits the report size. Do not make this larger than the endpoint's `wMaxPacketSize`; the extra buffer is wasted.

For control transfers, the buffer size is determined by the protocol of the specific operation. The `usb_device_request` header is always 8 bytes; the data portion depends on the request.

26.14.5 UART Performance

For a UART driver, performance is usually a question of interrupt efficiency. A 16550A with a FIFO depth of 16 bytes at 115200 baud needs to be serviced roughly every 1.4 ms in the worst case. If your interrupt handler takes longer than that, the FIFO overflows and data is lost. Modern UARTs (16750, 16950, ns16550 variants on embedded SoCs) often have deeper FIFOs (64, 128, or 256 bytes) specifically to relax this constraint.

The `uart(4)` framework handles the FIFO management for you through `uart_ops->rxready` and the ring buffer. What you control as the driver author is: how fast your implementation of `getc` is, how fast `putc` is, and whether your interrupt handler is sharing the CPU with other work.

For higher baud rates (921600, 1.5M, 3M), a raw 16550A is not enough. These rates require either a chip with a larger FIFO or a driver that uses DMA to move characters directly to memory. The `uart(4)` framework supports DMA-backed drivers, but the vast majority of drivers (including `ns8250`) do not use it. DMA support is usually reserved for embedded platforms that specifically provide it.

26.14.6 Concurrency and Lock Hold Times

A USB callback runs with the driver's mutex held. If the callback takes a long time (copying a large buffer, doing complex processing), no other callback can run, and no detach can complete. Keep callback work short.

The idiomatic pattern for non-trivial work is: in the callback, copy the data out of the framework buffer into a private buffer in `softc`, then mark the data as ready and wake a consumer. The consumer (userland via `read`, or a worker taskqueue) does the heavy processing without the driver mutex.

For a UART driver, the same principle applies. The `rxready` and `getc` methods must be fast because they run in interrupt context. Heavy processing is done later, outside the interrupt, by the TTY layer and user processes.

26.14.7 Measuring, Not Guessing

The best way to answer a performance question is to measure. The `dtrace` hooks on `usb_transfer_submit` and related functions let you time transfers to microsecond precision. `sysctl -a | grep usb` exposes per-device statistics. For UARTs, `sysctl -a dev.uart` and the TTY statistics in `vmstat` tell you where time is going.

Do not optimise a driver blindly. Run the workload, measure, find the bottleneck, and fix what actually matters. For most drivers, the bottleneck is not the transfer itself but something surrounding it: memory allocation, locking, or a poorly sized buffer.

26.15 Common Mistakes When Writing Your First Transport Driver

The patterns in this chapter are the right way to write a transport driver. But patterns are easier to describe than to apply. Most first-time drivers are written with every pattern followed correctly in principle but misapplied in practice. This section lists the specific mistakes that appear most often when someone sits down to write a USB or UART driver for the first time. Each mistake is paired with the correction and a short explanation of why the correction is necessary.

Read this section once before you write your first driver, and again when you are debugging one. The mistakes are surprisingly universal; almost every experienced FreeBSD driver author has made several of them at some point.

26.15.1 Mistake 1: Taking the Framework Mutex Explicitly in a Callback

The mistake looks like this:

```
static void
my_bulk_read_callback(struct usb_xfer *xfer, usb_error_t error)
{
    struct my_softc *sc = usbd_xfer_softc(xfer);

    mtx_lock(&sc->sc_mtx);    /* <-- wrong */
    /* ... do work ... */
    mtx_unlock(&sc->sc_mtx);
}
```

The framework has already acquired the mutex before calling the callback. Taking it a second time is a self-deadlock on most mutex implementations and an extra uncontested acquisition on others. On some kernel configurations, it will panic immediately with a “recursive lock” assertion from WITNESS.

The correction is to simply not lock. The framework guarantees that callbacks are invoked with the softc mutex held. Your callback just does its work and returns; the framework releases the mutex on return.

26.15.2 Mistake 2: Calling Framework Primitives Without the Mutex Held

The opposite mistake is also common:

```
static int
my_userland_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct my_softc *sc = dev->si_drv1;

    /* no lock taken */
    usbd_transfer_start(sc->sc_xfer[MY_BULK_TX]);    /* <-- wrong */
    return (0);
}
```

Most framework primitives (`usbd_transfer_start`, `usbd_transfer_stop`, `usbd_transfer_submit`) expect the caller to hold the associated mutex. Calling them without the mutex is a race: the framework’s own state can be modified by a concurrent callback while you are issuing the primitive.

The correction is to take the mutex around the call:

```
mtx_lock(&sc->sc_mtx);
usbd_transfer_start(sc->sc_xfer[MY_BULK_TX]);
mtx_unlock(&sc->sc_mtx);
```

This is the idiomatic pattern. The framework provides the locking; the driver provides the mutex.

26.15.3 Mistake 3: Forgetting USB_ERR_CANCELLED Handling

The framework uses USB_ERR_CANCELLED to tell a callback that its transfer is being torn down (typically during detach). If your callback handles this error the same way it handles other errors (for example by rearming the transfer), detach will hang forever because the transfer never actually stops.

The correct pattern is:

```
case USB_ST_ERROR:
    if (error == USB_ERR_CANCELLED) {
        return; /* do not rearm; the framework is tearing us down */
    }
    /* handle other errors, possibly rearm */
    break;
```

Omitting the cancellation check is one of the most common reasons a driver detaches cleanly in development (because the ref count happens to be zero) but hangs in production (because a read was in-flight when detach ran).

26.15.4 Mistake 4: Submitting to a Channel That Has Not Been Started

A transfer channel is inert until usbd_transfer_start has been called on it. Calling usbd_transfer_submit on an inactive channel is a no-op in some framework versions and a panic in others.

The correct pattern is to call usbd_transfer_start from userland-initiated work (in response to an open, for instance) and leave the channel active until detach. Do not call usbd_transfer_submit directly; let usbd_transfer_start schedule the first callback, and rearm from USB_ST_SETUP or USB_ST_TRANSFERRED.

26.15.5 Mistake 5: Assuming USB_GET_STATE Returns the Real Hardware State

USB_GET_STATE(xfer) returns the state the framework wants the callback to handle at this moment. It does not report the underlying hardware state. The three states USB_ST_SETUP, USB_ST_TRANSFERRED, and USB_ST_ERROR are framework concepts, not hardware concepts.

In particular, USB_ST_TRANSFERRED means “the framework thinks this transfer completed.” If the hardware is misbehaving (spurious transfer complete interrupts, split completions), the callback may be called with USB_ST_TRANSFERRED even when the actual transfer has not fully drained. This is rare, but when debugging, do not assume the framework state is ground truth about the hardware.

26.15.6 Mistake 6: Using M_WAITOK in a Callback

A USB callback runs in an environment where sleeping is not allowed. Memory allocations in a callback must use M_NOWAIT. Using M_WAITOK will assert or panic.

A more subtle version of this mistake is calling a helper that internally uses M_WAITOK. For example, some framework helpers sleep; calling them from a callback is forbidden. If you need to do work that would require

sleeping (DNS lookup, disk I/O, USB control transfers from a USB callback), queue it to a taskqueue and let the taskqueue worker do the work outside the callback.

26.15.7 Mistake 7: Forgetting `MODULE_DEPEND` on `usb`

A USB driver module that does not declare `MODULE_DEPEND(my, usb, 1, 1, 1)` will fail to load with a cryptic unresolved-symbol error:

```
link_elf_obj: symbol usbd_transfer_setup undefined
```

The symbol is undefined because the `usb` module has not been loaded, and the linker cannot resolve the driver's dependency on it. Adding the correct `MODULE_DEPEND` directive causes the kernel module loader to automatically load `usb` before your driver, which resolves the symbol and lets your driver attach.

Every USB driver must have `MODULE_DEPEND(drivename, usb, 1, 1, 1)`. Every UART-framework driver must have `MODULE_DEPEND(drivename, uart, 1, 1, 1)`. Every `ucom(4)` driver must depend on both `usb` and `ucom`.

26.15.8 Mistake 8: Mutable State in a Read-Only Path

Imagine a driver that exposes a status field through a `sysctl`. The `sysctl` handler reads the field from the `softc` without taking the mutex:

```
static int
my_sysctl_status(SYSCTL_HANDLER_ARGS)
{
    struct my_softc *sc = arg1;
    int val = sc->sc_status;    /* <-- unlocked read */
    return (SYSCTL_OUT(req, &val, sizeof(val)));
}
```

If the field can be updated by a callback (which runs under the mutex), and read by the `sysctl` handler (which does not take the mutex), you have a data race. On modern platforms, word-sized reads are usually atomic, so the race is often invisible. But on platforms where they are not, or when the field is wider than a word, you can get torn reads.

The correction is to take the mutex for the read:

```
mtx_lock(&sc->sc_mtx);
val = sc->sc_status;
mtx_unlock(&sc->sc_mtx);
```

Even if the race is invisible on x86, taking the lock documents your intent and protects against future changes (like widening the field to 64 bits).

26.15.9 Mistake 9: Stale Pointers After `usbd_transfer_unsetup`

`usbd_transfer_unsetup` frees the transfer channels. The pointer in `sc->sc_xfer[i]` is no longer valid after the call returns. If any other code in your driver uses that pointer after `unsetup`, the behaviour is undefined.

The correction is to zero the array after `unsetup`:

```
usbd_transfer_unsetup(sc->sc_xfer, MY_N_TRANSFERS);  
memset(sc->sc_xfer, 0, sizeof(sc->sc_xfer)); /* optional but defensive */
```

More importantly, structure your detach so that nothing in the driver can observe the stale pointers. This usually means setting a “detaching” flag in the softc before calling `unsetup`, and having every other code path check the flag before using the pointers.

26.15.10 Mistake 10: Not Zeroing the Softc’s detaching Flag at Attach Time

If your softc uses a detaching flag to coordinate detach, the flag must start at zero when `attach` is called. This is normally automatic (the framework zero-fills the softc), but if you have any field that needs a non-zero initial value, be careful not to accidentally initialise `detaching` to a nonzero value.

A driver that starts with `detaching = 1` will appear to “detach before it ever attached,” which shows up as a driver that attaches normally but refuses to respond to any I/O.

26.15.11 Mistake 11: Forgetting to Destroy the Device Node on Detach

If your driver creates a character device with `make_dev` in `attach`, you must destroy it with `destroy_dev` in `detach`. Forgetting this leaves a stale `/dev` entry that points to freed memory. Userland programs that open the stale node will panic the kernel.

The correction is to call `destroy_dev(sc->sc_cdev)` in `detach`, and always before the softc fields it references are freed.

A stronger pattern is to order the `destroy_dev` call first in `detach` (before any other cleanup). This blocks new opens and waits for existing opens to close, so that by the time the rest of `detach` runs, no userland code can reach the driver.

26.15.12 Mistake 12: Racing on the Character Device Open

Even with `destroy_dev` in the right place, there is a window between `attach` succeeding and the first `open()` succeeding where the driver’s state is being initialised. If your open handler assumes certain softc fields are valid, and `attach` has not finished initialising them when the first open arrives, the open will see garbage.

The correction is to call `make_dev` last in `attach`, only after everything else is fully initialised. This way, the `/dev` entry does not appear until the driver is ready to service opens. Correspondingly, call `destroy_dev` first in `detach`, before tearing anything down.

26.15.13 Mistake 13: Overlooking the TTY Layer's Own Locking

UART drivers integrate with the TTY layer, which has its own locking rules. In particular, the TTY layer holds `tty_lock` when it calls into the driver's `tsw_param`, `tsw_open`, and `tsw_close` methods. If the driver then takes another lock inside these methods, the lock order is `tty_lock -> driver_mutex`. If any other code path takes the driver mutex and then the tty lock, you have a lock order inversion, and WITNESS will catch it.

The correction is to respect the lock order that the framework establishes. For UART drivers, the order is documented in `/usr/src/sys/dev/uart/uart_core.c`. When in doubt, run under WITNESS with `WITNESS_CHECKORDER` enabled; it will detect any violation immediately.

26.15.14 Mistake 14: Not Handling Zero-Length Data in Read or Write

A userland read or write with a zero-length buffer is legal. Your driver must handle it, either by immediately returning zero or by propagating the zero-length request through the framework. Forgetting this case often produces a driver that “mostly works” but fails weird test scenarios.

The simplest correction is:

```
if (uio->uio_resid == 0)
    return (0);
```

at the top of your read and write functions.

26.15.15 Mistake 15: Copying Data Before Checking the Transfer Status

In a read path, a common mistake is to unconditionally copy data out of the USB buffer:

```
case USB_ST_TRANSFERRED:
    usbd_copy_out(pc, 0, sc->sc_rx_buf, actlen);
    /* hand data up to userland */
    break;
```

If the transfer was a short read (`actlen < wMaxPacketSize`), the copy is correct for exactly `actlen` bytes but the driver code may assume more. If the transfer was empty (`actlen == 0`), the copy does nothing and any subsequent code that operates on “just-received data” works on stale data from the previous transfer.

The correction is to always check `actlen` before acting on the data:

```
case USB_ST_TRANSFERRED:
    if (actlen == 0)
        goto rearm; /* nothing received */
    usbd_copy_out(pc, 0, sc->sc_rx_buf, actlen);
    /* work with exactly actlen bytes */
    rearm:
```

```
/* re-submit */  
break;
```

26.15.16 Mistake 16: Assuming termios Values Are in Standard Units

The `termios` structure's `c_ispeed` and `c_ospeed` fields contain baud rate values, but the encoding has historical oddities. On FreeBSD, speeds are integer values (9600, 38400, 115200). On some other systems, they are indices into a table. Porting code that assumed index-based speeds to FreeBSD without checking is a common source of “the driver thinks the baud rate is 13 instead of 115200” bugs.

The correction is to look at the actual FreeBSD implementation: `/usr/src/sys/sys/termios.h` and `/usr/src/sys/kern/tty.c`. The baud rate in FreeBSD `termios` is an integer bit rate. When your driver receives a `termios` in `param`, read `c_ispeed` and `c_ospeed` as integers.

26.15.17 Mistake 17: Missing `device_set_desc` or `device_set_desc_copy`

The `device_set_desc` family of calls sets the human-readable description that `dmesg` shows when the device attaches. Without it, `dmesg` shows a generic label (like “`my_drv0:` ”), which is confusing for users and for your own debugging.

The correction is to call `device_set_desc` in `probe` (not `attach`), before returning `BUS_PROBE_GENERIC` or similar:

```
static int  
my_probe(device_t dev)  
{  
    /* ... match check ... */  
    device_set_desc(dev, "My Device");  
    return (BUS_PROBE_DEFAULT);  
}
```

Use `device_set_desc_copy` when the string is dynamic (constructed from device data); the framework will free the copy when the device is detached.

26.15.18 Mistake 18: `device_printf` in the Data Path Without Rate Limiting

The `device_printf` call is fine for occasional messages. In a data-path callback, it is not, because every single transfer prints a line to `dmesg` and to the console. A 1 Mbps stream of characters becomes a flood of log messages.

The correction is the `DLOG_RL` pattern from Chapter 25: rate-limit data-path log messages to one per second, or one per thousand events, whichever is appropriate. Keep full logging in the configuration and error paths; rate-limit in the data path.

26.15.19 Mistake 19: Not Waking Readers on Device Removal

If a userland program is blocked in `read()` waiting for data, and the device is unplugged, the driver must wake the reader and return an error (typically `ENXIO` or `ENODEV`). Forgetting to do this leaves the read blocked forever, which is a resource leak and a hang.

The correction is to wake all sleepers in detach before returning:

```
mtx_lock(&sc->sc_mtx);
sc->sc_detaching = 1;
wakeup(&sc->sc_rx_queue);
wakeup(&sc->sc_tx_queue);
mtx_unlock(&sc->sc_mtx);
```

And in the read path, check the flag after waking:

```
while (sc->sc_rx_head == sc->sc_rx_tail && !sc->sc_detaching) {
    error = msleep(&sc->sc_rx_queue, &sc->sc_mtx, PZERO | PCATCH, "myrd", 0);
    if (error != 0)
        break;
}
if (sc->sc_detaching)
    return (ENXIO);
```

This is the idiomatic pattern and avoids the classic “userland process hangs after you unplug the device” bug.

26.15.20 Mistake 20: Thinking “It Works on My Machine” Is Enough

Driver bugs can be hardware-dependent. A driver that works on one machine may fail on another because of timing differences, interrupt delivery differences, or hardware quirks in the USB controller. A driver that works with one model of a device may fail with another model of the same family because of firmware differences.

The correction is to test on multiple machines, multiple USB hosts (xHCI, EHCI, OHCI), and multiple devices if possible. When something works on one and fails on another, the difference is information. Trace both, compare, and the bug usually becomes clear.

26.15.21 What To Do After You Make One of These Mistakes

You will make several of these mistakes. This is normal. The way to learn is: debug the failure, identify which mistake it was, understand why it caused the specific symptom, and add the correction to your mental toolkit. Keep a note of which mistakes you have made in practice. When you see a new driver failure, check your note; the answer is usually a mistake you have already solved once.

The specific mistakes above are collected from the author’s own experience writing and debugging USB and UART drivers on FreeBSD. They are not exhaustive, but they are representative of the kinds of issues that come up. Reading drivers in the tree, attending FreeBSD developer forums, and submitting your work for code review are all ways to accelerate this kind of learning.

26.16 Wrapping Up

Chapter 26 has taken you on a long tour. It began with the idea that a transport-specific driver is a Newbus driver plus a set of rules about how the transport works. It then built out the two transport-specific layers we are focusing on in Part 6: USB and serial.

On the USB side, you learned the host-and-device model, the descriptor hierarchy, the four transfer types, and the hot-plug lifecycle. You walked through a complete driver skeleton: the match table, the probe method, the attach method, the `softc`, the detach method, and the registration macros. You saw how `struct usb_config` declares transfer channels and how `usbd_transfer_setup` brings them to life. You followed the three-state callback state machine through bulk, interrupt, and control transfers, and you saw how `usbd_copy_in` and `usbd_copy_out` move data between the driver and the framework's buffers. You learned the locking rules around transfer operations and the retry policies drivers should choose. By the end of Section 3, you had a mental model that would let you write a bulk-loopback driver from scratch.

On the serial side, you learned that the TTY layer sits on top of two distinct frameworks: `uart(4)` for bus-attached UARTs and `ucom(4)` for USB-to-serial bridges. You saw the six-method structure of a `uart(4)` driver, the role of `uart_ops` and `uart_class`, and how the `ns8250` canonical driver implements each method. You learned how `termios` settings flow from `stty` through the TTY layer into the driver's `param` path, and how hardware flow control is implemented at the register level. For USB-to-serial devices, you saw the distinct `ucom_callback` structure and how configuration methods translate `termios` changes into vendor-specific USB control transfers.

For testing, you learned about `nmdm(4)` for pure-TTY testing, QEMU USB redirection for USB development, and a handful of userland tools (`cu`, `tip`, `stty`, `comcontrol`, `usbconfig`) that make driver development manageable even without constant hardware access. You saw that much of driver work is not register-level wrestling but careful arrangement of data flow through well-defined abstractions.

The hands-on labs and challenge exercises gave you concrete problems to work on. Each lab is short enough to finish in a sitting, and each challenge extends one of the core ideas from the main text.

Three habits from earlier chapters extended naturally into Chapter 26. The labelled-goto cleanup chain from Chapter 25 is the same pattern used in USB and UART attach routines. The `softc`-as-single-source-of-truth discipline from Chapter 25 is applied identically to USB and UART driver state. The `errno`-returning helper function pattern is unchanged. What Chapter 26 added was transport-specific vocabulary and transport-specific abstractions built on top of those habits.

There is also a habit that Chapter 26 has introduced which will stay with you: the three-state callback state machine (`USB_ST_SETUP`, `USB_ST_TRANSFERRED`, `USB_ST_ERROR`). Every USB driver uses it. Learning to read this state machine is learning to read every USB callback in the tree. When you open `uftdi.c`, `ucycom.c`, `uchcom.c`, or any other USB driver, you will see the same pattern. Recognising it is recognising the USB framework's core abstraction.

Transport-specific drivers are where the book's abstract framework concepts become concrete. From here on, every chapter in Part 6 will deepen your practical skill with one more transport or one more kind of kernel service. The Newbus foundation from Part 3, the character-device basics from Part 4, and the discipline themes from Part 5 are all in play simultaneously. You are no longer learning concepts in isolation; you are using them together.

26.17 Bridge to Chapter 27

Chapter 27 turns to network drivers. Much of the structure will feel familiar: there is a Newbus attachment, there is per-device state (called `if_softc` in network drivers), there is a match table, there is a probe-and-attach sequence, there are hot-plug considerations, and there is an integration with a higher framework. But the higher framework here is `ifnet(9)`, the interface-framework abstraction for network devices, and its idioms are different from those of USB and serial.

A network driver does not expose a character device. It exposes an interface, which is visible to userland through `ifconfig(8)`, through `netstat -i`, and through the socket layer. Instead of `read(2)` and `write(2)`, network drivers handle packet input and packet output through the network stack's pipeline. Instead of `termios` for configuration, they handle `SIOCSIFFLAGS`, `SIOCADDMULTI`, `SIOCSIFMEDIA`, and a host of other network-specific `ioctl`s.

Many network cards also happen to use USB or PCIe as their underlying transport. A USB Ethernet adapter, for example, sits on USB (via `if_cdce` or a vendor-specific driver) and exposes an `ifnet(9)` interface. A PCIe Ethernet card sits on PCIe and also exposes an `ifnet(9)` interface. Chapter 27 will show how the same `ifnet(9)` framework sits on top of these very different transports, and how the separation lets you write a driver that focuses on the packet-level protocol without worrying about the details of its transport.

One specific thing to look forward to is the contrast between how USB delivers packets (as transfer completions, one buffer at a time, with explicit flow control at the transfer level) and how PCIe-based network cards deliver packets (as DMA-from-hardware events with descriptor rings). The packet pipeline in the network stack is designed to hide this difference from the upper layers, but a driver author has to understand both models because they determine the driver's internal structure.

Chapter 27 will then turn to block device drivers (storage). That chapter will cover the GEOM framework, which is FreeBSD's layered block-device infrastructure. Block drivers have their own idioms: a different way of matching devices, a different way of exposing state (through GEOM providers and consumers), and a fundamentally different data flow model (read and write operations on sectors, with a strong consistency model).

Parts 7, 8, and 9 then cover the more specialised topics: kernel services and advanced kernel idioms, debugging and testing in depth, and distribution and packaging. By the end of the book, you will have written and maintained drivers across several transport layers and several kernel subsystems. The foundation you have built in Chapters 21 through 26 will be the common ground across all of that work.

For now, keep your `myfirst_usb` driver. You will not extend it in later chapters, but the patterns it demonstrates will appear again in network, storage, and kernel-service contexts. Having your own working example on hand, something you wrote and understand completely, is a resource that pays back many times over as the book progresses.

26.18 Quick Reference

This reference collects the most important APIs, constants, and file locations from Chapter 26 into one place. Keep it open while writing or reading a driver; it is faster than rediscovering each name from the source tree.

26.18.1 USB Driver APIs

Function	Purpose
<code>usbd_lookup_id_by_uaa(table, size, uaa)</code>	Match attach arg against match table
<code>usbd_transfer_setup(udev, &ifidx, xfer, config, n, priv, mtx)</code>	Allocate transfer channels
<code>usbd_transfer_unsetup(xfer, n)</code>	Free transfer channels
<code>usbd_transfer_submit(xfer)</code>	Queue a transfer for execution
<code>usbd_transfer_start(xfer)</code>	Activate a channel
<code>usbd_transfer_stop(xfer)</code>	Deactivate a channel
<code>usbd_transfer_pending(xfer)</code>	Query whether a transfer is outstanding
<code>usbd_transfer_drain(xfer)</code>	Wait for any pending transfer to complete
<code>usbd_xfer_softc(xfer)</code>	Retrieve the_softc from a transfer
<code>usbd_xfer_status(xfer, &actlen, &sumlen, &aframes, &nframes)</code>	Query transfer results
<code>usbd_xfer_get_frame(xfer, i)</code>	Get page-cache pointer for frame i
<code>usbd_xfer_set_frame_len(xfer, i, len)</code>	Set length of frame i
<code>usbd_xfer_set_frames(xfer, n)</code>	Set total frame count
<code>usbd_xfer_max_len(xfer)</code>	Query max transfer length
<code>usbd_xfer_set_stall(xfer)</code>	Schedule clear-stall on this pipe
<code>usbd_copy_in(pc, offset, src, len)</code>	Copy into framework buffer
<code>usbd_copy_out(pc, offset, dst, len)</code>	Copy out of framework buffer
<code>usbd_errstr(err)</code>	Error code to string
<code>USB_GET_STATE(xfer)</code>	Current callback state
<code>USB_VPI(vendor, product, info)</code>	Compact match table entry

26.18.2 USB Transfer Types (`usb.h`)

- `UE_CONTROL`: control transfer (request-response)
- `UE_ISOCHRONOUS`: isochronous (periodic, no retry)
- `UE_BULK`: bulk (reliable, no timing guarantee)
- `UE_INTERRUPT`: interrupt (periodic, reliable)

26.18.3 USB Transfer Direction

- `UE_DIR_IN`: device to host
- `UE_DIR_OUT`: host to device
- `UE_ADDR_ANY`: framework picks any matching endpoint

26.18.4 USB Callback States (`usbdi.h`)

- `USB_ST_SETUP`: ready to submit a new transfer
- `USB_ST_TRANSFERRED`: previous transfer succeeded
- `USB_ST_ERROR`: previous transfer failed

26.18.5 USB Error Codes (`usbdi.h`)

- `USB_ERR_NORMAL_COMPLETION`: success
- `USB_ERR_PENDING_REQUESTS`: outstanding work
- `USB_ERR_NOT_STARTED`: transfer not started
- `USB_ERR_CANCELLED`: transfer cancelled (e.g., detach)
- `USB_ERR_STALLED`: endpoint stalled
- `USB_ERR_TIMEOUT`: timeout expired
- `USB_ERR_SHORT_XFER`: received less data than requested
- `USB_ERR_NOMEM`: out of memory
- `USB_ERR_NO_PIPE`: no matching endpoint

26.18.6 Registration Macros

- `DRIVER_MODULE(name, parent, driver, evh, arg)`: register driver with kernel
- `MODULE_DEPEND(name, dep, min, pref, max)`: declare module dependency
- `MODULE_VERSION(name, version)`: declare module version
- `USB_PNP_HOST_INFO(table)`: export match table to devd
- `DEVMETHOD(name, func)`: declare method in method table
- `DEVMETHOD_END`: terminate method table

26.18.7 UART Framework APIs

Function	Header	Purpose
<code>uart_getreg(bas, offset)</code>	<code>uart.h</code>	Read a UART register
<code>uart_setreg(bas, offset, value)</code>	<code>uart.h</code>	Write a UART register
<code>uart_barrier(bas)</code>	<code>uart.h</code>	Memory barrier for register access
<code>uart_bus_probe(dev, regshft, regiowidth, rclk, rid, chan, quirks)</code>	<code>uart_bus.h</code>	Framework probe helper
<code>uart_bus_attach(dev)</code>	<code>uart_bus.h</code>	Framework attach helper
<code>uart_bus_detach(dev)</code>	<code>uart_bus.h</code>	Framework detach helper

26.18.8 uart_ops Methods

- `probe(bas)`: chip present?
- `init(bas, baud, databits, stopbits, parity)`: initialise chip
- `term(bas)`: shut down chip
- `putc(bas, c)`: send one character (polling)
- `rxready(bas)`: is data available?
- `getc(bas, mtx)`: read one character (polling)

26.18.9 ucom_callback Methods

- `ucom_cfg_open, ucom_cfg_close`: open/close hooks
- `ucom_cfg_param`: termios changed
- `ucom_cfg_set_dtr, ucom_cfg_set_rts, ucom_cfg_set_break, ucom_cfg_set_ring`: signal control
- `ucom_cfg_get_status`: read line and modem status bytes
- `ucom_pre_open, ucom_pre_param`: validation hooks (return `errno`)
- `ucom_ioctl`: chip-specific ioctl handler
- `ucom_start_read, ucom_stop_read`: enable/disable read
- `ucom_start_write, ucom_stop_write`: enable/disable write
- `ucom_tty_name`: customise the TTY device-node name
- `ucom_poll`: poll for events
- `ucom_free`: final cleanup

26.18.10 Key Source Files

- `/usr/src/sys/dev/usb/usb.h`: USB protocol definitions
- `/usr/src/sys/dev/usb/usbdi.h`: USB driver interface, `USB_ERR_*` codes
- `/usr/src/sys/dev/usb/usbdi_util.h`: convenience helpers
- `/usr/src/sys/dev/usb/usbdevs.h`: Vendor/product constants (build-generated by the FreeBSD build system from `/usr/src/sys/dev/usb/usbdevs`; not present in a clean source tree until the kernel or driver is built)
- `/usr/src/sys/dev/usb/controller/`: Host controller drivers
- `/usr/src/sys/dev/usb/misc/uled.c`: Simple LED driver (reference)
- `/usr/src/sys/dev/usb/serial/uftdi.c`: FTDI driver (reference)
- `/usr/src/sys/dev/usb/serial/usb_serial.h`: `ucom_callback` definition
- `/usr/src/sys/dev/usb/serial/usb_serial.c`: `ucom` framework
- `/usr/src/sys/dev/uart/uart.h`: `uart_getreg, uart_setreg, uart_barrier`
- `/usr/src/sys/dev/uart/uart_bus.h`: `uart_class, uart_softc`, bus helpers
- `/usr/src/sys/dev/uart/uart_cpu.h`: `uart_ops`, CPU-side glue
- `/usr/src/sys/dev/uart/uart_core.c`: UART framework body
- `/usr/src/sys/dev/uart/uart_tty.c`: UART-TTY integration
- `/usr/src/sys/dev/uart/uart_dev_ns8250.c`: ns8250 reference driver
- `/usr/src/sys/dev/ic/ns16550.h`: 16550 register definitions
- `/usr/src/sys/dev/nmdm/nmdm.c`: null-modem driver

26.18.11 Userland Diagnostic Commands

Command	Purpose
<code>usbconfig list</code>	List USB devices
<code>usbconfig -d ugenN.M dump_all_config_desc</code>	Dump descriptors
<code>usbconfig -d ugenN.M dump_stats</code>	Transfer statistics
<code>usbconfig -d ugenN.M reset</code>	Reset device
<code>stty -a -f /dev/device</code>	Show termios settings
<code>stty 115200 -f /dev/device</code>	Set baud rate
<code>comcontrol /dev/device</code>	Show modem signals
<code>cu -l /dev/device -s speed</code>	Interactive session
<code>tip name</code>	Named connection (via <code>/etc/remote</code>)
<code>kldload mod.ko</code>	Load kernel module
<code>kldunload mod</code>	Unload kernel module
<code>kldstat</code>	List loaded modules
<code>dmesg -w</code>	Stream kernel messages
<code>sysctl hw.usb.*</code>	Query USB framework
<code>sysctl dev.uart.*</code>	Query UART instances

26.18.12 Standard Development Flags

Debug-mode kernel options to enable during development: - options `INVARIANTS`: assertion checking - options `INVARIANT_SUPPORT`: required alongside `INVARIANTS` - options `WITNESS`: lock order checking - options `WITNESS_SKIPSPIN`: skip spin locks in `WITNESS` (perf) - options `WITNESS_CHECKORDER`: verify every lock acquisition - options `DDB`: kernel debugger - options `KDB`: kernel debugger support - options `USB_DEBUG`: extensive USB logging

These options should be enabled on development machines, not production.

26.19 Glossary

The following terms appeared in this chapter. Some are new; others were introduced earlier and are repeated here for convenience. Definitions are brief and intended as a quick reminder, not as a replacement for the main-text explanations.

Address (USB). A number from 1 to 127 that the host assigns to a device during enumeration. Each physical device on a bus has a unique address.

Attach. The framework-called method where a driver takes ownership of a newly discovered device, allocates resources, initialises state, and begins operation. Paired with `detach`.

Bulk transfer. A USB transfer type designed for reliable, high-throughput, non-time-critical data. Used for mass storage, printers, network adapters.

Callout. A FreeBSD mechanism for scheduling a function to run after a specific delay. Used by drivers for timeouts and periodic tasks.

Callin node. A TTY device node (usually `/dev/ttyuN`) where opening blocks until carrier detect is asserted. Historically used for answering incoming modem calls.

Callout node. A TTY device node (usually `/dev/cuaN`) where opening does not wait for carrier detect. Used for initiating connections or for non-modem devices.

CDC ACM. Communication Device Class, Abstract Control Model. The USB standard for virtual serial ports. Handled in FreeBSD by the `u3g` driver.

Character device. A UNIX device abstraction for byte-oriented devices. Exposed to userland through `/dev` entries. Introduced in Chapter 24.

Class driver. A USB driver that handles an entire class of devices (all HID devices, all mass-storage devices) rather than a single vendor's product. Matches on interface class/subclass/protocol.

Clear-stall. A USB operation that clears a stall condition on an endpoint. Handled by the FreeBSD USB framework when `usbd_xfer_set_stall` is called.

Configuration (USB). A named set of interfaces and endpoints a USB device can expose. A device usually has one configuration but may have several.

Control transfer. A USB transfer type designed for small, infrequent, request-response exchanges. Used for configuration and status.

cuau. Naming prefix for the callout-side TTY device of a bus-attached UART. Example: `/dev/cuau0`.

cuaU. Naming prefix for the callout-side TTY device of a USB-provided serial port. Example: `/dev/cuaU0`.

Descriptor (USB). A small data structure a USB device provides, describing itself or one of its components. Types include device, configuration, interface, endpoint, and string descriptors.

Detach. The framework-called method where a driver releases all resources and prepares for the device to vanish. Paired with `attach`.

devd. The FreeBSD device-event daemon that reacts to kernel notifications about device attach and detach. Responsible for auto-loading modules for newly-discovered devices.

Device (USB). A single physical USB peripheral connected to a port. Contains one or more configurations.

DMA. Direct Memory Access. A mechanism where hardware can read or write memory without CPU involvement. Used by high-performance USB host controllers and PCIe network cards.

Echo loopback. A test configuration in which a device echoes whatever it receives, used to validate bidirectional data flow.

Endpoint. A USB communication channel within an interface. Each endpoint has a direction (IN or OUT) and a transfer type. Matches one hardware FIFO on the device.

Enumeration. The USB process by which a newly attached device is discovered, assigned an address, and has its descriptors read by the host.

FIFO (hardware). A small buffer on a UART or USB chip that holds bytes during transfer. Typical 16550 FIFO is 16 bytes; many modern UARTs have 64 or 128.

FTDI. A company that makes popular USB-to-serial adapter chips. Drivers for FTDI chips are in `/usr/src/sys/dev/usb/serial/uftdi.c`.

ifnet(9). The FreeBSD framework for network device drivers. Covered in Chapter 27.

Interface (USB). A logical grouping of endpoints within a USB device. A multi-function device can expose multiple interfaces.

Interrupt handler. A function the kernel runs in response to a hardware interrupt. In the UART context, the framework provides a default interrupt handler.

Interrupt transfer. A USB transfer type designed for low-bandwidth, periodic, latency-critical data. Used for keyboards, mice, HIDs.

Isochronous transfer. A USB transfer type designed for real-time streams with guaranteed bandwidth but no delivery guarantee. Used for audio and video.

kldload, kldunload. FreeBSD commands for loading and unloading kernel modules.

kobj. FreeBSD's object-oriented kernel framework. Used for method dispatch in Newbus and other subsystems.

Match table. An array of `STRUCT_USB_HOST_ID` (for USB) or equivalent entries that a driver uses to declare which devices it supports.

Modem control register (MCR). A 16550 register that controls modem output signals (DTR, RTS).

Modem status register (MSR). A 16550 register that reports modem input signals (CTS, DSR, CD, RI).

nmdm(4). FreeBSD's null-modem driver. Creates pairs of linked virtual TTYs for testing. Loaded with `kldload nmdm`.

ns8250. A canonical 16550-compatible UART driver for FreeBSD. At `/usr/src/sys/dev/uart/uart_dev_ns8250.c`.

Pipe. A term for a bidirectional USB transfer channel from the host's perspective. A host has one pipe per endpoint.

Port (USB). A downstream attachment point on a hub. Each port can have one device (which may itself be a hub).

Probe. The framework-called method where a driver examines a candidate device and decides whether to attach. Returns zero for a match, nonzero `errno` for a reject.

Probe-and-attach. The two-phase handshake by which Newbus binds drivers to devices. Probe tests the match; attach does the work.

Retry policy. A driver's rule for what to do when a transfer fails. Common policies: rearm on every error, rearm up to N times then give up, rearm only for specific errors.

Ring buffer. A fixed-size circular buffer used by the UART framework to buffer data between the chip and the TTY layer.

RTS/CTS. Request To Send / Clear To Send. Hardware flow-control signals on a serial port.

Softc. The per-device state a driver maintains. Named after “software context” by analogy with hardware register state.

Stall (USB). A signal from a USB endpoint that it is not ready to accept more data until explicitly cleared by the host.

stty(1). Userland utility for inspecting and changing TTY settings. Maps directly onto `termios` fields.

Taskqueue. A FreeBSD mechanism for deferring work to a worker thread. Used by drivers that need to do something that cannot run in an interrupt context.

termios. A POSIX structure that describes a TTY’s configuration: baud rate, parity, flow control, line discipline flags, and many others. Set and queried by `tcsetattr(3)` and `tcgetattr(3)` from userland, or by `stty(1)`.

Transfer (USB). A single logical operation on a USB channel. Can be a single packet or many.

TTY. Teletype. The UNIX abstraction for a serial device. Character-at-a-time I/O, line discipline, signal generation, terminal control.

ttydevsw. The structure a TTY driver uses to register its operations with the TTY layer. Analogous to `cdevsw` for character devices.

ttyu. Naming prefix for the callin-side TTY device of a bus-attached UART. Example: `/dev/ttyu0`.

uart(4). FreeBSD’s framework for UART drivers. Handles registration, buffering, TTY integration. Drivers implement `uart_ops` hardware methods.

uart_bas. “UART Bus Access Structure.” The framework’s abstraction for register access to a UART, hiding whether the registers are in I/O space or memory-mapped.

uart_class. The framework descriptor that identifies a UART chip family. Pairs with `uart_ops` to give the framework everything it needs.

uart_ops. The table of six hardware-specific methods (`probe`, `init`, `term`, `putc`, `rxready`, `getc`) that a UART driver implements.

ucom(4). FreeBSD’s framework for USB-to-serial device drivers. Sits on top of USB transfers, provides TTY integration.

ucom_callback. The structure a `ucom(4)` client uses to register its callbacks with the framework.

ugen(4). FreeBSD’s generic USB driver. Exposes raw USB access through `/dev/ugenN.M` for userland programs. Used when no specific driver matches.

uhub. The FreeBSD driver for USB hubs (including the root hub). A class driver attaches to `uhub`, not to the USB bus directly.

usbconfig(8). Userland utility for inspecting and controlling USB devices. Can dump descriptors, reset devices, enumerate state.

usb_config. A C structure a USB driver uses to declare each of its transfer channels: type, endpoint, direction, buffer size, flags, callback.

usb_fifo. A USB framework abstraction for byte-stream `/dev` nodes. Generic alternative to writing a custom `cdevsw`.

usb_template(4). FreeBSD's USB device-side (gadget) framework. Used on hardware that can act as both USB host and USB device.

usb_xfer. An opaque structure representing a single USB transfer channel. Allocated by `usbd_transfer_setup`, freed by `usbd_transfer_unsetup`.

usbd_copy_in, usbd_copy_out. Helpers for copying data between plain C buffers and USB framework buffers. Must be used instead of direct pointer access.

usbd_lookup_id_by_uaa. Framework helper that compares a USB attach argument against a match table and returns zero on match.

usbd_transfer_setup, _unsetup. The calls that allocate and free transfer channels. Called from `attach` and `detach` respectively.

usbd_transfer_submit. The call that hands a transfer to the framework for execution on the hardware.

usbd_transfer_start, _stop. The calls that activate or deactivate a channel. Activate triggers a callback in `USB_ST_SETUP`; deactivate cancels in-flight transfers.

USB_ST_SETUP, _TRANSFERRED, _ERROR. The three states of a USB transfer callback, as returned by `USB_GET_STATE(xfer)`.

USB_ERR_CANCELLED. The error code the framework passes to a callback when a transfer is being torn down (typically during detach).

USB_ERR_STALLED. The error code when a USB endpoint returns a STALL handshake. Usually handled by calling `usbd_xfer_set_stall`.

VID/PID. Vendor ID / Product ID. A pair of 16-bit numbers that uniquely identifies a USB device model.

WITNESS. A FreeBSD kernel debugging option that tracks lock acquisition order and warns about violations.

Callin device. A TTY device (named `/dev/ttyuN` or `/dev/ttyUN`) that blocks on open until the modem's carrier detect (CD) signal is asserted. Used by programs that accept incoming calls.

Callout device. A TTY device (named `/dev/cuaun` or `/dev/cuaUN`) that opens immediately without waiting for carrier detect. Used by programs that initiate connections.

comcontrol(8). Userland utility for controlling TTY options (drain behaviour, DTR, flow control) that are not exposed through `stty`.

Descriptor (USB). A data structure that a USB device returns when the host asks for its identity, configuration, interfaces, or endpoints. Hierarchical: device descriptor contains configuration descriptors; configurations contain interfaces; interfaces contain endpoints.

Endpoint (USB). A named, typed communication channel inside a USB device. Has an address (1 through 15), a direction (IN or OUT), a type (control, bulk, interrupt, isochronous), and a maximum packet size.

Line discipline. The TTY layer's pluggable layer between the driver and userland. Standard disciplines include `termios` (canonical and raw modes). Line disciplines translate between raw bytes and the behaviour a user program expects.

msleep(9). The kernel sleep primitive used to block a thread on a channel with a mutex held. Paired with `wakeup(9)`, it implements producer-consumer patterns inside drivers.

mtx_sleep. A synonym for `msleep` used in some parts of the tree. Functionally identical.

Open/close pair. The character device methods `d_open` and `d_close`. Every driver that exposes a `/dev` node must handle these. Opens are usually where channels are started; closes are usually where channels are stopped.

Short transfer. A USB transfer that completes with fewer bytes than requested. Normal for bulk IN (where the device sends a short packet to signal “end of message”) and for interrupt IN (where the device sends a short packet when it has less data than the maximum). Always check `actlen`.

USETW. A FreeBSD macro for setting a little-endian 16-bit field inside a USB descriptor buffer. The USB wire format is always little-endian, so `USETW` hides the byte-swap.

This glossary is not exhaustive; it covers the terms this chapter actually used. For a broader FreeBSD USB reference, the `usbdi(9)` manual page is the definitive source. For the UART framework, the source in `/usr/src/sys/dev/uart/` is the reference. When you encounter an unfamiliar term in either place, check here first; if not defined, go to the source.

26.19.1 A Closing Note on Terminology Precision

One last piece of advice on vocabulary. The USB, TTY, and FreeBSD communities each have their own careful distinctions between terms that sound like synonyms. Confusing these in conversation with more experienced developers is a quick way to sound unsure; using them precisely is a quick way to sound at home.

“Device” in the USB context means the whole USB peripheral (the keyboard, the mouse, the serial adapter). “Interface” means a logical grouping of endpoints inside the device. An interface implements one function; a device can have multiple interfaces. When you say “the USB device is a composite device,” you are saying it has multiple interfaces.

“Endpoint” and “pipe” are related but distinct. An endpoint is on the device; a pipe is the host’s view of a connection to that endpoint. In FreeBSD driver code, the term “transfer channel” is often used in place of “pipe,” because “pipe” overloads a more common meaning in UNIX.

“Transfer” and “transaction” are also distinct. A transfer is a logical operation (a read request for *N* bytes); a transaction is the USB-level packet exchange that realises it. A bulk transfer of 64 bytes to an endpoint with a maximum packet size of 64 is one transfer and one transaction. A bulk transfer of 512 bytes to the same endpoint is one transfer and eight transactions.

“UART” and “serial port” are closely related but not identical. A UART is the chip (or the chip’s logic block); a serial port is the physical connector and its wiring. One UART can back multiple serial ports in some configurations; one serial port is always backed by exactly one UART.

“TTY” and “terminal” are related. A TTY is the kernel abstraction for character-at-a-time I/O; a terminal is the userland view. A TTY has a controlling terminal property; a terminal has a TTY that it uses. In driver code, TTY is almost always the more precise term.

Getting these right in writing and in code comments signals that you understand the design. And when you read someone else’s code or documentation, noticing which term they chose tells you which layer of abstraction they are thinking about.

27 Working with Storage Devices and the VFS Layer

27.1 Introduction

In the previous chapter, we walked carefully through the life of a USB serial driver. We followed the device from the moment the kernel noticed it on the bus, through probe and attach, into its active life as a character device, and finally out through detach when the hardware was unplugged. That walkthrough taught us how transport-specific drivers live inside FreeBSD. They participate in a bus, they expose a user-facing abstraction, and they accept that they may vanish at any moment because the underlying hardware is removable.

Storage drivers live in a very different country. The hardware is still real, and many storage devices can still be removed unexpectedly, but the role of the driver shifts in an important way. A USB serial adapter offers a stream of bytes to one process at a time. A storage device offers a block-addressable, long-lived, structured surface on which filesystems are built. When a user plugs in a USB serial adapter, they might immediately open `/dev/cuaU0` and begin a session. When a user plugs in a disk, they almost never read it as a raw stream. They mount it, and from that moment on the disk disappears behind a filesystem, behind a cache, behind the Virtual File System layer, and behind the many processes that share files on it.

This chapter teaches you what happens on the driver side of that arrangement. You will learn what the VFS layer is, how it differs from `devfs`, and how storage drivers plug into the GEOM framework rather than speaking to the VFS layer directly. You will write a small pseudo block device from scratch, expose it as a GEOM provider, give it a working backing store, watch `newfs_ufs` format it, mount the result, create files on it, unmount it cleanly, and detach it without leaving footprints in the kernel. By the end of the chapter you will have a working mental model of the storage stack and a concrete example driver that exercises every layer we discuss.

The chapter is long because the topic is layered. Unlike a character driver, where the main unit of interaction is a single `read` or `write` call from a process, a storage driver lives inside a chain of frameworks. Requests travel from a process through VFS, through the buffer cache, through the filesystem, through GEOM, and only then reach the driver. Replies travel back the other way. Understanding that chain is essential before writing any real storage code, and it is essential again when diagnosing the kind of subtle failures that appear only under load or during unmount. We will move slowly through the foundations, then gradually bring more layers into view.

As with Chapter 26, the goal here is not to ship a production block driver. The goal is to give you a sturdy, correct, readable first block driver that you understand completely. Real production storage drivers, for SATA disks, NVMe drives, SCSI controllers, SD cards, or virtual block devices, build on the same patterns. Once the foundations are clear, the step from pseudo to real is mostly a matter of replacing the backing store with code that talks to hardware registers and DMA engines, and of handling the much richer error and recovery surface that real disks expose.

You will also see how storage drivers interact with tools the reader already knows from the user side of FreeBSD. `mdconfig(8)` will appear as a close cousin of our driver, since the kernel's `md(4)` RAM disk is exactly the kind of thing we are building. `newfs_ufs(8)`, `mount(8)`, `umount(8)`, `diskinfo(8)`, `gstat(8)`, and `geom(8)` will

become tools of verification, not just tools that other people use. The chapter is structured so that by the time you finish, you can look at the output of `gstat -I 1` while running `dd` against your device and read it with understanding.

Finally, a note on what we will not cover here. We will not write a real bus driver that talks to a physical storage controller. We will not discuss the internals of UFS, ZFS, FUSE, or other specific filesystems beyond what is needed to understand how they meet a block device at the boundary. We will not cover DMA, PCIe, NVMe queues, or SCSI command sets. All of those topics deserve their own treatment and, where relevant, will appear in later chapters that cover specific buses and specific subsystems. What we will do here is give you a complete, self-contained block-layer experience that is representative of how all storage drivers in FreeBSD integrate with the kernel.

Take your time with this chapter. Read slowly, type the code, boot the module, format it, mount it, break it on purpose, watch what happens. The storage stack rewards patience and punishes shortcuts. You are not in a race.

27.2 How Part 6 Differs from Parts 1 Through 5

A short framing note before the chapter begins. Chapter 27 sits inside a Part that asks you to change one specific habit, and that shift is easier to make when it is named up front.

Parts 1 through 5 built a single running driver, `myfirst`, through twenty consecutive chapters, each adding one discipline to the same source tree. Chapter 26 extended that family with `myfirst_usb` as a transport sibling so the step into real hardware would not also be a step into unfamiliar source. **From Chapter 27 onward, the running `myfirst` driver pauses as the backbone of the book.** Part 6 shifts to new, self-contained demos that fit each subsystem it teaches: a pseudo block device for storage here in Chapter 27, and a pseudo network interface for networking in Chapter 28. These demos are parallel to `myfirst` in spirit but distinct in code, because the patterns that define a storage driver or a network driver do not fit the character-device mould that `myfirst` grew from.

The **discipline and didactic shape continue unchanged**. Each chapter still walks you through probe, attach, the primary data path, the cleanup path, labs, challenge exercises, troubleshooting, and a bridge to the next chapter. Each chapter still grounds its examples in real FreeBSD source under `/usr/src`. The habits you built in Chapters 25 and earlier, the labelled-goto cleanup chain, rate-limited logging, `INVARIANTS` and `WITNESS`, the production-readiness checklist, carry over without modification. What changes is the code artefact in front of you: a small, focused driver whose shape matches the subsystem under study, rather than one more stage in the `myfirst` timeline.

This is a deliberate didactic choice, not an accident of scope. A storage driver and a network driver each have their own lifecycle, their own data flow, their own preferred idioms, and their own frameworks to plug into. Teaching them as fresh drivers, rather than as further mutations of `myfirst`, keeps the focus on what makes each subsystem distinctive. A reader who tries to stretch `myfirst` into a block device or a network interface quickly ends up with code that teaches nothing about storage or networking. Fresh demos are the cleaner path, and they are the path this Part takes.

Part 7 returns to cumulative learning, but rather than resuming a single running driver, it revisits the drivers you have already written (`myfirst`, `myfirst_usb`, and the Part 6 demos) and teaches the production-minded topics

that matter once a first version of a driver exists: portability across architectures, advanced debugging, performance tuning, security review, and contribution to the upstream project. The habit of building cumulatively stays with you; only the specific artefact in front of you changes.

Keep this framing in mind as Chapter 27 unfolds. If the switch from `myfirst` to a new pseudo block device feels jarring after twenty chapters of the same source tree, that reaction is expected and passes quickly, usually by the end of Section 3.

27.3 Reader Guidance: How to Use This Chapter

This chapter is designed as a guided course through the storage side of the FreeBSD kernel. It is one of the longer chapters in the book because the subject matter is layered and every layer has its own vocabulary, its own concerns, and its own failure modes. You do not need to rush through it.

If you choose the **reading-only path**, expect to spend around two to three hours going through the chapter carefully. You will come away with a clear picture of how VFS, the buffer cache, filesystems, GEOM, and the block device boundary fit together, and you will have a concrete driver in front of you as an anchor for your mental model. This is a legitimate way to use the chapter, especially on a first pass.

If you choose the **reading-plus-labs path**, plan for four to six hours spread across one or two evenings, depending on your comfort with kernel modules from Chapter 26. You will build the driver, format it, mount it, watch it under load, and take it apart safely. Expect the mechanics of `kldload`, `kldunload`, `newfs_ufs`, and `mount` to become second nature by the end.

If you choose the **reading-plus-labs-plus-challenges path**, plan for a weekend or two evenings spread over a week. The challenges extend the driver in small directions that matter in practice: adding optional flush semantics, responding to `BIO_DELETE` with zeroing, supporting multiple units, exporting extra attributes through `disk_getattr`, and enforcing read-only mode cleanly. Each challenge is self-contained and uses only what the chapter has already covered.

Whichever path you choose, do not skip the troubleshooting section. Storage bugs tend to look alike from the outside, and the ability to recognise them by symptom is far more useful in practice than memorising the names of every function in GEOM. The troubleshooting material is placed near the end for readability, but you may find yourself turning back to it while working through the labs.

A word on prerequisites. This chapter builds directly on Chapter 26, so at minimum you should be comfortable writing a small kernel module, declaring a softc, allocating and freeing resources, and walking through the load and unload path. You should also be comfortable enough with the shell to run `kldload`, `kldstat`, `dmesg`, `mount`, and `umount` without stopping to look up flags. If any of that feels unfamiliar, it is worth revisiting Chapters 5, 14, and 26 before continuing.

You should work on a throwaway FreeBSD 14.3 system, a virtual machine, or a branch where you do not mind the occasional kernel panic. A panic is unlikely if you follow the text carefully, but the cost of a mistake on your development laptop is much higher than the cost of a mistake on a VM snapshot you can roll back. We have said this before and we will keep saying it: kernel work is safe when you work in a safe place.

27.3.1 Work Section by Section

The chapter is organised as a progression. Section 1 introduces VFS. Section 2 contrasts devfs with VFS and positions our driver in that contrast. Section 3 registers a minimal pseudo block device. Section 4 exposes it as a GEOM provider. Section 5 implements real read and write paths. Section 6 mounts a filesystem on top. Section 7 gives the device persistence. Section 8 teaches safe unmount and cleanup. Section 9 talks about refactoring, versioning, and what to do as the driver grows.

You are meant to read them in order. Each section assumes the previous sections are fresh in your mind, and the labs build on each other. If you jump in the middle, pieces will look strange.

27.3.2 Type the Code

Typing the code by hand remains the most effective way to internalise kernel idioms. The companion files under `examples/part-06/ch27-storage-vfs/` exist so that you can check your work, not so that you can skip the typing. Reading code is not the same as writing it.

27.3.3 Open the FreeBSD Source Tree

You will be asked several times to open real FreeBSD source files, not only the companion examples. The files of interest include `/usr/src/sys/geom/geom.h`, `/usr/src/sys/sys/bio.h`, `/usr/src/sys/geom/geom_disk.h`, `/usr/src/sys/dev/md/md.c`, and `/usr/src/sys/geom/zero/g_zero.c`. Each of these is a primary reference, and the prose in this chapter will often refer back to them. If you have not already cloned or installed the 14.3 source tree, now is a good moment to do so.

27.3.4 Use Your Lab Logbook

Keep your lab logbook from Chapter 26 open while you work. You will want to record the output of `gstat -I 1`, the messages emitted by `dmesg` when you load and unload the module, the time it takes to format the device, and any warnings or panics you see. Kernel work is much easier when you keep notes, because many symptoms look similar at first glance and the logbook lets you compare across sessions.

27.3.5 Pace Yourself

If you feel your understanding blurring in a particular section, stop. Read it again. Try a small experiment on the running module. Do not push through a section that has not settled. Storage drivers punish confusion more severely than character drivers, because confusion at the block layer often becomes filesystem corruption at the higher layer, and filesystem corruption takes time and care to repair even in a throwaway VM.

27.4 How to Get the Most Out of This Chapter

The chapter is structured so that every section adds exactly one new concept on top of what came before. To make the most of that structure, treat the chapter as a workshop rather than as a reference. You are not here to find a quick answer. You are here to build a correct mental model.

27.4.1 Work in Sections

Do not read the whole chapter end to end without stopping. Read one section, then pause. Try the experiment or lab that goes with it. Look at the related FreeBSD source. Write a few lines in your logbook. Only then move on. Storage programming in the kernel is strongly cumulative, and skipping ahead usually means that you will be confused about the next thing for a reason that was explained two sections ago.

27.4.2 Keep the Driver Running

Once you have loaded the driver in Section 3, keep it loaded as much as possible while you read. Modify it, reload, poke it with `gstat`, run `dd` against it, call `diskinfo` on it. Having a live, observable example is far more valuable than any amount of reading. You will notice things that no chapter could ever tell you about, because no chapter can show you real timing, real jitter, or real corner cases in your particular setup.

27.4.3 Consult Manual Pages

FreeBSD's manual pages are part of the teaching material, not a separate formality. Section 9 of the manual is where the kernel interfaces live. We will refer several times to pages such as `g_bio(9)`, `geom(4)`, `DEVICE_IDENTIFY(9)`, `disk(9)`, `bus_dma(9)`, and `devstat(9)`. Read them alongside this chapter. They are shorter than they look, and they are written by the same community that wrote the kernel you are working inside.

27.4.4 Type the Code, Then Mutate It

When you build the driver from the companion examples, type it first. Once it works, start changing things. Rename a method and watch the build fail. Remove an `if` branch and watch what happens when you load the module. Hardcode a smaller media size and watch `newfs_ufs` react. Kernel code becomes understandable through deliberate mutation far more than through pure reading.

27.4.5 Trust the Tooling

FreeBSD gives you a wealth of tools for inspecting the storage stack: `geom`, `gstat`, `diskinfo`, `dd`, `mdconfig`, `dmesg`, `kldstat`, `sysctl`. Use them. When something goes wrong, the first move is almost never to read more source. It is to ask the system what state it is in. `geom disk list` and `geom part show` are often more informative than five minutes of `grep`.

27.4.6 Take Breaks

Kernel work is cognitively dense. Two or three focused hours are usually more productive than a seven-hour sprint. If you catch yourself making the same typo three times, or copy-pasting without reading, that is your cue to stand up for ten minutes.

With those habits established, let us begin.

27.5 Section 1: What Is the Virtual File System Layer?

When a process opens a file on FreeBSD, it calls `open(2)` with a path. That path might resolve to a file on UFS, a file on ZFS, a file on a remotely mounted NFS share, a pseudo-file in `devfs`, a file under `procfs`, or even a file inside a FUSE-mounted userland filesystem. The process cannot tell. The process receives a file descriptor and then reads and writes as if there were only one kind of file in the world. That uniformity is not an accident. It is the work of the Virtual File System layer.

27.5.1 The Problem VFS Solves

Before VFS, UNIX kernels generally knew how to talk to one filesystem only. If you wanted a new filesystem, you modified the code paths for `open`, `read`, `write`, `stat`, `unlink`, `rename`, and every other system call that touched files. That approach worked for a while, but it did not scale. New filesystems arrived: NFS, for remote access. MFS, for in-memory scratch space. `Procfs`, for exposing process state. ISO 9660, for CD-ROM media. FAT, for interoperability. Every addition meant new forks in every file-related system call.

Sun Microsystems introduced the Virtual File System architecture in the mid-1980s as a way out of this mess. The idea is simple. The kernel talks to a single abstract interface, defined in terms of generic operations on generic file objects. Each concrete filesystem registers implementations of those operations, and the kernel calls them through function pointers. When the kernel needs to read a file, it does not know or care whether the file lives on UFS or NFS or ZFS. It knows there is a node with a `VOP_READ` method, and it calls that method.

FreeBSD adopted this architecture and has extended it significantly over the decades. The result is that adding a filesystem to FreeBSD no longer requires modifying the core system calls. A filesystem is a separate kernel module that registers a set of operations with VFS, and from that moment VFS routes the right requests to it.

27.5.2 The VFS Object Model

VFS defines three main kinds of objects.

The first is the **mount point**, represented in the kernel by `struct mount`. Every mounted filesystem has one, and it records where in the namespace the filesystem is attached, what flags it has, and which filesystem code is responsible for it.

The second is the **vnode**, represented by `struct vnode`. A vnode is the kernel's handle on a single file or directory within a mounted filesystem. It is not the file itself. It is the kernel's runtime representation of that file for as long as something in the kernel cares about it. Every file that a process has open has a vnode. Every directory the kernel is walking through has a vnode. When nothing holds a reference to a vnode, it can be reclaimed, and the kernel keeps a pool of them to avoid pressure on small-inode cases.

The third is the **vnode operations vector**, represented by `struct vop_vector`, which lists the operations each filesystem must implement on vnodes. The operations have names like `VOP_LOOKUP`, `VOP_READ`, `VOP_WRITE`, `VOP_CREATE`, `VOP_REMOVE`, `VOP_GETATTR`, and `VOP_SETATTR`. Each filesystem provides a pointer to its own vector, and the kernel invokes operations through these vectors whenever it needs to do anything to a file.

The elegant thing about this design is that from the system call side of the kernel, only the abstract interface matters. The system call layer calls `VOP_READ(vp, uio, ioflag, cred)` and does not care whether `vp` belongs to UFS, ZFS, NFS, or `tmpfs`. From the filesystem side, only the abstract interface matters too. UFS implements the vnode operations and never sees the system call code.

27.5.3 Where Storage Drivers Fit

Here is the question that matters for this chapter. If VFS is where filesystems live, where do storage drivers live?

The answer is: not directly inside VFS. A storage driver does not implement `VOP_READ`. It implements a much lower-level abstraction that looks like a disk. Filesystems then sit on top, consuming the disk-like abstraction, translating file-level operations into block-level operations, and calling down.

The chain of layers between a process and a block device in FreeBSD typically looks like this.

Each layer in this stack has a job. VFS hides filesystem differences from system calls. The filesystem translates files into blocks. The buffer cache holds recently used blocks in RAM. GEOM routes block requests through transforms, partitions, and mirrors. The storage driver converts block requests into real I/O. The hardware does the work.

For this chapter, almost everything we do happens at the bottom two layers: GEOM and the storage driver. We will touch the filesystem layer briefly when we mount UFS on our device, and we will touch VFS only in the sense that `mount(8)` calls it. The layers above GEOM are not our code.

27.5.4 VFS in the Kernel Source

If you want to look at VFS directly, the entry points are under `/usr/src/sys/kern/vfs_*.c`. The vnode layer lives in `vfs_vnops.c` and `vfs_subr.c`. The mount side lives in `vfs_mount.c`. The vnode operations vector is defined and handled in `vfs_default.c`. UFS, our primary filesystem in this chapter, lives under `/usr/src/sys/ufs/ufs/` and `/usr/src/sys/ufs/ffs/`. You do not need to read any of those to follow this chapter. You should know where they are so that you understand what sits above the code you are about to write.

27.5.5 What This Means for Our Driver

Because VFS is not our direct caller, we do not need to implement `VOP_` methods. We need to implement the block-layer interface that the filesystem ultimately calls into. That interface is defined by GEOM and, for disk-like devices in particular, by the `g_disk` subsystem. Our driver will expose a GEOM provider. A filesystem will consume it. The flow of I/O will go through `struct bio` rather than through `struct uio`, and the unit of work will be a block rather than a byte range.

This is also why storage drivers rarely interact with `cdevsw` or `make_dev` directly the way character drivers do. The `/dev` node for a disk is created by GEOM, not by the driver. The driver describes itself to GEOM, and GEOM publishes a provider, which then appears in `/dev` with an automatically generated name.

27.5.6 The VFS Call Chain in Practice

Let us trace what happens when a user runs `cat /mnt/myfs/hello.txt`, assuming `/mnt/myfs` is mounted on our future block device.

First, the process calls `open("/mnt/myfs/hello.txt", O_RDONLY)`. That goes to `sys_openat` in the system call layer, which asks VFS to resolve the path. VFS walks the path one component at a time, calling `VOP_LOOKUP` on each directory vnode. When it reaches `myfs`, it notices that the vnode is a mount point and crosses into the mounted filesystem. It eventually arrives at the vnode for `hello.txt` and returns a file descriptor.

Second, the process calls `read(fd, buf, 64)`. That goes to `sys_read`, which calls `vn_read`, which calls `VOP_READ` on the `vnode`. The UFS implementation of `VOP_READ` consults its `inode`, figures out which disk blocks hold the requested bytes, and asks the buffer cache for those blocks. If the blocks are not cached, the buffer cache calls `bread`, which ultimately builds a `struct bio` and hands it to GEOM.

Third, GEOM looks at the provider the filesystem is consuming. Through a chain of providers and consumers, the `bio` ends up at the bottom provider, which is our driver's provider. Our strategy function receives the `bio`, reads the requested bytes from our backing store, and calls `biodone` or `g_io_deliver` to complete the request.

Fourth, the reply travels back the other way. The buffer cache gets its data, the filesystem returns to `vn_read`, `vn_read` copies the data into the user buffer, and `sys_read` returns.

None of that code is ours except the last hop. But understanding the whole chain is what lets you make sensible design choices when you write the last hop.

27.5.7 Wrapping Up Section 1

VFS is the layer that unifies filesystems in FreeBSD. It sits between the system call interface and the various concrete filesystems, and it provides the abstraction that makes files look identical regardless of where they live. Storage drivers do not live inside VFS. They live at the bottom of the stack, far below VFS, behind GEOM and the buffer cache. Our job in this chapter is to write a driver that participates correctly in that lower layer, and to understand enough about the upper layers to avoid confusion when diagnosing problems.

In the next section, we will sharpen the distinction between `devfs` and VFS, because that distinction determines which mental model applies when you think about a given device node.

27.6 Section 2: `devfs` vs VFS

Beginners often assume that `devfs` and the Virtual File System layer are two names for the same thing. They are not. They are related, but they play very different roles. Getting this distinction right early saves a great deal of confusion later, especially when thinking about storage drivers, because storage drivers straddle both of them.

27.6.1 What `devfs` Is

`devfs` is a filesystem. That sounds circular, but it is true. `devfs` is implemented as a filesystem module, registered with VFS, and mounted at `/dev` on every FreeBSD system. When you read a file under `/dev`, you are reading through VFS, which hands the request to `devfs`, which recognises that the “file” you are reading is really a kernel device node and routes the call to the appropriate driver.

`devfs` has several special properties that distinguish it from an ordinary filesystem like UFS.

First, its contents are not stored on disk. The “files” in `devfs` are synthesised by the kernel based on which drivers are currently loaded and which devices are currently present. When a driver calls `make_dev(9)` to create `/dev/mybox`, `devfs` adds the corresponding node to its view. When the driver destroys that device with `destroy_dev(9)`, `devfs` removes the node. The user sees `/dev/mybox` appear and disappear in real time.

Second, the read and write paths for `devfs` nodes are not file data paths. When you write to `/dev/myserial0`, you are not appending bytes to a stored file. You are invoking the driver's `d_write` function through `cdevsw`, and that function decides what those bytes mean. In the case of a USB serial driver, they mean bytes to transmit on the wire. In the case of a pseudo device like `/dev/null`, they mean bytes to discard.

Third, the metadata of `devfs` nodes, such as permissions and ownership, is managed by a policy layer in the kernel rather than by the filesystem itself. `devfs_ruleset(8)` and the `devd` framework configure that policy.

Fourth, `devfs` supports cloning, which character drivers like `pty`, `tun`, and `bpf` use to create a new minor device whenever a process opens the node. This is how `/dev/ptyp0`, `/dev/ptyp1`, and their successors come into existence on demand.

27.6.2 What VFS Is

VFS, as we saw in Section 1, is the abstract filesystem layer. Every filesystem on a FreeBSD system, including `devfs`, is registered with VFS and invoked through VFS. VFS is not a filesystem. It is the framework that filesystems plug into.

When you open a file on UFS, the chain is: system call -> VFS -> UFS -> buffer cache -> GEOM -> driver. When you open a node in `devfs`, the chain is: system call -> VFS -> `devfs` -> driver. Both go through VFS. Only the UFS chain involves GEOM.

27.6.3 Why Storage Drivers Live on Both Sides

This is where storage drivers become interesting.

A storage driver exposes a block device, and that block device eventually appears as a node under `/dev`. For example, if we register our driver and tell GEOM about it, a node called `/dev/myblk0` may appear in `devfs`. When a user writes `dd if=image.iso of=/dev/myblk0`, they are writing through `devfs` to a special character interface that GEOM provides on top of our disk. The requests flow as BIO through GEOM and into our strategy function.

But when a user runs `newfs_ufs /dev/myblk0` and then `mount /dev/myblk0 /mnt`, the usage pattern changes. The kernel now mounts UFS on top of the device. When a process later reads a file under `/mnt`, the path is: system call -> VFS -> UFS -> buffer cache -> GEOM -> driver. The `/dev/myblk0` node in `devfs` is not even involved in the hot path. UFS and the buffer cache talk directly to the GEOM provider. The `devfs` node is essentially a handle that tools use to refer to the device, not the pipe that file data flows through during normal operation.

27.6.4 A Closer Look at the Buffer Cache

Between the filesystem and GEOM in the storage path sits the buffer cache. We have mentioned it several times without pausing to describe it. Let us pause now, because it explains several of the behaviours you will observe when testing your driver.

The buffer cache is a pool of fixed-size buffers in kernel memory, each of which holds one filesystem block. When a filesystem reads a block, the buffer cache gets involved: the filesystem asks the cache for the block, and the cache either returns a hit (the block is already in memory) or issues a miss (the cache allocates a buffer,

calls down through GEOM to fetch the data, and returns the buffer once the read completes). When a filesystem writes a block, the same cache path applies in reverse: the write fills a buffer, the buffer is marked dirty, and the cache schedules a write-back at some later point.

The buffer cache is why consecutive reads of the same file data do not always hit the driver. The first read misses, causing a BIO to travel to the driver. The second read hits the cache and returns immediately. This is a great feature for performance. It can be mildly confusing when you are first debugging a driver, because your `printf` in the strategy function does not fire on every user-space read.

The buffer cache is also why writes can appear to happen faster than the underlying driver. A `dd if=/dev/zero of=/mnt/myblk/big bs=1m count=16` may appear to complete in a fraction of a second because the writes land in the cache and the cache defers the actual BIOs for a while. The filesystem issues the real writes to GEOM over the next second or two. If the system crashes before that happens, the file on disk is incomplete. `sync(2)` forces the cache to flush to the underlying device. `fsync(2)` flushes only the buffers associated with a single file descriptor.

The buffer cache is distinct from the page cache. FreeBSD has both, and they cooperate. The page cache holds memory pages that back memory-mapped files and anonymous memory. The buffer cache holds buffers that back filesystem-block operations. Modern FreeBSD has largely unified them for many data paths, but the distinction still shows up in the source tree, particularly around `bread`, `bwrite`, `getblk`, and `brelease`, which are the buffer-cache side of the interface.

The buffer cache has a single most important implication for our driver: we will almost never see completely synchronous BIO traffic. When a filesystem wants to read a block, a BIO arrives in our strategy function; when a filesystem wants to write a block, another BIO arrives, but usually some time later than the write system call that prompted it. BIOs also arrive in bursts when the cache flushes. This is normal, and your driver must not make assumptions about timing or ordering across BIOs other than what is strictly documented. Each BIO is an independent request.

27.6.5 The Read and Write Paths

Let us trace a concrete example through the whole chain.

When a user runs `cat /mnt/myblk/hello.txt`, the shell runs `cat`, which calls `open("/mnt/myblk/hello.txt", O_RDONLY)`. The `open` goes to `sys_openat`, which hands off to VFS. VFS calls `namei` to walk the path. For each path component, VFS calls `VOP_LOOKUP` on the current directory's vnode. When VFS reaches the `myblk` mount, it crosses into UFS, which walks the UFS directory structure to find `hello.txt`. UFS returns the vnode for that file, and VFS returns a file descriptor.

The user then calls `read(fd, buf, 64)`. `sys_read` calls `vn_read`, which calls `VOP_READ` on the vnode. UFS's `VOP_READ` consults the inode to find the block address of the requested bytes, then calls `bread` on the buffer cache to fetch the block. The buffer cache either returns a hit or issues a BIO.

If it is a cache miss, the buffer cache allocates a fresh buffer, builds a BIO that asks for the relevant block from the underlying GEOM provider, and hands it off. The BIO travels down through GEOM, through our strategy function, and back. When the BIO completes, the buffer cache unblocks the waiting `bread` call. UFS then copies the requested bytes from the buffer into the user's `buf`. `read` returns.

For writes, the chain is symmetric but the timing is different. UFS's `VOP_WRITE` calls `bread` or `getblk` to obtain the target buffer, copies the user's data into the buffer, marks the buffer dirty, and calls `bwrite` or `bawrite` to

schedule the write-back. The user's `write` call returns long before the BIO is issued to the driver. Later, the buffer cache's syncer thread picks up dirty buffers and issues `BIO_WRITE` requests to the driver.

The net effect is that our driver's strategy function sees a stream of BIOs that is related to, but not identical to, the stream of user-space reads and writes. The buffer cache mediates the two.

In other words, the same storage driver can be reached two different ways.

1. **Raw access through `/dev`:** a user-space program opens `/dev/myblk0` and issues `read(2)` or `write(2)` calls. Those calls go through `devfs` and the GEOM character interface, ending up in our strategy function.
2. **Filesystem access through `mount`:** the kernel mounts a filesystem on the device. File I/O flows through VFS, the filesystem, the buffer cache, and GEOM. `devfs` is not part of the hot path for those requests.

Both paths converge at the GEOM provider, which is why GEOM is the correct abstraction for storage drivers even though character drivers typically deal with `devfs` more directly.

27.6.6 Why This Distinction Matters

This matters for two reasons.

First, it clarifies why we will not use `make_dev` for our block driver. `make_dev` is the right call for character drivers that want to publish a `cdevsw` under `/dev`. It is the wrong call for a block device, because GEOM creates the `/dev` node for us as soon as we publish a provider. If you call `make_dev` in a storage driver, you typically end up with two `/dev` nodes competing for the same device, one of which is not connected to the GEOM topology, which leads to confusing behaviour.

Second, the distinction explains why the kernel has two sets of tools for inspecting device state. `devfs_ruleset(8)`, `devfs.rules`, and per-node permissions belong to `devfs`. `geom(8)`, `gstat(8)`, `diskinfo(8)`, and the GEOM class tree belong to GEOM. When you are diagnosing a permissions problem, you look at `devfs`. When you are diagnosing an I/O problem, you look at GEOM.

27.6.7 A Concrete Example: `/dev/null` and `/dev/ada0`

Compare two examples you already know.

`/dev/null` is a classic character device. It lives under `/dev` because `devfs` creates it. The driver is `null(4)`, and its source is in `/usr/src/sys/dev/null/null.c`. When you write to `/dev/null`, `devfs` routes the request through `cdevsw` to the `null` driver's write function, which simply discards the bytes. There is no GEOM, no buffer cache, no filesystem. It is a raw `devfs` character node.

`/dev/ada0` is a block device. It also lives under `/dev`. But the node is created by GEOM, not by a direct `make_dev` call in the `ada` driver. When you read raw bytes from `/dev/ada0`, those bytes flow through GEOM's character interface layer and arrive at the `ada` driver's strategy function. When you mount UFS on `/dev/ada0` and then read a file, the file data flows through VFS, UFS, the buffer cache, and GEOM, and ends up in the same strategy function, without passing through `devfs` for each request.

The node in `devfs` is the same. The usage pattern is different. The driver must handle both.

27.6.8 How We Will Proceed

We will not write a character driver in this chapter. We already wrote one in Chapter 26. Instead, we will write a driver that registers with GEOM as a disk, and we will let GEOM create the `/dev` node for us. The devfs integration will be automatic.

This is the dominant pattern for block drivers in FreeBSD 14.3. You can see it in `md(4)`, in `ata(4)`, in `nvme(4)`, and in almost every other storage driver. Each of them registers with GEOM, each of them receives bio requests, and each of them lets GEOM handle the `/dev` node.

27.6.9 Wrapping Up Section 2

devfs and VFS are distinct layers. devfs is a filesystem mounted at `/dev`, and VFS is the abstract framework that all filesystems plug into, including devfs. Storage drivers interact with both, but through GEOM, which takes care of creating the `/dev` node and of routing requests from both raw-access and filesystem-access paths. For this chapter, we will use GEOM as our entry point and let it manage devfs on our behalf.

In the next section, we will begin building the driver. We will start with the minimum needed to register a pseudo block device with GEOM, without yet implementing real I/O. Once that is in place, we will add the backing store, the bio handler, and everything else in later sections.

27.7 Section 3: Registering a Pseudo Block Device

In this section we will create a skeleton driver that registers a pseudo block device with the kernel. We will not yet implement read or write. We will not yet wire it up to a backing store. Our goal is more modest and more important: we want to understand exactly what it takes to make the kernel recognise our code as a storage driver, publish a `/dev` node for it, and let tools like `geom(8)` see it.

Once that is working, everything we add later will be purely incremental. The registration itself is the step that feels most mysterious, and it is the one the rest of the driver builds on.

27.7.1 The `g_disk` API

FreeBSD gives storage drivers a high-level registration API called `g_disk`. It lives in `/usr/src/sys/geom/-geom_disk.c` and `/usr/src/sys/geom/geom_disk.h`. The API wraps the lower-level GEOM class machinery and exposes a simpler interface that matches what disk drivers usually need.

Using `g_disk` saves us from implementing a full `g_class` by hand. With `g_disk`, we allocate a `struct disk`, fill in a handful of fields and callback pointers, and call `disk_create`. The API takes care of building the GEOM class, creating the `geom`, publishing the provider, wiring up the character interface, starting devstat accounting, and making our device visible to userland through `/dev`.

Not every storage driver uses `g_disk`. GEOM classes that do transformations on other providers, like `g_nop`, `g_mirror`, `g_stripe`, or `g_el`, are built directly on the lower-level `g_class` machinery because they are not disk-shaped. But for anything that looks like a disk, and certainly for a pseudo-disk like ours, `g_disk` is the right starting point.

You can see the public structure in `/usr/src/sys/geom/geom_disk.h`. The shape is roughly the following, abbreviated for clarity.

```
struct disk {
    struct g_geom    *d_geom;
    struct devstat   *d_devstat;

    const char      *d_name;
    u_int           d_unit;

    disk_open_t      *d_open;
    disk_close_t     *d_close;
    disk_strategy_t   *d_strategy;
    disk_ioctl_t      *d_ioctl;
    disk_getattr_t    *d_getattr;
    disk_gone_t       *d_gone;

    u_int            d_sectorsize;
    off_t            d_mediasize;
    u_int            d_fwsectors;
    u_int            d_fwheads;
    u_int            d_maxsize;
    u_int            d_flags;

    void             *d_drv1;

    /* other fields elided */
};
```

The fields break down into three groups.

Identification: `d_name` is a short string like "myblk" that names the disk class, and `d_unit` is a small integer that distinguishes multiple instances. Together they form the `/dev` node name. A driver with `d_name = "myblk"` and `d_unit = 0` publishes `/dev/myblk0`.

Callbacks: the `d_open`, `d_close`, `d_strategy`, `d_ioctl`, `d_getattr`, and `d_gone` pointers are the functions the kernel will call into our driver. Of these, only `d_strategy` is strictly required, because that is the function that handles actual I/O. The others are optional and we will discuss them as they become relevant.

Geometry: `d_sectorsize`, `d_mediasize`, `d_fwsectors`, `d_fwheads`, and `d_maxsize` describe the disk's physical and logical shape. `d_sectorsize` is the size of a sector in bytes, typically 512 or 4096. `d_mediasize` is the total size of the device in bytes. `d_fwsectors` and `d_fwheads` are advisory hints used by partitioning tools. `d_maxsize` is the largest single I/O the driver can accept, which GEOM will use to split large requests.

Driver state: `d_drv1` is a generic pointer for the driver to stash its own context. It is the closest equivalent to `device_get_softc(dev)` in the Newbus world.

27.7.2 A Minimum Skeleton

Let us now sketch a minimum skeleton. We will place this in `examples/part-06/ch27-storage-vfs/myfirst_blk.c`. This initial version does almost nothing useful. It registers a disk, returns success on every operation, and unregisters cleanly on unload. But it is enough to appear in `/dev`, to be visible in `geom disk list`, and to be probed by `newfs_ufs` or `fdisk` without the kernel crashing.

```
/*
 * myfirst_blk.c - a minimal pseudo block device driver.
 *
 * This driver registers a single pseudo disk called myblk0 with
 * the g_disk subsystem. It is intentionally not yet capable of
 * performing real I/O. Sections 4 and 5 of Chapter 27 will add
 * the BIO handler and the backing store.
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/malloc.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/bio.h>

#include <geom/geom.h>
#include <geom/geom_disk.h>

#define MYBLK_NAME      "myblk"
#define MYBLK_SECTOR    512
#define MYBLK_MEDIASIZE (1024 * 1024) /* 1 MiB to start */

struct myblk_softc {
    struct disk    *disk;
    struct mtx     lock;
    u_int          unit;
};

static MALLOC_DEFINE(M_MYBLK, "myblk", "myfirst_blk driver state");

static struct myblk_softc *myblk_unit0;

static void
myblk_strategy(struct bio *bp)
{

```

```
/*
 * No real I/O yet. Mark every request as successful
 * but unimplemented so the caller does not hang.
 */
bp->bio_error = ENXIO;
bp->bio_flags |= BIO_ERROR;
bp->bio_resid = bp->bio_bcount;
biodone(bp);
}

static int
myblk_attach_unit(struct myblk_softc *sc)
{
    sc->disk = disk_alloc();
    sc->disk->d_name      = MYBLK_NAME;
    sc->disk->d_unit      = sc->unit;
    sc->disk->d_strategy   = myblk_strategy;
    sc->disk->d_sectorsize = MYBLK_SECTOR;
    sc->disk->d_mediasize  = MYBLK_MEDIASIZE;
    sc->disk->d_maxsize    = MAXPHYS;
    sc->disk->d_drv1       = sc;

    disk_create(sc->disk, DISK_VERSION);
    return (0);
}

static void
myblk_detach_unit(struct myblk_softc *sc)
{
    if (sc->disk != NULL) {
        disk_destroy(sc->disk);
        sc->disk = NULL;
    }
}

static int
myblk_loader(struct module *m, int what, void *arg)
{
    struct myblk_softc *sc;
    int error;
```

```

switch (what) {
case MOD_LOAD:
    sc = malloc(sizeof(*sc), M_MYBLK, M_WAITOK | M_ZERO);
    mtx_init(&sc->lock, "myblk lock", NULL, MTX_DEF);
    sc->unit = 0;
    error = myblk_attach_unit(sc);
    if (error != 0) {
        mtx_destroy(&sc->lock);
        free(sc, M_MYBLK);
        return (error);
    }
    myblk_unit0 = sc;
    printf("myblk: loaded, /dev/%s%u size=%jd bytes\n",
        MYBLK_NAME, sc->unit,
        (intmax_t)sc->disk->d mediasize);
    return (0);

case MOD_UNLOAD:
    sc = myblk_unit0;
    if (sc == NULL)
        return (0);
    myblk_detach_unit(sc);
    mtx_destroy(&sc->lock);
    free(sc, M_MYBLK);
    myblk_unit0 = NULL;
    printf("myblk: unloaded\n");
    return (0);

default:
    return (EOPNOTSUPP);
}

static moduledata_t myblk_mod = {
    "myblk",
    myblk_loader,
    NULL
};

DECLARE_MODULE(myblk, myblk_mod, SI_SUB_DRIVERS, SI_ORDER_MIDDLE);
MODULE_VERSION(myblk, 1);

```

Take a moment to read this through. Only a handful of moving pieces are visible, but each of them is doing real work.

The `myblk_softc` structure is the driver-local context. It holds a pointer to our `struct disk`, a mutex for future use, and the unit number. We allocate it on module load and free it on unload.

The `myblk_strategy` function is the callback that GEOM will invoke whenever a bio is directed at our device. In this first version, we simply fail every request with `ENXIO`. That is not polite, but it is correct as a placeholder: the kernel will not block waiting for us, and we will not pretend that I/O succeeded when it did not. In Section 5 we will replace this with a working handler.

The `myblk_attach_unit` function allocates a `struct disk`, fills in the identification, callbacks, and geometry fields, and publishes it with `disk_create`. The call to `disk_create` is what actually produces the `/dev` node and registers the disk in the GEOM topology.

The `myblk_detach_unit` function reverses that. `disk_destroy` asks GEOM to wither the provider, cancel any pending I/O, and remove the `/dev` node. We set `sc->disk` to `NULL` so that subsequent unload attempts do not try to free an already-freed structure, though in the load/unload path we follow that cannot happen.

The module loader is a standard `moduldata_t` boilerplate that you saw in Chapter 26. On `MOD_LOAD` it allocates the `_softc` and calls `myblk_attach_unit`. On `MOD_UNLOAD` it calls `myblk_detach_unit`, frees the `_softc`, and returns.

One line deserves special attention.

The call `disk_create(sc->disk, DISK_VERSION)` passes the current ABI version of the disk structure. `DISK_VERSION` is defined in `/usr/src/sys/geom/geom_disk.h` and increments every time the `g_disk` ABI changes incompatibly. If you compile a driver against the wrong tree, the kernel will refuse to register the disk and will print a diagnostic. This versioning is what allows the kernel to evolve without silently breaking out-of-tree drivers.

You may wonder why we do not use `MODULE_DEPEND` to declare a dependency on `g_disk`. The reason is that `g_disk` is not a loadable kernel module in the usual sense. It is a GEOM class declared in the kernel via `DECLARE_GEOM_CLASS(g_disk_class, g_disk)` in `/usr/src/sys/geom/geom_disk.c`, and it is always present whenever GEOM itself is compiled into the kernel. There is no separate `g_disk.ko` file you can unload or reload independently, and `MODULE_DEPEND(myblk, g_disk, ...)` would not resolve to a real module. The symbols we call (`disk_alloc`, `disk_create`, `disk_destroy`) come from the kernel itself.

27.7.3 The Makefile

The Makefile for this module is almost identical to the one from Chapter 26.

```
# Makefile for myfirst_blk.
#
# Companion file for Chapter 27 of
# "FreeBSD Device Drivers: From First Steps to Kernel Mastery".

KMOD      = myblk
SRCS      = myfirst_blk.c

# Where the kernel build machinery lives.
.include <bsd.kmod.mk>
```

Place this in the same directory as `myfirst_blk.c`. Running `make` will build `myblk.ko`. Running `make load` will load it if you have the kernel sources installed in the usual place. Running `make unload` will unload it.

27.7.4 Loading and Inspecting the Skeleton

Once the module is loaded, the kernel will have created a pseudo disk and a `/dev` node for it. Let us walk through what you should see.

```
# kldload ./myblk.ko
# dmesg | tail -n 1
myblk: loaded, /dev/myblk0 size=1048576 bytes
# ls -l /dev/myblk0
crw-r-----  1 root  operator  0x8b Apr 19 18:04 /dev/myblk0
# diskinfo -v /dev/myblk0
/dev/myblk0
      512          # sectorsize
    1048576        # mediasize in bytes (1.0M)
      2048         # mediasize in sectors
         0         # stripesize
         0         # stripeoffset
    myblk0        # Disk ident.
```

The `c` at the beginning of the permissions string tells us that GEOM has created a character device node, which is how FreeBSD exposes block-oriented devices under `/dev` in the modern kernel. The device major number, here `0x8b`, is assigned dynamically.

Now let us look at the GEOM topology.

```
# geom disk list myblk0
Geom name: myblk0
Providers:
1. Name: myblk0
   Mediasize: 1048576 (1.0M)
   Sectorsize: 512
   Mode: r0w0e0
   descr: (null)
   ident: (null)
   rotationrate: unknown
   fwsectors: 0
   fwheads: 0
```

Mode: `r0w0e0` means zero readers, zero writers, zero exclusive holders. Nobody is using the disk.

Now try something harmless.

```
# dd if=/dev/myblk0 of=/dev/null bs=512 count=1
dd: /dev/myblk0: Device not configured
0+0 records in
0+0 records out
0 bytes transferred in 0.000123 secs (0 bytes/sec)
```

The `Device not configured` error is the `ENXIO` we deliberately returned. Our strategy function ran, marked the BIO as failed, and `dd` faithfully reported the failure. This is the first real evidence that our driver is being reached by the kernel's block-layer code.

Try a read that expects success to fail loudly.

```
# newfs_ufs /dev/myblk0
newfs: /dev/myblk0: read-only
# newfs_ufs -N /dev/myblk0
/dev/myblk0: 1.0MB (2048 sectors) block size 32768, fragment size 4096
        using 4 cylinder groups of 0.31MB, 10 blks, 40 inodes.
super-block backups (for fsck_ffs -b #) at:
192, 832, 1472, 2112
```

The `-N` flag tells `newfs` to plan the filesystem layout without writing anything. We can see that it thinks of our device as a small disk with 2048 sectors of 512 bytes each. That matches the geometry we declared. It is not yet actually writing anything because our strategy function would still fail, but the planning works.

Finally, let us unload the module cleanly.

```
# kldunload myblk
# dmesg | tail -n 1
myblk: unloaded
# ls /dev/myblk0
ls: /dev/myblk0: No such file or directory
```

That is the complete life cycle of the skeleton.

27.7.5 Why the Failures Are Expected

At this stage, any user-space tool that actually tries to read or write data will fail. That is correct. Our strategy function does not yet know how to do anything, and we must not fake success. Faking success would lead to corruption the moment a filesystem tried to read back what it thought it had written.

The fact that the kernel and the tools gracefully handle our failure is evidence that the block layer is doing its job. A bio came down, the driver rejected it, the error propagated back up to user space, and no one crashed. That is the kind of behaviour we want.

27.7.6 How Things Fit Together

Before moving on, let us name the pieces so we can refer to them later without ambiguity.

Our **driver module** is `myblk.ko`. It is what the user loads with `kldload`.

Our **softc** is `struct myblk_softc`. It holds driver-local state. There is exactly one instance in this first version.

Our **disk** is a `struct disk` allocated by `disk_alloc` and registered with `disk_create`. The kernel owns its memory. We do not free it directly. We ask the kernel to free it by calling `disk_destroy`.

Our **geom** is the GEOM object the `g_disk` subsystem creates on our behalf. We do not see it directly in our code. It exists in the GEOM topology as the parent of our provider.

Our **provider** is the producer-facing face of our device. It is what other GEOM classes consume when they connect to us. GEOM automatically creates a character device node for our provider under `/dev`.

Our **consumer** is still empty. We have no one connected to us yet. Consumers are how GEOM classes that sit above us, like a partitioning layer or a filesystem's GEOM consumer, attach.

Our **/dev node** is `/dev/myblk0`. It is a live handle that user-space tools can use to issue raw I/O. When a filesystem is later mounted on the device, it will also refer to the device by this name, even though the hot I/O path will not pass through `devfs` for each request.

27.7.7 Wrapping Up Section 3

We built the smallest possible driver that participates in the FreeBSD storage stack. It registers a pseudo disk with the `g_disk` subsystem, publishes a `/dev` node through GEOM, accepts BIO requests, and declines them politely. It loads, it appears in `geom disk list`, and it unloads without leaks.

In the next section, we will look at GEOM more directly. We will understand what a provider really is, what a consumer really is, and how the class-based design lets transformations like partitioning, mirroring, encryption, and compression compose with our driver for free. That understanding will set us up for Section 5, where we replace the placeholder strategy function with one that actually serves reads and writes from a backing store.

27.8 Section 4: Exposing a GEOM-Backed Provider

The previous section let us register a disk with `g_disk` and take the word of the framework for what happens under the hood. That is a reasonable first step, and for many drivers it is all the involvement with GEOM that they ever need. But storage work rewards understanding the layer you are sitting on. When a filesystem mount fails, when `gstat` shows requests piling up, or when a `kldunload` blocks for longer than you expect, you will want to know the vocabulary of GEOM well enough to ask the right questions.

This section is a tour of GEOM from the storage-driver perspective. It is not an exhaustive reference. There are entire chapters in the FreeBSD Developer's Handbook devoted to GEOM, and we will not duplicate them. What we will do is describe the concepts and objects that matter to a driver author, and show how `g_disk` fits into that picture.

27.8.1 GEOM in One Page

GEOM is a storage framework. It sits between filesystems and the block drivers that talk to real hardware, and it composes by design. That composition is the whole point.

The idea is that a storage stack is built out of small transformations. One transformation presents a raw disk. Another transformation splits it into partitions. Another transformation mirrors two disks into one. Another transformation encrypts a partition. Another transformation compresses a filesystem. Each transformation is a small piece of code that takes in I/O requests from above, does something to them, and either returns a result directly or passes them along to the next layer below.

In GEOM's vocabulary, each transformation is a **class**. Each instance of a class is a **geom**. Each geom has some number of **providers**, which are its outputs, and some number of **consumers**, which are its inputs. Providers face upward toward the next layer. Consumers face downward toward the previous layer. A geom with no consumer is at the bottom of the stack: it must produce I/O on its own. A geom with no provider is at the top of the stack: it must terminate I/O and deliver it somewhere outside GEOM, typically into a filesystem or into a `devfs` character device.

Requests flow from providers to consumers through the stack. Replies flow back. The unit of I/O is a `struct bio`, which we will study in detail in Section 5.

27.8.2 A Concrete Example of Composition

Imagine you have a 1 TB SATA SSD. The kernel's `ada(4)` driver runs on the SATA controller and publishes a disk provider called `ada0`. That is a geom with no consumer at the bottom and one provider at the top.

You slice the SSD with `gpart`. The `PART` class creates a geom whose single consumer is attached to `ada0`, and which publishes multiple providers, one per partition: `ada0p1`, `ada0p2`, `ada0p3`, and so on.

You encrypt `ada0p2` with `geli`. The `ELI` class creates a geom whose single consumer is attached to `ada0p2`, and which publishes a single provider called `ada0p2.eli`.

You mount UFS on `ada0p2.eli`. UFS opens that provider, reads its superblock, and begins serving files.

When a process reads a file, the request travels from UFS, to `ada0p2.eli`, through the `geli` geom which decrypts the relevant blocks, to `ada0p2`, through the `PART` geom which offsets the block addresses, to `ada0`, where the `ada` driver talks to the SATA controller.

At no point does UFS know that its underlying storage is encrypted, partitioned, or even a physical disk. It just sees a provider. The layers below it can be as simple or as elaborate as the administrator chooses.

That composition is the reason GEOM exists. A single storage driver only needs to know how to be a reliable bottom-of-stack producer of I/O. Everything above it is reusable.

27.8.3 Providers and Consumers in Code

In the kernel, a provider is a `struct g_provider` and a consumer is a `struct g_consumer`. Both are defined in `/usr/src/sys/geom/geom.h`. As a disk driver author, you almost never allocate either directly. `g_disk` allocates a provider on your behalf when you call `disk_create`, and you never need a consumer, because a disk driver does not attach to anything underneath.

What you do need is a mental model of what they mean.

A provider is a named, seekable, block-addressable surface that something can read and write. It has a size, a sector size, a name, and some access counters. GEOM publishes providers in `/dev` via its character-device integration, so the administrator can refer to them by name.

A consumer is a channel from one geom into another geom's provider. The consumer is where the upper geom issues I/O requests, and it is where the upper geom registers access rights. When you mount UFS on `ada0p2.eli`, the mount operation causes a consumer to be attached inside UFS's GEOM hook, and that consumer acquires access rights on the `ada0p2.eli` provider.

27.8.4 Access Rights

Providers have three access counters: read (r), write (w), and exclusive (e). They are visible in `gstat` and `geom disk list` as `r0w0e0` or similar. Each number is incremented when a consumer asks for that kind of access and decremented when the consumer releases it.

An exclusive access is what `mount`, `newfs`, and similar administrative tools acquire when they need to be sure no other process is writing the device. An exclusive count of zero means no exclusive access is held. An exclusive count greater than zero means the provider is busy.

The access counts are not trivia. They are a real synchronisation tool. When you call `disk_destroy` to remove a disk, the kernel will refuse to destroy the provider if it still has open users, because destroying it under the feet of a mounted filesystem would be catastrophic. This is the same mechanism that makes `kldunload block` if the module is in use, but it operates at the GEOM layer, one level higher than the module subsystem.

You can watch the access counters change in real time.

```
# geom disk list myblk0 | grep Mode
Mode: r0w0e0
# dd if=/dev/myblk0 of=/dev/null bs=512 count=1 &
# geom disk list myblk0 | grep Mode
Mode: r1w0e0
```

When `dd` finishes, the mode returns to `r0w0e0`.

27.8.5 The BIO Object and Its Life Cycle

The unit of work in GEOM is the BIO, defined as `struct bio` in `/usr/src/sys/sys/bio.h`. A BIO represents one I/O request. It has a command (`bio_cmd`), an offset (`bio_offset`), a length (`bio_length`), a data pointer (`bio_data`), a byte count (`bio_bcount`), a residual (`bio_resid`), an error (`bio_error`), flags (`bio_flags`), and a number of other fields that we will meet as we need them.

The `bio_cmd` values tell the driver what kind of I/O is being requested. The most common values are `BIO_READ`, `BIO_WRITE`, `BIO_DELETE`, `BIO_GETATTR`, and `BIO_FLUSH`. `BIO_READ` and `BIO_WRITE` are what you expect. `BIO_DELETE` asks the driver to release the blocks in the range, the way `TRIM` does on SSDs or `mdconfig -d` does on a memory disk. `BIO_GETATTR` queries an attribute by name and is how GEOM layers discover partition

types, media labels, and other metadata. `BIO_FLUSH` asks the driver to commit outstanding writes to stable storage.

A BIO travels downward from one geom to the next via `g_io_request`. When it reaches the bottom of the stack, the driver's strategy function is called. When the driver is done, it completes the BIO by calling `biodone` or, at the GEOM class level, `g_io_deliver`. The completion call releases the BIO back up the stack.

`g_disk` drivers get a slightly simpler view because the `g_disk` infrastructure translates GEOM-level BIO handling into `biodone`-style completion. When you implement `d_strategy`, you receive a `struct bio` and you must eventually call `biodone(bp)` to complete it. You do not call `g_io_deliver` directly. The framework does.

27.8.6 The GEOM Topology Lock

GEOM has a global lock called the topology lock. It protects modifications to the tree of geoms, providers, and consumers. When a provider is created or destroyed, when a consumer is attached or detached, when access counts change, or when GEOM walks the tree to route a request, the topology lock is taken.

The topology lock is held across operations that can take time, which is unusual for kernel locks, so GEOM operates much of its real work asynchronously through a dedicated thread called the event queue. When you look at `g_class` definitions in the source tree, the `init`, `fini`, `access`, and similar methods are invoked in the context of the GEOM event thread, not in the context of the user process that triggered the operation.

For a driver using `g_disk`, this matters in one specific way. You should not hold your own driver lock across a call into GEOM-level functions, because GEOM may acquire the topology lock inside those functions, and nested locking in the wrong order leads to deadlock. `g_disk` is written carefully enough that you do not usually have to think about this as long as you follow the patterns we show. But the fact is worth knowing.

27.8.7 The GEOM Event Queue

GEOM processes many events on a single dedicated kernel thread called `g_event`. If you have the kernel running with debugging enabled, you can see it in `procstat -kk`. This thread picks up events placed on its queue and processes them one at a time. Typical events include creating a geom, destroying a geom, attaching a consumer, detaching a consumer, and retasting a provider.

A practical consequence is that some actions you take from your driver, such as `disk_destroy`, do not happen synchronously in the context of the calling thread. They get queued for the event thread, and the actual destruction happens a moment later. `disk_destroy` handles the waiting correctly so that by the time it returns, the disk is gone. But if you are chasing a subtle ordering bug, remembering that GEOM has its own thread can help.

27.8.8 How `g_disk` Wraps All of This

With that vocabulary in hand, we can now describe what `g_disk` does for us more precisely.

When we call `disk_alloc`, we receive a `struct disk` that is pre-initialised enough to be filled in. We set the name, unit, callbacks, and geometry, then call `disk_create`.

`disk_create` does the following for us, through the event queue:

1. creates a GEOM class if one does not already exist for this disk name,
2. creates a geom under that class,
3. creates a provider associated with the geom,
4. sets up devstat accounting so that `iostat` and `gstat` have data,
5. wires up GEOM's character-device interface so that `/dev/<name><unit>` appears,
6. arranges for BIO requests to flow into our `d_strategy` callback.

It also sets up a few optional behaviours. If we provide a `d_ioctl`, the kernel routes user-space `ioctl` calls on the `/dev` node through to our function. If we provide a `d_getattr`, GEOM routes `BIO_GETATTR` requests through to it. If we provide a `d_gone`, the kernel calls it if something outside our driver decides the disk is gone, such as a hotplug removal event.

On the teardown side, `disk_destroy` queues the removal, waits for all pending I/O to drain, releases the provider, destroys the geom, and frees the `struct disk`. We do not call `free` on the disk ourselves. The framework does that.

27.8.9 Where to Read Source

You now have enough vocabulary to benefit from reading the `g_disk` source directly. Open `/usr/src/sys/geom/geom_disk.c` and look for the following.

The function `disk_alloc` is early in the file. It is a simple allocator that returns a zeroed `struct disk`. Nothing dramatic.

The function `disk_create` is longer. Skim it and notice the event-based approach: most of the real work is queued rather than performed inline. Also notice the sanity checks on the disk's fields, which catch drivers that forget to set the sector size, the media size, or the strategy function.

The function `disk_destroy` is similarly event-queued. It guards the teardown with an access-count check, because destroying a disk that is still open would be a bug.

The function `g_disk_start` is the inner strategy function. It validates a BIO, updates devstat, and calls the driver's `d_strategy`.

Take a moment to look at the code. You do not need to understand every branch. You do need to recognise the overall shape: events for structural changes, inline work for I/O. That is the shape of most GEOM-based code.

27.8.10 Comparing `md(4)` and `g_zero`

Two real drivers make good reading as counterpoints to `g_disk`. The first is the `md(4)` driver, in `/usr/src/sys/dev/md/md.c`. This is a memory-disk driver that uses both `g_disk` and directly managed GEOM structures. It is the most thorough example of a storage driver in the tree, supporting multiple backing-store types, resizing, dumping, and many other features. It is a large file, but it is the closest relative of what we are building.

The second is `g_zero`, in `/usr/src/sys/geom/zero/g_zero.c`. This is a minimal GEOM class that reads always return zeroed memory and writes are discarded. It is roughly 145 lines and uses the lower-level `DECLARE_GEOM_CLASS` API directly rather than `g_disk`. It is a great counterpoint because it shows the GEOM

class mechanics without any of the disk-specific adornment. When you want to understand what `g_disk` hides, read `g_zero`.

27.8.11 Why Our Driver Uses `g_disk`

You might ask whether we should build our driver directly on the lower-level `g_class` API, the way `g_zero` does, to expose more of the machinery. We will not, for three reasons.

First, `g_disk` is the idiomatic choice for anything that looks like a disk, which our pseudo block device does. Reviewers of real FreeBSD driver patches would push back on a driver that used `g_class` directly when `g_disk` would do.

Second, `g_disk` gives us `devstat` integration, standard `ioctl`s, and `/dev` node management for free. Re-implementing those by hand would be a substantial distraction from the teaching goal of this chapter.

Third, the simpler the first working driver, the easier it is to reason about. We have plenty of code to write in the next few sections. We do not need to spend pages on class-level GEOM plumbing that `g_disk` already gets right.

That said, if you are curious, you should absolutely read `g_zero.c`. It is a small file and it reveals the mechanics that `g_disk` abstracts. The Wrapping Up for this section will point you to it one last time.

27.8.12 A Walk Through `g_class`

For readers who want a little more of the underlying machinery, let us walk through what a `g_class` structure looks like in code, without yet building one of our own.

The following is reproduced (slightly simplified) from `/usr/src/sys/geom/zero/g_zero.c`.

```
static struct g_class g_zero_class = {
    .name = G_ZERO_CLASS_NAME,
    .version = G_VERSION,
    .start = g_zero_start,
    .init = g_zero_init,
    .fini = g_zero_fini,
    .destroy_geom = g_zero_destroy_geom
};

DECLARE_GEOM_CLASS(g_zero_class, g_zero);
```

`.name` is the class name, used in `geom -t` output. `.version` must match `G_VERSION` for the running kernel; mismatched versions are rejected at load time. `.start` is the function called when a BIO arrives at a provider of this class. `.init` is called when the class is first instantiated, typically to create the initial geom and its provider. `.fini` is the teardown counterpart to `.init`. `.destroy_geom` is called when a specific geom under this class is being removed.

`DECLARE_GEOM_CLASS` is a macro that expands to a module declaration that loads this class into the kernel when the module is loaded. It hides the `moduledata_t`, the `SYSINIT`, and the `g_modevent` wiring behind a single line.

Our driver does not use `g_class` directly. `g_disk` does it for us, and the class it declares under the hood is the universal `DISK` class that all disk-shaped drivers share. But understanding the structure is useful because, if you ever write a transformation class (a GEOM-level encrypt, compress, or partition layer), you will define your own `g_class`.

27.8.13 The Life of a BIO, In Detail

We covered the BIO life cycle briefly earlier. Here it is in more detail, because every storage-driver bug touches this life cycle at some point.

A BIO originates somewhere above the driver. For our driver, the most common origins are:

1. **A filesystem's buffer-cache write-back.** UFS calls `bwrite` or `bawrite` on a buffer, which builds a BIO and hands it to GEOM through `g_io_request`.
2. **A filesystem's buffer-cache read.** UFS calls `bread`, which checks the cache and, on a miss, issues a BIO.
3. **A raw access through `/dev/myb1k0`.** A program calls `read(2)` or `write(2)` on the node. `devfs` and GEOM's character-device integration build a BIO and issue it.
4. **A tool-issued operation.** `newfs_ufs`, `diskinfo`, `dd`, and similar tools issue BIOs the same way as a raw access.

Once built, the BIO is routed through GEOM's topology. Each consumer -> provider hop along the way may transform or validate the BIO. For a simple stack (our driver with no intermediate geoms), there are no intermediate hops; the BIO arrives at our provider and is dispatched to our strategy function.

Inside `g_disk`, the strategy function is preceded by three small pieces of bookkeeping:

1. Some sanity checks (for instance, verifying that the BIO's offset and length are within the media).
2. A call to `devstat_start_transaction_bio` to start timing the request.
3. A call to the driver's `d_strategy`.

On completion, `g_disk` intercepts the `biodone` call, records the end time with `devstat_end_transaction_bio`, and forwards the completion up the stack.

From the driver's point of view, the only thing that matters is that `d_strategy` gets called, and that `biodone` is called once per BIO. Everything else is plumbing.

27.8.14 Error Propagation

When a BIO fails, the driver sets `bio_error` to an `errno` value and sets the `BIO_ERROR` flag in `bio_flags`. `biodone` is then called as normal.

Above the driver, GEOM's completion code checks for the error. If set, the error is propagated up the stack. The filesystem sees the error and decides what to do; typically, a read error on metadata is fatal and the filesystem reports EIO to user space. A write error is often delayed; the filesystem may retry, or may mark the associated buffer as needing attention on the next sync.

Common `errno` values in the BIO path:

- `EIO`: a generic I/O error. The kernel assumes the device is having trouble.

- `ENXIO`: the device is not configured or has gone away.
- `EOPNOTSUPP`: the driver does not support this operation.
- `EROFS`: the medium is read-only.
- `ENOSPC`: no space available.
- `EFAULT`: an address in the request is invalid. Very rare in the BIO path.

For our in-memory driver, the only errors that should ever appear are the bounds-check error (`EIO`) and the unknown-command error (`EOPNOTSUPP`).

27.8.15 What `g_disk` Does That You Do Not See

We have mentioned that `g_disk` takes care of several things on our behalf. Here is a fuller list.

- It creates the GEOM class for the `DISK` type if it does not already exist, and it shares this class among all disk drivers.
- It creates a geom under that class when we call `disk_create`.
- It creates a provider on the geom and publishes it in `/dev`.
- It wires up `devstat` accounting automatically.
- It handles the GEOM access protocol, converting user-space `open` and `close` calls on `/dev/myblk0` into provider access-count changes.
- It handles the GEOM character-device interface, converting read and write on `/dev/myblk0` into BIOs to our strategy function.
- It handles the `BIO_GETATTR` default cases (most attributes have sensible defaults).
- It handles withering on `disk_destroy`, waiting for in-flight BIOs.
- It forwards `d_ioctl` calls for ioctls it does not handle itself.

Each of these is a piece of code you would have to write if you built directly on `g_class`. Reading `/usr/src/sys/geom/geom_disk.c` is a good way to appreciate just how much `g_disk` does for us.

27.8.16 Inspecting Our Provider

Let us take our skeleton driver from Section 3, load it, and inspect it through GEOM's eyes.

```
# kldload ./myblk.ko
# geom disk list myblk0
Geom name: myblk0
Providers:
1. Name: myblk0
   Mediasize: 1048576 (1.0M)
   Sectorsize: 512
   Mode: r0w0e0
   descr: (null)
   ident: (null)
   rotationrate: unknown
   fwsectors: 0
   fwheads: 0
```

`geom disk list` shows us only the DISK class's geoms. Each of those geoms has one provider. We can also see the full class tree.

```
# geom -t | head -n 40
Geom      Class      Provider
ada0       DISK        ada0
  ada0p1    PART        ada0p1
  ada0p2    PART        ada0p2
  ada0p3    PART        ada0p3
myblk0     DISK        myblk0
```

Our geom is a sibling of the real disks, without any upper-layer class attached to it yet. In later sections we will see what happens when a filesystem attaches.

```
# geom stats myblk0
```

`geom stats` returns detailed performance counters. On an idle, unused device like ours, all the counters are zero.

```
# gstat -I 1
dT: 1.002s  w: 1.000s
 L(q)  ops/s    r/s    kBps    ms/r    w/s    kBps    ms/w    %busy Name
    0      0      0      0      0.0    0      0      0.0    0.0| ada0
    0      0      0      0      0.0    0      0      0.0    0.0| myblk0
```

`gstat` is a more compact view that updates live. We will use this heavily in later sections.

27.8.17 Wrapping Up Section 4

GEOM is a composable block-layer framework made of classes, geoms, providers, and consumers. Requests flow through it as `struct bio` objects, with `BIO_READ`, `BIO_WRITE`, and a handful of other commands. Access rights, topology locking, and event-driven structure management are the mechanisms that keep the framework safe to evolve under load. `g_disk` wraps all of this for disk-shaped drivers and gives them a friendlier interface with little loss of expressiveness.

Our skeleton driver is now a first-class GEOM participant, even though it cannot yet do any real I/O. In the next section, we will give it that missing piece. We will allocate a backing buffer, implement a strategy function that actually reads and writes, and watch the kernel's storage stack exercise our code from both raw-access and filesystem-access directions.

27.9 Section 5: Implementing Basic Read and Write

In Section 3 we returned `ENXIO` for every BIO. In Section 4 we learned enough about GEOM to know exactly what kind of request our strategy function receives and what its obligations are. In this section we will replace

that placeholder with a working handler that reads and writes real bytes against an in-memory backing store. By the end, our driver will serve traffic through `dd`, will return sane data, and will survive being formatted by `newfs_ufs`.

27.9.1 The Backing Store

Our backing store for now is simply an array of bytes in kernel memory, sized to match `d mediasize`. It is the simplest possible representation of a disk: a flat buffer. Real storage drivers replace this with hardware DMA, with a vnode-backed file, or with a swap-backed VM object, but a flat buffer is enough to teach every other concept in this chapter without distraction.

For 1 MiB we can simply `malloc` the buffer. For larger sizes we would need a different allocator, because the kernel heap does not scale gracefully to contiguous allocations of tens or hundreds of megabytes. `md(4)` avoids the issue for large memory disks by using page-at-a-time allocation and a custom indirection structure. We do not need that level of sophistication yet, but we will note the limitation in the code.

Let us update `myblk_softc` to include the backing store.

```
struct myblk_softc {
    struct disk      *disk;
    struct mtx       lock;
    u_int            unit;
    uint8_t          *backing;
    size_t           backing_size;
};
```

Two new fields: `backing` is the pointer to the kernel memory we allocated, and `backing_size` is the number of bytes we allocated. These should always be equal to `d mediasize`, but storing the size explicitly is cleaner than relying on indirection through `disk->d mediasize`.

Now, in `myblk_attach_unit`, allocate the backing buffer.

```
static int
myblk_attach_unit(struct myblk_softc *sc)
{
    sc->backing_size = MYBLK_MEDIASIZE;
    sc->backing = malloc(sc->backing_size, M_MYBLK, M_WAITOK | M_ZERO);

    sc->disk = disk_alloc();
    sc->disk->d_name      = MYBLK_NAME;
    sc->disk->d_unit      = sc->unit;
    sc->disk->d_strategy   = myblk_strategy;
    sc->disk->d_sectorsize = MYBLK_SECTOR;
    sc->disk->d_mediasize  = MYBLK_MEDIASIZE;
    sc->disk->d_maxsize    = MAXPHYS;
}
```

```

    sc->disk->d_drv1      = sc;

    disk_create(sc->disk, DISK_VERSION);
    return (0);
}

```

malloc with `M_WAITOK | M_ZERO` returns a zeroed buffer or sleeps until one is available. It cannot fail for small allocations on a healthy system, which is why we do not check the return value here. If we were allocating a very large buffer we might want `M_NOWAIT` and explicit error handling, but for 1 MiB `M_WAITOK` is the idiomatic choice.

`myblk_detach_unit` must free the backing store after destroying the disk.

```

static void
myblk_detach_unit(struct myblk_softc *sc)
{
    if (sc->disk != NULL) {
        disk_destroy(sc->disk);
        sc->disk = NULL;
    }
    if (sc->backing != NULL) {
        free(sc->backing, M_MYBLK);
        sc->backing = NULL;
        sc->backing_size = 0;
    }
}

```

Order matters here. We destroy the disk first, which ensures there are no more BIOs in flight. Only then do we free the backing buffer. If we freed the buffer first, an in-flight BIO might try to memcpy into or out of a pointer that no longer refers to our memory, and the kernel would crash on the next I/O.

27.9.2 The Strategy Function

Now for the heart of the change. Replace the placeholder `myblk_strategy` with a function that actually services BIOs.

```

static void
myblk_strategy(struct bio *bp)
{
    struct myblk_softc *sc;
    off_t offset;
    size_t len;
}

```

```
sc = bp->bio_disk->d_drv1;
offset = bp->bio_offset;
len = bp->bio_bcount;

if (offset < 0 ||
    offset > sc->backing_size ||
    len > sc->backing_size - offset) {
    bp->bio_error = EIO;
    bp->bio_flags |= BIO_ERROR;
    bp->bio_resid = len;
    biodone(bp);
    return;
}

switch (bp->bio_cmd) {
case BIO_READ:
    mtx_lock(&sc->lock);
    memcpy(bp->bio_data, sc->backing + offset, len);
    mtx_unlock(&sc->lock);
    bp->bio_resid = 0;
    break;

case BIO_WRITE:
    mtx_lock(&sc->lock);
    memcpy(sc->backing + offset, bp->bio_data, len);
    mtx_unlock(&sc->lock);
    bp->bio_resid = 0;
    break;

case BIO_DELETE:
    mtx_lock(&sc->lock);
    memset(sc->backing + offset, 0, len);
    mtx_unlock(&sc->lock);
    bp->bio_resid = 0;
    break;

case BIO_FLUSH:
    /*
     * In-memory backing store is always "flushed".
     * Nothing to do.
     */
    bp->bio_resid = 0;
    break;
```

```
default:
    bp->bio_error = EOPNOTSUPP;
    bp->bio_flags |= BIO_ERROR;
    bp->bio_resid = len;
    break;
}

biodone(bp);
}
```

Let us read this carefully. It is not a long function, but every line is doing something that matters.

The first line finds our softc. GEOM gives us the BIO with a pointer to the disk in `bp->bio_disk`. We stashed our softc in `d_drv1` during `disk_create`, so we retrieve it from there. This is the block-driver equivalent of `device_get_softc(dev)` in the Newbus world.

The second pair of lines extract the offset and length of the request. `bio_offset` is a byte offset into the media. `bio_bcount` is the number of bytes to transfer. GEOM has already translated file-level operations through whatever layers sit above us into a linear byte range.

The bounds check that follows is defensive programming. GEOM will not normally send us a request that exceeds the media size, because it splits and validates BIOs on our behalf. But defensive drivers check anyway, because a silently accepted out-of-bounds write can smash kernel memory, and because the cost of the check is a few instructions per request. We also guard against arithmetic overflow by rewriting the obvious `offset + len > backing_size` check as `len > backing_size - offset`, which cannot overflow because `offset <= backing_size` at this point.

The switch is where the real work happens. Each BIO command gets its own case.

`BIO_READ` copies `len` bytes from our backing store at `offset` into `bp->bio_data`. GEOM has allocated `bp->bio_data` for us, and it will be released when the BIO completes. Our job is just to fill it.

`BIO_WRITE` copies `len` bytes from `bp->bio_data` into our backing store at `offset`. Symmetrical to the read case.

`BIO_DELETE` zeroes the range. For a real disk, `BIO_DELETE` is how filesystems signal that a range of blocks is no longer in use, and the disk is free to reclaim it. SSDs use it to drive TRIM. For our in-memory driver, there is nothing to reclaim, but zeroing the range is a reasonable response because it reflects the “data is gone” semantics.

`BIO_FLUSH` is a request to commit outstanding writes to stable storage. Our storage is never volatile in the sense that a FLUSH would help: every memcopy is already visible to the next memcopy in the same order it was issued. We return success with nothing to do.

Any other command we do not recognise gets `EOPNOTSUPP`. GEOM layers above us will see this and react accordingly.

At the end, `biodone(bp)` completes the BIO. This is not optional. Every BIO that enters the strategy function must leave through `biodone` exactly once, or the BIO will be leaked, the caller will block forever, and you will have a difficult time diagnosing the issue.

27.9.3 The Role of `bio_resid`

Notice the handling of `bp->bio_resid`. This field represents the number of bytes remaining to transfer after the driver is done. When the full transfer succeeds, `bio_resid` is zero. When the transfer fails completely, `bio_resid` equals `bio_bcount`. When the transfer partially succeeds, `bio_resid` is the number of bytes that did not make it.

Our driver either transfers everything or nothing, so we set `bio_resid` to either 0 (success) or `len` (error). A real hardware driver might set it to an intermediate value if a transfer stopped partway through. Filesystems and user-space tools use `bio_resid` to figure out how much data actually moved.

27.9.4 The Lock

We take `sc->lock` around the `memcpy`. For an in-memory driver that services one request at a time, the lock is not doing much visible work: the kernel's BIO scheduling makes truly concurrent requests unlikely on our toy device. But the lock is good hygiene. GEOM does not promise that your strategy function will be invoked serially, and even if it did, a future change to the driver to add an asynchronous worker thread would require the lock anyway. Adding it now is cheaper than adding it later.

A more sophisticated driver might use a fine-grained lock, or might use an MPSAFE approach that relies on atomic operations. For now, a coarse mutex around the `memcpy` is fine. It is correct, it is easy to reason about, and it does not hurt performance on a pseudo device.

27.9.5 Rebuilding and Reloading

After updating the source and `kldunload`-ing the old version, rebuild and reload.

```
# make
cc -O2 -pipe -fno-strict-aliasing ...
# kldunload myblk
# kldload ./myblk.ko
# dmesg | tail -n 1
myblk: loaded, /dev/myblk0 size=1048576 bytes
```

Now let us try some real I/O.

```
# dd if=/dev/zero of=/dev/myblk0 bs=4096 count=16
16+0 records in
16+0 records out
65536 bytes transferred in 0.001104 secs (59 MB/sec)
# dd if=/dev/myblk0 of=/dev/null bs=4096 count=16
16+0 records in
16+0 records out
65536 bytes transferred in 0.000512 secs (128 MB/sec)
```

We wrote 64 KiB of zeros and read them back. The speeds you see will depend on your hardware and on how much the buffer cache helps, but any speed above a few MB/sec is fine for a first run.

```
# dd if=/dev/random of=/dev/myblk0 bs=4096 count=16
16+0 records in
16+0 records out
65536 bytes transferred in 0.001233 secs (53 MB/sec)
# dd if=/dev/myblk0 of=pattern.bin bs=4096 count=16
16+0 records in
16+0 records out
# dd if=/dev/myblk0 of=pattern2.bin bs=4096 count=16
16+0 records in
16+0 records out
# cmp pattern.bin pattern2.bin
#
```

We wrote random data, read it back twice, and confirmed that both reads return the same content. Our driver is now a coherent store.

27.9.6 A Quick Look Under Load

Let us run a short stress test and watch `gstat`.

In one terminal:

```
# while true; do dd if=/dev/urandom of=/dev/myblk0 bs=4096 \
    count=256 2>/dev/null; done
```

In another terminal:

```
# gstat -I 1 -f myblk0
dT: 1.002s w: 1.000s
L(q) ops/s r/s kBps ms/r w/s kBps ms/w %busy Name
    0   251    0    0  0.0  251  1004  0.0  2.0| myblk0
```

About 250 write operations per second at 4 KiB each, approximately 1 MB/sec. The latency is very low because the backing store is RAM. For a real disk the numbers would be very different, but the structure of what you are watching is the same.

Stop the stress test with `Ctrl-C` on the first terminal.

27.9.7 Refining the Driver with `ioctl` Support

Many storage tools send an `ioctl` to the device to query geometry or to issue commands. GEOM handles the common ones for us, but if we provide a `d_ioctl` callback, the kernel will route unknown `ioctls` through to our function. For now we do not implement any custom `ioctl`. We only note that the hook exists.

```
static int
myblk_ioctl(struct disk *d, u_long cmd, void *data, int flag,
            struct thread *td)
{
    (void)d; (void)data; (void)flag; (void)td;

    switch (cmd) {
        /* No custom ioctls yet. */
        default:
            return (ENOIOCTL);
    }
}
```

We register the callback by assigning `sc->disk->d_ioctl = myblk_ioctl`; before calling `disk_create`. Returning `ENOIOCTL` from the default case tells GEOM that we do not handle the command and gives it the chance to pass the request to its own default handler.

27.9.8 Refining the Driver with getattr Support

GEOM uses `BIO_GETATTR` to ask storage devices for named attributes. A filesystem might ask for `GEOM::rotation_rate` to know whether it is on spinning media. The partitioning layer might ask for `GEOM::ident` to get a stable identifier. A `d_getattr` callback is the hook that lets us respond.

```
static int
myblk_getattr(struct bio *bp)
{
    struct myblk_softc *sc;

    sc = bp->bio_disk->d_drv1;

    if (strcmp(bp->bio_attribute, "GEOM::ident") == 0) {
        if (bp->bio_length < sizeof("MYBLK0"))
            return (EFAULT);
        strncpy(bp->bio_data, "MYBLK0", bp->bio_length);
        bp->bio_completed = strlen("MYBLK0") + 1;
        return (0);
    }

    /* Let g_disk fall back to default behaviour. */
    (void)sc;
    return (-1);
}
```

The return-value convention for `d_getattr` is worth pausing on, because it trips up many first-time readers. Returning 0 with `bio_completed` set tells `g_disk` that we handled the attribute successfully. Returning a positive `errno` value (such as `EFAULT` for a too-small buffer) tells `g_disk` that we handled the attribute but the operation failed. Returning -1 tells `g_disk` that we did not recognise the attribute and it should try its built-in default handler. That is why we return -1 at the bottom: we want `g_disk` to answer standard attributes such as `GEOM::fwsectors` on our behalf. For our driver, responding to `GEOM::ident` with a short string is enough to show up in `diskinfo -v`. Register this with `sc->disk->d_getattr = myblk_getattr`; before `disk_create`.

27.9.9 Partial Writes and Short Reads

Our driver does not actually produce partial writes or short reads, because the backing store is in RAM and every transfer either fully succeeds or fully fails. But for a real hardware driver, partial transfers are normal: a disk may return a few sectors successfully and then fail on a bad sector. The BIO framework supports this through `bio_resid`, and a driver should set `bio_resid` to the number of bytes that did not complete.

The practical guidance is to always set `bio_resid` explicitly before calling `biodone`. If the transfer fully succeeded, set it to zero. If it partially succeeded, set it to the residual. If it fully failed, set it to `bio_bcount`. Forgetting to set `bio_resid` leaves whatever garbage was in the field when the BIO was allocated, which can confuse callers.

27.9.10 Common Mistakes in Strategy Functions

Before we continue, let us name three common mistakes that appear in first-time strategy functions.

Forgetting `biodone`. Every path out of the strategy function must call `biodone(bp)` on the BIO. If you forget, the BIO is leaked and the caller hangs. This is the single most common source of “my mount hangs” problems.

Holding a lock across `biodone`. `biodone` may call upward into GEOM or into a filesystem’s completion handler. Those handlers may take other locks, or may need to acquire locks you already hold, leading to lock-order reversal and potential deadlock. The safest pattern is to drop your lock before calling `biodone`. Our simple version does this implicitly: the `mtx_unlock` is always inside the switch, and `biodone` runs after the switch.

Returning from the strategy function with an error code. `d_strategy` is a void function. Errors are reported by setting `bio_error` and the `BIO_ERROR` flag on the BIO, not by returning. Compilers catch this if you declare the function correctly, but beginners sometimes write it as returning `int`, which causes compiler warnings that should not be ignored.

27.9.11 Chained BIOs and BIO Hierarchies

A BIO can have a child. GEOM uses this when a transformation class needs to split, combine, or transform a request into one or more downstream requests. For example, a mirror class might take a `BIO_WRITE` and issue two child BIOs, one to each mirror member. A partition class might take a `BIO_READ` and issue a single child BIO with the offset shifted into the underlying provider’s address space.

The parent-child relationship is recorded in `bio_parent`. When a child completes, its error is propagated to the parent by `biodone`, which accumulates errors and delivers the parent when all children have completed.

Our driver does not produce child BIOs. It receives them as leaves of the chain. From the driver's perspective, every BIO is self-contained: it has an offset, a length, and a data buffer, and our job is to service it.

But if you ever find yourself needing to split a BIO inside your driver (for example, if a request spans a boundary that your backing store handles in separate chunks), you can use `g_clone_bio` to create a child BIO, `g_io_request` to dispatch it, and `g_std_done` or a custom completion handler to reassemble the parent. The pattern is visible in several places in the kernel, including `g_mirror` and `g_raid`.

27.9.12 The Thread Context of the Strategy Function

The strategy function runs in whatever thread submitted the BIO. For filesystem-originated BIOs, that is typically the filesystem's syncer thread or a buffer-cache worker. For direct user-space access, it is the user thread that called `read` or `write` on `/dev/myblk0`. For GEOM transformations, it might be the GEOM event thread or a class-specific worker thread.

What this means for your driver is that `d_strategy` can run in many different thread contexts. You cannot assume that `curthread` belongs to any particular process, and you cannot block for a long time or the calling filesystem (or user program) will stall.

If your strategy function needs to do something slow (I/O against a vnode, waiting for hardware, or complex locking), the right pattern is to enqueue the BIO on an internal queue and have a dedicated worker thread process it. This is what `md(4)` does for all backing types, because vnode I/O (for instance) can block arbitrarily long.

Our driver is entirely in-memory and does `memcpy` only, so we do not need a worker thread. But understanding the pattern is important for the future.

27.9.13 A Worked Example: Reading Across a Boundary

Suppose a filesystem issues a `BIO_READ` with offset 100000 and length 8192. That spans bytes 100000 through 108191. Let us trace how our strategy function handles it.

1. `bp->bio_cmd` is `BIO_READ`.
2. `bp->bio_offset` is 100000.
3. `bp->bio_bcount` is 8192.
4. `bp->bio_data` points to a kernel buffer (or a user buffer mapped into the kernel) where the 8192 bytes should go.

Our code computes `offset = 100000` and `len = 8192`. The bounds check passes: $100000 + 8192 = 108192$, which is less than our `backing_size` of 32 MiB (33554432).

The switch enters the `BIO_READ` case. We acquire the lock, `memcpy` 8192 bytes from `sc->backing + 100000` into `bp->bio_data`, and release the lock. We set `bp->bio_resid = 0` to indicate a complete transfer. We fall through to `biodone(bp)`, which completes the BIO.

The filesystem receives the completion, notices the error is zero, and uses the 8192 bytes. The read is complete.

Now suppose, instead, the offset was 33554431 and the length was 2 bytes. That is one byte inside the backing store and one byte past the end.

1. `offset = 33554431.`
2. `len = 2.`

The bounds check: `offset > sc->backing_size` evaluates `33554431 > 33554432`, which is false. `len > sc->backing_size - offset` evaluates `2 > 33554432 - 33554431`, which evaluates to `2 > 1`, which is true. The check fails, and we fall into the error path: set `bio_error = EIO`, set the `BIO_ERROR` flag, set `bio_resid = 2`, and call `biodone`. The filesystem sees the error and handles it.

Notice how we used subtraction to avoid the overflow risk. Had we written `offset + len > sc->backing_size`, and had `offset` and `len` both been close to the maximum of `off_t`, the addition could wrap around to a small number and the check would silently pass for a malformed request. Defensive bounds checks always rearrange arithmetic to avoid overflow.

27.9.14 The Devstat Side Effect

One pleasant feature of using `g_disk` is that devstat accounting is automatic. Every BIO we service is counted by `iostat` and `gstat`. No extra code is needed.

You can verify this with `iostat -x 1` in another terminal while running the stress loop.

extended device statistics										
device	r/s	w/s	kr/s	kw/s	ms/r	ms/w	ms/o	ms/t	qlen	%b
ada0	0	2	0	48	0.0	0.1	0.0	0.1	0	0
myblk0	0	251	0	1004	0.0	0.0	0.0	0.0	0	2

If our driver were built on the raw `g_class` API rather than `g_disk`, we would have to wire up devstat ourselves. This is one of the small quality-of-life features that `g_disk` gives us for free.

27.9.15 Wrapping Up Section 5

We replaced the placeholder strategy function with a working handler. Our driver now services `BIO_READ`, `BIO_WRITE`, `BIO_DELETE`, and `BIO_FLUSH` correctly against an in-memory backing store. It participates in devstat, it cooperates with `gstat`, and it accepts real traffic from `dd`.

In the next section, we will cross the boundary from raw block access to filesystem access. We will format the device with `newfs_ufs`, mount it, create files on it, and observe how the request path changes when a real filesystem sits above the provider.

27.10 Section 6: Mounting a Filesystem on the Device

Up to this point, our driver has been exercised through raw access: `dd`, `diskinfo`, and similar tools reading and writing the entire surface as a flat byte range. That is a valuable mode, but it is not the mode most storage devices live in. Storage devices in real life serve filesystems. This section takes our driver the last mile: we will format it, mount a real filesystem on it, create files, and observe how the kernel's block-layer plumbing routes requests when a filesystem is in the picture.

This is also the first section where the theoretical distinction between raw access and filesystem access becomes concrete. Understanding the difference, and being able to see it in action, is one of the most useful insights a storage-driver author can acquire.

27.10.1 The Plan

We will do the following in this section, in order.

1. Increase the media size of our driver from 1 MiB to something large enough to hold a usable UFS filesystem.
2. Build and load the updated driver.
3. Run `newfs_ufs` against the device to create a filesystem.
4. Mount the filesystem on a scratch directory.
5. Create some files and verify that the data is read back correctly.
6. Unmount the filesystem.
7. Reload the module and watch what happens.

By the end, you will have seen a complete filesystem on top of your own block driver.

27.10.2 Increasing the Media Size

UFS has a minimum practical size. You can create tiny UFS filesystems, but the overhead of the superblock, cylinder groups, and inode tables takes a noticeable fraction of the space on anything smaller than a few megabytes. For our purposes, 32 MiB is a comfortable size: it is small enough that the backing store still fits in a plain `malloc`, and large enough that UFS has room to breathe.

Update the size definitions at the top of `myfirst_blk.c`.

```
#define MYBLK_SECTOR      512
#define MYBLK_MEDIASIZE  (32 * 1024 * 1024) /* 32 MiB */
```

Rebuild.

```
# make clean
# make
# kldunload myblk
# kldload ./myblk.ko
# diskinfo -v /dev/myblk0
/dev/myblk0
    512          # sectorsize
 33554432       # mediasize in bytes (32M)
   65536        # mediasize in sectors
    0           # stripesize
    0           # stripeoffset
```

32 MiB is enough.

27.10.3 Formatting with newfs_ufs

`newfs_ufs` is the standard UFS formatter on FreeBSD. It lays down the superblock, the cylinder groups, the root inode, and all the other structures a UFS filesystem requires. Let us run it on our device.

```
# newfs_ufs /dev/myblk0
/dev/myblk0: 32.0MB (65536 sectors) block size 32768, fragment size 4096
    using 4 cylinder groups of 8.00MB, 256 blks, 1280 inodes.
super-block backups (for fsck_ffs -b #) at:
192, 16576, 32960, 49344
```

A few things happened under the hood.

`newfs_ufs` opened `/dev/myblk0` for writing, which caused the GEOM access count to tick up. Our strategy function then received a stream of writes: the superblock first, then the cylinder groups, then the empty root directory, then the several backup superblocks. Each of those writes is a BIO, and each BIO was handled by our driver.

You can verify that `newfs_ufs` really wrote to the device by reading a few bytes back.

```
# dd if=/dev/myblk0 bs=1 count=16 2>/dev/null | hexdump -C
00000000  00 00 00 00 00 00 00 00  00 00 00 00 00 00 00 00
```

The first few bytes of a UFS partition are deliberately zero because the superblock does not sit at offset zero: it is at offset 65536 (block 128) to leave room for boot blocks and other preambles. Let us peek there.

```
# dd if=/dev/myblk0 bs=512 count=2 skip=128 2>/dev/null | hexdump -C | head
00010000  00 00 00 00 00 00 00 00  00 00 00 00 00 00 00 00
00010010  80 00 00 00 80 00 00 00  a0 00 00 00 00 00 00 00
...
```

You should see non-zero bytes now. That is the superblock that `newfs_ufs` laid down on our backing store.

27.10.4 Mounting the Filesystem

Create a mount point and mount the filesystem.

```
# mkdir -p /mnt/myblk
# mount /dev/myblk0 /mnt/myblk
# mount | grep myblk
/dev/myblk0 on /mnt/myblk (ufs, local)
# df -h /mnt/myblk
```

Filesystem	Size	Used	Avail	Capacity	Mounted on
/dev/myblk0	31M	8.0K	28M	0%	/mnt/myblk

Our pseudo device is now a real filesystem. Watch the GEOM access counts.

```
# geom disk list myblk0 | grep Mode
Mode: r1w1e1
```

r1w1e1 means one reader, one writer, one exclusive holder. The exclusive hold is UFS: it has told GEOM that it is the sole authority over writes to the device until it is unmounted.

27.10.5 Creating and Reading Files

Let us actually use the filesystem.

```
# echo "hello from myblk" > /mnt/myblk/hello.txt
# ls -l /mnt/myblk
total 4
-rw-r--r--  1 root  wheel  17 Apr 19 18:17 hello.txt
# cat /mnt/myblk/hello.txt
hello from myblk
```

Note what just happened. The call `echo "hello from myblk" > /mnt/myblk/hello.txt` traveled through the system call layer to `sys_openat`, then to VFS, then to UFS, which opened the root directory's inode, created a new inode for `hello.txt`, allocated a data block, copied the 17 bytes into the buffer cache, and scheduled a write-back. The buffer cache eventually called down to GEOM, which called down to our strategy function, which copied those bytes into our backing store.

When you then ran `cat`, the request traveled down the same stack. Except, because the data was still in the buffer cache from the recent write, UFS did not actually need to read from our device. The buffer cache served the read from RAM. If you unmount and remount, you will see an actual read.

```
# umount /mnt/myblk
# mount /dev/myblk0 /mnt/myblk
# cat /mnt/myblk/hello.txt
hello from myblk
```

That second `cat` probably did cause `BIO_READ` requests to reach our driver, because the unmount-and-remount cycle invalidated the buffer cache for that filesystem.

27.10.6 Watching the Traffic

`gstat` shows us the BIO traffic in real time. Open another terminal and run `gstat -I 1 -f myblk0`. Then in the first terminal, create a big file.

```
# dd if=/dev/zero of=/mnt/myblk/big bs=1m count=16
16+0 records in
16+0 records out
16777216 bytes transferred in 0.150 secs (112 MB/sec)
```

In the `gstat` terminal, you should see a burst of writes, perhaps spread across a second or two depending on how quickly the buffer cache flushes.

L(q)	ops/s	r/s	kBps	ms/r	w/s	kBps	ms/w	%busy	Name
0	128	0	0	0.0	128	16384	0.0	12.0	myblk0

These are the 4 KiB or 32 KiB (depending on UFS's block size) writes that UFS is issuing to fill the file. We can verify the file's presence.

```
# ls -lh /mnt/myblk
total 16460
-rw-r--r--  1 root  wheel   16M Apr 19 18:19 big
-rw-r--r--  1 root  wheel   17B Apr 19 18:17 hello.txt
# du -ah /mnt/myblk
16M      /mnt/myblk/big
4.5K     /mnt/myblk/hello.txt
16M      /mnt/myblk
```

And we can delete it again to watch the `BIO_DELETE` traffic.

```
# rm /mnt/myblk/big
```

UFS by default does not issue `BIO_DELETE` unless the filesystem was mounted with the `trim` option, so on a plain mount you will see almost no BIO traffic on delete: UFS just marks the blocks as free in its own metadata. To see `BIO_DELETE`, we would need to mount with `-o trim`, which we will cover briefly in the labs.

27.10.7 Unmounting

Unmount the filesystem before unloading the module.

```
# umount /mnt/myblk
# geom disk list myblk0 | grep Mode
Mode: r0w0e0
```

The access count dropped back to zero as soon as UFS released its exclusive hold. Our driver is now free to be unloaded or further mucked with.

27.10.8 Attempting to Unload While Mounted

What happens if you forget the `umount` and try to unload the module?

```
# mount /dev/myblk0 /mnt/myblk
# kldunload myblk
kldunload: can't unload file: Device busy
```

The kernel refuses. The `g_disk` subsystem knows that our provider still has an active exclusive holder, and it will not let `disk_destroy` proceed until the hold is released. This is the same mechanism we saw in Chapter 26 protecting the USB serial device during an active session, lifted to the GEOM layer.

This is a safety feature. Unloading the module while a filesystem is mounted on the backing device would cause the kernel to panic on the next BIO: the strategy function would no longer exist, but UFS would still try to call into it.

Unmount first, then unload.

```
# umount /mnt/myblk
# kldunload myblk
# kldstat | grep myblk
#
```

Clean.

27.10.9 A Brief Anatomy of UFS on Top of Our Driver

Now that we have UFS mounted on our device, it is worth pausing to notice what is actually on the backing store. UFS is a well-documented filesystem, and seeing its structures in place on a device we control is illuminating.

The first 65535 bytes of a UFS filesystem are reserved for the boot area. On our device, these bytes are all zero because `newfs_ufs` does not write a boot sector by default.

At offset 65536 lives the superblock. The superblock is a fixed-size structure that describes the geometry of the filesystem: the block size, the fragment size, the number of cylinder groups, the location of the root inode, and many other invariants. `newfs_ufs` writes the superblock first, and it also writes backup copies at predictable offsets in case the primary is corrupted.

Following the superblock come the cylinder groups. Each cylinder group holds inodes, data blocks, and meta-data for a chunk of the filesystem's address space. The number and size of cylinder groups depends on the filesystem size. Our 32 MiB filesystem has four cylinder groups of 8 MiB each.

Within each cylinder group sit inode blocks. Each inode is a small structure (256 bytes on FreeBSD UFS2) that describes a single file or directory: its type, owner, permissions, timestamps, size, and the block addresses of its data.

Finally, the data blocks themselves hold file contents. These are allocated from the free-block map in the cylinder group.

When we wrote "hello from myblk" into `/mnt/myblk/hello.txt`, the kernel did roughly the following:

1. VFS asked UFS to create a new file `hello.txt` in the root directory.
2. UFS allocated an inode from the root cylinder group's inode table.
3. UFS updated the root directory's inode to include an entry for `hello.txt`.
4. UFS allocated a data block for the file.
5. UFS wrote the 17 bytes of content into that data block.
6. UFS wrote the updated inode back.
7. UFS wrote the updated directory entry back.
8. UFS updated its internal bookkeeping.

Each of those steps turned into one or more BIOs to our driver. Most were small writes on metadata blocks. The file content itself was one BIO. UFS's Soft Updates feature orders the writes to ensure crash consistency.

If you want to see these BIOs in action, run your DTrace one-liner from Lab 7 while creating a file. You will see a small burst of writes around the time of the echo.

27.10.10 How Mount Actually Works

The `mount(8)` command is a wrapper around the `mount(2)` system call. That system call takes a filesystem type, a source device, and a target mount point, and it asks the kernel to perform the mount.

The kernel's response is to find the appropriate filesystem code by type (UFS, ZFS, tmpfs, etc.) and to call its mount handler, which in UFS's case is `ufs_mount` in `/usr/src/sys/ufs/ffs/ffs_vfsops.c`. The mount handler validates the source, opens it as a GEOM consumer, reads the superblock, verifies that it is well-formed, allocates an in-memory mount structure, and installs it in the namespace.

From our driver's point of view, none of this is visible. We see a series of BIOs: first a few reads for the superblock, then whatever UFS needs to bootstrap its in-memory state. Once mount has succeeded, UFS issues BIOs on its own schedule as the filesystem is used.

If mount fails, UFS reports an error and the kernel's mount code cleans up. The GEOM consumer is detached, the access count drops, and the namespace is left alone. Our driver does not need to do anything special on mount failure.

27.10.11 The GEOM Character Interface

Earlier in the chapter we said that raw access through `/dev/myblk0` goes through "GEOM's character interface". Here is what that means in more detail.

GEOM publishes a character device for every provider. This is not the same as a `cdev` created with `make_dev`; it is a specialised path within GEOM that presents a provider as a character device to `devfs`. The code for this lives in `/usr/src/sys/geom/geom_dev.c`.

When a user program opens `/dev/myblk0`, `devfs` routes the open to GEOM's character-interface code, which attaches a consumer to our provider with the requested access mode. When the program writes, GEOM's character-interface code builds a BIO and issues it to our provider, which routes it to our strategy function. When the program closes the file descriptor, GEOM detaches the consumer, releasing the access.

The character-interface layer translates between `struct uio` (the user-space I/O descriptor) and `struct bio` (the block-layer I/O descriptor). It splits large user I/O into multiple BIOs when necessary, respecting the `d_maxsize` we specified.

All of this is invisible to our driver. We just receive BIOS. But knowing that the character interface exists helps you understand why certain user-space operations map to certain BIO patterns, and why `d_maxsize` matters.

27.10.12 What Filesystems Need from a Block Driver

Now that we have actually mounted a filesystem on our driver, we can describe more precisely what a filesystem requires from a block driver underneath.

A filesystem needs **correct reads and writes**. If a write at offset `X` is followed by a read at offset `X`, the read must return what the write put there, up to the granularity of the sector size. We guaranteed this with `memcpy` into and out of our backing store.

A filesystem needs **correct bounds**. The block driver must not accept reads or writes that extend beyond the media size. We check this explicitly in the strategy function.

A filesystem needs **stable media size**. The size of the device must not change under the filesystem's feet once it is mounted, because filesystem metadata encodes offsets and counts that assume a fixed size. Our driver holds the media size constant.

A filesystem needs **crash safety**, to the extent the underlying storage provides it. UFS can recover from an unclean shutdown if the backing store does not lose previously committed writes. Our RAM-backed driver loses everything on reboot, but it is at least self-consistent while running. In Section 7, we will introduce options for persistence.

A filesystem sometimes needs **flush semantics**. A call to `BIO_FLUSH` should ensure that all previously issued writes are durable before returning. Our RAM-backed driver trivially satisfies this, because there is no deferred writeback in its path.

Finally, a filesystem benefits from **fast sequential access**. This is a quality-of-service matter rather than a correctness matter, but our driver is fine in this regard because `memcpy` is fast.

27.10.13 Raw Access Versus Filesystem Access, Visualised

Let us draw the two access paths side by side, using our actual driver as the anchor.

Raw access:	Filesystem access:
<code>dd(1)</code>	<code>cat(1)</code>
<code>v</code>	<code>v</code>
<code>open("/dev/myblk0")</code>	<code>open("/mnt/myblk/hello.txt")</code>
<code>v</code>	<code>v</code>
<code>read(fd, ...)</code>	<code>read(fd, ...)</code>
<code>v</code>	<code>v</code>
<code>sys_read</code>	<code>sys_read</code>

The last two hops are identical. Our strategy function is called exactly the same way regardless of whether the request came from `dd` or from `cat` on a mounted file. This is the great advantage of living at the block layer: we do not need to distinguish between the two paths. The upper layers sort out how to translate file-level operations into block-level operations, and we deal in blocks.

27.10.14 Watching the Request Path with DTrace

If you want to see the request path explicitly, DTrace can help.

```
# dtrace -n 'fbt::myblk_strategy:entry { printf("cmd=%d off=%lld len=%u", \
    args[0]->bio_cmd, args[0]->bio_offset, args[0]->bio_bcount); }'
```

With the probe running, do something on the mounted filesystem in another terminal and watch the BIOs arrive. You will see reads come through in 512-byte to 32 KiB chunks, depending on UFS's block size and what operation you performed. Running `dd if=/dev/zero of=/mnt/myblk/test bs=1m count=1` produces a burst of 32 KiB writes.

DTrace is one of the most capable observability tools FreeBSD provides, and it comes alive with storage work because the BIO path is so instrumented. We will use it more in later chapters, but even a one-liner like the above is enough to make the abstract path concrete.

27.10.15 Wrapping Up Section 6

Our pseudo block device now plays the full role of a storage device: raw access through `dd`, filesystem access through UFS, and safe coexistence with kernel unmount protections. The strategy function we wrote in Section 5 did not need to change at all for UFS to work, because UFS and `dd` share the same block-layer protocol below them.

We have also seen the end-to-end flow: VFS at the top, UFS just below, the buffer cache between, GEOM below that, and our driver at the very bottom. That flow is the same for every storage driver in FreeBSD. You now know how to occupy the bottom of it.

In the next section, we will turn our attention to persistence. A RAM-backed device is convenient for testing but loses its contents on every reload. We will discuss options for making the backing store persistent, what trade-offs each option brings, and how to add one of them to our driver.

27.11 Section 7: Persistence and In-Memory Backing Stores

Our driver is self-consistent while running. If you write a byte at offset X, you can read it back at offset X moments later. If you create a file on the mounted filesystem, you can read it again until you unmount or unload. This is already useful for testing and for short-lived workloads.

It is not, however, durable. Unload the module and the backing buffer is freed. Reboot the machine and every byte vanishes. For a teaching driver that is arguably a feature: it reboots clean, it does not accumulate state across runs, and it cannot silently corrupt a previous session. But understanding the options for making storage persistent is essential for real driver work, so this section walks through the major choices and then shows how to add the simplest kind of persistence to our driver.

27.11.1 Why Persistence Is Hard

Storage persistence is not just about where the bytes live. It is about three intertwined properties.

Durability means that once a write returns, the data is safe against a crash. On a hardware disk, durability is typically coupled with the disk's own cache policy: the write hits the drive's internal buffer, then the platter, then the drive reports completion. `BIO_FLUSH` is the hook that gives filesystems a way to demand flush-to-platter semantics.

Consistency means that a read at offset X returns the most recent write at offset X, not some earlier or partial version. Consistency is usually provided by the hardware or by careful locking in the driver.

Crash safety means that after an unclean shutdown, the state of the storage is usable. Either it reflects all committed writes, or it reflects a well-defined prefix of them. UFS has SU+J (Soft Updates with Journaling) to help recover from a crash; ZFS uses copy-on-write and atomic transactions. All of that relies on a block layer that behaves predictably.

For a teaching driver, we do not need to address all three with full rigour. We need to understand what the choices are and to pick one that fits our goals.

27.11.2 The Options

There are four common ways to back a pseudo block device.

In-memory backing (our current choice). Fast, simple, lost on reload. Implemented as a `malloc`'d buffer. Scales poorly past a few MiB because it demands contiguous kernel memory.

Page-at-a-time in-memory backing. `md(4)` uses this internally for large memory disks. Instead of one big buffer, the driver keeps an indirection table of page-sized allocations and fills them on demand. This scales to very large sizes and avoids wasting memory on sparse regions, but it is more complex.

Vnode backing. The driver opens a file in the host filesystem and uses it as the backing store. `mdconfig -t vnode` is the classic example. Reads and writes go through the host's filesystem, which gives persistence at the cost of speed and of a dependency on the host filesystem's correctness. This is how FreeBSD often boots from a memory-disk image embedded in the kernel: the kernel loads the image, presents it as `/dev/md0`, and the root filesystem runs on it.

Swap backing. The driver uses a swap-backed VM object as the backing store. `mdconfig -t swap` uses this. It provides persistence across reboots only to the extent that swap is persistent, which on most systems it is not. But it provides a very large sparse address space without consuming physical memory until touched, which is useful for scratch storage.

For this chapter, we will stick with the in-memory option. It is the simplest, it is enough for the labs, and it demonstrates every other concept cleanly. We will discuss how to switch to vnode-backed storage as an exercise, and we will point to `md(4)` for those who want to see a full-featured implementation.

27.11.3 Saving and Restoring the Buffer

If we want our device to remember its contents across reloads, without changing the backing approach, we can save the buffer to a file on unload and restore it on load. This is not elegant, but it is direct, and it illustrates the contract clearly: the driver is responsible for getting the backing bytes into memory before the first BIO arrives and for flushing them to safety before the last BIO leaves.

In our case, the mechanics would look like this.

On module load, after allocating the backing buffer but before calling `disk_create`, optionally read a file on the host filesystem into the buffer. On module unload, after `disk_destroy` has completed, optionally write the buffer back to that file.

Doing this cleanly from inside the kernel requires the vnode API. The kernel provides `vn_open`, `vn_rdw`, and `vn_close`, which together let a module read or write a path in the host filesystem. These are not APIs we want to use casually, because they are not designed for high-throughput I/O from inside a driver, and because they run on whatever filesystem happens to be mounted at that path, which is not always safe. But for a one-shot save and restore at load and unload time, they are acceptable.

For teaching purposes we will not implement this. The correct way to persist a block device's contents is to use a real backing store, not to snapshot a RAM buffer. But understanding the technique helps clarify the contract.

27.11.4 The Contract With Upper Layers

Whatever your backing store, the contract with upper layers is precise.

A BIO_WRITE that completes successfully must be visible to all subsequent BIO_READ requests, regardless of buffering layers. Our in-memory driver satisfies this because `memcpy` is the visible effect.

A BIO_FLUSH that completes successfully must have made all previously successful BIO_WRITE requests durable. Our in-memory driver satisfies this trivially because there is no lower layer between our `memcpy`

and the backing memory; all writes are “durable” in the sense we can offer. A real disk driver typically issues a cache-flush command to the hardware in response to `BIO_FLUSH`.

A `BIO_DELETE` may discard data but must not corrupt neighbouring blocks. Our in-memory driver satisfies this by zeroing only the requested range. A real SSD driver might issue TRIM for the range; a real HDD driver typically has no hardware support for DELETE and can safely ignore it.

A `BIO_READ` must return the media contents or an error; it must not return uninitialised memory, stale cached data from a different transaction, or random bytes. Our in-memory driver satisfies this by zeroing the backing on allocation and writing only through the strategy function.

If you keep these four rules in mind as you design a new driver, you will avoid nearly every correctness bug that plagues new storage drivers.

27.11.5 What `md(4)` Does Differently

The kernel’s `md(4)` driver is a mature, multi-type memory-disk driver. It supports five backing types: `malloc`, `preload`, `swap`, `vnode`, and `null`. Each type has its own strategy function that knows how to serve requests for that backing kind. Reading `/usr/src/sys/dev/md/md.c` is a valuable follow-up to this chapter because it shows how a real driver handles all of the cases we are glossing over.

A few specific things `md(4)` does that we do not.

`md(4)` uses a dedicated worker thread per unit. Incoming BIOs are queued on the `softc`, and the worker thread dequeues them one by one and dispatches them. This lets the strategy function be very simple: just enqueue and signal. It also isolates blocking work in the worker, which matters for the `vnode` backing type because `vn_rdwr` can block.

`md(4)` uses `DEV_BSHIFT` (which is 9, meaning 512-byte sectors) consistently and uses integer arithmetic rather than floating point to handle offsets. This is standard practice in the block layer.

`md(4)` has a full `ioctl` surface for configuration. The `mdconfig` tool talks to the kernel through `ioctls` on `/dev/mdctl`, and the driver supports `MDIOCATTACH`, `MDIOCDETACH`, `MDIOCQUERY`, and `MDIOCRESIZE`. We have not implemented anything comparable, because for our pseudo device the configuration is baked in at compile time.

`md(4)` uses `DISK_VERSION_06`, which is the current version of the `g_disk` ABI. Our driver does the same, through the `DISK_VERSION` macro.

If you want to see a production-quality pseudo block device, `md(4)` is the canonical reference. Almost everything we are building would, in a real driver, grow to resemble the shape of `md(4)` over time.

27.11.6 A Note on Swap-Backed Memory

One technique worth naming, even though we will not use it here, is swap-backed memory. Instead of a `malloc`’d buffer, a driver can allocate a VM object of type `OBJT_SWAP` and map pages from it on demand. The pages are backed by swap space, which means they can be paged out when the system is under memory pressure and paged back in when touched. This gives you a very large, sparse, on-demand backing store that behaves like RAM when hot and like disk when cold.

md(4) uses exactly this approach for its swap-backed memory disks. The swap VM object acts as a backing store that the kernel's VM subsystem manages for us, without the driver needing to allocate contiguous physical memory up front. The OBJT_SWAP object can hold terabytes of addressable space on a system with only gigabytes of RAM, because most of that space is never touched.

If you ever need to prototype a block device larger than a few hundred MiB, swap-backed memory is likely the right tool. The VM API for it lives in `/usr/src/sys/vm/swap_pager.c`. Reading it is not light work, but it is educational.

27.11.7 A Note on Preloaded Images

FreeBSD has a mechanism called **preloaded modules**. During boot, the loader can bring in not just kernel modules but also arbitrary data blobs, which are made available to the kernel through `preload_fetch_addr` and `preload_fetch_size`. md(4) uses this to expose preloaded filesystem images as `/dev/md*` devices, which is one of the ways FreeBSD can boot entirely from a memory-disk root.

Preloaded images are not a persistence mechanism per se. They are a way to ship data with a kernel module. But they are often used in embedded systems, where the root filesystem is too precious to live on writable storage.

27.11.8 A Small Extension: Persisting Across Module Reloads Only

We are not going to add real persistence to our driver, but this is a good moment to talk about what it would actually take to make a backing store survive a module unload and reload within the same kernel boot. The naive first idea, and one that beginners reach for quickly, is to put the backing pointer in a file-scope static variable and simply not free it in the unload handler. Let us look at why that does not work and what does.

Consider this sketch:

```
static uint8_t *myblk_persistent_backing; /* wishful thinking */
static size_t  myblk_persistent_size;
```

The intuition is that if we allocate `myblk_persistent_backing` on first attach and refuse to free it on detach, a subsequent `kldload` will see the pointer still set and reuse the buffer. The problem is that this picture ignores how a KLD is actually loaded and unloaded. When `kldunload` removes our module, the kernel reclaims the module's text, data, and `.bss` segments along with the rest of its image. Our static pointer does not persist in some stable location; it vanishes together with the module. When `kldload` then brings the module back, the kernel allocates a fresh `.bss`, zeroes it, and our pointer starts life as `NULL` again. The `malloc'd` buffer we allocated on the previous attach is still sitting in kernel heap somewhere, but we have lost every handle to it. We have leaked it.

`SYSUNINIT` does not help either, because in a KLD context it fires on `kldunload`, not on some later “final tear-down” event. Registering a `SYSUNINIT` to free the buffer would free it on every unload, which is exactly what we did not want. There is no KLD-level hook that means “the module file is really, truly being removed from memory for good” distinct from plain `kldunload`.

Two techniques actually achieve cross-unload persistence, and both are used by md(4) in production. The first is a **file-backed store**. Instead of allocating a kernel heap buffer, the driver opens a file on an existing filesystem

using the vnode I/O API (`VOP_READ`, `VOP_WRITE`, and the vnode reference taken via `vn_open`) and services BIOs by reading from and writing to that file. On unload, the driver closes the file; on the next load, it re-opens it. The persistence is real because it lives in a filesystem whose state is independent of our module. This is exactly what `md -t vnode -f /path/to/image.img` does, and you can study it in `/usr/src/sys/dev/md/md.c`.

The second technique is a **swap-backed store**. The driver allocates a VM object of type `OBJT_SWAP`, as we mentioned earlier, and maps pages from it on demand. The pager lives at a higher level of the kernel than our module, so the object can outlive any particular `kldunload` as long as something else holds a reference to it. In practice, `md(4)` uses this for swap-backed memory disks, and it ties the object's lifetime to a kernel-wide list rather than to a module instance.

For our teaching driver, we will not implement either technique. The point of showing this discussion is to make sure you understand why the apparent shortcut does not work, so that you do not spend an afternoon debugging a buffer that keeps disappearing after `kldunload`. If you want to experiment with real cross-unload persistence, read `md.c` carefully, particularly the `MD_VNODE` and `MD_SWAP` branches in `mdstart_vnode` and `mdstart_swap`, and note how the backing objects are attached to the per-unit `struct md_s` rather than to module-scope globals. That structural choice is what makes those backends work across module lifecycles.

27.11.9 Sketching a Vnode-Backed Strategy Function

To make the earlier discussion concrete, let us sketch what a vnode-backed strategy function looks like at the code level. We are not going to drop this into our teaching driver. We are showing it so that you can see what the “real” solution involves and can recognise the same shape in `md.c` when you read it.

The idea is that the per-unit `softc` holds a reference to a vnode, acquired at attach time from a path provided by the administrator. The strategy function translates each BIO into a `vn_rdwr` call at the right offset and completes the BIO based on the result.

Attach acquires the vnode:

```
static int
myblk_vnode_attach(struct myblk_softc *sc, const char *path)
{
    struct nameidata nd;
    int flags, error;

    flags = FREAD | FWRITE;
    NDINIT(&nd, LOOKUP, FOLLOW, UIO_SYSSPACE, path);
    error = vn_open(&nd, &flags, 0, NULL);
    if (error != 0)
        return (error);
    NDFREE_PNBUF(&nd);
    VOP_UNLOCK(nd.ni_vp);
    sc->vp = nd.ni_vp;
    sc->vp_cred = curthread->td_ucred;
    crhold(sc->vp_cred);
}
```

```

    return (0);
}

```

`vn_open` looks up the path and returns a locked, referenced `vnode`. We then drop the lock, because we want to hold a reference without blocking other operations, and we hang the `vnode` pointer on our `softc`. We also keep a reference to the credentials we will use for subsequent I/O.

The strategy function services BIOs against the `vnode`:

```

static void
myblk_vnode_strategy(struct bio *bp)
{
    struct myblk_softc *sc = bp->bio_disk->d_drv1;
    int error;

    switch (bp->bio_cmd) {
    case BIO_READ:
        error = vn_rdwr(UIO_READ, sc->vp, bp->bio_data,
            bp->bio_length, bp->bio_offset, UIO_SYSSPACE,
            IO_DIRECT, sc->vp_cred, NOCRED, NULL, curthread);
        break;
    case BIO_WRITE:
        error = vn_rdwr(UIO_WRITE, sc->vp, bp->bio_data,
            bp->bio_length, bp->bio_offset, UIO_SYSSPACE,
            IO_DIRECT | IO_SYNC, sc->vp_cred, NOCRED, NULL,
            curthread);
        break;
    case BIO_FLUSH:
        error = VOP_FSYNC(sc->vp, MNT_WAIT, curthread);
        break;
    case BIO_DELETE:
        /* Vnode-backed devices usually do not support punching
         * holes through BIO_DELETE without additional plumbing.
         */
        error = EOPNOTSUPP;
        break;
    default:
        error = EOPNOTSUPP;
        break;
    }

    if (error != 0) {
        bp->bio_error = error;
        bp->bio_flags |= BIO_ERROR;
        bp->bio_resid = bp->bio_bcount;
    }
}

```

```

    } else {
        bp->bio_resid = 0;
    }
    biodone(bp);
}

```

Notice how the shape of the switch is identical to our RAM-backed strategy function. The only difference is what the case arms do: instead of memcpy into a buffer, we call `vn_rdwr` against a vnode. The framework above us, GEOM and the buffer cache, does not know or care which backend we chose.

Detach releases the vnode:

```

static void
myblk_vnode_detach(struct myblk_softc *sc)
{
    if (sc->vp != NULL) {
        (void)vn_close(sc->vp, FREAD | FWRITE, sc->vp_cred,
            curthread);
        sc->vp = NULL;
    }
    if (sc->vp_cred != NULL) {
        crfree(sc->vp_cred);
        sc->vp_cred = NULL;
    }
}

```

`vn_close` releases the vnode reference and, if this was the last reference, allows the vnode to be recycled. The credentials are reference-counted the same way.

Why does this give us cross-unload persistence? Because the state we care about, namely the contents of the backing store, lives in a file on a real filesystem whose lifetime is completely independent of our module. When we call `kldunload`, the vnode reference is released and the file closes; its contents on disk are preserved by the filesystem. When we call `kldload` again and attach, we open the file again and pick up where we left off.

The remaining subtleties are substantial. Error paths need to release the vnode if `vn_open` succeeded but subsequent registration steps failed. Calls to `vn_rdwr` can sleep, which means the strategy function must not be called from a context that disallows sleeping; in practice, that is why `md(4)` uses a dedicated worker thread for vnode-backed units. Reading a file can race with the administrator modifying it, so production drivers usually take measures to detect concurrent external changes. `VOP_FSYNC` is not free, so a fast path that batches writes before flushing is typical. And the vnode lifetime itself is bound by VFS's own reference counting, which interacts with unmount of the containing filesystem.

We will not add this to our teaching driver, but when you read `mdstart_vnode` in `/usr/src/sys/dev/md/md.c`, you will recognise every one of these issues handled carefully and explicitly.

27.11.10 Wrapping Up Section 7

Persistence is a layered concept. Durability, consistency, and crash safety are all part of what a real storage device must provide, and different backing stores give different subsets of those guarantees. For a teaching driver, a `malloc`'d in-memory buffer is a reasonable choice, and we can add “survives module reload” semantics without much code by detaching the buffer from the per-instance `softc`.

For production, the techniques grow more elaborate: page-at-a-time allocation, swap-backed VM objects, vnode-backed files, dedicated worker threads, `BIO_FLUSH` coordination, and careful handling of every error path. `md(4)` is the canonical example in the FreeBSD tree, and reading it is strongly recommended.

In the next section, we will focus on the teardown path in detail. We will look at how GEOM coordinates unmount, detach, and cleanup; how access counts gate the module unload path; and how our driver should behave when something goes wrong mid-teardown. Storage unmount bugs are some of the nastier kinds of kernel bug, and careful attention here pays off for the rest of your driver-writing career.

27.12 Section 8: Safe Unmount and Cleanup

Storage drivers handle the end of their lives with more care than character drivers because the stakes are higher. When a character driver unloads cleanly, the worst thing that can happen is that an open session is torn down, possibly with some bytes in flight being lost. When a storage driver unloads while a filesystem is mounted on it, the worst thing that can happen is that the kernel panics on the next BIO, and the user is left with a filesystem image that may or may not have been in a consistent state when the driver disappeared.

The good news is that the kernel's defences make the catastrophic case almost impossible if you use `g_disk` correctly. The refusal of `kldunload` to proceed when the GEOM access count is non-zero, which we saw in Section 6, is the primary safety net. But it is not the only concern. This section walks through the teardown path in detail so that you know what to expect, what to implement, and what to test.

27.12.1 The Expected Teardown Sequence

The nominal sequence of events when a user wants to remove a storage driver is as follows.

1. The user unmounts every filesystem that is mounted on the device.
2. The user closes any program that has `/dev/myblk0` open for raw access.
3. The user calls `kldunload`.
4. The module unload function calls `disk_destroy`.
5. `disk_destroy` queues the provider for withering, which runs on the GEOM event thread.
6. The withering process waits for any in-flight BIO to complete.
7. The provider is removed from the GEOM topology and the `/dev` node is destroyed.
8. `disk_destroy` returns control to our unload function.
9. Our unload function frees the `softc` and the backing store.
10. The kernel unloads the module.

Each step has its own failure modes. Let us walk through them.

27.12.2 Step 1: Unmount

The user runs `umount /mnt/myblk`. VFS asks UFS to flush the filesystem, which causes the buffer cache to issue any pending writes to GEOM, which routes them to our driver. Our strategy function services the writes and calls `biodone`. The buffer cache reports success; UFS disposes of its in-memory state; VFS releases the mount point. The consumer that UFS had attached to our provider is detached. The access count drops.

Our driver does not do anything special during this phase. We keep handling BIOs as they arrive until UFS stops issuing them.

27.12.3 Step 2: Close Raw Access

The user ensures that no program holds `/dev/myblk0` open. If a `dd` is running, kill it. If a shell has the device open via `exec`, close that. Until every open handle is released, the access count will remain non-zero on at least one of the `r`, `w`, or `e` counters.

Again, our driver does nothing special. The `close(2)` calls on `/dev/myblk0` propagate through `devfs`, through GEOM's character-device integration, and release their access. No BIOs are issued for close.

27.12.4 Step 3: kldunload

The user runs `kldunload myblk`. The kernel's module subsystem calls our unload function with `MOD_UNLOAD`. Our unload function calls `myblk_detach_unit`, which calls `disk_destroy`.

At this point, our driver is about to stop existing. We must not be holding any lock that could block, we must not be blocking on our own worker threads (we do not have any in this design), and we must not be issuing new BIOs. Nothing we do now should cause new work for the kernel.

27.12.5 Step 4: disk_destroy

`disk_destroy` is the point of no return. Reading the source in `/usr/src/sys/geom/geom_disk.c` reveals that it does three things:

1. It sets a flag on the disk to indicate that destruction is in progress.
2. It queues a GEOM event that will actually dismantle the provider.
3. It waits for the event to complete.

While we are waiting, the GEOM event thread picks up the event and walks our geom. If the access counts are zero, the event proceeds. If they are not zero, the event panics with a message about trying to destroy a disk that still has users.

This is where the importance of Step 1 and Step 2 shows up. If you skip them and try to unload while the filesystem is mounted, the panic happens here. Fortunately, `g_disk` refuses to reach the panic because the module subsystem has already refused the unload earlier, but if you were to bypass the module subsystem and call `disk_destroy` directly from some other context, this is the check that protects the kernel.

27.12.6 Step 5 to 7: Withering

The GEOM withering process is how providers are removed from the topology. It works by marking the provider as withered, cancelling any BIOs that were queued but not yet delivered, waiting for any in-flight BIOs to complete, removing the provider from the geom's provider list, and then removing the geom from the class. The `/dev` node is removed as part of this.

During withering, the strategy function may still be called for BIOs that were in flight before the withering started. Our strategy function will handle them normally, because our driver does not know or care that withering is in progress. The framework is responsible for ensuring no new BIOs are issued after the point of no return.

If our driver had worker threads, a queue, or other internal state, we would need to coordinate with withering carefully. `md(4)` is a good example of a driver that does this: its worker thread watches for a shutdown flag and drains its queue before exiting. Since our driver is entirely synchronous and single-threaded, we do not have this complication.

27.12.7 Step 8 to 9: Free Resources

Once `disk_destroy` returns, the disk is gone, the provider is gone, and no more BIOs will arrive. It is safe to free the backing store and destroy the mutex.

```
static void
myblk_detach_unit(struct myblk_softc *sc)
{
    if (sc->disk != NULL) {
        disk_destroy(sc->disk);
        sc->disk = NULL;
    }
    if (sc->backing != NULL) {
        free(sc->backing, M_MYBLK);
        sc->backing = NULL;
        sc->backing_size = 0;
    }
}
```

Our unload function then destroys the mutex and frees the softc.

```
case MOD_UNLOAD:
    sc = myblk_unit0;
    if (sc == NULL)
        return (0);
    myblk_detach_unit(sc);
    mtx_destroy(&sc->lock);
    free(sc, M_MYBLK);
```

```
myblk_unit0 = NULL;
printf("myblk: unloaded\n");
return (0);
```

27.12.8 Step 10: Module Unload

The module subsystem unloads the .ko file. At this point, the driver is gone. Any attempt to reference the module by name will fail until the user loads it again.

27.12.9 What Can Go Wrong

The happy path is smooth. Let us enumerate the unhappy paths and how to recognise them.

kldunload returns Device busy. The filesystem is still mounted, or a program still has the raw device open. Unmount and close, then retry. This is the most common failure, and it is benign.

disk_destroy never returns. Something is holding a BIO that will never complete, and the withering process is waiting for it. In practice, this happens if your strategy function fails to call biodone on some path. Look at `procstat -kk` of the `g_event` thread; if it is stuck in `g_waitfor_event`, you have a leaked BIO. The fix is in your strategy function: ensure that every path calls `biodone` exactly once.

The kernel panics with “g_disk: destroy with open count”. Your driver called `disk_destroy` while the provider still had users. This should not happen if you only call `disk_destroy` from the module unload path, because the module subsystem refuses to unload busy modules. But if you call `disk_destroy` in response to some other event, you must check the access count yourself or tolerate the panic.

The kernel panics with “Freeing free memory”. Your driver tried to free the softc or the backing store twice. Check your detach path for race conditions or for early exits that free and then fall through to free again.

The kernel panics with “Page fault in kernel mode”. Something is dereferencing a freed pointer, most often the backing store after it has been freed while a BIO is still in flight. The fix is to ensure `disk_destroy` completes before freeing anything the strategy function touches.

27.12.10 The d_gone Callback

There is one more piece of the teardown story worth discussing. The `d_gone` callback is invoked when something other than our driver decides the disk should go away. The canonical example is hotplug removal: a user yanks a USB drive, the USB stack tells the storage driver the device is gone, and the storage driver wants to tell GEOM to tear down the disk as gracefully as possible even though I/O will start failing.

Our driver is a pseudo device; it does not have a physical disappearance event. But registering a `d_gone` callback costs nothing and makes the driver slightly more robust against future extensions.

```
static void
myblk_disk_gone(struct disk *dp)
{
```

```
    printf("myblk: disk_gone(%s%u)\n", dp->d_name, dp->d_unit);  
}
```

Register it with `sc->disk->d_gone = myblk_disk_gone;` before `disk_create`. The function is called by `g_disk` when `disk_gone` is invoked. You can trigger it manually during development by calling `disk_gone(sc->disk)` from a test path; you will not usually call it yourself in a pseudo driver.

Note the difference between `disk_gone` and `disk_destroy`. `disk_gone` says “this disk has physically vanished; stop accepting I/O and mark the provider as error-returning”. `disk_destroy` says “remove this disk from the topology and free its resources”. In a hot-unplug path, `disk_gone` is usually called first (by the bus driver, when it notices the device is gone), and `disk_destroy` is called later (by the module unload, or by the bus driver’s detach function). Between the two calls, the disk still exists in the topology but all I/O fails. Our driver does not implement this dual-phase teardown; a USB mass storage driver, for instance, must.

27.12.11 Testing the Teardown

Teardown bugs are often discovered not by careful testing but by accident, months later, when some user finds an unusual sequence that triggers them. It is much cheaper to test teardown deliberately.

Here are the tests I recommend running on any new storage driver.

Basic unload. Load, format, mount, unmount, unload. Verify `dmesg` shows our load and unload messages and nothing else. Repeat ten times to catch slow leaks.

Unload without unmount. Load, format, mount. Attempt to unload. Verify the unload is refused. Unmount, then unload. Verify no lingering state.

Unload under load. Load, format, mount, start a `dd if=/dev/urandom of=/mnt/myblk/stress bs=1m count=64`. While the `dd` runs, attempt to unload. Verify the unload is refused. Wait for `dd` to finish. Unmount. Unload. Verify clean.

Unload with raw open. Load. In another terminal, run `cat > /dev/myblk0` to hold the device open. Attempt to unload. Verify the unload is refused. Kill the `cat`. Unload. Verify clean.

Reload stress. Load, unload, load, unload in a tight loop for a minute. If `vmstat -m` or `zpool list` starts showing leaks, investigate.

Panic on corruption. This one is harder: deliberately corrupt the module state via a kernel debugger hook and verify that the driver does not silently return bad data. In practice, few beginners do this, and it is not required for a teaching driver.

If all of these pass, you have a reasonably robust teardown. Continue testing every change that touches the unload path.

27.12.12 The Idempotency Principle

A good teardown path is idempotent: calling it twice is no worse than calling it once. This matters because error paths during attach may call the teardown before everything has been set up.

Write your teardown to check whether each resource was actually allocated before trying to free it.

```
static void
myblk_detach_unit(struct myblk_softc *sc)
{
    if (sc == NULL)
        return;

    if (sc->disk != NULL) {
        disk_destroy(sc->disk);
        sc->disk = NULL;
    }
    if (sc->backing != NULL) {
        free(sc->backing, M_MYBLK);
        sc->backing = NULL;
        sc->backing_size = 0;
    }
}
```

Setting pointers to NULL after freeing them is a small discipline that pays off. It makes double-free mistakes obvious at runtime (they become no-ops rather than corruptions), and it makes the teardown function idempotent.

27.12.13 Ordering and Reverse Order

A general teardown guideline: free resources in the reverse order of allocation. If attach goes A -> B -> C, detach should go C -> B -> A.

In our driver, attach goes malloc backing -> disk_alloc -> disk_create. So detach goes disk_destroy -> free backing. We skip freeing the disk because disk_destroy frees it for us.

This pattern is universal. Every well-written teardown function reverses the allocation order. When you see a detach that runs in the same order as the attach, suspect a bug.

27.12.14 The MOD_QUIESCE Event

There is a third module event we have not mentioned: MOD_QUIESCE. It is delivered before MOD_UNLOAD and gives the module a chance to refuse unload if the driver is in a state where unloading is unsafe.

For most drivers, the GEOM access-count check is sufficient, and implementing MOD_QUIESCE is not needed. But if your driver has internal state that makes unload unsafe independent of GEOM (for example, a cache that must be flushed), MOD_QUIESCE is where you decline the unload by returning an error.

Our driver does not implement MOD_QUIESCE. The default behaviour is to accept it silently, which is the right thing for us.

27.12.15 Coordinating With Future Worker Threads

If you ever add a worker thread to the driver, the teardown contract changes. You must:

1. Signal the worker to stop, typically by setting a flag on the softc.
2. Wake the worker if it is sleeping, typically with `wakeup` or `cv_signal`.
3. Wait for the worker to exit, typically with a `kthread_exit`-visible termination flag.
4. Only then call `disk_destroy`.
5. Free the softc and backing store.

Skipping any of these steps is a recipe for a panic. The usual failure mode is that the worker thread is sleeping inside a function that touches softc state after the softc has been freed. `md(4)` handles this carefully, and it is worth reading its worker shutdown code if you plan to add a worker to your own driver.

27.12.16 Cleanup in the Face of Errors

One last concern: what happens if `attach` fails partway through? Suppose `disk_alloc` succeeds, but `disk_create` fails. Or suppose we add code that validates the sector size and rejects invalid configurations before calling `disk_create`.

The pattern for handling this is “single cleanup path”. Write the `attach` function so that any failure jumps to a cleanup label that unwinds everything allocated so far, in reverse order.

```
static int
myblk_attach_unit(struct myblk_softc *sc)
{
    int error;

    sc->backing_size = MYBLK_MEDIASIZE;
    sc->backing = malloc(sc->backing_size, M_MYBLK, M_WAITOK | M_ZERO);

    sc->disk = disk_alloc();
    sc->disk->d_name      = MYBLK_NAME;
    sc->disk->d_unit      = sc->unit;
    sc->disk->d_strategy   = myblk_strategy;
    sc->disk->d_ioctl      = myblk_ioctl;
    sc->disk->d_getattr    = myblk_getattr;
    sc->disk->d_gone       = myblk_disk_gone;
    sc->disk->d_sectorsize = MYBLK_SECTOR;
    sc->disk->d_mediasize  = MYBLK_MEDIASIZE;
    sc->disk->d_maxsize    = MAXPHYS;
    sc->disk->d_drv1       = sc;

    error = 0; /* disk_create is void; no error path from it */
    disk_create(sc->disk, DISK_VERSION);
    return (error);
}
```

```
/*
 * Future expansion: if we add a step that can fail between
 * disk_alloc and disk_create, use a cleanup label here.
 */
}
```

For our driver, `disk_alloc` does not fail in practice (it uses `M_WAITOK`), and `disk_create` is a void function that queues the real work asynchronously. So the attach path cannot really fail. But the pattern of preparing a single cleanup label is worth keeping in mind for drivers that grow more complex.

27.12.17 Wrapping Up Section 8

Safe unmount and cleanup for a storage driver comes down to a small set of disciplines: handle every BIO through to `biodone`, never hold locks during completion callbacks, only call `disk_destroy` when the provider has no users, free resources in the reverse order of allocation, and test the teardown under load. The `g_disk` framework handles most of the hard parts; your job is to avoid breaking its invariants.

In the next section, we will step back from the teardown specifics and talk about how to let a storage driver grow. We will discuss refactoring, versioning, how to support multiple units cleanly, and what to do when the driver becomes more than a single source file. These are the habits that turn a teaching driver into something you can keep evolving for a long time.

27.13 Section 9: Refactoring and Versioning

Our driver fits in a single file and solves one problem: it exposes a single pseudo disk of a fixed size, backed by RAM. That is a useful teaching starting point, but it is not where most real drivers live. A real storage driver evolves. It grows `ioctl` support. It grows multi-unit support. It grows tunable parameters. It splits into multiple source files. Its on-disk representation, if any, goes through format changes. It accumulates a history of compatibility choices.

This section is about the habits that let a driver grow gracefully. We will not add massive new features here; the companion labs and challenges will do that. What we will do is survey the refactoring and versioning questions that arise as any storage driver matures, and we will point to the FreeBSD-idiomatic answers for each.

27.13.1 Multi-Unit Support

Right now our driver supports exactly one instance, hardcoded as `myblk0`. If you wanted two or three pseudo disks, the current code would need duplicate `softcs` and duplicate disk registrations. Real drivers solve this with a data structure that can hold any number of units.

The idiomatic FreeBSD pattern is a global list protected by a lock. The `softc` is allocated per unit and linked into the list. A loader-time tunable or an `ioctl`-driven call decides when to create a new unit. The unit number is allocated from a `unrhdr` (unique number range) allocator.

A sketch:

```

static struct mtx      myblk_list_lock;
static LIST_HEAD(, myblk_softc) myblk_list =
    LIST_HEAD_INITIALIZER(myblk_list);
static struct unrhdr    *myblk_unit_pool;

static int
myblk_create_unit(size_t mediasize, struct myblk_softc **scp)
{
    struct myblk_softc *sc;
    int unit;

    unit = alloc_unr(myblk_unit_pool);
    if (unit < 0)
        return (ENOMEM);

    sc = malloc(sizeof(*sc), M_MYBLK, M_WAITOK | M_ZERO);
    mtx_init(&sc->lock, "myblk unit", NULL, MTX_DEF);
    sc->unit = unit;
    sc->backing_size = mediasize;
    sc->backing = malloc(mediasize, M_MYBLK, M_WAITOK | M_ZERO);

    sc->disk = disk_alloc();
    sc->disk->d_name      = MYBLK_NAME;
    sc->disk->d_unit      = sc->unit;
    sc->disk->d_strategy  = myblk_strategy;
    sc->disk->d_sectorsize = MYBLK_SECTOR;
    sc->disk->d_mediasize  = mediasize;
    sc->disk->d_maxsize    = MAXPHYS;
    sc->disk->d_drv1       = sc;
    disk_create(sc->disk, DISK_VERSION);

    mtx_lock(&myblk_list_lock);
    LIST_INSERT_HEAD(&myblk_list, sc, link);
    mtx_unlock(&myblk_list_lock);

    *scp = sc;
    return (0);
}

static void
myblk_destroy_unit(struct myblk_softc *sc)
{
    mtx_lock(&myblk_list_lock);

```

```
LIST_REMOVE(sc, link);
mtx_unlock(&myblk_list_lock);

disk_destroy(sc->disk);
free(sc->backing, M_MYBLK);
mtx_destroy(&sc->lock);
free_unr(myblk_unit_pool, sc->unit);
free(sc, M_MYBLK);
}
```

The loader initialises the unit pool once, and then individual units can be created and destroyed independently. This is very close to the pattern `md(4)` uses.

We will not refactor our chapter driver to multi-unit yet, because the added code distracts from the other teaching goals. But you should know that this is where the driver would go. Supporting multiple units is one of the first extensions real drivers need.

27.13.2 Ioctl Surface for Runtime Configuration

With multiple units comes the need to configure them at runtime. You do not want to compile a new module every time you want a second unit or a different size. The answer is an ioctl on a control device.

`md(4)` follows this pattern. There is a single `/dev/mdctl` device, and `mdconfig(8)` talks to it with ioctls. `MDIO-ATTACH` creates a new unit with a specified size and backing type. `MDIOCDETACH` destroys a unit. `MDIOQUERY` reads the state of a unit. `MDIOCRESIZE` changes the size.

For a driver of any sophistication, this is the right place to invest. Compile-time configuration via macros is fine for a toy. Runtime configuration via ioctls is what real administrators want.

If you were to add this to our driver, you would:

1. Create a `cdev` for the control device using `make_dev`.
2. Implement `d_ioctl` on the `cdev`, switching on a small set of ioctl numbers you define.
3. Write a user-space tool that issues the ioctls.

This is a substantial addition, which is why we mention it here without implementing it. Chapter 28 and later chapters will revisit this pattern.

27.13.3 Splitting the Source File

At some point, a driver outgrows a single file. The usual decomposition for a FreeBSD storage driver is roughly:

- `driver_name.c`: the public module entry, ioctl dispatch, and attach/detach wiring.
- `driver_name_bio.c`: the strategy function and BIO path.
- `driver_name_backing.c`: the backing-store implementation.
- `driver_name_util.c`: small helpers, validation, and debug printing.

- `driver_name.h`: the shared header that declares the softc, enums, and function prototypes.

The Makefile is updated to list all of them in `SRCS`, and the build system handles the rest. This is the shape of `md(4)`, of `ata(4)`, and of most substantial drivers in the tree.

We will keep our driver in one file for the chapter. But when the challenges or your own extensions push it past, say, 500 lines, a decomposition like the above is the right move. Readers who want a concrete example should look at `/usr/src/sys/dev/ata/`, which splits a complex driver across many files along clean lines.

27.13.4 Versioning

A storage driver has several kinds of versioning to care about.

Module version, declared with `MODULE_VERSION(myblk, 1)`. This is a monotonically increasing integer that other modules or userland tools can check. Bump it whenever you change the module's external behaviour in a way that cannot be detected from the code.

Disk ABI version, encoded in `DISK_VERSION`. This is the version of the `g_disk` interface that your driver was compiled against. If the kernel's `g_disk` changes incompatibly, it increments the version, and a driver compiled against the old version will fail to register. You do not set this directly; you pass the `DISK_VERSION` macro through `disk_create`, and it picks up whatever version the compile found in `geom_disk.h`. You should recompile drivers against the kernel you are targeting.

On-disk format version, for drivers that have any on-disk metadata. If your driver stamps a magic number and a version into a reserved sector, you must handle upgrades. Our driver has no on-disk format, so this does not apply yet, but it would if we added a proper backing-store header.

Ioctl number version. Once you define ioctls, their numbers are part of the userland ABI. Changing them breaks older userland tools. Use `_IO`, `_IOR`, `_IOW`, `_IOWR` with stable magic letters, and do not repurpose numbers.

For our chapter driver, the only version we care about right now is the module version. But keeping these four kinds of versioning in mind saves pain later.

27.13.5 Debugging and Observability Helpers

As the driver grows, you will want to observe its state more richly than `dmesg` alone allows. Three tools are worth introducing now.

sysctl nodes. FreeBSD's `sysctl(3)` framework lets a module publish read-only or read-write variables that user-space tools can query. You create a tree under a chosen name and attach values to it. The pattern is standard; in roughly ten lines of code you can expose the number of BIOs serviced, the number of bytes read and written, and the current media size.

```
SYSCTL_NODE(_dev, OID_AUTO, myblk, CTLFLAG_RD, 0,  
    "myblk driver parameters");  
static u_long myblk_reads = 0;  
SYSCTL_ULONG(_dev_myblk, OID_AUTO, reads, CTLFLAG_RD, &myblk_reads,  
    0, "Number of BIO_READ requests serviced");
```

Devstat. We are already using this through `g_disk`. It gives `iostat` and `gstat` their data. No further work needed.

DTrace probes. The SDT framework lets a module define static DTrace probes that incur zero cost when the probe is not being watched. These are especially useful in the BIO path because they let you see live request flow without recompiling.

```
#include <sys/sdt.h>
SDT_PROVIDER_DECLARE(myblk);
SDT_PROBE_DEFINE3(myblk, , strategy, request,
    "int" /* cmd */, "off_t" /* offset */, "size_t" /* length */);

/* inside myblk_strategy: */
SDT_PROBE3(myblk, , strategy, request,
    bp->bio_cmd, bp->bio_offset, bp->bio_bcount);
```

You can then watch with `dtrace -n 'myblk::strategy:request {...}'`.

For the chapter driver we will not add all of this, but these are the patterns you should reach for as the driver grows.

27.13.6 Naming Stability

One habit that is easy to overlook: do not rename things casually. The name `myblk` is in the device node, in the module version record, in the `devstat` name, possibly in `sysctl` nodes, in DTrace probes, and in documentation. Renaming it cascades through all of those. For a project driver, pick a name you can live with forever. `md`, `ada`, `nvd`, `zvol`, and other storage drivers have kept their names for years because renaming is an ABI-affecting change for user-space tooling.

27.13.7 Keeping the Teaching Driver Simple

Everything in this section is a direction your driver might grow in. None of it is required for the teaching driver in this chapter. We are pointing at the directions so that you can recognise them when you see them in real driver source, and so that when you extend your own driver you do not have to invent these patterns from scratch.

The companion `myfirst_blk.c` remains a single file at the end of this chapter. Its README documents the extension points, and the challenge exercises add some of them. Beyond that, you are free to keep extending it, and every extension you make will use these patterns in some form.

27.13.8 A Short Design Patterns Recap

At this point we have accumulated enough patterns that listing them helps. When you start your next storage driver, these are the patterns to reach for.

The `softc` pattern. One per-instance struct to hold everything the driver needs. Pointed at by `d_drv1`. Retrieved inside callbacks via `bp->bio_disk->d_drv1`.

The attach/detach pair. Attach allocates, initialises, and registers. Detach reverses the sequence. Both must be idempotent.

The switch-and-biodone pattern. Every strategy function switches on `bio_cmd`, services each command, sets `bio_resid`, and calls `biodone` exactly once.

The defensive bounds check. Validate offset and length against media size, using subtraction to avoid overflow.

The coarse lock pattern. A single mutex around the hot path is often enough for a teaching driver. Split it only when performance demands.

The reverse-order teardown. Free resources in the opposite order of allocation.

The null-after-free pattern. After freeing a pointer, set it to `NULL`. Catches double-frees.

The single cleanup label. In attach functions that can fail, all failures jump to a single cleanup label that unwinds state so far.

The versioned ABI. Pass `DISK_VERSION` to `disk_create`. Declare `MODULE_VERSION`. Use `MODULE_DEPEND` on every kernel module you rely on.

The deferred-work pattern. Work that must block (like `vnode` I/O) belongs in a worker thread, not in `d_strategy`.

The observability-first habit. Add `printf`, `sysctl`, or `DTrace` probes as you build. Observability retrofitted late is harder than observability designed in.

These are not exhaustive, but they are the patterns you will use most often. Each of them appears somewhere in our driver, and each of them appears throughout the real FreeBSD storage code.

27.13.9 Wrapping Up Section 9

A maturing storage driver grows in predictable directions: multi-unit support, runtime configuration through `ioctl`s, multiple source files, and stable versioning of every interface it exposes. None of this has to appear in the first version. Knowing where the growth will happen lets you make early choices that do not need to be undone later.

We have now covered every concept the chapter set out to teach. Before the hands-on labs, one more topic deserves a dedicated section, because it will repay you many times over as a driver author: observing a running storage driver. In the next section, we will look at the tools FreeBSD gives you for watching your driver in real time and for measuring its behaviour in a disciplined way.

27.14 Section 10: Observability and Measuring Your Driver

Writing a storage driver is mostly a matter of getting the structure right. Once the structure is right, the driver just runs. But for the structure to stay right, you must be able to observe what is happening while the driver runs. You will want to know how many BIOs per second are hitting the strategy function, how long each one takes, how the latency distribution looks, how much memory the backing store consumes, whether any BIOs are getting retried, and whether any path is leaking completion.

FreeBSD gives you a remarkable set of tools for this, many of which we have already used casually. In this section we will walk through the most important ones in turn, with the goal of making you comfortable enough to reach for the right tool when the next strange symptom appears.

27.14.1 gstat

`gstat` is the first tool to reach for. It updates a per-provider view of I/O activity in real time, and it shows you exactly what is happening at the GEOM layer.

```
# gstat -I 1
dT: 1.002s  w: 1.000s
L(q)  ops/s    r/s    kBps    ms/r    w/s    kBps    ms/w    %busy Name
  0    117      0      0      0.0    117    468     0.1    1.1| ada0
  0      0      0      0      0.0      0      0     0.0    0.0| myblk0
```

The columns, from left to right, are:

- `L(q)`: queue length. The number of BIOs currently outstanding on this provider.
- `ops/s`: total operations per second, regardless of direction.
- `r/s`: reads per second.
- `kBps` (for reads): read throughput in kilobytes per second.
- `ms/r`: average read latency, in milliseconds.
- `w/s`: writes per second.
- `kBps` (for writes): write throughput in kilobytes per second.
- `ms/w`: average write latency, in milliseconds.
- `%busy`: the percentage of time the provider was not idle.
- `Name`: the provider name.

For a driver you have just built, `gstat` tells you at a glance whether the kernel is sending traffic to your device and how your driver is performing relative to real disks. If the numbers look wildly different from what you expect, you have a starting point for investigation.

`gstat -p` shows only providers (the default). `gstat -c` shows only consumers, which is less useful for driver debugging. `gstat -f <regex>` filters by name. `gstat -b` batches the output one screen at a time instead of refreshing in place.

27.14.2 iostat

`iostat` has a more traditional style but provides the same underlying data. It is useful when you want a text log rather than an interactive display.

```
# iostat -x myblk0 1

                extended device statistics
device      r/s      w/s      kr/s      kw/s  ms/r  ms/w  ms/o  ms/t qlen  %b
myblk0         0     128         0     512   0.0   0.1   0.0   0.1    0    2
myblk0         0     128         0     512   0.0   0.1   0.0   0.1    0    2
```

`iostat` can watch multiple devices at once and can be redirected to a log file for later analysis. For quick live views, `gstat` is usually better.

27.14.3 diskinfo

`diskinfo` is less about live traffic and more about static properties. We have already used it to confirm our media size.

```
# diskinfo -v /dev/myblk0
/dev/myblk0
    512          # sectorsize
 33554432      # mediasize in bytes (32M)
   65536      # mediasize in sectors
     0         # stripesize
     0         # stripeoffset
  myblk0      # Disk ident.
```

`diskinfo -c` runs a timing test, reading a few hundred megabytes and reporting the sustained rate. This is useful for a first-order performance comparison.

```
# diskinfo -c /dev/myblk0
/dev/myblk0
    512          # sectorsize
 33554432      # mediasize in bytes (32M)
   65536      # mediasize in sectors
     0         # stripesize
     0         # stripeoffset
  myblk0      # Disk ident.
```

I/O command overhead:

time to read 10MB block	0.000234 sec	=	0.000 msec/sector
time to read 20480 sectors	0.001189 sec	=	0.000 msec/sector
calculated command overhead		=	0.000 msec/sector

Seek times:

Full stroke:	250 iter in	0.000080 sec =	0.000 msec
Half stroke:	250 iter in	0.000085 sec =	0.000 msec
Quarter stroke:	500 iter in	0.000172 sec =	0.000 msec
Short forward:	400 iter in	0.000136 sec =	0.000 msec
Short backward:	400 iter in	0.000137 sec =	0.000 msec
Seq outer:	2048 iter in	0.000706 sec =	0.000 msec
Seq inner:	2048 iter in	0.000701 sec =	0.000 msec

Transfer rates:

```

outside:      102400 kbytes in  0.017823 sec =  5746 MB/sec
inside:       102400 kbytes in  0.017684 sec =  5791 MB/sec

```

These numbers are unusually fast because the backing store is RAM. On a real disk they would look very different, and comparing the numbers across devices is often the first diagnosis step for performance problems.

27.14.4 sysctl

`sysctl` is how the kernel exposes its internal variables to user space. Many subsystems publish data through `sysctl`. You can browse the storage-related `sysctls` with:

```

# sysctl -a | grep -i kern.geom
# sysctl -a | grep -i vfs

```

Adding your own `sysctl` tree to your driver, as we discussed in Section 9, lets you expose whatever metrics your driver needs to track, without the ceremony of defining a new tool.

27.14.5 vmstat

`vmstat -m` shows memory allocation by `MALLOC_DEFINE` tag. Our driver uses `M_MYBLK`, so we can see how much memory our driver has allocated.

```

# vmstat -m | grep myblk
      myblk      1  32768K      -      12  32K, 32M

```

The columns are type, number of allocations, current size, protection requests, total requests, and possible sizes. For a driver that holds a 32 MiB backing store, the current size of 32 MiB is exactly what we expect. If it grew over time without an equivalent decrease on unload, we would have a leak.

`vmstat -z` shows zone allocator statistics. Much storage-related state lives in zones (GEOM providers, BIOS, disk structures), and `vmstat -z` is where to look if you suspect GEOM-level leaks.

27.14.6 procstat

`procstat` shows per-thread kernel stacks. It is indispensable when something is stuck.

```

# procstat -kk -t $(pgrep -x g_event)
  PID   TID COMM                TDNAME                KSTACK
  4 100038 geom                -                mi_switch sleepq_switch ...

```

If the `g_event` thread is sleeping, the GEOM layer is idle. If it is stuck in a function with your driver's name on its stack, you have a BIO that is not completing.

```
# procstat -kk $(pgrep -x kldload)
```

If `kldload` or `kldunload` is stuck, this shows you exactly where. Most often the culprit is a `disk_destroy` waiting for BIOs to drain.

27.14.7 DTrace for the Block Layer

We introduced DTrace briefly in Section 6 and in Lab 7. Here let us go a little deeper, because DTrace is the single most effective tool for understanding live storage behaviour.

The Function Boundary Tracing (FBT) provider lets you place probes on the entry and return of nearly any kernel function. For our driver's strategy function, the probe name is `fbt::myblk_strategy:entry` for the entry and `fbt::myblk_strategy:return` for the return.

A simple one-liner that counts BIOs by command:

```
# dtrace -n 'fbt::myblk_strategy:entry \
    { @c[args[0]->bio_cmd] = count(); }'
```

When you interrupt the script (with `Ctrl-C`), it prints a count per command value. `BIO_READ` is 1, `BIO_WRITE` is 2, `BIO_DELETE` is 3, `BIO_GETATTR` is 4, and `BIO_FLUSH` is 5. (The exact numbers are in `/usr/src/c/sys/sys/bio.h`.)

A latency histogram:

```
# dtrace -n '
fbt::myblk_strategy:entry { self->t = timestamp; }
fbt::myblk_strategy:return /self->t/ {
    @lat = quantize(timestamp - self->t);
    self->t = 0;
}'
```

This gives you a log-scale histogram of how long each strategy-function execution took. For our in-memory driver, most buckets should be in the hundreds-of-nanoseconds range; anything in the millisecond range for an in-memory driver is suspicious.

A breakdown of I/O size:

```
# dtrace -n 'fbt::myblk_strategy:entry \
    { @sz = quantize(args[0]->bio_bcount); }'
```

This shows you the distribution of BIO sizes. For a UFS-backed filesystem, you should see peaks at 4 KiB, 8 KiB, 16 KiB, and 32 KiB. For a raw `dd` with `bs=1m`, you should see a peak at 1 MiB (or the `MAXPHYS` cap, whichever is smaller).

DTrace is extraordinarily capable. The one-liners above barely scratch the surface. Two books to pick up, if you want to go deeper, are the original Sun “DTrace Guide” and Brendan Gregg’s “DTrace Book”. Both are older than FreeBSD 14.3 but the fundamentals still apply.

27.14.8 kgdb and Crash Dumps

When your driver panics, FreeBSD can capture a crash dump. Configure the dump device in `/etc/rc.conf` (typically `dumpdev="AUTO"`) and verify with `dumpon`.

After a panic, reboot. `/var/crash/vmcore.last` (a symlink) points to the most recent dump. `kgdb /boot/kernel/kernel /var/crash/vmcore.last` opens the dump for inspection. Useful commands inside `kgdb`:

- `bt`: backtrace of the thread that panicked.
- `info threads`: list all threads in the crashed system.
- `thread N` then `bt`: backtrace of thread `N`.
- `print *var`: inspect a variable.
- `list function`: show source around a function.

If you have compiled your module with debugging symbols (the default for most kernel configurations), `kgdb` can show you source-level variables in your own code. This is a transformative capability once you get used to it.

27.14.9 ktrace

`ktrace` is a user-space-oriented tool, but it can be useful for storage debugging when you want to see exactly what system calls a user program is making. If `newfs_ufs` is behaving oddly, you can trace it:

```
# ktrace -f /tmp/newfs.ktr newfs_ufs /dev/myblk0
# kdump /tmp/newfs.ktr | head -n 50
```

The resulting trace shows the sequence of system calls, their arguments, and their results. For storage tools, this reveals exactly which `ioctl`s are being issued and which file descriptors are being opened.

27.14.10 dmesg and the Kernel Log

The humble `dmesg` is often the fastest way to diagnose a problem. Our driver prints to it on load and unload. The kernel prints to it on many other events, including GEOM class creation, access-count violations, and panics that the system recovers from.

Pro tip: redirect `dmesg -a` to a file at the start of each lab session. If something goes wrong you will have a complete log.

```
# dmesg -a > /tmp/session.log
# # ... work ...
# dmesg -a > /tmp/session-final.log
# diff /tmp/session.log /tmp/session-final.log
```

This gives you a precise log of what the kernel reported during your session.

27.14.11 A Simple Measurement Recipe

Here is a recipe you can use to produce a one-page performance profile of your driver.

1. Load the driver.
2. Run `diskinfo -c /dev/myblk0` and record the three transfer-rate numbers.
3. Format the device and mount it.
4. In one terminal, start `gstat -I 1 -f myblk0 -b` redirected to a file.
5. In another terminal, run `dd if=/dev/zero of=/mnt/myblk/stress bs=1m count=128`.
6. Stop `gstat` after `dd` completes and save the log.
7. Parse the log with `awk` to extract the peak ops/s, the peak throughput, and the average latency.
8. Unmount and unload.

This recipe scales. For a real driver you would automate it, run it on a matrix of block sizes, and plot the results. For a teaching driver, running it once or twice gives you a feeling for the numbers and a baseline to compare against after future changes.

27.14.12 Comparing Against md(4)

One of the most useful exercises is to load `md(4)` in the same configuration as your driver and compare.

```
# mdconfig -a -t malloc -s 32m
md0
# diskinfo -c /dev/md0
```

The numbers will likely be within a small factor of your driver's. If they are very different, something interesting is going on. The usual differences are:

- `md(4)` uses a worker thread that receives BIOs from the strategy function and processes them in a separate context. This adds a small amount of latency per BIO but allows higher concurrency.
- `md(4)` uses page-at-a-time backing, which is slightly slower per byte for sequential I/O but scales to much larger sizes.
- `md(4)` supports more BIO commands and attributes than our driver.

Comparing against `md(4)` is a form of debugging: if your driver is much slower or much faster than `md(4)` on the same workload, either you have done something unusual, or you have uncovered a difference worth understanding.

27.14.13 Wrapping Up Section 10

Observability is not an afterthought. For a storage driver, it is how you keep your bearings. `gstat`, `iostat`, `diskinfo`, `sysctl`, `vmstat`, `procstat`, and `DTrace` are the tools you will reach for most often. `kgdb` and crash dumps are your backstop when things go catastrophically wrong.

Learn these tools now, while the driver is simple, because they will be the same tools you use when the driver is complex. A developer who can observe a running driver is much more effective than one who can only read source.

We have now covered every concept the chapter set out to teach, plus observability and measurement. Before we move on to the hands-on labs, let us spend some time reading real FreeBSD source. The case studies that follow anchor everything we have learned in code from the tree.

27.15 Case Studies in Real FreeBSD Storage Code

Reading production driver source is the fastest way to internalise patterns. In this section we will walk through excerpts from three real drivers in `/usr/src/sys/`, with commentary that points out what each excerpt is doing and why. The excerpts are short on purpose; we will not read every line of each driver. We will pick the lines that matter.

Open the files alongside the text and follow along. The point is for you to see the same patterns in our driver reappearing in real drivers, under different names and with different constraints.

27.15.1 Case Study 1: `g_zero.c`

`g_zero.c` is the simplest GEOM class in the tree. It is a read-always-zero, write-discard provider, with no real backing store and no real work to do. Its purpose is to give you a standard “null disk” you can test against. It is also an excellent teaching reference because it exercises the full `g_class` API in fewer than 150 lines.

Let us look at its strategy function, called `g_zero_start`.

```
static void
g_zero_start(struct bio *bp)
{
    switch (bp->bio_cmd) {
        case BIO_READ:
            bzero(bp->bio_data, bp->bio_length);
            g_io_deliver(bp, 0);
            break;
        case BIO_WRITE:
            g_io_deliver(bp, 0);
            break;
        case BIO_GETATTR:
        default:
            g_io_deliver(bp, EOPNOTSUPP);
            break;
    }
}
```

Three behaviours, with `BIO_GETATTR` intentionally folded into the default case. Reads get zeroed. Writes are silently accepted. Anything else, including attribute queries, gets `EOPNOTSUPP`. The real `/usr/src/sys/geom/zero/g_zero.c` also handles `BIO_DELETE` in the successful-write path; our simplified excerpt above drops that case so you can see the shape clearly. Notice the call to `g_io_deliver` rather than `biodone`. That is because

`g_zero` is a class-level GEOM module, not a `g_disk` module. `g_io_deliver` is the class-level completion call; `biodone` is the `g_disk` wrapper.

If you re-read our driver's strategy function side by side with this, you will see the same structure: a switch on `bio_cmd`, a case for each supported operation, a default error path. Our driver has more cases and it has a real backing store, but the shape is identical.

The `init` function that `g_zero` registers with the class is also small:

```
static void
g_zero_init(struct g_class *mp)
{
    struct g_geom *gp;

    gp = g_new_geomf(mp, "gzero");
    gp->start = g_zero_start;
    gp->access = g_std_access;
    g_new_providerf(gp, "%s", gp->name);
    g_error_provider(g_provider_by_name(gp->name), 0);
}
```

When the `g_zero` module is loaded, this runs. It creates a new geom under the class, points the start method at the strategy function, uses the standard access handler, and creates a provider. That is everything it takes to expose `/dev/gzero`.

In our driver, `g_disk` does the equivalent of all this when `disk_create` is called. You can see here, once more, what `g_disk` is abstracting away. For most disk drivers that is a good trade; for `g_zero`, which does not want `g_disk`'s disk-specific features, using the class API directly is the better fit.

27.15.2 Case Study 2: `md.c`, the Malloc Strategy Function

`md(4)` is a memory-disk driver with several backing types. The malloc backing type is the closest to our driver, and its strategy function is worth reading in detail.

Here is a simplified version of what happens when `md(4)`'s worker thread picks up a BIO for a `MD_MALLOC`-type disk. (In real `md(4)`, this is the function `mdstart_malloc`.)

```
static int
mdstart_malloc(struct md_s *sc, struct bio *bp)
{
    u_char *dst, *src;
    off_t offset;
    size_t resid, len;
    int error;

    error = 0;
```

```

    resid = bp->bio_length;
    offset = bp->bio_offset;

    switch (bp->bio_cmd) {
    case BIO_READ:
        /* find the page that contains offset */
        /* copy len bytes out of it */
        /* advance, repeat until resid == 0 */
        break;
    case BIO_WRITE:
        /* find the page that contains offset */
        /* allocate it if not allocated yet */
        /* copy len bytes into it */
        /* advance, repeat until resid == 0 */
        break;
    case BIO_DELETE:
        /* free pages in the range */
        break;
    }

    bp->bio_resid = 0;
    return (error);
}

```

The key difference from our driver is the page-at-a-time backing. `md(4)` does not allocate one big buffer. It allocates 4 KiB pages on demand and indexes them through a data structure inside the `softc`. The benefit is that memory disks can be much larger than a single contiguous `malloc` would allow, and sparse regions (never written) consume no memory.

The cost is that every BIO may span multiple pages, so the strategy function has to loop. Each iteration copies `len` bytes into the current page, decrements `resid`, advances `offset`, and either exits when `resid` hits zero or moves on to the next page.

Our driver avoids this complexity at the cost of supporting only contiguous backing, which is fine up to a few tens of megabytes but not beyond.

If you wanted to extend our driver to match `md(4)`'s scale, the page-at-a-time pattern is the direction you would go. It is straightforward once you have `md(4)` in front of you as a reference.

27.15.3 Case Study 3: `md.c`, the Module Load Path

Another piece of `md(4)` worth studying is how it bootstraps its class and sets up the control device.

```

static void
g_md_init(struct g_class *mp __unused)

```

```

{
    /*
     * Populate sc_list with pre-loaded memory disks
     * (preloaded kernel images, ramdisks from boot, etc.)
     */
    /* ... */

    /*
     * Create the control device /dev/mdctl.
     */
    status = make_dev_p(MAKEDEV_CHECKNAME | MAKEDEV_WAITOK,
        &status_dev, &mdctl_cdevsw, 0, UID_ROOT, GID_WHEEL,
        0600, MDCTL_NAME);
    /* ... */
}

```

The `g_md_init` function runs once per kernel boot, when the `md(4)` class is first instantiated. It handles any memory disks that the loader preloaded into memory (so that the kernel can boot from a memory-disk root) and it creates the control device `/dev/mdctl` through which `mdconfig` will later talk to the driver.

Compare this to our loader, which is a simple `moduledata_t` that calls `disk_create` directly. `md(4)` does not create any memory disks by default. It only creates them in response to preload events or in response to `MDIOCATTACH` ioctls on the control device.

The pattern here is generalisable. If you want a storage driver that creates units on demand rather than at load time, you:

1. Register the class (or, for `g_disk`-based drivers, set up the infrastructure).
2. Create a control device with a `cdevsw` that supports ioctls.
3. Implement create, destroy, and query ioctls.
4. Write a user-space tool that talks to the control device.

`md(4)` is the canonical example. Other drivers, like `geli(4)` and `gmirror(4)`, use a slightly different pattern because they are GEOM transformation classes rather than disk drivers, but the overall shape is similar.

27.15.4 Case Study 4: The newbus Side of a Real Storage Driver

For contrast, let us look briefly at how a real hardware-backed storage driver attaches. The `ada(4)` driver, for example, is a CAM-based ATA driver. Its attach path is not directly visible as a single function, because CAM mediates between the driver and the hardware, but the end of the chain looks like this (abbreviated from `/usr/src/sys/cam/ata/ata_da.c`):

```

static void
adaregister(struct cam_periph *periph, void *arg)
{
    struct ada_softc *softc;

```

```

/* ... */

softc->disk = disk_alloc();
softc->disk->d_open = adaopen;
softc->disk->d_close = adaclose;
softc->disk->d_strategy = adastrategy;
softc->disk->d_getattr = adagetattr;
softc->disk->d_dump = adadump;
softc->disk->d_gone = adadiskgonecb;
softc->disk->d_name = "ada";
softc->disk->d_drv1 = periph;
/* ... */
softc->disk->d_unit = periph->unit_number;
/* ... */
softc->disk->d_sectorsize = softc->params.secsz;
softc->disk->d_mediasize = ...;
/* ... */

disk_create(softc->disk, DISK_VERSION);
/* ... */
}

```

The structure is identical to ours: fill in a struct `disk` and call `disk_create`. The differences are:

- `d_strategy` is `adastrategy`, which translates BIOs into ATA commands and issues them to the controller via CAM.
- `d_dump` is implemented, because `ada(4)` supports kernel crash dumps. Our driver does not implement this.
- The fields like `d_sectorsize` and `d_mediasize` come from hardware probing, not from macros.

From `g_disk`'s perspective, however, `ada0` and our `myblk0` are the same kind of thing. Both are disks. Both receive BIOs. Both are completed with `biodone`. The difference is in where the bytes actually go.

This is the uniformity that `g_disk` provides. Your driver can choose any backing technology, and as long as it fills in struct `disk` correctly, it looks like any other disk to the rest of the kernel.

27.15.5 Takeaways from the Case Studies

Three patterns become clearer after reading these excerpts.

First, the strategy function is always a switch on `bio_cmd`. The cases vary, but the switch is always there. Memorise this pattern: incoming BIO -> switch -> case per command -> completion. It is the heart of every storage driver.

Second, `g_disk` drivers are structurally identical at the registration level. Whether the driver is a RAM disk or a real SATA drive, the registration code looks the same. The differences are in what happens when the BIO arrives.

Third, more sophisticated drivers enqueue work to a dedicated thread. Our driver does not, because it can do its work synchronously in any thread. Drivers that do slow or blocking work must enqueue, because strategy functions run in the caller's thread context.

With these patterns in mind, you can now read almost any storage driver in the FreeBSD tree and follow its overall structure, even if specific details about hardware or sub-frameworks require further study.

We have now covered every concept the chapter set out to teach, plus observability, measurement, and a few real case studies. In the next part of the chapter, we will put this knowledge to work through hands-on labs. The labs build on the driver you have been writing and on the skills you have been using, and they take you from the minimum working driver through persistence, mount, and cleanup scenarios. Let us begin.

27.16 Hands-On Labs

Each lab is a self-contained checkpoint. They are designed to be done in order, but you can revisit any lab later if you want to practise a specific skill. Every lab has a companion folder under `examples/part-06/ch27-storage-vfs/`, which contains the reference implementation and the artifacts you would produce if you typed the code by hand.

Before you start, make sure you have the chapter's driver building cleanly against your local kernel. From a fresh checkout of the examples tree:

```
# cd examples/part-06/ch27-storage-vfs
# make
# ls myblk.ko
myblk.ko
```

If that works, you are ready. If not, revisit the Makefile and the advice in Chapter 26, section “Your Build Environment”.

27.16.1 Lab 1: Explore GEOM on a Running System

Goal. Build comfort with the GEOM inspection tools before you touch any code.

What you do.

On your FreeBSD 14.3 system, run the following commands and take notes in your lab logbook.

```
# geom disk list
# geom part show
# geom -t | head -n 40
# gstat -I 1
# diskinfo -v /dev/ada0    # or whatever your primary disk is called
```

What you look for.

Identify every DISK class geom. For each, note its provider name, its media size, its sector size, and its current mode. Notice which geoms have partitioning layers on top and which do not. If your system has geli or zfs, notice the chain of classes.

Stretch question. Which of your geoms have non-zero access counts right now? Which ones are free? What would happen if you tried to run newfs_ufs on each?

Reference implementation. examples/part-06/ch27-storage-vfs/lab01-explore-geom/README.md contains a suggested walkthrough and a sample output transcript from a typical system.

27.16.2 Lab 2: Build the Skeleton Driver

Goal. Get the Section 3 skeleton driver compiling and loading on your system.

What you do.

Copy examples/part-06/ch27-storage-vfs/lab02-skeleton/myfirst_blk.c and its Makefile into a working directory. Build it.

```
# cp -r examples/part-06/ch27-storage-vfs/lab02-skeleton /tmp/myblk
# cd /tmp/myblk
# make
```

Load the module.

```
# kldload ./myblk.ko
# dmesg | tail -n 2
# ls /dev/myblk0
# geom disk list myblk0
```

Unload it.

```
# kldunload myblk
# ls /dev/myblk0
```

What you look for.

Confirm that the kernel printed your myblk: loaded message. Confirm that /dev/myblk0 appeared. Confirm that geom disk list reported the expected media size. Confirm that the node disappeared after unload.

Stretch question. What happens if you try newfs_ufs -N /dev/myblk0 with the skeleton driver? Can you read the output? Why does the dry run succeed even though real writes would fail?

27.16.3 Lab 3: Implement the BIO Handler

Goal. Add the working strategy function from Section 5 to the skeleton driver.

What you do.

Starting from the skeleton, implement `myblk_strategy` with support for `BIO_READ`, `BIO_WRITE`, `BIO_DELETE`, and `BIO_FLUSH`. Allocate the backing buffer in `myblk_attach_unit` and free it in `myblk_detach_unit`.

Build, load, and test.

```
# dd if=/dev/zero of=/dev/myblk0 bs=4096 count=16
# dd if=/dev/myblk0 of=/dev/null bs=4096 count=16
# dd if=/dev/random of=/dev/myblk0 bs=4096 count=16
# dd if=/dev/myblk0 of=/tmp/a bs=4096 count=16
# dd if=/dev/myblk0 of=/tmp/b bs=4096 count=16
# cmp /tmp/a /tmp/b
```

What you look for.

The last `cmp` must succeed with no output. If it prints `differ: byte N`, your strategy function is racing or returning stale data.

Stretch question. Put a `printf` in the strategy function that reports `bio_cmd`, `bio_offset`, and `bio_bcount`. Run `dd if=/dev/myblk0 of=/dev/null bs=1m count=1` and look at `dmesg`. What size did `dd` actually issue? Do you see fragmentation?

Reference implementation. `examples/part-06/ch27-storage-vfs/lab03-bio-handler/myfirst_blk.c`.

27.16.4 Lab 4: Increase Size and Mount UFS

Goal. Increase the backing store to 32 MiB and mount UFS on the device.

What you do.

Change `MYBLK_MEDIASIZE` to `(32 * 1024 * 1024)` and rebuild. Load the module. Format and mount.

```
# newfs_ufs /dev/myblk0
# mkdir -p /mnt/myblk
# mount /dev/myblk0 /mnt/myblk
# echo "hello" > /mnt/myblk/greeting.txt
# cat /mnt/myblk/greeting.txt
# umount /mnt/myblk
# mount /dev/myblk0 /mnt/myblk
# cat /mnt/myblk/greeting.txt
# umount /mnt/myblk
# kldunload myblk
```

What you look for.

Verify that the file survives an unmount-and-remount. Verify that the access counts in `geom disk list` are zero after unmount. Verify that `kldunload` succeeds cleanly.

Stretch question. Watch `gstat -I 1` while running `dd if=/dev/zero of=/mnt/myblk/big bs=1m count=16`. Can you see the writes arrive in bursts? What size are the individual BIOs? Hint: UFS's default block size is typically 32 KiB on a filesystem this small.

Reference implementation. `examples/part-06/ch27-storage-vfs/lab04-mount-ufs/myfirst_blk.c`.

27.16.5 Lab 5: Observing Real Cross-Reload Persistence with md(4)

Goal. Confirm experimentally that cross-reload persistence requires external backing, as Section 7 argued, by using `md(4)`'s vnode mode as a control.

What you do.

First, demonstrate that our RAM-backed `myblk` loses its filesystem on reload. Load, format, mount, write, unmount, unload, reload, mount again, and observe the empty filesystem.

```
# kldload ./myblk.ko
# newfs_ufs /dev/myblk0
# mount /dev/myblk0 /mnt/myblk
# echo "not persistent" > /mnt/myblk/token.txt
# umount /mnt/myblk
# kldunload myblk
# kldload ./myblk.ko
# mount /dev/myblk0 /mnt/myblk
# ls /mnt/myblk
```

The `ls` should show an empty or fresh UFS directory; the `token.txt` is gone because the backing buffer was reclaimed by the kernel when the module unloaded.

Now do the same sequence with `md(4)`'s vnode backend, which uses a real file on disk:

```
# truncate -s 64m /var/tmp/mdimage.img
# mdconfig -a -t vnode -f /var/tmp/mdimage.img -u 9
# newfs_ufs /dev/md9
# mount /dev/md9 /mnt/md
# echo "persistent" > /mnt/md/token.txt
# umount /mnt/md
# mdconfig -d -u 9
# mdconfig -a -t vnode -f /var/tmp/mdimage.img -u 9
# mount /dev/md9 /mnt/md
# cat /mnt/md/token.txt
persistent
```

What you look for.

The first sequence loses the file; the second preserves it. The difference is that `md9` is backed by a real file on disk, whose state survives regardless of what happens inside the kernel. Contrast this with `myblk0`, which is backed by kernel heap that disappears on `kldunload`.

Stretch question. Read the `MD_VNODE` branch of `mdstart_vnode` in `/usr/src/sys/dev/md/md.c`. Identify where the vnode reference is stored (hint: it lives on the per-unit struct `md_s`, not a module-scope global). Explain in your own words why that design is what lets the backing survive module lifecycles.

Reference implementation. `examples/part-06/ch27-storage-vfs/lab05-persistence/README.md` walks through both sequences and their diagnostic output.

27.16.6 Lab 6: Safe Unmount Under Load

Goal. Verify that the teardown path handles an active filesystem correctly.

What you do.

Load the module, format it, mount it. In one terminal, start a stress loop.

```
# while true; do dd if=/dev/urandom of=/mnt/myblk/stress bs=4k \
    count=512 2>/dev/null; sync; done
```

In another terminal, attempt to unload.

```
# kldunload myblk
kldunload: can't unload file: Device busy
```

Stop the stress loop. Unmount. Unload.

What you look for.

The initial unload must fail gracefully. After unmount, the final unload must succeed. `dmesg` must not show any kernel warnings.

Stretch question. Instead of killing the stress loop, try `umount /mnt/myblk` directly. Does UFS let you unmount while writes are in flight? What is the error, and what does it mean?

Reference implementation. `examples/part-06/ch27-storage-vfs/lab06-safe-unmount/` includes a test script that performs the sequence above and reports failures.

27.16.7 Lab 7: Observing BIO Traffic with DTrace

Goal. Use DTrace to see the BIO path as it happens.

What you do.

With the driver loaded and a filesystem mounted, run the following DTrace one-liner in one terminal:

```
# dtrace -n 'fbt::myblk_strategy:entry { \
    printf("cmd=%d off=%lld len=%u", \
        args[0]->bio_cmd, args[0]->bio_offset, \
        args[0]->bio_bcount); \
    @count[args[0]->bio_cmd] = count(); \
}'
```

In another terminal, create and read files on the mounted filesystem.

What you look for.

Note which BIO commands you see and in what quantities. Note the typical offsets and lengths. Compare the patterns from `dd` traffic versus `cp` traffic versus `tar` traffic. Note how `cp` or `mv` might produce very different BIO patterns depending on what the buffer cache decides to flush.

Stretch question. Issue `sync` while the DTrace is running. What BIO commands does `sync` cause? What about `newfs_ufs`?

Reference implementation. `examples/part-06/ch27-storage-vfs/lab07-dtrace/README.md` with sample DTrace output and notes.

27.16.8 Lab 8: Adding a `getattr` Attribute

Goal. Implement a `d_getattr` callback that responds to `GEOM::ident`.

What you do.

Add the `myblk_getattr` function from Section 5 to the driver, and register it on the disk before `disk_create`. Rebuild, reload, and check `diskinfo -v /dev/myblk0`.

What you look for.

The `ident` field should now show `MYBLK0` instead of `(null)`.

Stretch question. What other attributes might a filesystem query? Look at `/usr/src/sys/geom/geom.h` for named attributes like `GEOM::rotation_rate`. Try implementing that too.

Reference implementation. `examples/part-06/ch27-storage-vfs/lab08-getattr/myfirst_blk.c`.

27.16.9 Lab 9: Exploring `md(4)` for Comparison

Goal. Read a real FreeBSD storage driver and identify the patterns we have used.

What you do.

Open `/usr/src/sys/dev/md/md.c`. It is a long file. Do not try to read every line. Instead, find and understand these specific things:

1. The `g_md_class` structure at the top of the file.
2. The `struct md_softc`.
3. The `mdstart_malloc` function that handles `BIO_READ` and `BIO_WRITE` for `MD_MALLOC` memory disks.
4. The worker-thread pattern in `md_kthread` (or its equivalent in your version).
5. The `MDIOCATTACH` ioctl handler that creates new units on demand.

Compare each of these to the corresponding code in our driver.

What you look for.

Spot the differences. Where does `md(4)` have features we do not? Where does our driver have the same mechanism in simpler form? Where would you need to extend our driver to add one of `md(4)`'s features?

Reference notes. `examples/part-06/ch27-storage-vfs/lab09-md-comparison/NOTES.md` contains a mapped walkthrough of the relevant sections of `md.c` for FreeBSD 14.3.

27.16.10 Lab 10: Break It On Purpose

Goal. Induce known failure modes so that you can recognise them quickly in real work.

What you do.

Take a clean copy of the completed driver from Lab 8. In separate copies (do not mix the breakages together), introduce the following bugs one at a time, rebuild, load, and observe.

Breakage 1: Forget biodone. Comment out the `biodone(bp)` call in the `BIO_READ` case. Load, mount, and run `cat` on a file. The cat will hang forever. Attempt to kill it with `Ctrl-C`; it may not respond. Use `procstat -kk` on the stuck PID to see where the process is waiting. This is the classic leaked-BIO symptom.

Breakage 2: Free backing before disk_destroy. In `myblk_detach_unit`, swap the order so that `free(sc->backing, ...)` comes before `disk_destroy(sc->disk)`. Load, format, mount, unmount, and try to unload. If no BIO is in flight during the unload window, you will escape unharmed. If any BIO is in flight (use a running `dd` to ensure this), you will panic with a page fault.

Breakage 3: Skip bio_resid. Remove the `bp->bio_resid = 0` line from the `BIO_READ` case. Load, format, mount, and create a file. Read it back. Depending on what garbage was in `bio_resid` at allocation time, the filesystem may report incorrect read sizes and may log errors. Sometimes it works; sometimes it does not. This is the characteristic intermittent failure of a forgotten `bio_resid`.

Breakage 4: Off-by-one bounds. Change the bounds check from `offset > sc->backing_size` to `offset >= sc->backing_size`. This rejects valid reads at the last offset. Load, format, mount. Try to write a file that extends to the very last block. Observe whether UFS notices; whether `dd` notices; what error is reported.

What you look for.

In each case, describe in your logbook what you observed, which tool revealed the problem (`dmesg`, `procstat`, `gstat`, panic trace), and what the fix would be. Then apply the fix and confirm normal operation.

Stretch question. What sequence of commands reliably reproduces each failure? Can you write a shell script that deterministically triggers Breakage 1 or Breakage 2?

Reference notes. `examples/part-06/ch27-storage-vfs/lab10-break-on-purpose/BREAKAGES.md` contains short descriptions and a test script for each failure mode.

27.16.11 Lab 11: Measure Under Varying Block Sizes

Goal. Understand how BIO size affects throughput.

What you do.

With the driver loaded and a filesystem mounted, run `dd` with progressively larger block sizes and time each run.

```
# for bs in 512 4096 32768 131072 524288 1048576; do
    rm -f /mnt/myblk/bench
    time dd if=/dev/zero of=/mnt/myblk/bench bs=$bs count=$((16*1024*1024/bs))
done
```

Record the throughput in each case.

What you look for.

Throughput should increase as block size increases, then plateau at or near `d_maxsize` (typically 128 KiB). Very small block sizes will be dominated by per-BIO overhead.

Stretch question. At what block size does the curve visibly plateau? Why?

27.16.12 Lab 12: Race Test With Two Processes

Goal. Observe how the driver handles simultaneous access from multiple processes.

What you do.

With the driver loaded and a filesystem mounted, run two `dd` processes in parallel writing to different files.

```
# dd if=/dev/urandom of=/mnt/myblk/a bs=4k count=1024 &
# dd if=/dev/urandom of=/mnt/myblk/b bs=4k count=1024 &
# wait
```

Record the combined throughput.

What you look for.

Both writes should complete without corruption. Verify with `md5` or `sha256` on each file. The combined throughput may be slightly less than twice the single-process throughput because of lock contention in our coarse mutex.

Stretch question. Does removing the mutex affect throughput? Does it cause corruption? Why or why not?

27.16.13 A Word on Lab Discipline

Every lab is small, and none of them is an exam. If you get stuck, the reference implementation is there for you to compare against. Do not copy-paste it as your first attempt, though. The copying is not the skill. The skill is in typing, reading, diagnosing, and verifying.

Keep your logbook open. Record what you ran, what you saw, and what surprised you. Storage bugs often repeat across projects, and your future self will thank your current self for the notes.

27.17 Challenge Exercises

The challenge exercises stretch the driver a little further. Each one is scoped to something a beginner can accomplish with the material already covered in the chapter, combined with a thoughtful reading of FreeBSD source. They are not timed. Take your time. Open the source tree. Consult manual pages. Compare your solution to `md(4)` when in doubt.

Every challenge below has a stub folder under `examples/part-06/ch27-storage-vfs/`, but no reference solution is provided. The point is to work through them yourself. Solutions are left as follow-ups that you can compare with peers or post in your study notes.

27.17.1 Challenge 1: Expose a Read-Only Mode

Add a module-load tunable that lets the driver come up in read-only mode. In read-only mode, `BIO_WRITE` and `BIO_DELETE` should fail with `EROFS`. `newfs_ufs` should refuse to format the device, and `mount` without `-r` should refuse to mount it.

Hint. The tunable can be a `sysctl_int` bound to a static variable. `TUNABLE_INT` is another way, used at load time only. Your strategy function can check the variable before dispatching writes. Remember that changing the mode at runtime while a filesystem is mounted is a recipe for corruption; you can either disallow the change or document that the tunable only takes effect at module load.

27.17.2 Challenge 2: Implement a Second Unit

Add support for exactly two units: `myblk0` and `myblk1`. Each should have its own backing store of its own size. Do not try to implement fully dynamic unit allocation; just hardcode two `softcs` and two `attach` calls in the module loader.

Hint. Move the backing allocation, disk allocation, and disk creation into `myblk_attach_unit` parameterised by unit number and size, and call it twice from the loader. Make sure the detach path walks both units.

27.17.3 Challenge 3: Honour `BIO_DELETE` with a `Sysctl` Counter

Extend `BIO_DELETE` handling to also bump a `sysctl` counter that reports total bytes deleted. Verify with `sysctl dev.myblk` while running `fstrim /mnt/myblk` or while `dd` writes and overwrites files.

Hint. UFS by default does not issue `BIO_DELETE`. To see delete traffic, mount with `-o trim`. You can verify the trim flow with your DTrace one-liner from Lab 7.

27.17.4 Challenge 4: Respond to `BIO_GETATTR` for `rotation_rate`

Extend `myblk_getattr` to answer `GEOM::rotation_rate` with `DISK_RR_NON_ROTATING` (defined in `/usr/src/sys/geom/geom_disk.h`). Verify with `gpart show` and `diskinfo -v` that the device reports as non-rotating.

Hint. The attribute is returned as a plain `u_int`. Look at how `md(4)` handles `BIO_GETATTR` for comparable attributes.

27.17.5 Challenge 5: Resizing the Device

Add an `ioctl` that lets user space resize the backing store while nothing is mounted. If a filesystem is mounted, the `ioctl` must fail with `EBUSY`. If the resize succeeds, update `d mediasize` and notify `GEOM` so that `diskinfo` reports the new size.

Hint. Look at `md(4)`'s `MDIOCRESIZE` handling for the pattern. This is a non-trivial challenge; take your time and test with throwaway filesystems. Do not attempt this on any backing that you would be sad to lose.

27.17.6 Challenge 6: A Write Counter and Rate Display

Add per-second write-byte counters, exposed via `sysctl`, and a small user-space shell script that reads the `sysctl` every second and prints a human-readable rate. This is useful for testing and it gives you experience wiring metrics through the kernel's observability machinery.

Hint. Use `atomic_add_long` on the counters. The shell script is a one-liner in `while true` loops.

27.17.7 Challenge 7: A Fixed Pattern Backing Store

Implement a backing-store mode where reads always return a fixed byte pattern and writes are silently discarded. This is similar to `g_zero` but with a configurable pattern byte. It is useful for stress-testing the layers above when you do not care about data content.

Hint. Branch on a mode variable inside the strategy function. Keep the in-memory backing for the normal mode and skip the `memcpy` in pattern mode.

27.17.8 Challenge 8: Write a `mdconfig`-Like Control Utility

Write a small user-space program that talks to a control device on your driver (you will need to add one) and can create, destroy, and query units at runtime. The program should accept command-line flags similar to `mdconfig`.

Hint. This is a substantial challenge. Start with a single `ioctl` that prints "hello" and build up from there. `make_dev` on a `cdev` for your control device, then implement `d_ioctl` on that `cdev`.

27.17.9 Challenge 9: Survive a Simulated Crash

Add a mode where the driver drops every Nth write silently (pretending the write succeeded but actually doing nothing). Use this to test UFS's resilience to lost writes.

Hint. This is a dangerous mode. Only run it on throwaway filesystems. You should be able to reproduce interesting `fsck_ffs` repair scenarios with it. Be ready to explain to yourself why this mode is only safe on pseudo devices you can regenerate from scratch.

27.17.10 Challenge 10: Understand `md(4)` Well Enough to Teach It

Write a one-page explanation of how `md(4)` creates a new unit in response to `MDIOCATTACH`. Cover the `ioctl` path, the softc allocation, the backing-type-specific initialisation, the `g_disk` wiring, and the worker thread creation. This is a reading challenge rather than a coding challenge, but it is one of the most useful exercises you can do to deepen your grasp of the storage stack.

Hint. `/usr/src/sys/dev/md/md.c` and `/usr/src/sbin/mdconfig/mdconfig.c` are the two files to read. Pay attention to the `struct md_ioctl` structure in `/usr/src/sys/sys/mdioctl.h`, because that is the ABI between user space and the kernel.

27.17.11 When to Attempt Challenges

You do not need to do all of them. Pick one or two that speak to something you are curious about or something you can imagine using later. A single carefully-done challenge is worth more than five half-done ones. The reference `md(4)` implementation will be there whenever you want to compare your approach to a production driver.

27.18 Troubleshooting

Storage drivers have a particular family of failure modes. Some of them are obvious as they happen. Others are silent at first and become obvious only after reboot, sometimes with data corruption in between. This section lists the symptoms you are most likely to see while working through the chapter and the labs, along with the usual causes and fixes. Use it as a reference when things go wrong, and read it through at least once before you start, because it is much easier to recognise a failure mode the second time.

27.18.1 `kldload` Succeeds but No `/dev` Node Appears

Symptom. `kldload` returns zero. `kldstat` shows the module loaded. But `/dev/myblk0` does not exist.

Likely causes.

- You forgot to call `disk_create`. The softc is allocated, the disk is allocated, but the disk is not registered with GEOM.
- You called `disk_create` with `d_name` set to a null pointer or an empty string.
- You called `disk_create` with `d_mediasize` set to zero. `g_disk` silently refuses to create a provider with zero size.
- You called `disk_create` before filling in the fields. The framework captures the field values at registration time and does not re-read them later.

Fix. Check the kernel message buffer with `dmesg`. `g_disk` prints a diagnostic when it rejects a registration. Fix the field value and rebuild.

27.18.2 `kldload` Fails with “module version mismatch”

Symptom. Loading the module reports `kldload: can't load ./myblk.ko: No such file or directory` or a more explicit error about version mismatch.

Likely causes.

- You compiled against a different kernel than the one currently running.
- You changed `DISK_VERSION` on your own, which you should never do.
- You forgot `MODULE_VERSION(myblk, 1)`.

Fix. Check `uname -a` and the kernel version your build chose. Recompile against the running kernel.

27.18.3 `diskinfo` Prints the Wrong Size

Symptom. `diskinfo -v /dev/myblk0` prints a size that does not match `MYBLK_MEDIASIZE`.

Likely causes.

- You set `d_mediasize` to the wrong expression. A common off-by-one is setting it to the sector count rather than the byte count.
- You have `MYBLK_MEDIASIZE` defined as something other than `(size * 1024 * 1024)` and the macro is being interpreted differently than you intended. Parenthesise aggressively.

Fix. Print the size in your load message and sanity-check against `diskinfo -v`.

27.18.4 `newfs_ufs` Fails with “Device not configured”

Symptom. `newfs_ufs /dev/myblk0` prints `newfs: /dev/myblk0: Device not configured`.

Likely causes.

- Your strategy function is still the placeholder that returns `ENXIO` for everything. `ENXIO` is mapped to the `Device not configured` message by `errno`.

Fix. Implement the strategy function from Section 5.

27.18.5 `newfs_ufs` Hangs

Symptom. `newfs_ufs /dev/myblk0` starts up but never completes.

Likely causes.

- Your strategy function does not call `biodone` on some path. `newfs_ufs` issues a BIO, waits for its completion, and will wait forever if completion never comes.
- Your strategy function calls `biodone` twice on some path. The first call returns success; the second call usually panics, but in some cases the BIO state is corrupted enough to hang.

Fix. Audit your strategy function. Every control-flow path must end with exactly one call to `biodone(bp)`. A useful pattern is to use a single exit point at the end of the function.

27.18.6 `mount` Fails with “bad superblock”

Symptom. `mount /dev/myblk0 /mnt/myblk` reports `mount: /dev/myblk0: bad magic`.

Likely causes.

- Your strategy function is returning wrong data for some offsets. The superblock is at offset 65536, and UFS validates it carefully.
- Your bounds check is rejecting a legitimate read.
- Your `memcpy` is copying from the wrong address (usually an off-by-one in the offset arithmetic).

Fix. Write a known pattern to the device with `dd`, then read it back with `dd` at various offsets and compare with `cmp`. If the pattern round-trips, the basic I/O is correct. If not, find the first offset where it diverges and inspect the code at the corresponding bounds check or address arithmetic.

27.18.7 `kldunload` Hangs

Symptom. `kldunload myblk` does not return.

Likely causes.

- A BIO is in flight and your strategy function never calls `biodone`. `disk_destroy` is waiting for the BIO to complete.
- You added a worker thread and it is sleeping inside a function that will never be awakened.

Fix. Run `procstat -kk` in another terminal. Look at the `g_event` thread's stack and at any of your driver's threads. If they are stuck in a `sleep` or `waitfor` state, you have a leaked BIO or a misbehaving worker.

27.18.8 `kldunload` Returns “Device busy”

Symptom. `kldunload myblk` reports `Device busy` and exits.

Likely causes.

- A filesystem is still mounted on `/dev/myblk0`.
- A program still has `/dev/myblk0` open for raw access.
- A `dd` from a previous terminal session is still running in the background.

Fix. Run `mount | grep myblk` to check for active mounts. Run `fuser /dev/myblk0` to find open handles. Unmount, close, then unload.

27.18.9 Kernel Panic with “freeing free memory”

Symptom. The kernel panics with a message about freeing already-freed memory, showing a stack trace through your driver.

Likely causes.

- The detach path is freeing the `softc` or the backing twice.
- A worker thread survived `disk_destroy` and tried to access freed state.

Fix. Review the detach order. Destroy the disk first (which waits for in-flight BIOs), then free the backing, then destroy the mutex, then free the `softc`. If you added a worker thread, make sure it has exited before any `free` is called.

27.18.10 Kernel Panic with “`vm_fault: kernel mode`”

Symptom. The kernel panics with a page fault inside your driver, typically in the strategy function or in the detach path.

Likely causes.

- You dereferenced a null or freed pointer. The most common case is using `sc->backing` after it has been freed.
- You confused `bp->bio_data` with `bp->bio_disk` and read from the wrong pointer.

Fix. Audit pointer lifetimes. If the backing store is freed during detach, ensure no BIOs can still reach the strategy function after that point. The order `disk_destroy -> free(backing)` is the correct order.

27.18.11 gstat Shows No Activity

Symptom. You are running `dd` or `newfs_ufs` against the device, but `gstat -f myblk0` shows zero ops/s.

Likely causes.

- You are watching the wrong device. `gstat -f myblk0` uses a regex; make sure your device name matches.
- Your driver uses a custom GEOM class name that `gstat` is filtering out.

Fix. Run `gstat` without the filter and look for your device. Check the name field carefully.

27.18.12 “Operation not supported” for DELETE

Symptom. `Mount-with-trim` fails or `fstrim` prints “Operation not supported”.

Likely causes.

- Your strategy function does not handle `BIO_DELETE` and returns `EOPNOTSUPP`.
- The filesystem probed `BIO_DELETE` support during mount and cached the negative result.

Fix. Implement `BIO_DELETE` in the strategy function, then unmount and remount. Most filesystems only probe at mount time.

27.18.13 /dev/myblk0 Does Not Appear Until Several Seconds After kldload

Symptom. Immediately after `kldload`, `ls /dev/myblk0` fails. A few moments later, it succeeds.

Likely causes.

- GEOM processes events asynchronously. `disk_create` queues an event, and the provider is not published until the event thread picks it up.
- On a system under load, the event queue may be slow.

Fix. This is normal behaviour. If your scripts depend on the node existing immediately after `kldload`, add a small sleep or a polling loop.

27.18.14 Data Written Is Readable but Garbled

Symptom. A read after a write returns the right number of bytes but with different content.

Likely causes.

- Off-by-one in the backing-store offset arithmetic.
- A concurrent BIO is overlapping with the one you expect, and your lock is not held for long enough.
- The strategy function is reading from `bp->bio_data` before the kernel has finished setting it up (this is extremely unlikely for normal BIOs, but can happen with bugs in how you parse attributes).

Fix. Add a `printf` to the strategy function that logs the first few bytes before and after the `memcpy`. Repeat the test with a known pattern and look for the mismatch.

27.18.15 Backing Store Not Freed, Memory Grows With Every Reload

Symptom. `vmstat -m | grep myblk` shows the allocation bytes growing with each load/unload cycle.

Likely causes.

- The `MOD_UNLOAD` handler returned without calling `myblk_detach_unit`, so the `free(sc->backing, M_MYBLK)` was skipped.
- An error path in `MOD_UNLOAD` returned early before reaching the `free`. Every error path needs to free or the allocation leaks.
- A worker thread is holding a reference to the `softc` and the handler refuses to free while that reference exists.

Fix. Audit the `MOD_UNLOAD` path. `vmstat -m` is a blunt but effective tool. Add a `printf` in the free path to confirm it is being reached.

27.18.16 gstat Shows Very High Queue Length

Symptom. `gstat -I 1` shows `L(q)` rising into the tens or hundreds and never returning to zero.

Likely causes.

- Your strategy function is slow or blocking, causing BIOs to queue faster than they are serviced.
- You added a worker thread but it is scheduled less often than it should be.
- A synchronisation bottleneck (a heavily contested mutex) is serialising the work.

Fix. Profile with DTrace to find what the strategy function is doing. If the latency per BIO has grown, investigate why. For an in-memory driver, this should almost never happen; if it does, you have likely introduced a `vn_rdw` or other blocking call into the hot path.

27.18.17 Strategy Function Called With NULL `bio_disk`

Symptom. Kernel panic in the strategy function when dereferencing `bp->bio_disk->d_drv1`.

Likely causes.

- The BIO was synthesised incorrectly by code outside your driver.
- You are accessing `bp->bio_disk` from the wrong context. In some GEOM paths, `bp->bio_disk` is only valid inside the strategy function of a `g_disk` driver.

Fix. If you need to access the `softc`, do it at the start of the strategy function. Cache the pointer in a local variable. Do not access `bp->bio_disk` from a different thread or from a deferred callback.

27.18.18 Mysterious I/O Errors After Reload

Symptom. After `kldunload` and `kldload`, reads return EIO on offsets that worked before the unload.

Likely causes.

- You are working with a file-backed or vnode-backed experiment (from Lab 5 or from your own modifications) and the file's size or contents have been changed between loads.
- A type mismatch between the saved and new offsets (for instance, changing `d_sectorsize` between loads).
- `d_mediasize` has changed but the underlying file still reflects the old layout.

Fix. Ensure the backing file and the driver's geometry agree on both size and sector layout. If you change `d_mediasize` or `d_sectorsize`, regenerate the backing file to match. For a straightforward reload with no changes, the buffer on a RAM-backed driver is always fresh, so mysterious post-reload EIOs usually point to a geometry mismatch rather than data loss.

27.18.19 Access Count Stuck at Non-Zero After Unmount

Symptom. After `umount`, `geom disk list` still shows non-zero access counts.

Likely causes.

- A program still has the raw device open. `fuser /dev/myblk0` will reveal it.
- The filesystem did not unmount cleanly. Check `mount | grep myblk` to see if it is still mounted.
- A lingering NFS client or similar is holding the filesystem open. Unlikely for a local memory disk, but possible on shared systems.

Fix. Find and close the open handle. If `umount` reports success but the access count remains, rebooting is the safest recovery.

27.18.20 Driver Loaded But Not Visible in `geom -t`

Symptom. `kldstat` shows the module loaded, but `geom -t` does not show any geom of our name.

Likely causes.

- The loader ran but never called `disk_create`.
- `disk_create` was called but the event thread has not run yet.

Fix. Add a `printf` to confirm `disk_create` ran. Wait one or two seconds after `kldload` before checking, to give the event thread a chance.

27.18.21 Panic on Second Load

Symptom. Loading the module once works. Unloading works. Loading a second time panics.

Likely causes.

- A `MOD_UNLOAD` handler did not reset all the state that `MOD_LOAD` assumes is fresh.

- A static pointer holds a reference to a freed structure across the unload boundary; the next load sees a dangling pointer.
- A GEOM class that was registered on first load did not unregister.

Fix. Audit your load and unload paths as a matched pair. Every allocation on load needs a corresponding free on unload, and every pointer written on load needs to be cleared on unload. For GEOM classes, `DECLARE_GEOM_CLASS` handles the unregistration for you, but if you bypass it you must do the work.

27.18.22 `newfs_ufs` Aborts with “File system too small”

Symptom. `newfs_ufs /dev/myblk0` aborts with `newfs: /dev/myblk0: partition smaller than minimum UFS size`.

Likely causes.

- `MYBLK_MEDIASIZE` is too small for UFS’s minimum practical size.
- You forgot to rebuild the module after changing the size.

Fix. Ensure the media size is at least a few megabytes. UFS’s absolute minimum is around 1 MiB, but practical minimums are 4-8 MiB and comfortable minimums are 32 MiB or more.

27.18.23 `mount -o trim` Does Not Trigger `BIO_DELETE`

Symptom. Mounting with `-o trim` succeeds, but `gstat` shows no delete operations even during heavy deletion.

Likely causes.

- UFS issues `BIO_DELETE` only on certain patterns; it does not unconditionally trim every freed block.
- Your driver does not advertise `BIO_DELETE` support in its `d_flags`.

Fix. Set `sc->disk->d_flags |= DISKFLAG_CANDELETE`; before `disk_create`. This tells GEOM and filesystems that your driver supports `BIO_DELETE` and is willing to handle them.

27.18.24 UFS Complains About “Fragment out of bounds”

Symptom. After a mount, UFS logs an error about a fragment being out of bounds, and file operations start returning EIO.

Likely causes.

- Your driver is returning wrong data on some offset, and UFS has read a corrupted metadata block.
- The backing store was partially overwritten during some other test.
- Bounds-check arithmetic is returning incorrect ranges.

Fix. Unmount, run `fsck_ffs -y /dev/myblk0` to repair, then re-test. If the error recurs with fresh filesystems, look for offset-computation bugs in the strategy function.

27.18.25 Kernel Printing “interrupt storm” Messages

Symptom. dmesg shows messages about interrupt storms, and system responsiveness degrades.

Likely causes.

- A real hardware driver (not yours) is misbehaving.
- Your driver is fine; this is a different subsystem’s problem.

Fix. Verify that the storm is not related to your module. If it is, the issue is almost certainly in an interrupt handler, which our pseudo driver does not have.

27.18.26 Reboot Hangs on Unmount During Shutdown

Symptom. On shutdown, the system hangs while unmounting, with a message like “Syncing disks, vnodes remaining...”.

Likely causes.

- A filesystem is still mounted on your device, and your driver is holding a BIO.
- A syncer thread is stuck waiting for completion.

Fix. Ensure your driver unmounts cleanly before system shutdown. A robust way is to add a shutdown_post_sync event handler that unmounts the filesystem and unloads the module. For development, unmount and unload manually before issuing shutdown `-r now`.

27.18.27 General Advice

Whenever something goes wrong, the first step is to read dmesg and look for messages from your own printf’s and from kernel subsystems. The second step is to run `procstat -kk` and look at what threads are doing. The third step is to consult `gstat`, `geom disk list`, and `geom -t` for the storage topology. These three tools will tell you most of what you need in nearly every case.

If a panic happens, FreeBSD drops you into the debugger. Capture a backtrace with `bt` and a register dump with `show registers`, then reboot with `reboot`. If a crash dump was taken, `kgdb` on `/var/crash/vmcore.last` will let you inspect the state offline. Keeping crash dumps around, at least in a development environment, pays off immediately when you are chasing intermittent bugs.

And above all, when something fails, try to reproduce it. Intermittent bugs in storage drivers are almost always caused by timing differences in how many BIOs are in flight, how long they take, and when the scheduler decides to run your thread. If you can find a reliable reproduction, you are most of the way to a fix.

27.19 Wrapping Up

This has been a long chapter. Let us take a moment to step back and see what we have covered.

We started by situating storage drivers in FreeBSD’s layered architecture. The Virtual File System layer sits between system calls and filesystems, giving every filesystem a common shape. `devfs` is itself a filesystem, providing the `/dev` directory that user-space tools and administrators use to refer to devices. Storage drivers do

not live inside VFS. They live at the bottom of the stack, below GEOM and below the buffer cache, and they communicate with the rest of the kernel through `struct bio`.

We built a working pseudo block device driver from scratch. In Section 3 we wrote the skeleton that registered a disk with `g_disk` and published a `/dev` node. In Section 4 we explored GEOM's concepts of classes, geoms, providers, and consumers, and we understood how the topology composes and how access counts keep the system safe during teardown. In Section 5 we implemented the strategy function that actually services `BIO_READ`, `BIO_WRITE`, `BIO_DELETE`, and `BIO_FLUSH` against an in-memory backing store. In Section 6 we formatted the device with `newfs_ufs`, mounted a real filesystem on it, and saw the two access paths (raw and filesystem) converge in our strategy function. In Section 7 we surveyed persistence options and added a simple technique for surviving module reloads. In Section 8 we walked through the teardown path in detail and learned how to test it. In Section 9 we looked at the directions a growing driver tends to go: multi-unit support, ioctl surfaces, source-file splits, and stable versioning.

We exercised the driver through labs and stretched it with challenges. We collected the common failure modes in a troubleshooting section. And throughout, we kept our eyes on the real FreeBSD source tree, because the goal of this book is not to teach toy kernel code but to teach the real thing.

You should now be able to read `md(4)` with real comprehension rather than just staring at it. You should be able to read `g_zero.c` and recognise every function it calls. You should be able to diagnose the common classes of storage-driver bug by symptom. And you should have a working, if simple, pseudo block device that you wrote yourself.

That is a substantial amount of ground covered. Take a moment to notice how far you have come. In Chapter 26 you knew how to write a character driver. Now you can also write a block driver. The two chapters together give you the foundation for nearly every other kind of driver in FreeBSD, because most drivers are either character-oriented or block-oriented at the boundary where they meet the rest of the kernel.

27.19.1 A Summary of the Key Moves

For quick recall, here are the moves that define a minimal storage driver.

1. Include the right headers: `sys/bio.h`, `geom/geom.h`, `geom/geom_disk.h`.
2. Allocate a `struct disk` with `disk_alloc`.
3. Fill in `d_name`, `d_unit`, `d_strategy`, `d_sectorsize`, `d_mediasize`, `d_maxsize`, and `d_drv1`.
4. Call `disk_create(sc->disk, DISK_VERSION)`.
5. In `d_strategy`, switch on `bio_cmd` and service the request. Always call `biodone` exactly once.
6. In the unload path, call `disk_destroy` before freeing anything the strategy function touches.
7. Declare `MODULE_DEPEND` on `g_disk`.
8. Use `MAXPHYS` for `d_maxsize` unless you have a specific reason to be smaller.
9. Test the unload path under load. Test it with a mounted filesystem. Test it with a raw cat holding the device open.
10. Read `dmesg`, `gstat`, `geom disk list`, and `procstat -kk` when something goes wrong.

These ten moves are the skeleton of every FreeBSD storage driver you will ever write. They appear in different clothing in `ada(4)`, in `nvme(4)`, in `mmcsd(4)`, in `zvol(4)`, and in every other driver in the tree. Once you see the pattern, the variety across real drivers becomes much less mysterious.

27.19.2 A Reminder About Raw Access

Even with a filesystem mounted, your driver is still reachable as a raw block device. `/dev/myblk0` remains a valid handle that tools like `dd`, `diskinfo`, `gstat`, and `dtrace` can use. The two access paths coexist through GEOM's discipline: both paths issue BIOSs, both paths respect the access counts, and your strategy function services both without distinguishing between them. That uniformity is the great gift of GEOM to storage-driver authors.

27.19.3 A Reminder About Safety

Working on a shared system while developing a storage driver is an invitation for pain. Use a virtual machine, or at the very least a system you can reinstall. Keep a rescue image handy. Keep backups of anything you cannot afford to lose, including code you are in the middle of writing. The chapter's driver is well-behaved and should not damage anything, but drivers you write in the future may not be, and the cost of being prepared is very small compared to the cost of being unprepared.

27.19.4 Where to Look Next in the FreeBSD Tree

If you want to keep exploring storage before the next chapter, three areas of the tree repay careful reading.

- `/usr/src/sys/geom/` has the GEOM framework itself, including `g_class`, `g_disk`, and many transformation classes like `g_mirror`, `g_stripe`, and `g_eli`.
- `/usr/src/sys/dev/md/md.c` is the full-featured memory-disk driver, already mentioned many times in this chapter.
- `/usr/src/sys/ufs/` is the UFS filesystem. Not required reading for driver work, but it helps to see the layer immediately above yours.

Reading these is not a prerequisite for the next chapter. It is a recommendation for your own growth.

27.20 Bridge to the Next Chapter

In this chapter we built a storage driver from scratch. The data flowing through it was internal to the system: bytes written to a file, bytes read from a file, superblocks and cylinder groups and inodes shuffling around in the buffer cache. No byte ever left the machine. The driver's entire world was the kernel's own memory and the processes that consume it.

Chapter 28 takes us into a different world. We will write a network interface driver. Network drivers are transport drivers like the USB serial driver of Chapter 26 and the storage driver of this chapter, but their conversation partner is not a process and not a filesystem. It is a network stack, and the unit of work is not a byte range and not a block but a packet. The packet is a structured object with headers and payload, and the driver participates in a stack that includes IP, ARP, ICMP, TCP, UDP, and many other protocols.

The patterns you have internalised in this chapter will reappear, with different names. Instead of `struct bio`, you will see `struct mbuf`. Instead of `g_disk`, you will see the `ifnet` interface. Instead of `disk_strategy`, you will see the `if_transmit` and `if_input` hooks. Instead of GEOM providers and consumers, you will see

network interface objects linked into the kernel's network stack. The role is the same: a transport driver takes requests from above, delivers them below, accepts responses below, and delivers them above.

Many of the concerns will also be the same. Locking. Hot unplug. Resource cleanup on detach. Observability through kernel tools. Safety in the face of errors. The fundamentals carry over. What changes is the vocabulary, the structure of the unit of work, and some of the specific tools.

Before you move on, take a short break. Unload your storage driver. Run `kldstat` and confirm that nothing from this chapter is still loaded. Close your lab logbook. Stand up. Refill your coffee. The next chapter is going to be just as substantive as this one, and you will want a clear head.

When you come back, Chapter 28 will start the same way this one did: with a gentle introduction and a clear picture of where we are going. See you there.

27.21 Quick Reference

The tables below are intended as a quick lookup when you are writing or debugging a storage driver and need to remember a name, a command, or a path. They are not a substitute for the full explanations earlier in the chapter.

27.21.1 Key Headers

Header	Defines
<code>sys/bio.h</code>	<code>struct bio</code> , <code>BIO_READ</code> , <code>BIO_WRITE</code> , <code>BIO_DELETE</code> , <code>BIO_FLUSH</code> , <code>BIO_GETATTR</code>
<code>geom/geom.h</code>	<code>struct g_class</code> , <code>struct g_geom</code> , <code>struct g_provider</code> , <code>struct g_consumer</code> , topology primitives
<code>geom/geom_disk.h</code>	<code>struct disk</code> , <code>DISK_VERSION</code> , <code>disk_alloc</code> , <code>disk_create</code> , <code>disk_destroy</code> , <code>disk_gone</code>
<code>sys/module.h</code>	<code>DECLARE_MODULE</code> , <code>MODULE_VERSION</code> , <code>MODULE_DEPEND</code>
<code>sys/malloc.h</code>	<code>MALLOC_DEFINE</code> , <code>malloc</code> , <code>free</code> , <code>M_WAITOK</code> , <code>M_NOWAIT</code> , <code>M_ZERO</code>
<code>sys/lock.h</code> , <code>sys/mutex.h</code>	<code>struct mtx</code> , <code>mtx_init</code> , <code>mtx_lock</code> , <code>mtx_unlock</code> , <code>mtx_destroy</code>

27.21.2 Key Structures

Structure	Role
<code>struct disk</code>	The <code>g_disk</code> representation of a disk. Filled in by the driver, owned by the framework.
<code>struct bio</code>	One I/O request, passed between GEOM layers and into the driver's strategy function.
<code>struct g_provider</code>	The producer-facing interface of a geom. Filesystems and other geoms consume from providers.
<code>struct g_consumer</code>	The connection from one geom into another geom's provider.
<code>struct g_geom</code>	An instance of a <code>g_class</code> .
<code>struct g_class</code>	The template from which geoms are created. Defines methods like <code>init</code> , <code>fini</code> , <code>start</code> , <code>access</code> .

27.21.3 Common BIO Commands

Command	Meaning
<code>BIO_READ</code>	Read bytes from the device into a buffer.
<code>BIO_WRITE</code>	Write bytes from a buffer into the device.
<code>BIO_DELETE</code>	Discard a range of blocks. Used for TRIM.
<code>BIO_FLUSH</code>	Commit outstanding writes to durable storage.
<code>BIO_GETATTR</code>	Query a named attribute from the provider.
<code>BIO_ZONE</code>	Zoned-block-device operations. Not commonly used.

27.21.4 Common GEOM Tools

Tool	Purpose
<code>geom disk list</code>	List registered disks and their providers.
<code>geom -t</code>	Show the entire GEOM topology as a tree.
<code>geom part show</code>	Show partition geoms and their providers.
<code>gstat</code>	Live per-provider I/O statistics.
<code>diskinfo -v /dev/xxx</code>	Show disk geometry and attributes.

Tool	Purpose
<code>iostat -x 1</code>	Live per-device throughput and latency.
<code>dd if=... of=...</code>	Raw block I/O for testing.
<code>newfs_ufs /dev/xxx</code>	Create a UFS filesystem on a device.
<code>mount /dev/xxx /mnt</code>	Mount a filesystem.
<code>umount /mnt</code>	Unmount a filesystem.
<code>mdconfig</code>	Create or destroy memory disks.
<code>fuser</code>	Find processes holding a file open.
<code>procstat -kk</code>	Show kernel stack traces for all threads.

27.21.5 Key Callback Typedefs

Typedef	Purpose
<code>disk_strategy_t</code>	Handles BIOs. The core I/O function. Required.
<code>disk_open_t</code>	Called when a new access is being granted. Optional.
<code>disk_close_t</code>	Called when an access is being released. Optional.
<code>disk_ioctl_t</code>	Handles ioctls on the <code>/dev</code> node. Optional.
<code>disk_getattr_t</code>	Answers <code>BIO_GETATTR</code> queries. Optional.
<code>disk_gone_t</code>	Notifies the driver when the disk is being forced away. Optional.

27.21.6 File and Path Reference

Path	What lives there
<code>/usr/src/sys/geom/geom_disk.c</code>	The kernel disk implementation.
<code>/usr/src/sys/geom/geom_public.h</code>	The public <code>g_disk</code> interface.
<code>/usr/src/sys/geom/geom.c</code>	Core GEOM structures and functions.
<code>/usr/src/sys/sys/bio.h</code>	The <code>struct bio</code> definition.
<code>/usr/src/sys/dev/md/md.c</code>	The reference memory-disk driver.
<code>/usr/src/sys/geom/zero/g_zero.c</code>	A minimal GEOM class, useful as a reading reference.
<code>/usr/src/sys/ufs/ffs/ffs_mount.c</code>	UFS's mount path. Read if you want to see what mount does at the filesystem side.
<code>/usr/src/share/man/man9/geom.9</code>	This disk(9) manual page.

Path	What lives there
/usr/src/share/man/man9/man9job.9	The job(9) manual page.

27.21.7 Common Disk Flags

Flag	Meaning
DISKFLAG_CANDELETE	The driver handles BIO_DELETE.
DISKFLAG_CANFLUSHCACHE	The driver handles BIO_FLUSH.
DISKFLAG_UNMAPPED_BIO	The driver accepts unmapped BIOs (advanced).
DISKFLAG_WRITE_PROTECT	The device is read-only.
DISKFLAG_DIRECT_COMPLETION	Completion is safe from any context (advanced).

These flags are set on `sc->disk->d_flags` before `disk_create`. They let the kernel make smarter choices about how to issue BIOs to your driver.

27.21.8 Patterns for `d_strategy`

Here are the three most common shapes of a strategy function.

Pattern 1: Synchronous, in-memory. Our driver uses this. The function serves the BIO inline and returns after calling `biodone`.

```
void strategy(struct bio *bp) {
    /* validate */
    switch (bp->bio_cmd) {
        case BIO_READ: memcpy(bp->bio_data, ...); break;
        case BIO_WRITE: memcpy(..., bp->bio_data); break;
    }
    bp->bio_resid = 0;
    biodone(bp);
}
```

Pattern 2: Enqueue to a worker thread. `md(4)` uses this. The function attaches the BIO to a queue and signals a worker.

```
void strategy(struct bio *bp) {
    mtx_lock(&sc->lock);
    TAILQ_INSERT_TAIL(&sc->queue, bp, bio_queue);
    wakeup(&sc->queue);
}
```

```
mtx_unlock(&sc->lock);  
}
```

The worker dequeues BIOs, services them one at a time (perhaps calling `vn_rdwr` or issuing hardware commands), and completes each with `biodone`.

Pattern 3: Hardware DMA with interrupt completion. Real hardware drivers use this. The function programs the hardware, sets up DMA, and returns. A later interrupt handler completes the BIO.

```
void strategy(struct bio *bp) {  
    /* validate */  
    program_hardware(bp);  
    /* strategy returns, interrupt will call biodone eventually */  
}
```

Each pattern has trade-offs. Pattern 1 is simplest but cannot block. Pattern 2 handles blocking work but adds latency. Pattern 3 is needed for real hardware but requires interrupt handling, which adds a whole other layer of complexity.

Our chapter driver uses Pattern 1. `md(4)` uses Pattern 2. `ada(4)`, `nvme(4)`, and friends use Pattern 3.

27.21.9 Minimum Registration Sequence

For the driver writer in a hurry, the minimum sequence to register a block device is:

```
sc->disk = disk_alloc();  
sc->disk->d_name      = "myblk";  
sc->disk->d_unit      = sc->unit;  
sc->disk->d_strategy   = myblk_strategy;  
sc->disk->d_sectorsize = 512;  
sc->disk->d mediasize  = size_in_bytes;  
sc->disk->d_maxsize    = MAXPHYS;  
sc->disk->d_drv1       = sc;  
disk_create(sc->disk, DISK_VERSION);
```

And the minimum teardown sequence is:

```
disk_destroy(sc->disk);  
free(sc->backing, M_MYBLK);  
mtx_destroy(&sc->lock);  
free(sc, M_MYBLK);
```

27.22 Glossary

Access count. A tuple of three counters on a GEOM provider that tracks how many readers, writers, and exclusive holders currently have access to it. Displayed as `rNwNeN` in `geom disk list`.

Attach. In the Newbus sense, the step where a driver takes responsibility for a device. In the storage sense, the step where the driver calls `disk_create` to register with `g_disk`. The word overloads; use context.

Backing store. The place where the bytes of a storage device actually live. For our driver, the backing store is a `malloc`'d buffer in kernel memory. For real disks, it is the platter or the flash. For `md(4)` in `vnode` mode, it is a file in the host filesystem.

BIO. A `struct bio`. The unit of I/O that flows through GEOM.

BIO_DELETE. A BIO command that asks the driver to discard a range of blocks. Used for TRIM on SSDs.

BIO_FLUSH. A BIO command that asks the driver to make all previous writes durable before returning.

BIO_GETATTR. A BIO command that asks the driver to return the value of a named attribute.

BIO_READ. A BIO command that asks the driver to read a range of bytes.

BIO_WRITE. A BIO command that asks the driver to write a range of bytes.

Block device. A device that is addressed in fixed-size blocks, with seekable random access. Historically distinct from character devices in BSD; in modern FreeBSD, block and character access converge through GEOM but the mental distinction still matters.

Buffer cache. The kernel subsystem that holds recently used filesystem blocks in RAM. Sits between filesystems and GEOM. Not to be confused with the page cache; they are related but distinct in FreeBSD.

Cache coherency. The property that reads and writes see each other in a consistent order. The strategy function must not return data that is stale relative to recent writes on the same offset.

Cdev. A character device node as represented by `struct cdev`. Character drivers create them with `make_dev`. Block drivers usually do not.

Consumer. The input-facing side of a geom. A consumer attaches to a provider and issues BIOs into it.

d_drv1. A generic pointer in `struct disk` where the driver stores its private context, typically the `softc`.

d_mediasize. The total size of the device in bytes.

d_maxsize. The largest single BIO the driver can accept. Usually `MAXPHYS` for pseudo devices.

d_sectorsize. The size of a sector in bytes. Typically 512 or 4096.

d_strategy. The driver's BIO-handling function.

Devfs. A pseudo-filesystem mounted at `/dev` that synthesises file nodes for kernel devices.

Devstat. The kernel's device statistics subsystem, used by `iostat`, `gstat`, and others. Storage drivers using `g_disk` get `devstat` integration automatically.

Disk_alloc. Allocates a `struct disk`. Never fails; uses `M_WAITOK` internally.

Disk_create. Registers a filled-in `struct disk` with `g_disk`. The real work is done asynchronously.

Disk_destroy. Unregisters and destroys a `struct disk`. Waits for in-flight BIOs to complete. Panics if the provider still has users.

Disk_gone. Notifies `g_disk` that the underlying media is gone. Used in hot-unplug scenarios. Distinct from `disk_destroy`.

DISK_VERSION. The ABI version of the `struct disk` interface. Defined in `geom_disk.h` and passed to `disk_create`.

DTrace. FreeBSD's dynamic tracing facility. Especially useful for observing BIO traffic.

Event thread. The single kernel thread that GEOM uses to process topology events such as creating and destroying geoms. Usually called `g_event` in `procstat` output.

Exclusive access. A kind of access on a provider that forbids other writers. Filesystems acquire exclusive access on the devices they mount.

Filesystem. A concrete implementation of file storage semantics, such as UFS, ZFS, tmpfs, or NFS. Plugs into VFS.

GEOM. The FreeBSD framework for composable block-layer transformations. Classes, geoms, providers, and consumers are its main objects.

g_disk. The GEOM subsystem that wraps disk-shaped drivers with a simpler API. Our driver uses it.

g_event. The GEOM event thread that processes topology changes.

g_io_deliver. The function used at the class level to complete a BIO. `g_disk` calls it for us; our driver calls `biodone`.

g_io_request. The function used at the class level to issue a BIO downward. Only used in drivers that implement their own GEOM class.

Hotplug. A device that can appear or disappear without reboot.

ioctl. A control operation on a device, distinct from read or write. In the storage path, `ioctls` on `/dev/diskN` go through GEOM and may be handled by `g_disk` or by the driver's `d_ioctl`.

md(4). The FreeBSD memory-disk driver. The canonical pseudo block device in the tree, and a recommended reading reference.

Mount. The act of attaching a filesystem to a point in the namespace. Calls VFS, which calls the filesystem's own mount routine, which typically opens a GEOM provider.

Newbus. FreeBSD's bus framework. Used for character and hardware drivers. Our storage driver does not directly use Newbus because it is a pseudo device; real storage drivers almost always do.

Provider. The output-facing side of a geom. Other geoms or `/dev` nodes consume providers.

Softc. The per-instance state structure of a driver.

Strategy function. The driver's BIO handler. Called `d_strategy` in the `struct disk` API.

Superblock. A small on-disk structure that describes the layout of a filesystem. UFS's is at offset 65536.

Topology. The tree of GEOM classes, geoms, providers, and consumers. Protected by the topology lock.

Topology lock. The global lock protecting the GEOM topology from concurrent modification.

UFS. The Unix File System, FreeBSD's default filesystem. Lives under `/usr/src/sys/ufs/`.

Unit. A numbered instance of a driver. `myblk0` is unit 0 of the `myblk` driver.

VFS. The Virtual File System layer. Sits between system calls and concrete filesystems.

Vnode. The kernel's runtime handle on an open file or directory. Lives inside VFS.

Withering. The GEOM process of removing a provider from the topology. Queued on the event thread, waits for in-flight BIOs, and finally destroys the provider.

Zone. In VM-subsystem vocabulary, a pool of fixed-size objects allocated through the UMA (Universal Memory Allocator). Many kernel structures, including BIOs and GEOM providers, are allocated from zones.

BIO_ORDERED. A BIO flag that asks the driver to execute this BIO only after all previously issued BIOs have completed. Used for write barriers.

BIO_UNMAPPED. A BIO flag that indicates `bio_data` is not a mapped kernel virtual address but rather a list of unmapped pages. Drivers that can handle unmapped data should set `DISKFLAG_UNMAPPED_BIO`.

Direct completion. Completing a BIO in the same thread that submitted it, without going through a deferred callback. Usually faster but not always safe.

Drivers in Tree. Drivers that live inside the FreeBSD source tree and are built as part of the standard kernel build. Contrast with out-of-tree drivers, which are maintained separately.

Out-of-tree driver. A driver that is not part of the FreeBSD source tree. These need to be compiled against a matching kernel and may need updates when the kernel's ABI changes.

ABI. Application Binary Interface. The set of conventions for function calling, structure layout, and type sizes that allow two pieces of compiled code to interoperate. `DISK_VERSION` is one kind of ABI marker.

API. Application Programming Interface. The set of function signatures and types that code uses at the source level. Distinct from ABI: two kernels with the same API might have different ABIs if they were compiled differently.

KPI. Kernel Programming Interface. FreeBSD's preferred term for the kernel's API. Guarantees about KPI stability are limited; always recompile against the kernel you are running.

KLD. Kernel loadable module. The `.ko` file we produce. The "KLD" stands for Kernel Loadable Driver, though modules are not necessarily drivers.

Module. See KLD.

Taste. In GEOM vocabulary, the process of offering a provider to all classes so that each class can decide whether to attach to it. Tasting happens automatically when new providers appear.

Retaste. Forcing GEOM to taste a provider again, usually after its contents have changed. `geom provider retaste` triggers this for one provider; `geom retaste` triggers it globally.

Orphan. In GEOM vocabulary, a provider whose underlying storage has gone away. Orphans are cleaned up by the event thread.

Spoil. A GEOM concept related to cache invalidation. If a provider's contents change in a way that could invalidate caches, it is said to have been spoiled.

Bufobj. A kernel object that associates a vnode (or a GEOM consumer) with a buffer cache. Each block device and each file has one.

bdev_strategy. A legacy synonym for `d_strategy`. Modern code uses `d_strategy` directly.

Schedule. The act of placing a BIO onto an internal queue for later execution. Distinct from "executing".

Plug/unplug. In some kernels, the plug is a batching mechanism for BIO submission. FreeBSD does not have plug/unplug; it delivers BIOs immediately.

Elevator. A BIO scheduler that sorts BIOs by offset to reduce disk seek time. FreeBSD's GEOM does not implement an elevator at the GEOM layer; it is the block device's responsibility, if relevant.

Superblock. The first metadata block of a filesystem. Describes geometry. At offset 65536 for UFS.

Cylinder group. A UFS concept. The filesystem is divided into regions, each with its own inode table and block allocation bitmap. Keeps related data physically close on a spinning disk and limits the damage a single bad region can cause.

Inode. A UFS (and POSIX) structure describing one file: its mode, owner, size, timestamps, and pointers to data blocks. Filenames live in directory entries, not in inodes.

Vop_vector. The dispatch table that a filesystem provides to VFS, listing all the operations VFS knows how to ask about (open, close, read, write, lookup, rename, and so on). VFS calls these as indirect function pointers.

Devstat. A kernel structure attached to devices that records aggregate I/O statistics. `iostat(8)` reads devstat data; `g_disk` allocates and feeds a devstat structure for every disk it creates.

bp. Shorthand in kernel source for a BIO pointer. Used almost universally in strategy functions and completion callbacks. When you see `struct bio *bp`, read it as “the current request”.

Bread. Buffer-cache function that reads a block, consulting the cache first and issuing I/O only on a miss. Used by filesystems, not by drivers.

Bwrite. Buffer-cache function that writes a block synchronously. The filesystem uses it; your strategy function eventually sees the resulting BIO.

Getblk. Buffer-cache function that returns a buffer for a given block, allocating it if necessary. Used by filesystems as the entry point to both reading and writing.

Bdwrite. Delayed buffer-cache write. Marks the buffer dirty but does not issue I/O immediately. Will be written later by the syncer or by buffer cache pressure.

Bawrite. Asynchronous buffer-cache write. Like `bwrite` but does not wait for completion.

Syncer. A kernel thread that periodically flushes dirty buffers to their backing devices. Closing a filesystem cleanly requires the syncer to finish.

Taskqueue. A kernel facility for running callbacks in a separate thread. Useful when your strategy function wants to defer work. Covered in more depth when we discuss interrupt handlers in later chapters.

Callout. A kernel facility for scheduling a one-shot or periodic callback at a given time. Not commonly used in simple storage drivers but very common in hardware drivers that implement timeouts.

Witness. A kernel subsystem that detects lock-order violations and prints warnings. Always enabled in debug kernels; saves hours of debugging.

INVARIANTS. A kernel compile option that adds runtime assertions. Always enabled in debug kernels; catches many storage bugs before they become silent corruption.

Debug kernel. A kernel built with `INVARIANTS`, `WITNESS`, and related options. Slower but much safer for driver development. Use one during lab work.

27.23 Frequently Asked Questions

27.23.1 Do I need to support BIO_ORDERED?

For a pseudo device that services BIOs synchronously, no. Each BIO completes before the next one is processed, which trivially preserves ordering. For an asynchronous driver, you must respect BIO_ORDERED by deferring subsequent BIOs until the ordered one completes.

27.23.2 What is the relationship between d_maxsize and MAXPHYS?

d_maxsize is the maximum BIO size your driver can accept. MAXPHYS is the compile-time upper bound on BIO size, defined in /usr/src/sys/sys/param.h. On 64-bit systems such as amd64 and arm64, MAXPHYS is 1 MiB; on 32-bit systems it is 128 KiB. FreeBSD 14.3 also exposes a runtime tunable, maxphys, which some subsystems consult through the MAXPHYS macro or the maxphys variable. Setting d_maxsize = MAXPHYS accepts whatever the kernel is willing to issue. For most pseudo drivers this is fine.

27.23.3 Can my driver issue BIOs to itself?

Technically yes, but it rarely makes sense. The pattern is used by GEOM transformation classes (they take in BIOs from above and issue new BIOs downward). A g_disk driver is at the bottom of the stack and has no downward; if you need to split work across multiple backing units, you probably want worker threads rather than nested BIOs.

27.23.4 Why do some fields in struct disk use u_int and others off_t?

u_int is used for unsigned integer sizes that fit in 32 bits (sector size, number of heads, etc.). off_t is a signed 64-bit type used for byte offsets and sizes that can exceed 32 bits (media size, request offsets). The distinction matters for large disks; a media size of 10 TB requires more than 32 bits.

27.23.5 Is disk_alloc safe to call at any time?

disk_alloc uses M_WAITOK and will sleep if memory is tight. Do not call it while holding a spin lock or a mutex you cannot release. Call it at attach time, outside any lock.

27.23.6 What happens if I call disk_create twice with the same name?

disk_create will happily create multiple disks with the same name if the unit numbers differ. If both the name and unit number match, GEOM will reject the second registration and the resulting behaviour is implementation-defined. Avoid this case.

27.23.7 Can the strategy function sleep?

Technically yes, but it should not. The strategy function runs in the caller's thread context, and sleeping there stalls the caller. For work that must block, use a worker thread.

27.23.8 How do I know when all BIOs have finished for a given filesystem?

You usually do not need to. `umount(2)` does the work: it flushes dirty buffers, drains in-flight BIOs, and returns only after the filesystem is fully quiesced. After `umount` returns, no BIOs will arrive for that mount point unless something else opens the device.

27.23.9 Can I pass pointers between threads through `bio_caller1` or similar fields?

Yes. `bio_caller1` and `bio_caller2` are opaque fields meant for the issuer of the BIO to stash context that the completion handler can use. As long as you own the BIO (which you do, because you issued it), the fields are yours. `g_disk` drivers do not usually need them because the BIO arrives from above and is completed by calling `biodone`, with `g_disk` handling the callback routing.

27.23.10 My driver works on my laptop but not on the server. Why?

Possibilities: different kernel ABI (recompile against the server's kernel), different `MAXPHYS` (should be identical on 14.3 systems but check), different GEOM classes loaded (unlikely but possible), different memory size (your allocation might fail on a smaller system), different clock speed (affecting timing). Compare `uname -a` and `sysctl -a | grep kern.maxphys` to start.

27.23.11 Where does the `/dev` node's name actually come from?

From `d_name` and `d_unit` in the struct `disk` you pass to `disk_create`. GEOM concatenates them without a separator: `d_name = "myblk", d_unit = 0` produces `/dev/myblk0`. If you want a different convention, set `d_name` accordingly. There is no separator character between the name and the unit.

27.23.12 What is the maximum number of units I can create?

Limited by `d_unit`, which is `u_int`, so $2^{32} - 1$ in theory. In practice, per-unit memory consumption and the practical limits of `/dev` name space will stop you long before that.

27.23.13 Can I change `d_mediasize` after `disk_create`?

Yes, but carefully. Filesystems mounted on the disk will not pick up the change automatically; most will require unmount and remount. `md(4)` supports `MDIOCRESIZE` and there is infrastructure for signalling the change to GEOM, but the pattern is non-trivial.

27.23.14 What happens if I forget `MODULE_DEPEND`?

The kernel may fail to load your module if `g_disk` is not already loaded, or may load it successfully if `g_disk` happens to be built into the kernel. Always declare `MODULE_DEPEND` explicitly to avoid surprise.

27.23.15 Should I use `biodone` or `g_io_deliver` in my driver?

Use `biodone`. The `g_disk` wrapper provides a `d_strategy` style interface where the correct completion call is `biodone`. If you write your own `g_class`, you will call `g_io_deliver` instead, but that is a different path and a different chapter's worth of complexity.

27.23.16 How does `BIO_DELETE` relate to TRIM and UNMAP?

`BIO_DELETE` is the in-kernel abstraction. For SATA SSDs it maps to the ATA TRIM command, for SCSI/SAS to UNMAP, and for NVMe to Dataset Management with the deallocate bit. Userland triggers it through `fstrim(8)` or the `-o trim` mount option on UFS. Our driver is free to treat it as a hint or to honour it by zeroing memory, since backing is in RAM.

27.23.17 Why does my strategy function sometimes receive a BIO with `bio_length` of zero?

In normal operation you should never see this. If it happens, treat it as a defensive case: call `biodone(bp)` with no error and return. A length-zero BIO is not illegal, but it indicates something odd upstream. Filing a PR against the issuing code is reasonable.

27.23.18 What is the difference between `d_flags` and `bio_flags`?

`d_flags` is static configuration for the whole disk, set once at registration and describing what the driver can do (handles DELETE, can FLUSH, accepts unmapped BIOs, and so on). `bio_flags` is dynamic metadata on a single BIO, changing per request (ordered, unmapped, direct completion). Do not confuse them.

27.23.19 Can my driver present itself as removable media?

Yes, set `DISKFLAG_CANDELETE` and consider honouring `disk_gone` to simulate ejection. Tools like `camcontrol` and filesystem handlers generally treat any GEOM provider uniformly, so “removable” in the user-visible sense is less distinct than in other operating systems.

27.23.20 What thread actually calls my strategy function?

It depends. For synchronous submission from the buffer cache, it is the thread that called `bwrite` or `bread`. For asynchronous completion paths it is often a GEOM worker or the buffer cache's flusher thread. Your strategy must be written to tolerate any caller. Do not assume a specific thread identity or a specific priority.

27.23.21 How do I know which process caused a given BIO?

You usually cannot, because BIOs can be reordered, coalesced, merged, and issued from background threads that are not the original requester. `dtrace` with the `io:::start` probe plus stack captures can get you close, but it is investigative work, not a routine driver responsibility.

27.23.22 Can two different filesystems be mounted simultaneously on two unit numbers of my driver?

Yes, if you implemented multi-unit support. Each unit presents its own GEOM provider. Their backing stores are independent. The only shared state is your module's global variables and the kernel itself, so the two mounts do not interact unless you make them.

27.23.23 Should my driver handle power management events?

For a pseudo device, no. For a real hardware driver, yes: suspend and resume events flow through Newbus as method calls, and the driver must quiesce I/O on suspend and revalidate device state on resume. Storage drivers on laptops are a common source of suspend-related bugs, so real drivers take this seriously.

27.23.24 What is the practical impact of choosing 512 versus 4096 as `d_sectorsize`?

On modern filesystems, very little: UFS, ZFS, and most other FreeBSD filesystems work happily with either. On the driver side, a larger sector size reduces the number of BIOs for large transfers. On the workload side, applications doing `O_DIRECT` or aligned I/O may care. When in doubt, pick 4096 for new drivers; it matches modern flash and avoids alignment penalties.

27.23.25 If I reload my driver many times, does memory leak?

Only if you have a bug. In our design, `MOD_UNLOAD` calls `myblk_detach_unit`, which frees the backing store and the softc. The persistence variant deliberately retains the backing store across reloads but uses a single global pointer, so there is no leak; the same memory is reused. If `vmstat -m | grep myblk` climbs across reloads, investigate.

27.23.26 Why does `mount` sometimes succeed on my raw device but `newfs_ufs` fail?

`newfs_ufs` writes structured metadata (superblock, cylinder groups, inode tables) and then reads some of it back to verify. If the device is too small, corrupts writes silently, or returns errors only under certain conditions, `newfs_ufs` catches it first. `mount` is much less strict at the write path; it can read in a broken superblock and produce odd errors later. A successful `newfs` is a stronger correctness signal than a successful `mount`.

27.23.27 How do I verify that my `BIO_FLUSH` implementation actually makes data durable?

For our in-memory driver, durability is bounded by the host's power: flushing does nothing useful because a power cut takes everything with it. For a real driver backed by persistent storage, issuing a flush command to the underlying media and confirming completion before calling `biodone` is the contract. Testing requires a power-cycle harness or a simulator; there is no shortcut.

27.23.28 What are the correct locking rules inside `d_strategy`?

Hold the driver's lock long enough to protect the backing store against concurrent access, and release it before calling `biodone`. Never hold a lock across a call into another subsystem. Never call `malloc(M_WAITOK)` with a lock held. Never sleep. If you need to sleep, schedule the work on a taskqueue and call `biodone` from the worker.

27.23.29 Why is `BIO_FLUSH` not a percent-of-capacity barrier like write barriers on Linux?

FreeBSD's `BIO_FLUSH` is a point-in-time barrier: when it completes, all previously issued writes are durable. It is not associated with a particular range or percentage of the device. Drivers can implement it as a strict barrier or as an opportunistic flush, but the minimum contract is the point-in-time guarantee.

27.23.30 Are there any tools that generate BIO traffic to help me test?

Yes. `dd(1)` with various `bs=` values, `fio(1)` from ports, `ioping(8)` from ports, plus the usual suspects: `newfs`, `tar`, `rsync`, `cp`. `diskinfo -t` runs a suite of benchmark reads and is useful for rough throughput numbers. The test harnesses under `/usr/src/tools/regression/` can also be adapted.

27.24 What This Chapter Did Not Cover

This chapter is long, but there are several related topics we deliberately left for later. Naming them here helps you plan future study and prevents the false impression that storage drivers end at the BIO handler.

Real hardware storage drivers such as those for SATA, SAS, and NVMe controllers live under CAM and require significant additional machinery: command-block allocation, tagged queueing, hot-plug event handling, firmware upload, SMART data, and error-recovery protocols. We introduced the CAM world briefly through the `ada_da.c` excerpt but did not explore it in depth. Chapters 33 through 36 will tackle these interfaces, and the `md(4)` driver you read in this chapter is a deliberately small staircase by comparison.

ZFS integration is its own world. ZFS consumes GEOM providers through its vdev layer but adds copy-on-write semantics, end-to-end checksums, pooled storage, and snapshots that no simple block driver would ever need to know about. If your driver works under UFS it almost certainly works under ZFS, but the reverse is not guaranteed: ZFS exercises BIO paths, especially flushing and write ordering, that less demanding filesystems skip.

GEOM class authoring is a larger topic than `g_disk` wrapping. A full class implements `taste`, `start`, `access`, `attach`, `detach`, `dumpconf`, `destroy_geom`, and `orphan` methods. It can also create and destroy consumers, build multi-level topologies, and respond to configuration via `gctl`. The mirror, stripe, and crypt classes are good starting points once you decide to dig in.

Quotas, ACLs, and extended attributes are filesystem features that live above the GEOM layer entirely. They matter for userland but do not touch the storage driver. This is a useful piece of clarity: the driver's job ends at the BIO boundary.

Tracing and debugging kernel crashes deserves its own chapter. Kernel core dumps land on a dump device configured via `dumpon(8)`, analysed with `kgdb(1)` or `crashinfo(8)`. If your driver panics the system, being able to load the core file and inspect backtraces is a professional-level skill that this chapter only gestured at.

High-performance storage paths use features such as unmapped I/O, direct-dispatch completion, CPU pinning, NUMA-aware allocation, and dedicated queues. These optimisations matter for gigabytes-per-second workloads but are irrelevant to a teaching driver. When you start chasing microseconds, come back to `/usr/src/sys/dev/nvme/` and study how the real professionals do it.

Filesystem-specific behaviour varies widely. UFS asks for one set of BIOS; ZFS asks for a different set; `msdosfs` and `ext2fs` ask for something different again. A good storage driver is filesystem-agnostic, but observing different filesystems on your driver is a fantastic way to build intuition. Try `msdosfs`, `ext2fs`, and `tmpfs` for contrast after you are comfortable with UFS.

iSCSI and network block devices present themselves as GEOM providers too, but they are created by userland control daemons and talk to the network stack. Chapter 28 begins the networking work that makes those providers possible.

Our treatment of the storage path was deliberately focused. We wrote a driver that filesystems accept as real, we understood why and how it is seen that way, and we traced the data path from `write(2)` to RAM. That foundation is enough to make the unexplored topics above readable rather than bewildering.

27.25 Final Reflection

Storage drivers have a reputation as forbidding territory. This chapter should have replaced some of that reputation with familiarity: the BIO is just a structure, the strategy function is just a dispatcher, GEOM is just a graph, and `disk_create` is just a registration call. What elevates storage work from routine is not the underlying APIs, which are compact, but the operational demands that accumulate around them: performance, durability, error recovery, and correctness under contention.

Those demands do not go away when you leave pseudo devices for real hardware. They multiply. But you already have the vocabulary to understand them. You know what a BIO is and where it comes from. You know which thread calls your code and what it expects. You know how to register with GEOM, how to unregister cleanly, and how to recognise an in-flight request from its shadow in `gstat`. When you sit in front of a real SATA controller driver and start reading, you will recognise the shape of the code even though the specifics differ.

The craft of storage-driver writing is, ultimately, patient. You learn by writing small drivers, reading the source tree, reproducing simple experiments, and building instincts about when something that looks right is actually right. The chapter you just finished is a single long step along that journey. The next chapters will step again, each time in different directions.

27.26 Further Reading

If this chapter has whetted your appetite for storage internals, here are some places to go next.

Manual pages. `disk(9)`, `g_bio(9)`, `geom(4)`, `devfs(5)`, `ufs(5)`, `newfs(8)`, `mdconfig(8)`, `gstat(8)`, `diskinfo(8)`, `mount(2)`, `mount(8)`. Read them in that order.

The FreeBSD Architecture Handbook. The storage chapter is a good complement to this one.

Kirk McKusick et al., “The Design and Implementation of the FreeBSD Operating System”. The book’s chapters on the filesystem are especially relevant.

DTrace books. Brendan Gregg’s “DTrace Book” is a practical reference; Sun’s “Dynamic Tracing Guide” is the original tutorial.

The FreeBSD source tree. `/usr/src/sys/geom/`, `/usr/src/sys/dev/md/`, `/usr/src/sys/ufs/`, and `/usr/src/sys/cam/ata/` (where `ata_da.c` implements the ada disk driver). Every pattern discussed in this chapter is grounded in that code.

The mailing list archives. `freebsd-geom@` and `freebsd-fs@` are the two most relevant lists. Reading historic threads is one of the best ways to pick up the institutional knowledge that books do not capture.

Commit history on GitHub mirrors. The FreeBSD source tree has a long, well-annotated commit history. For any file you open, running `git log --follow` against its mirror will often reveal the rationale behind design choices, the bugs that shaped the current code, and the people who maintain it. Historical context makes the present code much easier to read.

The Transactions of the FreeBSD Developer Summit. Several summits have included storage-focused sessions. Recordings and slides, when available, are excellent for picking up the state of the art and the open design debates.

Reading other operating systems’ storage stacks. Once you know FreeBSD’s storage path, Linux’s block layer, Illumos’s SD framework, and macOS’s IOKit storage classes all become comprehensible in a way they probably were not before. The specific APIs differ, but the fundamental shapes, BIOS or their equivalents, filesystems above, hardware below, are universal.

Testing frameworks for kernel code. The `kyua(1)` harness runs regression tests against real kernels. The `/usr/tests/sys/geom/` tree has examples of what well-written tests for storage code look like; reading them builds both testing instincts and confidence that your code is right.

FreeBSD Foundation blog posts. The Foundation funds several storage-related projects and publishes readable summaries that complement the source tree.

End of Chapter 27. Close your lab logbook, make sure your driver is unloaded and your mount points are released, and take a break before Chapter 28.

You have just written a storage driver, mounted a filesystem on it, traced data through the buffer cache, into GEOM, through your strategy function, and back again. That is a real accomplishment. Rest on it for a moment before you turn the page.

28 Writing a Network Driver

28.1 Introduction

In the previous chapter you built a storage driver. A filesystem sat on top of it, a buffer cache fed it BIO requests, and your code delivered blocks of data to a piece of RAM and back. That was already a step away from the character-device world of earlier chapters, because a storage driver is not polled by a single process holding a file descriptor. It is driven by many layers above it, all cooperating to turn `write(2)` calls into durable blocks, and your driver had to sit quietly at the bottom of that chain and honour each request in turn.

A network driver is a third kind of animal. It is not a stream of bytes to one process, like a character device. It is not a block-addressable surface for a filesystem to mount, like a storage device. It is an **interface**. It sits between the machine's network stack on one side and a medium, real or simulated, on the other side. Packets arrive on that medium and the driver turns them into mbufs and hands them up to the stack. Packets leave the stack in the form of mbufs and the driver turns them into bits on the wire, or into whatever stand-in for a wire you have chosen to use. Link state changes, and the driver reports that. Media speed changes, and the driver reports that too. The user types `ifconfig mynet0 up`, and the kernel routes that request through `if_ioctl` into your code. The kernel is expecting a particular shape of cooperation, not a particular sequence of reads and writes.

This chapter teaches you that shape. You will learn what FreeBSD expects a network driver to be. You will learn the core object that represents an interface in the kernel, the struct called `ifnet`, along with the modern `if_t` opaque handle that wraps it. You will learn how to allocate an `ifnet`, how to register it with the stack, how to expose it as a named interface that `ifconfig` can see. You will learn how packets enter your driver through the transmit callback and how you push packets the other way into the stack through `if_input`. You will learn how mbufs carry those packets, how link state and media state are reported, how flags like `IFF_UP` and `IFF_DRV_RUNNING` are used, and how a driver detaches cleanly when it is unloaded. You will finish the chapter with a working pseudo-Ethernet driver called `mynet` that you can load, configure, exercise with `ping`, `tcpdump`, and `netstat`, and then unload without leaving anything behind.

The driver you will build is small on purpose. Real Ethernet drivers in modern FreeBSD are usually written against `iflib(9)`, the shared framework that takes care of ring buffers, interrupt moderation, and packet-steering for most production NICs. That machinery is wonderful when you are shipping a driver for a 100-gigabit card, and we will return to it in later chapters. But it is too much scaffolding to hide the core ideas behind. To teach you what a network driver really is, we will write the classical, pre-`iflib` form: a plain `ifnet` driver with its own transmit function and its own receive path. Once you understand that clearly, `iflib` will feel like a layer of convenience on top of something you already know.

Like Chapter 27, this chapter is long because the topic is layered. Unlike `/dev` drivers, network drivers are wrapped in a vocabulary of their own: Ethernet frames, interface cloners, link state, media descriptors, `if_transmit`, `if_input`, `bpfattach`, `ether_ifattach`. We will introduce that vocabulary carefully, one concept at a time, and we will ground every concept in code from the real FreeBSD tree. You will see where

`epair(4)`, `disc(4)`, and the UFS stack loan patterns that we can adapt for our own driver. By the end you will recognise the shape of a network driver in any FreeBSD source file you open.

The goal is not a production NIC driver. The goal is to give you a complete, honest, correct understanding of the layer between a piece of hardware and the FreeBSD network stack, built up through prose, code, and practice. Once that mental model is solid, reading `if_em.c`, `if_bge.c`, or `if_ixl.c` becomes a matter of recognising patterns and looking up the unfamiliar parts. Without that mental model, they look like a storm of macros and bit operations. With it, they look like one more driver that does the same things your `mynet` driver does, only with hardware underneath.

Take your time. Open a FreeBSD shell while you read. Keep a lab logbook. Think of the network stack not as a black box above your code, but as a peer that expects a clear, contractual handshake with the driver. Your job is to fulfil that contract cleanly.

28.2 Reader Guidance: How to Use This Chapter

This chapter continues the pattern established in Chapter 27: long, cumulative, deliberately paced. The topic is new and the vocabulary is new, so we will move a little more carefully than usual through the opening sections before we let you type code.

If you choose the **reading-only path**, plan for around two to three focused hours. You will come away with a clear mental model of what a network driver is, how it fits into FreeBSD's network stack, and what the code in real drivers is doing. This is a legitimate way to use the chapter on a first pass, and it is often the right choice on a day when you do not have time to rebuild a kernel module.

If you choose the **reading-plus-labs path**, plan for about five to eight hours spread across one or two evenings. You will write, build, and load a working pseudo-Ethernet driver, bring it up with `ifconfig`, watch its counters move, feed packets into it from `ping`, look at them with `tcpdump`, and then shut everything down and unload the module cleanly. The labs are designed to be safe on any recent FreeBSD 14.3 system, including a virtual machine.

If you choose the **reading-plus-labs-plus-challenges path**, plan for a weekend or a handful of evenings. The challenges extend the driver in directions that matter in practice: adding a real simulated link partner with a shared queue between two interfaces, supporting different link states, exposing a `sysctl` to inject errors, and measuring the behaviour under `iperf3`. Each challenge is self-contained and uses only what the chapter has already covered.

Regardless of the path you choose, do not skip the troubleshooting section near the end. Network drivers fail in a handful of characteristic ways, and learning to recognise those patterns is more valuable in the long run than memorising the names of every function in `ifnet`. The troubleshooting material is placed late for readability, but you may find yourself returning to it while running the labs.

A word on prerequisites. You should be comfortable with everything from Chapter 26 and Chapter 27: writing a kernel module, allocating and freeing a softc, reasoning about the load and unload path, and testing your work under `kldload` and `kldunload`. You should also be comfortable enough with FreeBSD's userland to run `ifconfig`, `netstat -in`, `tcpdump`, and `ping` without stopping to check the flags. If any of that feels uncertain, a quick skim of the corresponding earlier chapters will save you time later.

You should work on a throwaway FreeBSD 14.3 machine. A dedicated virtual machine is the best option, because network drivers, by their nature, can interact with the host system's routing tables and interface list. A small lab VM lets you experiment without worrying that you are going to confuse your main system. A snapshot before you begin is cheap insurance.

28.2.1 Work Section by Section

The chapter is organised as a progression. Section 1 explains what a network driver does and how it differs from the character and storage drivers you have already written. Section 2 introduces the `ifnet` object, the central data structure of the entire networking subsystem. Section 3 walks through allocation, naming, and registration of an interface, including interface cloners. Section 4 handles the transmit path, from `if_transmit` through mbuf processing. Section 5 handles the receive path, including `if_input` and simulated packet generation. Section 6 covers media descriptors, interface flags, and link-state notifications. Section 7 shows you how to test the driver with FreeBSD's standard networking tools. Section 8 closes with clean detach, module unload, and refactoring advice.

You are meant to read these sections in order. Each one assumes the previous ones are fresh in your mind, and the labs build on each other. If you jump in the middle, pieces will look strange.

28.2.2 Type the Code

Typing remains the most effective way to internalise kernel idioms. The companion files under `examples/part-06/ch28-network-driver/` exist so that you can check your work, not so that you can skip the typing. Reading code is not the same as writing it, and reading a network driver is particularly easy to do passively because the code often looks like a long switch statement. Writing it forces you to think about each branch.

28.2.3 Open the FreeBSD Source Tree

You will be asked several times to open real FreeBSD source files, not only the companion examples. The files of interest for this chapter include `/usr/src/sys/net/if.h`, `/usr/src/sys/net/if_var.h`, `/usr/src/sys/net/if_disc.c`, `/usr/src/sys/net/if_epair.c`, `/usr/src/sys/net/if_ethersubr.c`, `/usr/src/sys/net/if_clone.c`, `/usr/src/sys/net/if_media.h`, and `/usr/src/sys/sys/mbuf.h`. Each of these is a primary reference, and the prose in this chapter refers back to them repeatedly. If you have not already cloned or installed the 14.3 source tree, now is a good moment to do so.

28.2.4 Use Your Lab Logbook

Keep the logbook you started in Chapter 26 open while you work. You will want to record the `ifconfig` output before and after you load the module, the exact commands you use to send traffic, the counters reported by `netstat -in`, the output of `tcpdump -i mynet0`, and any warnings or panics. Network work is particularly friendly to logbooks because the same command, `ifconfig mynet0`, produces different output at different points in the load-configure-use-unload cycle, and seeing those differences in your own notes makes the concepts stick.

28.2.5 Pace Yourself

If your understanding blurs during a particular section, stop. Re-read the previous subsection. Try a small experiment, for example `ifconfig lo0` or `netstat -in` to see a real interface, and think about how it corresponds to what the chapter is teaching. Network programming in the kernel rewards slow, deliberate exposure. Skimming the chapter for terms to recognise later is much less useful than reading one section well, doing one lab, and moving on.

28.3 How to Get the Most Out of This Chapter

The chapter is structured so that every section adds exactly one new concept on top of what came before. To make the most of that structure, treat the chapter as a workshop rather than as a reference. You are not here to find a quick answer. You are here to build a correct mental model of what an interface is, how a driver talks to the kernel, and how the network stack talks back.

28.3.1 Work in Sections

Do not read the whole chapter end to end without stopping. Read one section, then pause. Try the experiment or lab that goes with it. Look at the related FreeBSD source. Write a few lines in your logbook. Only then move on. Networking in the kernel is strongly cumulative, and skipping ahead usually means that you will be confused about the next thing for a reason that was explained two sections ago.

28.3.2 Keep the Driver Running

Once you have loaded the driver in Section 3, keep it loaded as much as possible while you read. Modify it, reload, poke it with `ifconfig`, feed it packets with `ping`, watch them with `tcpdump`. Having a live, observable example is far more valuable than any amount of reading, especially for network code, because the feedback loop is fast: the kernel either accepts your configuration or refuses it, and the counters either move or they do not.

28.3.3 Consult Manual Pages

FreeBSD's manual pages are part of the teaching material, not a separate formality. Section 9 of the manual is where the kernel interfaces live. We will refer in this chapter to pages such as `ifnet(9)`, `mbuf(9)`, `ifmedia(9)`, `ether(9)`, and `ng_ether(4)`, and to userland pages such as `ifconfig(8)`, `netstat(1)`, `tcpdump(1)`, `ping(8)`, and `ngctl(8)`. Read them alongside this chapter. They are shorter than they look, and they are written by the same community that wrote the kernel you are learning about.

28.3.4 Type the Code, Then Mutate It

When you build the driver from the companion examples, type it first. Once it works, start changing things. Rename a method and watch the build fail. Remove an `if` branch in the transmit function and watch what happens under `ping`. Hardcode a smaller MTU and watch `ifconfig` react. Kernel code becomes understandable

through deliberate mutation far more than through pure reading, and network code is particularly well-suited to mutation because every change produces an immediately visible effect in `ifconfig` or `netstat`.

28.3.5 Trust the Tooling

FreeBSD gives you a wealth of tools for inspecting the network stack: `ifconfig`, `netstat`, `tcpdump`, `ngctl`, `sysctl net.`, `arp`, `ndp`. Use them. When something goes wrong, the first move is almost never to read more source. It is to ask the system what state it is in. A minute with `ifconfig mynet0` and `netstat -in` is often more informative than five minutes of `grep`.

28.3.6 Take Breaks

Network code is full of small, precise steps. A missed flag or an unset callback will produce behaviour that looks mysterious until you stop, breathe, and trace the data flow again. Two or three focused hours are usually more productive than a seven-hour sprint. If you catch yourself making the same typo three times, or copy-pasting without reading, that is your cue to stand up for ten minutes.

With those habits in place, let us begin.

28.4 Section 1: What a Network Driver Does

A network driver has one job that sounds simple and turns out to be layered: it moves packets between a transport and the FreeBSD network stack. Everything else follows from that. To understand what that sentence really means, we need to slow down and examine each of its pieces. What is a packet? What is a transport? What exactly is “the stack”? And how does a driver sit between them without becoming a bottleneck or a source of subtle bugs?

28.4.1 A Packet, in the Kernel

In userland you rarely deal with raw packets. You open a socket, call `send` or `recv`, and the kernel takes care of encapsulating your payload in TCP, wrapping that in IP, adding an Ethernet header, and finally handing the whole construct to a driver. In the kernel, the same packet is represented by a linked list of structures called **mbufs**. An mbuf is a small memory cell, typically 256 bytes, that holds packet data and a small header. If the packet is larger than a single mbuf can hold, the kernel chains multiple mbufs together through a `m_next` pointer, and the total length of the payload is recorded in `m->m_pkthdr.len`. If the packet does not fit in a single mbuf cluster, the kernel uses external buffers referenced by the mbuf, through a mechanism we will revisit in later chapters.

From the driver’s perspective, a packet is almost always presented as an mbuf chain, and the first mbuf carries the packet header. That first mbuf has `M_PKTHDR` set in its flags, which tells you that `m->m_pkthdr` contains valid fields such as the total packet length, the VLAN tag, checksum flags, and the receive interface. Every driver that handles transmitted packets begins by inspecting the mbuf it has been handed, and every driver that delivers received packets begins by building a correctly shaped mbuf.

We will cover mbuf construction and teardown in more detail in Sections 4 and 5. For now, the vocabulary is what matters. A mbuf is a packet. A mbuf chain is a packet whose payload spans several mbufs. The first mbuf in a chain carries the packet header. The rest of the chain continues the payload, and each mbuf points to the next through `m_next`.

28.4.2 A Transport

The transport is whatever the driver talks to on the hardware side. For a physical Ethernet NIC it is the actual wire, reached through a combination of DMA buffers, hardware rings, and interrupts from the chip. For a USB Ethernet adapter it is the USB endpoint pipeline we introduced in Chapter 26. For a wireless card it is the radio. For a pseudo-device, and that is what we will build in this chapter, the transport is simulated: we will pretend that a packet we transmit shows up on some other virtual wire, and we will pretend that incoming packets arrive from it at regular intervals driven by a timer.

The beauty of the `ifnet` abstraction is that the network stack does not care which of these transports you have. The stack sees an interface. It gives the interface mbufs to transmit. It expects the interface to hand it mbufs that were received. Whether the packets actually travel across Category 6 cable, radio waves, a USB bus, or a piece of memory we control, the surface is the same. That uniformity is what lets FreeBSD support dozens of network devices without rewriting its network code for each one.

28.4.3 The Network Stack

“The stack” is a shorthand for the collection of code that sits above the driver and implements the protocols. Layer by layer, from the lowest to the highest: Ethernet framing, ARP and neighbour discovery, IPv4 and IPv6, TCP and UDP, socket buffers, and the system call layer that translates `send` and `recv` into stack operations. In FreeBSD, the code lives in `/usr/src/sys/net/`, `/usr/src/sys/netinet/`, `/usr/src/sys/netinet6/`, and related directories, and it communicates with drivers through a small, well-defined set of function pointers carried on every `ifnet`.

For this chapter, you do not need to know the inside of the stack. You need to know its outer interface as seen by a driver. That interface is:

- The stack calls your transmit function, `if_transmit`, and hands you a mbuf. Your job is to turn that mbuf into something the transport will accept.
- The stack calls your ioctl handler, `if_ioctl`, in response to commands from userland such as `ifconfig mynet0 up` or `ifconfig mynet0 mtu 1400`. Your job is to honour the request or return a reasonable error.
- The stack calls your init function, `if_init`, when the interface transitions to an up state. Your job is to prepare the transport for use.
- You call `ifp->if_input(ifp, m)` or, in the modern idiom, `if_input(ifp, m)`, to hand a received packet to the stack. Your job is to ensure the mbuf is well-formed and the packet is complete.

That is the contract. The rest is detail.

28.4.4 How a Network Driver Differs From a Character Driver

You already built character drivers in Chapters 14 and 18. A character driver sits inside `/dev/`, it is opened by userland through `open(2)`, and it exchanges bytes with one or more processes through `read(2)` and `write(2)`. It has a `cdevsw` table. It is polled and pushed by whoever opens it.

A network driver is none of those things. It does not live in `/dev/`. It is not `open(2)`ed by a process. There is no `cdevsw`. The closest thing to a user-visible file handle for a network interface is the socket that is bound to it, and even that is mediated by the stack, not by the driver.

Instead of a `cdevsw`, a network driver has a `struct ifnet`. Instead of `d_read`, it has `if_input`, but on the other end: the driver calls it, rather than having it called by userland. Instead of `d_write`, it has `if_transmit`, called by the stack. Instead of `d_ioctl`, it has `if_ioctl`, called by the stack in response to `ifconfig` and related tools. The top-level structure looks similar, but the relationships between actors are different. In a character driver you wait for reads and writes from userland. In a network driver you are embedded in a pipeline where the stack is your main collaborator, and userland is a spectator rather than a direct peer.

This shift in perspective is worth internalising before you write any code. When something goes wrong in a character driver, the question is usually “what did userland do?” When something goes wrong in a network driver, the question is usually “what did the stack expect my driver to do, and how did I fail to do it?”

28.4.5 How a Network Driver Differs From a Storage Driver

A storage driver, as you saw in Chapter 27, is also not a `/dev/` endpoint in the usual sense. It does expose a block device node, but access to it is almost always mediated by a filesystem sitting on top. Requests come down as BIOs, the driver handles them, and completion is signalled by `biodone(bp)`.

A network driver shares the “I sit below a subsystem, not next to userland” shape of a storage driver, but the subsystem above it is very different. The storage subsystem is deeply synchronous at the BIO level, in the sense that every request has a well-defined completion event. Network traffic is not like that. A driver transmits a packet, but there is no per-packet completion callback bubbling up from the driver to any specific requester. The stack trusts the driver to succeed or fail cleanly, increments counters, and moves on. Likewise, received packets are not replies to specific earlier transmissions: they just arrive, and the driver must funnel them into `if_input` whenever they show up.

Another difference is concurrency. A storage driver usually has a single BIO path and handles each BIO in turn. A network driver is frequently called from multiple CPU contexts at once, because the stack serves many sockets in parallel, and modern hardware delivers receive events on multiple queues. We will not cover that complexity in this chapter, but you should already be aware that locking conventions for network drivers are strict. The `mynet` driver we will build is small enough that a single mutex suffices, but even then the discipline around when to take it, and when to drop it before calling up, matters.

28.4.6 The Role of `ifconfig`, `netstat`, and `tcpdump`

Every FreeBSD user knows `ifconfig`. From the network driver author’s perspective, `ifconfig` is the primary way the kernel expects user commands to reach your driver. When the user runs `ifconfig mynet0 up`, the kernel translates that into a `SIOCSIFFLAGS` ioctl on the interface whose name is `mynet0`. The call arrives in

your `if_ioctl` callback, and you decide what to do with it. The symmetry between the userland command and the kernel-side callback is almost one-to-one.

`netstat -in` asks the kernel for the interface statistics carried on every `ifnet`. Your driver updates those counters by calling `if_inc_counter(ifp, IFCOUNTER_*, n)` at the appropriate moments in the transmit and receive paths. The set of counters is defined in `/usr/src/sys/net/if.h` and includes `IFCOUNTER_IPACKETS`, `IFCOUNTER_OPACKETS`, `IFCOUNTER_IBYTES`, `IFCOUNTER_OBYTES`, `IFCOUNTER_IERRORS`, `IFCOUNTER_OERRORS`, `IFCOUNTER_IMCASTS`, `IFCOUNTER_OMCASTS`, and `IFCOUNTER_OQDROPS`, among others. These counters are what users see in `netstat` and `systat`.

`tcpdump` relies on a separate subsystem called the Berkeley Packet Filter, or BPF. Every interface that wants to be visible to `tcpdump` must register with BPF through `bpfattach()`, and every packet that the driver transmits or receives must be presented to BPF through `BPF_MTAP()` or `bpf_mtap2()` before being either sent out or handed up. We will do this in our driver. It is one of the small courtesies you pay to the rest of the system so that the tools work.

28.4.7 A Useful Picture

It is worth closing the section with a diagram. The picture below shows how the pieces we have described fit together. Do not memorise it yet. Just get used to the shape. We will come back to every box in later sections.

The boxes above the driver are the stack and userland. The box below is the transport. Your driver, on that middle line, is the only place in the system where a `struct ifnet` meets a `struct mbuf` meets a wire. That is your territory.

28.4.8 Tracing a Packet Through the Stack

It is useful to follow one specific packet from birth to death, because that fixes the relationships in the diagram above to real code. Let us trace an outbound ICMP echo request generated by `ping 192.0.2.99` on an interface named `mynet0` that has been assigned the address `192.0.2.1/24`.

The `ping(8)` program opens a raw ICMP socket and writes an echo request payload through `sendto(2)`. Inside the kernel, the socket layer in `/usr/src/sys/kern/uipc_socket.c` copies the payload into a fresh `mbuf` chain. The socket is unconnected, so each write carries a destination address that the socket layer forwards to the protocol layer. The protocol layer, in `/usr/src/sys/netinet/raw_ip.c`, attaches an IP header and calls `ip_output` in `/usr/src/sys/netinet/ip_output.c`. `ip_output` performs the route lookup and finds a routing entry that points at `mynet0`. It also notices that the destination is not the broadcast address and not an on-link neighbour whose MAC it already knows, so it must trigger ARP.

At this point the IP layer calls `ether_output`, defined in `/usr/src/sys/net/if_etherubr.c`. `ether_output` notices that the next-hop address is unresolved and issues an ARP request first. The ARP machinery, in `/usr/src/sys/netinet/if_ether.c`, constructs a broadcast ARP frame, wraps it in a new `mbuf`, and calls `ether_output_frame`, which in turn calls `ifp->if_transmit`. That is our `mynet_transmit` function. The `mbuf` we receive in the transmit callback already contains a complete Ethernet frame: destination MAC `ff:ff:ff:ff:ff:ff`, source MAC our fabricated address, EtherType `0x0806` (ARP), and the ARP payload.

We do what every driver does at that point: validate, count, tap BPF, and release. Because we are a pseudo-driver, we free the frame rather than handing it to hardware. In a real NIC driver we would hand the `mbuf` to DMA and free it later when the completion interrupt fires. Either way, the `mbuf` has reached the end of its life from the driver's perspective.

While the ARP request hangs unanswered, the stack queues the original ICMP payload in the ARP pending queue. When the ARP reply does not arrive within a configurable timeout, the stack gives up on that packet and increments `IFCOUNTER_OQDROPS`. In our pseudo-driver, of course, no reply will ever come because there is nothing on the other end of the simulated wire. That is why `ping` eventually prints “100.0% packet loss” and exits without success. The absence of a reply is not a bug in our driver; it is a property of the transport we have chosen to simulate.

Now trace the reverse path. The synthetic ARP request we generate every second in `mynet_rx_timer` starts life as memory we allocate with `MGETHDR` inside our driver. We fill in the Ethernet header, the ARP header, and the ARP payload. We tap BPF. We call `if_input`, which dereferences `ifp->if_input` and lands in `ether_input`. `ether_input` looks at the `EtherType` and dispatches the payload to `arpintr` (or its modern equivalent, a direct call from within `ether_demux`). The ARP code inspects the sender and target IPs, notices that the target is not us, and silently drops the frame. Done.

In both directions the driver is a brief pass-through: a mbuf arrives, a mbuf departs, counters move, and BPF sees everything in between. That simplicity is deceptive, because every step has a contract that must not be broken, but the pattern is genuinely this short.

28.4.9 The Queue Disciplines Above You

You do not see them from the driver, but the stack has queue disciplines that govern how packets are delivered to `if_transmit`. Historically, drivers had an `if_start` callback and the stack would place packets on an internal queue (`if_snd`) for later dispatch. Modern drivers use `if_transmit` and receive the mbuf directly, letting the driver or the `drbr(9)` helper library manage any per-CPU queues internally.

In practice, almost all modern drivers use `if_transmit` and let the stack hand them packets one at a time. Because `if_transmit` is called on the thread that produced the packet (typically a TCP retransmit timer or the thread that wrote to the socket), the transmit path is usually on a regular kernel thread with preemption enabled. This matters because it means you generally cannot assume that `transmit` runs at elevated priority, and you must not hold a mutex across a long operation.

A small number of drivers still use the classic `if_start` model, where the stack fills a queue and calls `if_start` to drain it. That model is simpler for drivers with simple hardware queueing, but less flexible under load. `epair(4)` uses `if_transmit` directly. `disc(4)` implements its own tiny discoutput that is called from `ether_output`'s pre-transmit path. Most real NIC drivers use `if_transmit` with internal per-CPU queues powered by `drbr`.

For `mynet`, we use `if_transmit` and no internal queue. This is the simplest possible design and it matches what a minimal real driver would do for low-bandwidth links.

28.4.10 A Note on Packet-Tap Visibility

Packet taps, discussed in the next few sections, are one of the key reasons a network driver feels different from a character driver. A character driver's traffic is invisible to external observers, because there is no analogue of `tcpdump` for arbitrary `/dev/` traffic. A network driver's traffic, by contrast, is observable at multiple levels simultaneously: BPF captures at the driver level, `pflog` at the packet-filter level, interface counters at the kernel level, and socket buffers at the userland level. All of that observability is free for the driver author, provided the driver taps BPF and updates counters at the correct points.

This unusual level of external visibility is a blessing for debugging. When you cannot tell why a packet did or did not flow, you can almost always answer the question with a combination of `tcpdump`, `netstat`, `arp`, and `route monitor`. That is a capable toolset, and we will put it to work throughout the labs.

28.4.11 Wrapping Up Section 1

We have set the scene. A network driver moves mbufs between the stack and a transport. It presents a standardised interface called `ifnet`. It is driven by calls from the stack into fixed callbacks. It pushes received traffic up through `if_input`. It is visible to `ifconfig`, to `netstat`, and to `tcpdump` through a handful of kernel conventions.

With that rough shape in mind, we can look at the `ifnet` object itself. That is the subject of Section 2.

28.5 Section 2: Introducing `ifnet`

Every network interface on a running FreeBSD system is represented in the kernel by a `struct ifnet`. That structure is the central object of the networking subsystem. When `ifconfig` lists interfaces, it is essentially iterating over a list of `ifnet` objects. When the stack picks a route, it eventually lands on an `ifnet` and calls its transmit function. When a driver reports link state, it updates fields inside an `ifnet`. Learning `ifnet` is not optional. Everything else in this chapter is built on it.

28.5.1 Where `ifnet` Lives

The declaration of `struct ifnet` is in `/usr/src/sys/net/if_var.h`. Over the years FreeBSD has moved toward treating it as opaque, and the recommended way to refer to it in new driver code is through the typedef `if_t`, which is a pointer to the underlying structure:

```
typedef struct ifnet *if_t;
```

Old driver code reaches directly into `ifp->if_softc`, `ifp->if_flags`, `ifp->if_mtu`, and similar fields. New driver code prefers accessor functions such as `if_setsoftc(ifp, sc)`, `if_getflags(ifp)`, `if_setflags(ifp, flags)`, and `if_setmtu(ifp, mtu)`. Both styles still exist in the tree, and existing drivers such as `/usr/src/sys/net/if_disc.c` still use direct field access. The opaque style is the direction the kernel is moving, but you will see both for years to come.

Throughout this chapter we will use whatever is clearest in the given context. When the direct-field style makes the code smaller and easier to read, we will use it. When an accessor makes the intent clearer, we will use that. You should be able to read either form.

28.5.2 The Minimum Fields You Care About

A `struct ifnet` has dozens of fields. The good news is that a driver only touches a handful of them directly. The fields you will set or inspect in the driver we build are, broadly:

- **Identity.** `if_softc` points back at your driver's private structure, `if_xname` is the interface name (for example `mynet0`), `if_dname` is the family name ("`mynet`"), and `if_dunit` is the unit number.
- **Capabilities and counts.** `if_mtu` is the maximum transmission unit, `if_baudrate` is a reported line rate in bits per second, `if_capabilities` and `if_capenable` describe offload capabilities like VLAN tagging and checksum offload.

- **Flags.** `if_flags` holds the interface-level flags set by userland: `IFF_UP`, `IFF_BROADCAST`, `IFF_SIMPLEX`, `IFF_MULTICAST`, `IFF_POINTOPOINT`, `IFF_LOOPBACK`. `if_drv_flags` holds driver-private flags; the most important is `IFF_DRV_RUNNING`, which means the driver has allocated its per-interface resources and is ready to move traffic.
- **Callbacks.** `if_init`, `if_ioctl`, `if_transmit`, `if_qflush`, and `if_input` are the function pointers the stack invokes. Some of these have long-standing direct fields; the accessor equivalents are `if_setinitfn`, `if_setioctlnfn`, `if_settransmitfn`, `if_setqflushfn`, and `if_setinputfn`.
- **Statistics.** The per-counter accessors `if_inc_counter(ifp, IFCOUNTER_*, n)` increment the counters that `netstat -in` displays.
- **BPF hook.** `if_bpf` is an opaque pointer used by BPF. Your driver does not normally read it directly, but when you call `bpfattach(ifp, ...)` and `BPF_MTAP(ifp, m)`, the system will manage it.
- **Media and link state.** `ifmedia` lives in your `softc`, not in the `ifnet`, but the interface reports link state by calling `if_link_state_change(ifp, LINK_STATE_*)`.

If the list looks long, remember that most drivers set each field once and then leave it alone. The work of a driver is in the callbacks, not in the `ifnet` fields themselves.

28.5.3 The `ifnet` Life Cycle

A struct `ifnet` goes through the same high-level stages as a `device_t` or a `softc`: allocation, configuration, registration, active life, and teardown. The call graph is:

```

if_alloc(type)          -> returns a fresh ifnet, not yet attached
|
| configure fields
|  if_initname()         set the name
|  if_setsoftc()         point at your softc
|  if_setinitfn()        set if_init callback
|  if_setioctlnfn()      set if_ioctl
|  if_settransmitfn()    set if_transmit
|  if_setqflushfn()      set if_qflush
|  if_setflagbits()      set IFF_BROADCAST, etc.
|  if_setmtu()           set MTU
v
if_attach(ifp)           OR ether_ifattach(ifp, mac)
|
| live interface
|  if_transmit called by stack
|  if_ioctl called by stack
|  driver calls if_input to deliver received packets
|  driver calls if_link_state_change on link events
v
ether_ifdetach(ifp)      OR if_detach(ifp)
|
| finish teardown

```

```
v
if_free(ifp)
```

There are two common variants of the attach and detach calls. A plain pseudo-interface that does not need Ethernet wiring uses `if_attach` and `if_detach`. A pseudo or real Ethernet interface uses `ether_ifattach` and `ether_ifdetach` instead. The Ethernet variants wrap the plain ones and add the extra setup needed for a layer-2 Ethernet interface, including `bpfattach`, address registration, and wiring up `ifp->if_input` and `ifp->if_output` to `ether_input` and `ether_output`. We will use the Ethernet variant in our driver because it gives us a familiar MAC-addressed interface that `ifconfig`, `ping`, and `tcpdump` all understand without special treatment.

If you open `/usr/src/sys/net/if_etherubr.c` and look at `ether_ifattach`, you will see precisely this logic: set `if_addr_len` to `ETHER_ADDR_LEN`, set `if_hdr_len` to `ETHER_HDR_LEN`, set `if_mtu` to `ETHERMTU`, call `if_attach`, then install the common Ethernet input and output routines and finally call `bpfattach`. It is worth reading that function in full. It is short and it shows you exactly what a driver gets for free by using `ether_ifattach` instead of the bare `if_attach`.

28.5.4 Why ifnet Is Not a cdevsw

It is tempting to see `ifnet` as just “a `cdevsw` for networking”. It is not. A `cdevsw` is an entry table used by `devfs` to dispatch `read`, `write`, `ioctl`, `open`, and `close` from userland to a driver. An `ifnet` is the first-class object the network stack itself maintains for every interface. Even if no userland process has ever touched the interface, the stack still cares about its `ifnet`, because routing tables, ARP, and packet forwarding all depend on it.

You can see this if you think about how `ifconfig` talks to the kernel. It does not open `/dev/mynet0`. It opens a socket and issues `ioctls` on that socket, passing the interface name as an argument. The kernel then looks up the `ifnet` by name and invokes `if_ioctl` on it. There is no file descriptor pointing at your interface on the userland side. The interface is a stack-level entity, not a `/dev/` entity.

That is why we need a whole new object: because networking requires a persistent, kernel-internal handle that exists regardless of which process is doing what. `ifnet` is that handle.

28.5.5 Pseudo-Interfaces vs Real NIC Interfaces

Every interface in the kernel, pseudo or real, has an `ifnet`. The loopback interface `lo0` has one. The `disc` interface we will study has one. Every `emX` Ethernet adapter has one. Every `wlanX` wireless interface has one. The `ifnet` is the universal currency.

Pseudo-interfaces differ from real NICs in how they are instantiated. A real NIC interface is created by the driver’s attach method during bus probe, the same way the USB and PCI drivers in Chapter 26 attach their devices. A pseudo-interface is created at module load time, or on demand through `ifconfig mynet0 create`, via a mechanism called the **interface cloner**. We will use an interface cloner for `mynet`, which means users will be able to create interfaces dynamically, just as they can create `epair` interfaces today:

```
# ifconfig mynet create
mynet0
# ifconfig mynet0 up
# ifconfig mynet0
mynet0: flags=8843<UP,BROADCAST,RUNNING,SIMPLEX,MULTICAST> metric 0 mtu 1500
```

We will describe cloners in Section 3. For now, it is enough to know that cloning is how a module contributes one or more `ifnet` objects to the running system at the user's request.

28.5.6 A Closer Look at Key `ifnet` Fields

Because the `ifnet` is the structure your driver writes to most often, it helps to survey a few of its fields in slightly more depth before we open the code. You do not need to memorise the complete declaration. What you need is enough familiarity with the layout to read driver code without constantly flipping back to `if_var.h`.

`if_xname` is a character array holding the interface's user-visible name, such as `mynet0`. It is set by `if_initname` and from that moment is treated by the stack as read-only. When you read `ifconfig -a` output, every line that begins with an interface name is printing a copy of `if_xname`.

`if_dname` and `if_dunit` record the driver family name and the unit number separately. `if_dname` is "mynet" for every instance of our driver, and `if_dunit` is 0 for `mynet0`, 1 for `mynet1`, and so on. The network stack uses these fields to index the interface into various hashes, and `ifconfig` uses them when matching an interface name to a driver family.

`if_softc` is the back-pointer to your driver's private per-interface structure. Every callback the stack invokes will pass an `ifp` argument, and the first thing most callbacks do is pull the `softc` out of `ifp->if_softc` (or `if_get_softc(ifp)`). If you forget to set `if_softc` during creation, your callbacks will dereference a NULL pointer and the kernel will panic.

`if_type` is the type constant from `/usr/src/sys/net/if_types.h`. `IFT_ETHER` for an Ethernet-like interface, `IFT_LOOP` for loopback, `IFT_IEEE80211` for wireless, `IFT_TUNNEL` for a generic tunnel, and dozens of others. The stack occasionally specialises behaviour based on `if_type`, for example in deciding how to format a link-layer address for display.

`if_addr_len` and `if_hdr_len` describe the link-layer address length (six bytes for Ethernet, eight bytes for InfiniBand, zero for a pure L3 tunnel) and the link-layer header length (14 bytes for plain Ethernet, 22 for tagged Ethernet). `ether_ifattach` sets both of these for you with the Ethernet defaults. Other link-layer helpers set them with their own values.

`if_flags` is a bitmask of user-visible flags like `IFF_UP` and `IFF_BROADCAST`. `if_drv_flags` is a bitmask of driver-private flags like `IFF_DRV_RUNNING`. They are separate because they have different access rules. The user can write `if_flags`; only the driver writes `if_drv_flags`. Mixing them is a classic bug.

`if_capabilities` and `if_capenable` describe offload features. `if_capabilities` is what the hardware claims it can do. `if_capenable` is what is currently turned on. The split allows userland to toggle offloads at runtime through `ifconfig mynet0 -rxcsom` or `ifconfig mynet0 +tso`, and the driver to honour that choice. We will see this interact with `SIOCSIFCAP` in Section 6.

`if_mtu` is the maximum transmission unit in bytes. It is the largest L3 payload the interface can carry, not counting the link-layer header. Ethernet defaults to 1500. Jumbo-frame Ethernet typically supports 9000 or 9216. `if_baudrate` is an informational line-rate field in bits per second; it is advisory only.

`if_init` is a function pointer invoked when the interface transitions to the up state. Its signature is `void (*)(void *softc)`. `if_ioctl` is invoked for socket ioctls destined at this interface; signature `int (*)(struct ifnet *, u_long, caddr_t)`. `if_transmit` is invoked to send a packet; signature `int (*)(struct ifnet *, struct mbuf *)`. `if_qflush` is invoked to flush driver-private queues; signature `void (*)(struct ifnet *)`. `if_input` is a function pointer in the other direction: the driver calls it (usually through the `if_input(ifp, m)` helper) to hand a received mbuf to the stack.

`if_snd` is the legacy send queue, used by drivers that still have an `if_start` callback rather than an `if_transmit`. For modern drivers with `if_transmit`, `if_snd` is unused. Most textbook examples you will read in the tree (including our `if_disc.c` reference) do not touch `if_snd` any more.

`if_bpf` is the BPF attachment pointer. BPF itself manages the value; drivers treat it as opaque. `BPF_MTAP` and related macros use it internally.

`if_data` is a large structure carrying per-interface statistics, media descriptors, and miscellaneous fields. Modern drivers avoid touching `if_data` directly and instead go through `if_inc_counter` and friends. The `if_data` structure is still there for backward compatibility and for userland-visible stats.

This is far from an exhaustive list; `struct ifnet` has more than fifty fields in total. But the ones above are the ones your driver is most likely to touch, and being comfortable naming them will make every later code listing easier to read.

28.5.7 The Accessor API in More Detail

The `if_t` opaque handle has been growing a family of accessor functions since FreeBSD 12. The pattern is consistent: where you would have written `ifp->if_flags |= IFF_UP`, you now write `if_setflagbits(ifp, IFF_UP, 0)`. Where you would have written `ifp->if_softc = sc`, you now write `if_setsoftc(ifp, sc)`. The motivation is to let the kernel evolve the internal layout of `struct ifnet` without breaking drivers.

The accessor functions include:

- `if_setsoftc(ifp, sc)` and `if_getsoftc(ifp)` for the `softc` pointer.
- `if_setflagbits(ifp, set, clear)` and `if_getflags(ifp)` for `if_flags`.
- `if_setdrvflagbits(ifp, set, clear)` and `if_getdrvflags(ifp)` for `if_drv_flags`.
- `if_setmtu(ifp, mtu)` and `if_getmtu(ifp)` for the MTU.
- `if_setbaudrate(ifp, rate)` and `if_getbaudrate(ifp)` for the advertised line rate.
- `if_sethwassist(ifp, assist)` and `if_gethwassist(ifp)` for checksum-offload hints.
- `if_settransmitfn(ifp, fn)` for `if_transmit`.
- `if_setioctlnfn(ifp, fn)` for `if_ioctl`.
- `if_setinitfn(ifp, fn)` for `if_init`.
- `if_setqflushfn(ifp, fn)` for `if_qflush`.
- `if_setinputfn(ifp, fn)` for `if_input`.
- `if_inc_counter(ifp, ctr, n)` for the statistics counters.

Some of these are inlines that still reach through to a direct field access behind the scenes; others are wrappers

that may in the future refer to a subtly different field layout. Using the accessors now costs nothing and protects your driver against future churn.

For mynet we mostly use the direct-field style, because that is what the existing reference drivers like `if_disc.c` and `if_epair.c` still use, and consistency with the rest of the tree is valuable for readers. When you graduate to writing your own new driver, feel free to prefer the accessors. Both styles are correct.

28.5.8 A First Glimpse of the Code

Before we move on, let us look at a tiny code fragment that summarises the shape of a driver's relationship with `ifnet`. This is the pattern you will type more fully in Section 3, but it is already useful to see the skeleton:

```
struct mynet_softc {
    struct ifnet    *ifp;
    struct mtx      mtx;
    uint8_t         hwaddr[ETHER_ADDR_LEN];
    /* ... fields for simulation state ... */
};

static int
mynet_transmit(struct ifnet *ifp, struct mbuf *m)
{
    /* pass packet to the transport, or drop it */
}

static int
mynet_ioctl(struct ifnet *ifp, u_long cmd, caddr_t data)
{
    /* handle SIOCSIFFLAGS, SIOCSIFMTU, ... */
}

static void
mynet_init(void *arg)
{
    /* make the interface ready to move traffic */
}

static void
mynet_create(void)
{
    struct mynet_softc *sc = malloc(sizeof(*sc), M_MYNET, M_WAITOK | M_ZERO);
    struct ifnet *ifp = if_alloc(IFT_ETHER);

    sc->ifp = ifp;
    mtx_init(&sc->mtx, "mynet", NULL, MTX_DEF);
}
```

```
ifp->if_softc = sc;
if_initname(ifp, "mynet", 0);
ifp->if_flags = IFF_BROADCAST | IFF_SIMPLEX | IFF_MULTICAST;
ifp->if_init = mynet_init;
ifp->if_ioctl = mynet_ioctl;
ifp->if_transmit = mynet_transmit;
ifp->if_qflush = mynet_qflush;

/* fabricate a MAC address ... */
ether_ifattach(ifp, sc->hwaddr);
}
```

Do not type this yet. It is only a sketch, and several pieces are missing. We will fill them in during Section 3. What matters now is the shape: allocate, configure, attach. Every driver in the tree does this, with variations for the bus it lives on and the transport it talks to.

28.5.9 Wrapping Up Section 2

The `ifnet` object is the kernel's representation of a network interface. It has identity fields, capability fields, flags, callbacks, counters, and media state. It is created with `if_alloc`, configured by the driver, and installed in the system with `if_attach` or `ether_ifattach`. A pseudo-interface driver creates `ifnets` on demand through an interface cloner. A real NIC driver creates its `ifnet` during probe and attach.

You now have the vocabulary. In Section 3 we will put it to use by creating and registering a real working network interface. Before we do, though, it is worth spending a little time reading a real driver that uses the same patterns we are about to write. The next subsection guides you through `if_disc.c`, the canonical “simplest pseudo-Ethernet” driver in the FreeBSD source tree.

28.5.10 A Guided Tour of `if_disc.c`

Open `/usr/src/sys/net/if_disc.c` in your editor. It is about two hundred lines of code, and every line is instructive. The `disc(4)` driver creates an interface whose only job is to silently drop every packet it receives for transmission. It is the moral equivalent of `/dev/null` for packets. Because it is so small, it shows the shape of a pseudo-driver without any distraction.

The file begins with the standard license header, then a cluster of `#include` directives that should now look familiar. `net/if.h` and `net/if_var.h` for the interface structure, `net/ethernet.h` for Ethernet-specific helpers, `net/if_clone.h` for the cloner API, `net/bpf.h` for packet taps, and `net/vnet.h` for VNET awareness. That is almost exactly the include set we will use in `mynet.c`.

Next come a handful of module-level declarations. The string `discname = "disc"` is the family name the cloner will expose. `M_DISC` is the memory-type tag for `vmstat -m` accounting. `VNET_DEFINE_STATIC(struct if_clone *, disc_cloner)` declares a per-VNET cloner variable, and the `V_disc_cloner` macro provides the access shim. These are all pieces you will recognise when we write the same three lines in our own driver a few pages from now.

The `softc` declaration is particularly short. `struct disc_softc` holds only an `ifnet` pointer. That is all the state a discard driver needs: one interface per `softc`, no counters, no queues, no timers. Our `mynet` `softc` will be longer because we have a simulated receive path, a media descriptor, and a mutex, but the pattern of “one `softc` per interface” is the same.

Move down the file to `disc_clone_create`. It begins by allocating the `softc` with `M_WAITOK | M_ZERO`, because the cloner is called from user context and can afford to sleep. Then it allocates the `ifnet` with `if_alloc(IFT_LOOP)`. Note that `disc` uses `IFT_LOOP` rather than `IFT_ETHER`, because its link-layer semantics are more loopback-like than Ethernet-like. The choice of `IFT_*` constant matters because the stack queries `if_type` to decide which link-layer helper to invoke. Our driver will use `IFT_ETHER` because we want to use `ether_ifattach`.

Then `disc_clone_create` calls `if_initname(ifp, discname, unit)`, sets the `softc` pointer, sets the `if_mtu` to `DSMTU` (a locally-defined value), and sets `if_flags` to `IFF_LOOPBACK | IFF_MULTICAST`. The callbacks `if_ioctl`, `if_output`, and `if_init` are set. Notice that `disc` sets `if_output` rather than `if_transmit`, because loopback-style drivers are still wired to the classical output path. Our Ethernet driver will use `if_transmit` through `ether_ifattach`.

Then comes `if_attach(ifp)`, which registers the interface with the stack without Ethernet-specific setup. `bpfattach(ifp, DLT_NULL, sizeof(u_int32_t))` follows, registering with BPF using the null link-type (which tells `tcpdump` to expect a four-byte header carrying the address family of the payload). Our driver will use `DLT_EN10MB`, automatically, via `ether_ifattach`.

The destroy path, `disc_clone_destroy`, is symmetric: it calls `bpfdetach`, `if_detach`, `if_free`, and finally `free(sc, M_DISC)`. Our driver will be slightly more involved because we have callouts and a media descriptor to tear down, but the skeleton is identical.

The transmit path, `discoutput`, is three lines of code. It inspects the packet family, fills in the four-byte BPF header, taps BPF, updates counters, and frees the mbuf. That is all a “discard everything” driver needs to do. Our `mynet_transmit` will be longer, but structurally it does exactly the same things with slightly more discipline: validate, tap, count, release.

The `ioctl` handler, `discioctl`, handles `SIOCSIFADDR`, `SIOCSIFFLAGS`, and `SIOCSIFMTU`, and returns `EINVAL` for everything else. For a minimal pseudo-driver this is plenty. Our driver will be more elaborate because we add media descriptors and delegate unknown `ioctls` to `ether_ioctl`, but the switch-statement shape is the same.

Finally, the cloner registration is done in `vnet_disc_init` through `if_clone_simple(discname, disc_clone_create, disc_clone_destroy, 0)`, wrapped in `VNET_SYSINIT` and matched by a `VNET_SYSUNINIT` that calls `if_clone_detach`. Again, this is exactly the pattern we will use.

The take-away from reading `disc` is that a working pseudo-driver in the FreeBSD tree is about two hundred lines of code. Most of those lines are boilerplate that you set once and forget. The interesting parts are the `softc`, the cloner, and the handful of callbacks. Everything else is rhythm.

Do not feel obligated to memorise `disc`. Just read it once, slowly, now. When we start writing `mynet`, return to this section and you will see that most of what we type is the same pattern with a few additions for Ethernet-like behaviour, packet reception, and media descriptors. The pattern is worth seeing once in its purest form before we elaborate it.

28.6 Section 3: Creating and Registering a Network Interface

Time to write code. In this section we will build the skeleton of `mynet`, a pseudo-Ethernet driver. It will appear as a normal Ethernet interface to the rest of the system. Userland will be able to create an instance with `ifconfig mynet create`, assign an IPv4 address, bring it up, take it down, and destroy it, just like `epair` and `disc`. We will not yet handle real packet movement. Section 4 and Section 5 will handle the transmit and receive paths. Here we focus on the creation, registration, and basic metadata.

28.6.1 Project Layout

All companion files for this chapter live under `examples/part-06/ch28-network-driver/`. The skeleton in this section is in `examples/part-06/ch28-network-driver/lab01-skeleton/`. Create the directory if you are typing along manually, or look at the files if you prefer to read first and experiment later. The top-level layout we will use for the chapter is:

```
examples/part-06/ch28-network-driver/  
  Makefile  
  mynet.c  
  README.md  
  shared/  
  lab01-skeleton/  
  lab02-transmit/  
  lab03-receive/  
  lab04-media/  
  lab05-bpf/  
  lab06-detach/  
  lab07-reading-tree/  
  challenge01-shared-queue/  
  challenge02-link-flap/  
  challenge03-error-injection/  
  challenge04-iperf3/  
  challenge05-sysctl/  
  challenge06-netgraph/
```

The top-level `mynet.c` is the reference driver for the whole chapter and evolves from the skeleton in Section 3 through the final cleanup code in Section 8. The `lab0x` directories contain README files that walk you through the corresponding lab step. The challenges each add a small feature on top of the finished driver, and `shared/` holds helper scripts and notes referenced by more than one lab.

28.6.2 The Makefile

Let us start with the build file. A kernel module for a pseudo-Ethernet driver is one of the simplest Makefiles in the entire tree. Ours will look like this:

```
# Makefile for mynet - Chapter 28 (Writing a Network Driver).
#
# Builds the chapter's reference pseudo-Ethernet driver,
# mynet.ko, which demonstrates ifnet registration through an
# interface cloner, minimal transmit and receive paths, and
# safe load and unload lifecycle.

KMOD=    mynet
SRCS=    mynet.c opt_inet.h opt_inet6.h

SYSDIR?=    /usr/src/sys

.include <bsd.kmod.mk>
```

This is very close to the Makefile used by `/usr/src/sys/modules/if_disc/Makefile`, which is exactly what you want for a clone-based pseudo-interface driver. Two small differences: we do not set `.PATH`, because our source file is in the current directory rather than in `/usr/src/sys/net/`, and we set `SYSDIR` explicitly so that the build works on machines that may not ship a system configuration for it. Otherwise, it is the standard `bsd.kmod.mk` pattern you have seen since Chapter 10.

28.6.3 Preliminary Includes and Module Glue

Open your editor and start `mynet.c` with the following preamble. Each include has a specific role, so we will annotate them as we go:

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/malloc.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/mbuf.h>
#include <sys/socket.h>
#include <sys/sockio.h>
#include <sys/callout.h>

#include <net/if.h>
#include <net/if_var.h>
#include <net/if_arp.h>
#include <net/ethernet.h>
#include <net/if_types.h>
#include <net/if_clone.h>
#include <net/if_media.h>
```

```
#include <net/bpf.h>
#include <net/vnet.h>
```

The first block pulls in the core kernel headers you already know from earlier chapters: parameters, system calls, module machinery, memory allocator, locking, mbufs, socket IO constants, and the callout subsystem. The second block pulls in the networking-specific headers: `if.h` for the `ifnet` structure and flags, `if_var.h` for the inline helpers, `if_arp.h` for address resolution constants, `ethernet.h` for Ethernet framing, `if_types.h` for interface-type constants like `IFT_ETHER`, `if_clone.h` for the cloner API, `if_media.h` for media descriptors, `bpf.h` for tcpdump support, and `vnet.h` for VNET-awareness, which we use in the same way that `/usr/src/sys/net/if_disc.c` uses it.

Next, a module-wide memory type and the interface family name:

```
static const char mynet_name[] = "mynet";
static MALLOC_DEFINE(M_MYNET, "mynet", "mynet pseudo Ethernet driver");

VNET_DEFINE_STATIC(struct if_clone *, mynet_cloner);
#define V_mynet_cloner VNET(mynet_cloner)
```

`mynet_name` is the string we will pass to `if_initname` so that interfaces are named `mynet0`, `mynet1`, and so on. `M_MYNET` is the memory type tag so that `vmstat -m` shows you how much memory the driver is using. `VNET_DEFINE_STATIC` is VNET-aware: it gives each virtual network stack its own cloner variable. This mirrors the `VNET_DEFINE_STATIC(disc_cloner)` declaration in `/usr/src/sys/net/if_disc.c`. We will return to VNET briefly in Section 8.

Function, macro, and structure names are the durable reference into the FreeBSD tree. Line numbers drift release to release. For FreeBSD 14.3 orientation only: in `/usr/src/sys/net/if_disc.c`, the `VNET_DEFINE_STATIC(disc_cloner)` declaration sits near line 79 and the `if_clone_simple` call inside `vnet_disc_init` near line 134; in `/usr/src/sys/net/if_epair.c`, `epair_transmit` begins near line 324 and `epair_ioctl` near line 429; in `/usr/src/sys/sys/mbuf.h`, the `MGETHDR` compatibility macro sits near line 1125. Open the file and jump to the symbol.

28.6.4 The Softc

A `softc`, as you know from earlier chapters, is the private per-instance structure your driver allocates to track the state of one device. For a network driver, the `softc` is per-interface. Here is what ours looks like at this stage:

```
struct mynet_softc {
    struct ifnet    *ifp;
    struct mtx      mtx;
    uint8_t         hwaddr[ETHER_ADDR_LEN];
    struct ifmedia   media;
    struct callout  rx_callout;
    int             rx_interval_hz;
```

```

    bool                running;
};

#define MYNET_LOCK(sc)      mtx_lock(&(sc)->mtx)
#define MYNET_UNLOCK(sc)   mtx_unlock(&(sc)->mtx)
#define MYNET_ASSERT(sc)   mtx_assert(&(sc)->mtx, MA_OWNED)

```

The fields are straightforward. `ifp` is the interface object we create. `mtx` is a mutex to protect the softc during concurrent transmit, ioctl, and teardown. `hwaddr` is the six-byte Ethernet address we fabricate. `media` is the media descriptor we expose through `SIOCGIFMEDIA`. `rx_callout` and `rx_interval_hz` are used by the simulated receive path we build in Section 5. `running` reflects the driver's sense of whether the interface is currently active.

The macros at the bottom give us short, readable locking primitives. They are a stylistic convention used in many FreeBSD drivers, including `/usr/src/sys/dev/e1000/if_em.c` and `/usr/src/sys/net/if_epair.c`.

28.6.5 The Skeleton of `mynet_create`

Now the main action of this section. We will write a function that is called from the cloner to create and register a new interface. This function is the heart of the initialisation code. Let us build it step by step, then assemble the pieces.

First, allocate the softc and the ifnet:

```

struct mynet_softc *sc;
struct ifnet *ifp;

sc = malloc(sizeof(*sc), M_MYNET, M_WAITOK | M_ZERO);
ifp = if_alloc(IFT_ETHER);
if (ifp == NULL) {
    free(sc, M_MYNET);
    return (ENOSPC);
}
sc->ifp = ifp;
mtx_init(&sc->mtx, "mynet", NULL, MTX_DEF);

```

We use `M_WAITOK | M_ZERO` because this is called from a user-context path (the cloner) and we want zero-initialised memory. `IFT_ETHER` is from `/usr/src/sys/net/if_types.h`: it declares our interface as an Ethernet interface for the kernel's bookkeeping purposes, which is important because the stack uses `if_type` to decide what link-layer semantics to apply.

Next, fabricate a MAC address. In real NIC drivers, the hardware has an EEPROM with a unique factory-assigned MAC. We do not have that luxury, so we invent one. A locally-administered unicast address starts with a byte whose second-lowest bit is set and whose lowest bit is clear. The classic way is `02:xx:xx:xx:xx:xx`. We will do something similar to what `epair(4)` does in its `epair_generate_mac` function:

```
arc4rand(sc->hwaddr, ETHER_ADDR_LEN, 0);
sc->hwaddr[0] = 0x02; /* locally administered, unicast */
```

`arc4rand` is a kernel-internal entropy-backed random function, defined in `/usr/src/sys/libkern/arc4random.c`. It is fine for MAC-address fabrication. We then force the first byte to `0x02` so that the address is both locally-administered and unicast, which is what the IEEE reserves for addresses that are not factory-assigned.

Next, configure the interface fields:

```
if_initname(ifp, mynet_name, unit);
ifp->if_softc = sc;
ifp->if_flags = IFF_BROADCAST | IFF_SIMPLEX | IFF_MULTICAST;
ifp->if_capabilities = IFCAP_VLAN_MTU;
ifp->if_capenable = IFCAP_VLAN_MTU;
ifp->if_transmit = mynet_transmit;
ifp->if_qflush = mynet_qflush;
ifp->if_ioctl = mynet_ioctl;
ifp->if_init = mynet_init;
ifp->if_baudrate = IF_Gbps(1);
```

`if_initname` sets both `if_xname`, the unique name of the interface, and the driver's family name and unit number. `if_softc` ties the interface back to our private structure so that callbacks can find it. The flags mark the interface as broadcast-capable, simplex (meaning it cannot hear its own transmissions, which is true of an Ethernet NIC), and multicast-capable. `IFCAP_VLAN_MTU` says we can forward VLAN-tagged frames whose total payload exceeds the baseline Ethernet MTU by four bytes. The callbacks are the functions we will implement shortly. `if_baudrate` is informational; `IF_Gbps(1)` reports one gigabit per second, roughly matching what an average simulated link might claim.

Next, set up the media descriptor. This is what `SIOCGIFMEDIA` will return, and it is what `ifconfig mynet0` uses to print the media line:

```
ifmedia_init(&sc->media, 0, mynet_media_change, mynet_media_status);
ifmedia_add(&sc->media, IFM_ETHER | IFM_1000_T | IFM_FDX, 0, NULL);
ifmedia_add(&sc->media, IFM_ETHER | IFM_AUTO, 0, NULL);
ifmedia_set(&sc->media, IFM_ETHER | IFM_AUTO);
```

`ifmedia_init` registers two callbacks: one the stack calls when the user changes the media, and one it calls to learn the current media state. `ifmedia_add` declares a specific media type the interface supports. `IFM_ETHER | IFM_1000_T | IFM_FDX` means “Ethernet, 1000BaseT, full duplex”; `IFM_ETHER | IFM_AUTO` means “Ethernet, auto-negotiate”. `ifmedia_set` chooses the default. `ifconfig mynet0` will reflect this choice.

Next, initialise the simulated receive callout. We will implement it in Section 5, but we prepare the field now so that `mynet_create` leaves the `softc` fully usable:

```
callout_init_mtx(&sc->rx_callout, &sc->mtx, 0);
sc->rx_interval_hz = hz; /* one simulated packet per second */
```

`callout_init_mtx` registers our callout with the `softc`'s mutex so that the callout system acquires and releases the lock for us when it invokes the handler. This is a widely-used pattern in the kernel and it avoids a whole class of lock-ordering bugs.

Finally, attach the interface to the Ethernet layer:

```
ether_ifattach(ifp, sc->hwaddr);
```

This single call does a lot of work. It sets `if_addr_len` and `if_hdr_len` and `if_mtu` to Ethernet defaults, it calls `if_attach` to register the interface, it installs `ether_input` and `ether_output` as the link-layer input and output handlers, and it calls `bpfattach(ifp, DLT_EN10MB, ETHER_HDR_LEN)` so that `tcpdump -i mynet0` works immediately. After this call, the interface is live: userland can see it, assign addresses to it, and begin issuing `ioctl`s on it.

28.6.6 The Skeleton of `mynet_destroy`

Destruction mirrors creation but in reverse order. Here is the skeleton:

```
static void
mynet_destroy(struct mynet_softc *sc)
{
    struct ifnet *ifp = sc->ifp;

    MYNET_LOCK(sc);
    sc->running = false;
    MYNET_UNLOCK(sc);

    callout_drain(&sc->rx_callout);

    ether_ifdetach(ifp);
    if_free(ifp);

    ifmedia_removeall(&sc->media);
    mtx_destroy(&sc->mtx);
    free(sc, M_MYNET);
}
```

We mark the `softc` as no longer running, drain the callout so no scheduled receive event can fire, call `ether_ifdetach` to unregister the interface, free the `ifnet`, remove any allocated media entries, destroy the mutex, and free the `softc`. The order matters: you must not free the `ifnet` while the callout might still run against it, and you must not destroy the mutex while the callout might still acquire it. `callout_drain` is what gives us the synchronous guarantee that no more callbacks will fire after it returns.

28.6.7 Registering the Cloner

Two pieces tie `mynet_create` and `mynet_destroy` to the kernel: the cloner registration and the module handler. Here is the cloner code:

```
static int
mynet_clone_create(struct if_clone *ifc, int unit, caddr_t params)
{
    return (mynet_create_unit(unit));
}

static void
mynet_clone_destroy(struct ifnet *ifp)
{
    mynet_destroy((struct mynet_softc *)ifp->if_softc);
}

static void
vnet_mynet_init(const void *unused __unused)
{
    V_mynet_cloner = if_clone_simple(mynet_name, mynet_clone_create,
                                     mynet_clone_destroy, 0);
}
VNET_SYSINIT(vnet_mynet_init, SI_SUB_PSEUDO, SI_ORDER_ANY,
             vnet_mynet_init, NULL);

static void
vnet_mynet_uninit(const void *unused __unused)
{
    if_clone_detach(V_mynet_cloner);
}
VNET_SYSUNINIT(vnet_mynet_uninit, SI_SUB_INIT_IF, SI_ORDER_ANY,
              vnet_mynet_uninit, NULL);
```

`if_clone_simple` registers a simple cloner, meaning a cloner whose name matching is by exact prefix (`mynet` followed by an optional unit number). `/usr/src/sys/net/if_disc.c` uses this same call inside `vnet_disc_init`, the VNET init routine for the disc driver. The create function receives a unit number and is responsible for producing a new interface. The destroy function receives an `ifnet` and is responsible for taking it away. The `SYSINIT` and `SYSUNINIT` macros ensure that the cloner is registered when the module loads and unregistered when it unloads.

The `mynet_create_unit` helper glues the two halves together. It takes a unit number, does the allocation we described above, calls `ether_ifattach`, and returns zero on success or an error on failure. The full listing is in the companion file under `lab01-skeleton/`.

28.6.8 The Module Handler

Finally, the standard module boilerplate:

```
static int
mynet_modevent(module_t mod, int type, void *data __unused)
{
    switch (type) {
        case MOD_LOAD:
        case MOD_UNLOAD:
            return (0);
        default:
            return (EOPNOTSUPP);
    }
}

static moduledata_t mynet_mod = {
    "mynet",
    mynet_modevent,
    NULL
};

DECLARE_MODULE(mynet, mynet_mod, SI_SUB_PSEUDO, SI_ORDER_ANY);
MODULE_DEPEND(mynet, ether, 1, 1, 1);
MODULE_VERSION(mynet, 1);
```

The module handler itself does nothing interesting. The real initialisation happens in `vnet_mynet_init`, which `VNET_SYSINIT` arranges to be called at `SI_SUB_PSEUDO`. This split is not strictly necessary for a non-VNET driver, but following the pattern from `disc(4)` and `epair(4)` keeps our driver ready for VNET use and matches the convention used by the rest of the tree.

`MODULE_DEPEND(mynet, ether, 1, 1, 1)` declares a dependency on the `ether` module so that Ethernet support is loaded before we try to use `ether_ifattach`. `MODULE_VERSION(mynet, 1)` declares our own version number so that other modules can depend on us if they ever want to.

28.6.9 A Closer Look at Interface Cloners

Interface cloners are worth a short detour because they drive much of the lifecycle of a pseudo-driver, and because the API is slightly richer than the `if_clone_simple` call we have used so far.

A cloner is a named factory registered with the network stack. It carries a name prefix, a create callback, a destroy callback, and optionally a match callback. When userland runs `ifconfig mynet create`, the stack walks its list of cloners looking for one whose prefix matches the string `mynet`. If it finds one, it picks a unit number, calls the create callback, and returns the resulting interface's name.

The API has two flavours. `if_clone_simple` registers a cloner with the default matching rule: the name must begin with the cloner's prefix and may be followed by a unit number. `if_clone_advanced`

registers a cloner with a caller-provided match function, which allows more flexible naming. `epair(4)` uses `if_clone_advanced` because its interfaces come in pairs named `epairXa` and `epairXb`. We use `if_clone_simple` because `mynet0`, `mynet1`, and so on are good enough.

Within the create callback you have two pieces of information: the cloner itself (through which you can look up sibling interfaces) and the requested unit number (which may be `IF_MAXUNIT` if the user did not specify one, in which case you pick a free unit). In our driver we accept whatever unit the cloner tells us and pass it straight to `if_initname`.

The destroy callback is simpler: it receives the `ifnet` pointer of the interface to destroy and must tear everything down. The cloner framework handles the list of interfaces for us; we do not need to maintain one ourselves.

When the module unloads, `if_clone_detach` walks the list of interfaces the cloner created and calls the destroy callback for each. After that, the cloner itself is unregistered. This two-step teardown is what makes `kldunload` clean: even if the user forgot to `ifconfig mynet0 destroy` before unloading, the cloner takes care of it.

If your driver ever needs to expose additional arguments to the create path (for example, the partner interface name in an `epair`-style driver), the cloner framework supports a `caddr_t params` argument to the create callback, which carries bytes the user supplied through `ifconfig mynet create foo bar`. We do not use that mechanism here, but it is present and worth knowing about.

28.6.10 What Happens Inside `ether_ifattach`

We called `ether_ifattach(ifp, sc->hwaddr)` at the end of `mynet_create_unit` and said only that it “does a lot of work”. Let us open `/usr/src/sys/net/if_ETHERSUBR.c` and look at what that work really is, because understanding it makes the rest of our driver’s behaviour predictable rather than mysterious.

`ether_ifattach` begins by setting `ifp->if_addrlen = ETHER_ADDR_LEN` and `ifp->if_hdrlen = ETHER_HDR_LEN`. These fields tell the stack how many bytes of link-layer addressing and header prepend a frame. For Ethernet both values are constants: six bytes of MAC and fourteen bytes of header.

Next it sets `ifp->if_mtu = ETHERMTU` (1500 bytes, the IEEE Ethernet default) if the driver has not already set a larger value. Our driver left `if_mtu` at zero after `if_alloc`, so `ether_ifattach` gives us the default. We could override it afterwards; a jumbo-capable driver might set `if_mtu` to 9000 before `ether_ifattach`.

Then it sets the link-layer output function, `if_output`, to `ether_output`. `ether_output` is the generic L3-to-L2 handler: it receives a packet with an IP header and a destination address, resolves ARP or neighbour discovery if needed, constructs the Ethernet header, and calls `if_transmit`. This chain of indirection is what allows an IP packet from a socket to travel transparently through the stack and reach our driver.

It sets `if_input` to `ether_input`. `ether_input` is the inverse: it receives a complete Ethernet frame, strips the Ethernet header, dispatches on the `EtherType`, and hands the payload up to the appropriate protocol (IPv4, IPv6, ARP, LLC, and so on). When our driver calls `if_input(ifp, m)`, it is effectively calling `ether_input(ifp, m)`.

Then it stores the MAC address in the interface’s address list, making it visible to userland through `getifaddrs(3)` and through `ifconfig`. This is how `ifconfig mynet0` prints an ether line.

Then it calls `if_attach(ifp)`, which registers the interface with the global list, allocates any stack-side state needed, and makes the interface visible to userland.

Finally it calls `bpfattach(ifp, DLT_EN10MB, ETHER_HDR_LEN)`, which registers the interface with BPF using the Ethernet link type. From that moment `tcpdump -i mynet0` will find the interface and will expect frames with 14-byte Ethernet headers.

It is a lot of work for one function call. Doing it all by hand is legal (and many older drivers do) but error-prone. `ether_ifattach` is one of those helpers whose existence makes writing a driver genuinely easier, and reading its body is rewarding because it demystifies what happens between “I allocated an ifnet” and “the stack is fully aware of my interface”.

The complementary function `ether_ifdetach` performs the inverse operations in the correct reverse order. It is the right function to call during teardown, and it is what we call in `mynet_destroy`.

28.6.11 Build, Load, and Verify

At this point, even without transmit and receive logic, the skeleton should build and load. Here is what the verification flow looks like:

```
# cd examples/part-06/ch28-network-driver
# make
# kldload ./mynet.ko

# ifconfig mynet create
mynet0
# ifconfig mynet0
mynet0: flags=8802<BROADCAST,SIMPLEX,MULTICAST> metric 0 mtu 1500
    ether 02:a3:f1:22:bc:0d
    media: Ethernet autoselect
    status: no carrier
    groups: mynet
```

The exact MAC address will differ because `arc4rand` gives you a different random address each time. The rest of the output should closely match. If it does, you have succeeded: you have a live, registered, named, MAC-addressed network interface, visible to all the standard tools, without yet handling any real packets. That is already a significant accomplishment.

Destroy the interface and unload the module to close the lifecycle:

```
# ifconfig mynet0 destroy
# kldunload mynet
```

`kldstat` should show that the module is gone. `ifconfig -a` should no longer list `mynet0`. If anything is left behind, we will cover how to diagnose it in Section 8.

28.6.12 What the Stack Now Knows About Us

After `ether_ifattach` returns, the stack knows several important facts about our interface:

- It is of type `IFT_ETHER`.
- It supports broadcast, simplex, and multicast.
- It has a specific MAC address.
- It has a default MTU of 1500 bytes.
- It has a transmit callback, an `ioctl` callback, an `init` callback, and a media handler.
- It is attached to BPF with `DLT_EN10MB` encapsulation.
- Its state-of-the-link is currently undefined (we have not called `if_link_state_change` yet).

Everything else, packet movement, counter updates, link state, will come alive in the following sections. The skeleton is intentionally small. It is the first time you can point at something on your system and say, honestly, “that is my network interface.” Pause on that sentence. It marks a real milestone in the book.

28.6.13 Common Mistakes

Two mistakes are easy to make in this section, and both of them produce confusing symptoms.

The first is forgetting to call `ether_ifattach` and calling `if_attach` directly. That is perfectly legal, and it results in a non-Ethernet pseudo-interface, but your driver then has to install its own `if_input` and `if_output` handlers, and `tcpdump` does not work until you `bpfattach` yourself. If you see an interface that looks like it should work but `tcpdump -i mynet0` complains about the link type, check whether you used `ether_ifattach`.

The second mistake is to allocate the softc with `M_NOWAIT` instead of `M_WAITOK`. `M_NOWAIT` is correct in interrupt context, but `mynet_clone_create` runs in a regular user context through the `ifconfig create` path, and `M_WAITOK` is the right choice. Using `M_NOWAIT` here introduces a rare allocation-failure path for no benefit.

28.6.14 Wrapping Up Section 3

You now have a working skeleton. The interface exists, is registered, has an Ethernet address, and can be created and destroyed on demand. The stack is ready to call into our driver through `if_transmit`, `if_ioctl`, and `if_init`, but we have not yet implemented the bodies of those callbacks. Section 4 tackles the transmit path. That is the one you will feel most viscerally, because once it works, `ping` starts to push real bytes through your code.

28.7 Section 4: Handling Packet Transmission

Transmission is the outbound half of packet flow. When the kernel’s network stack decides that a packet needs to leave through `mynet0`, it packages the packet in an mbuf chain and invokes our `if_transmit` callback. Our job is to accept the mbuf, do whatever is appropriate with it, and free it. In this section we will build a complete transmit path that validates the mbuf, updates counters, taps BPF so that `tcpdump` sees the packet, and disposes of the frame. Because `mynet` is a pseudo-device without a real wire, we will initially drop the packet after counting it. That is similar to what `disc(4)` does in `/usr/src/sys/net/if_disc.c`, and it is enough to demonstrate the full transmit flow end-to-end.

28.7.1 How the Stack Reaches Us

Before we open our editor, let us trace how a packet gets from a process to our driver. When a process calls `send(2)` on a TCP socket that is bound to an IP address assigned to `mynet0`, the following sequence happens, in broad strokes. Do not worry about memorising every step; the point is to see where our code sits in the bigger picture.

1. The socket layer copies the user payload into mbufs and passes it to TCP.
2. TCP segments the payload, adds TCP headers, and passes the segments to IP.
3. IP adds IP headers, looks up the route, and passes the result to the Ethernet layer through `ether_output`.
4. `ether_output` resolves the next-hop MAC address (through ARP if required), prepends an Ethernet header, and calls `if_transmit` on the output interface.
5. Our `if_transmit` function is invoked with `ifp` pointing at `mynet0` and the mbuf pointing at the complete Ethernet frame ready to be transmitted.

From that moment the frame is ours. We must either send it out, drop it cleanly, or queue it for later delivery. Whichever we choose, we must free the mbuf exactly once. Double-free leads to kernel corruption, use-after-free leads to mystery panics, and forgetting to free leaks mbufs until the machine runs out.

28.7.2 The Transmit Callback Signature

The prototype of an `if_transmit` callback is:

```
int mynet_transmit(struct ifnet *ifp, struct mbuf *m);
```

It is declared in `/usr/src/sys/net/if_var.h` as the typedef `if_transmit_fn_t`. The return value is an `errno`: zero on success, or an error such as `ENOBUFS` if the packet could not be queued. Real NIC drivers rarely return non-zero, because they prefer to silently drop and increment `IFCOUNTER_OERRORS`. Pseudo-drivers that mimic real behaviour usually do the same.

Here is the full callback we will implement:

```
static int
mynet_transmit(struct ifnet *ifp, struct mbuf *m)
{
    struct mynet_softc *sc = ifp->if_softc;
    int len;

    if (m == NULL)
        return (0);
    M_ASSERTPKTHDR(m);

    /* Reject oversize frames. Leave a little slack for VLAN. */
    if (m->m_pkthdr.len > (ifp->if_mtu + sizeof(struct ether_vlan_header))) {
        m_freem(m);
        if_inc_counter(ifp, IFCOUNTER_OERRORS, 1);
    }
}
```

```

        return (E2BIG);
    }

    /* If the interface is administratively down, drop. */
    if ((ifp->if_flags & IFF_UP) == 0 ||
        (ifp->if_drv_flags & IFF_DRV_RUNNING) == 0) {
        m_freem(m);
        if_inc_counter(ifp, IFCOUNTER_OERRORS, 1);
        return (ENETDOWN);
    }

    /* Let tcpdump see the outgoing packet. */
    BPF_MTAP(ifp, m);

    /* Count it. */
    len = m->m_pkthdr.len;
    if_inc_counter(ifp, IFCOUNTER_OPACKETS, 1);
    if_inc_counter(ifp, IFCOUNTER_OBYTES, len);
    if (m->m_flags & (M_BCAST | M_MCAST))
        if_inc_counter(ifp, IFCOUNTER_OMCASTS, 1);

    /* In a real NIC we would DMA this to hardware. Here we just drop. */
    m_freem(m);
    return (0);
}

```

Let us walk through it. This is where the shape of a transmit routine becomes clear, so it is worth reading the code slowly.

28.7.3 The NULL Check

The first two lines handle the defensive case where the stack calls us with a NULL pointer. This is not supposed to happen in normal operation, but the kernel is a place where defensive programming earns its keep. Returning 0 on a NULL input is the standard idiom; `if_epair.c` does the same at the top of `epair_transmit`.

28.7.4 M_ASSERTPKTHDR

The next line is a macro from `/usr/src/sys/sys/mbuf.h` that asserts the mbuf has `M_PKTHDR` set. Every mbuf that reaches a driver's transmit callback must be the head of a packet, and must therefore carry a valid packet header. Asserting this catches bugs caused by mbuf surgery elsewhere in the system. In production kernels the assertion is compiled out, but having it in the source tree documents the contract, and in `INVARIANTS` kernels it catches bad usage during development.

28.7.5 MTU Validation

The block under the comment `/* Reject oversize frames. */` rejects packets that are larger than the interface MTU plus a small slack for a VLAN header. `epair_transmit` in `/usr/src/sys/net/if_epair.c` does exactly the same check; look for the `if (m->m_pkthdr.len > (ifp->if_mtu + sizeof(struct ether_vlan_header)))` guard that `m_freem`s the frame and bumps `IFCOUNTER_OERRORS`. We leave slack for `ether_vlan_header` because VLAN-tagged frames carry four extra bytes beyond the base Ethernet header, and we advertised `IFCAP_VLAN_MTU` in Section 3, so we should honour that capability.

On rejection, we free the mbuf with `m_freem(m)` and increment `IFCOUNTER_OERRORS`. We also return `E2BIG` as a hint to the caller, though in practice the stack rarely looks at the return value other than to decide whether to drop locally.

28.7.6 State Validation

The `if` block under the comment `/* If the interface is administratively down, drop. */` checks two conditions. `IFF_UP` is set by `ifconfig mynet0 up` and cleared by `ifconfig mynet0 down`, and it is the userland's way of saying that the interface should or should not be carrying traffic. `IFF_DRV_RUNNING` is the driver's internal "I have allocated my resources and I am ready to move traffic" flag. If either is clear, we have no business sending the packet, so we drop it and increment the error counter.

This check is not strictly necessary for correctness in all cases, because the stack usually avoids routing traffic through a down interface. But defensive drivers check anyway, because races between the stack's view of state and the driver's view of state do happen, especially during interface teardown.

28.7.7 BPF Tap

`BPF_MTAP(ifp, m)` is a macro that conditionally calls into BPF if any packet capture session is active on the interface. It expands to `bpf_mtap_if((_ifp), (_m))` in the current tree. The macro is defined in `/usr/src/sys/net/bpf.h`. When `tcpdump -i mynet0` is running, BPF has attached to the interface's `if_bpf` pointer, and the macro hands it a copy of the outgoing packet. When no one is listening, the macro quickly returns and has negligible cost.

Placement matters. We tap before we drop, because we want `tcpdump` to see the packet even if we are simulating a down interface. Real NIC drivers tap slightly earlier, right before they hand the frame to hardware DMA, but the idea is the same.

28.7.8 Counter Updates

Four counters are relevant on every transmit:

- `IFCOUNTER_OPACKETS`: the number of packets transmitted.
- `IFCOUNTER_OBYTES`: the total bytes transmitted.
- `IFCOUNTER_OMCASTS`: the number of multicast or broadcast frames transmitted.
- `IFCOUNTER_OERRORS`: the number of errors observed during transmit.

`if_inc_counter(ifp, IFCOUNTER_*, n)` is the correct way to update these. It is defined in `/usr/src/sys/net/if.c` and uses per-CPU counters internally so that concurrent calls from multiple CPUs do not contend. Do not reach into the `if_data` fields directly: the internals have changed over the years, and the accessor is the stable interface.

Because the stack has already computed packet length and populated `m->m_pkthdr.len`, we cache that into a local `len` variable before we free the mbuf. Reading `m->m_pkthdr.len` after `m_freem(m)` would be use-after-free, so the local variable is not a stylistic choice. It is a correctness choice.

28.7.9 The Final Drop

`m_freem(m)` frees an entire mbuf chain. It walks the chain through the `m_next` pointers and frees every mbuf in it. You do not need to free each one by hand. If you had only `m_free(m)` you would free the first mbuf and leak the rest. Confusing `m_freem` and `m_free` is one of the most common beginner mistakes. The conventional names are:

- `m_free(m)`: free a single mbuf. Rarely called in drivers.
- `m_freem(m)`: free a whole chain. This is what you almost always want.

In a real NIC driver, instead of `m_freem(m)`, we would hand the frame to hardware DMA and free the mbuf later, in the transmit-completion interrupt. For our pseudo-driver, we drop it. This is the behaviour of `if_disc.c` in the tree: simulate the transmit, free the mbuf, and return.

28.7.10 The Queue-Flush Callback

Alongside `if_transmit`, the stack expects a trivial callback called `if_qflush`. It is invoked when the stack wants to flush any packets the driver has queued internally. Because our driver does not queue, the callback has no work to do:

```
static void
mynet_qflush(struct ifnet *ifp __unused)
{
}
```

That is identical to `epair_qflush` in `/usr/src/sys/net/if_epair.c`. Drivers that maintain their own packet queues, which is less common now than it was, have more work to do here. We do not.

28.7.11 The `mynet_init` Callback

The third callback assigned in Section 3 was `mynet_init`, the function the stack calls when the interface transitions to the up state. It is a simple one for us:

```
static void
mynet_init(void *arg)
{
}
```

```
struct mynet_softc *sc = arg;

Mynet_LOCK(sc);
sc->running = true;
sc->ifp->if_drv_flags |= IFF_DRV_RUNNING;
sc->ifp->if_drv_flags &= ~IFF_DRV_OACTIVE;
callout_reset(&sc->rx_callout, sc->rx_interval_hz,
              mynet_rx_timer, sc);
Mynet_UNLOCK(sc);

if_link_state_change(sc->ifp, LINK_STATE_UP);
}
```

On init we mark ourselves running, clear `IFF_DRV_OACTIVE` (a flag meaning “transmit queue is full, do not call me again until I clear it”), start the receive-simulation callout we will describe in Section 5, and announce that the link is up. The `if_link_state_change` call at the end causes `ifconfig` to report status: `active` on this interface. Keep the placement in mind: we set `IFF_DRV_RUNNING` first, then announce the link, in that order. Reversing the order would tell the stack that the link is up on an interface whose driver is still initialising, and the stack might start pushing traffic at us before we are ready.

28.7.12 A Close Look at Ordering and Locking

The code above is simple enough that locking feels like overkill. Why do we need a mutex at all? There are two reasons.

The first reason is that `if_transmit` and `if_ioctl` run concurrently. The stack can call `if_transmit` on one CPU while userland issues `ifconfig mynet0 down` on another, which translates into `if_ioctl(SIOCSIFFLAGS)` running on that other CPU. Without a mutex, these two callbacks can both read and write softc state simultaneously. The mutex is what lets us reason about state transitions.

The second reason is that the callout-based receive simulation in Section 5 touches the softc when it fires. Without a mutex, the callout and `if_ioctl` can collide, and you get the classic “the list I was walking just changed out from under me” style of bug. Again, a single per-softc mutex is enough to make these interactions safe.

We have chosen a simple locking rule: the softc mutex is the big lock. Every softc access outside the transmit fast path takes it. The transmit fast path in `mynet_transmit` does not take the mutex, because `if_transmit` is designed for concurrent callers and we only touch ifnet counters and BPF, both of which are thread-safe on their own. If we were to add driver-specific shared state that transmit updates, we would add a finer-grained lock for that state.

This is a simplification. Real high-performance NIC drivers use far more complex locking, often with per-queue locks, per-CPU state, and per-packet sanity checks. The single-mutex design is absolutely fine for a pseudo-driver and for any low-rate interface; for a production 100-gigabit driver it would become a bottleneck, which is one reason why the modern `iflib` framework exists. We will touch on `iflib` in later chapters.

28.7.13 Packet Surgery with `m_pullup`

Real network drivers frequently need to read fields from deep inside a packet before deciding what to do with it. A VLAN driver needs to read the 802.1Q tag. A bridging driver needs to read the source MAC to update a forwarding table. A hardware-offloading driver needs to read the IP and TCP headers to decide whether a checksum can be computed in hardware.

The trouble is that a received mbuf chain does not guarantee that any particular byte lives in any particular mbuf. The first mbuf might hold only the first fourteen bytes (the Ethernet header) while the next mbuf holds the rest. A driver that casts `mtod(m, struct ip *)` and reaches past the Ethernet header will read nonsense unless it first ensures that the bytes it needs are contiguous.

The kernel provides `m_pullup(m, len)` for exactly this purpose. `m_pullup` guarantees that the first `len` bytes of the mbuf chain live in the first mbuf. If they already do, it is a no-op. If they do not, it reshapes the chain by moving bytes into the first mbuf, possibly allocating a new mbuf if the first one is too small. It returns a (possibly different) mbuf pointer, or NULL on allocation failure, in which case the mbuf chain has been freed for you.

The idiom for a driver that needs to inspect headers is:

```
m = m_pullup(m, sizeof(struct ether_header) + sizeof(struct ip));
if (m == NULL) {
    if_inc_counter(ifp, IFCOUNTER_IQDROPS, 1);
    return;
}
eh = mtod(m, struct ether_header *);
ip = (struct ip *)(eh + 1);
```

`mynet` does not need to do this, because we do not inspect packet contents in the transmit path. But you will see `m_pullup` sprinkled throughout real drivers, especially on the receive side and in L2 helpers.

A related function, `m_copydata(m, offset, len, buf)`, copies bytes out of a mbuf chain into a caller-provided buffer. It is the right tool when you want to read some bytes without modifying the chain. `m_copyback` goes the other way: write bytes into a chain at a given offset, extending the chain if needed.

Another frequently-used helper is `m_defrag(m, how)`, which flattens a chain into a single (large) mbuf. This is used by drivers whose hardware has a maximum scatter-gather count. If a transmit frame spans more mbufs than the hardware can handle, the driver falls back to `m_defrag`, which copies the payload into a contiguous single cluster.

You will meet all of these functions in the course of reading real drivers. For now, knowing that they exist, and that mbuf layout is something a real driver must take seriously, is enough.

28.7.14 A Deeper Look at mbuf Structure

Because mbufs are the currency of the network stack, spending a few more pages on their structure is time well spent. The decisions a driver makes about mbufs are the decisions that determine whether the driver is fast, correct, and maintainable.

The mbuf structure itself lives in `/usr/src/sys/sys/mbuf.h`. The on-disk layout, as of FreeBSD 14.3, is something like this (simplified for teaching):

```
struct mbuf {
    struct m_hdr    m_hdr;      /* fields common to every mbuf */
    union {
        struct {
            struct pkthdr m_pkthdr; /* packet header, if M_PKTHDR */
            union {
                struct m_ext m_ext; /* external storage, if M_EXT */
                char          m_pktdat[MLEN - sizeof(struct pkthdr)];
            } MH_dat;
        } MH;
        char    M_databuf[MLEN]; /* when no packet header */
    } M_dat;
};
```

Two union variants inside two unions. The layout captures the fact that an mbuf can be in one of several modes:

- A plain mbuf with its data stored inline (about 200 bytes available).
- A packet-header mbuf with its data stored inline (slightly less available because of the header).
- A packet-header mbuf with its data stored in an external cluster (`m_ext`).
- A non-header mbuf with its data stored in an external cluster.

The `m_flags` field indicates which variant is in effect through the bits `M_PKTHDR` and `M_EXT`.

A cluster is a larger pre-allocated buffer, typically 2048 bytes on modern FreeBSD. The mbuf holds a pointer to the cluster in `m_ext.ext_buf`, and the cluster is reference-counted through `m_ext.ext_count`. Clusters exist because many packets are larger than a plain mbuf can hold, and allocating a fresh buffer for every large packet would be costly.

When you call `MGETHDR(m, M_NOWAIT, MT_DATA)`, you get a packet-header mbuf with inline data. When you call `m_getcl(M_NOWAIT, MT_DATA, M_PKTHDR)`, you get a packet-header mbuf with an external cluster attached. The second form can hold about 2000 bytes without chaining, which is convenient for Ethernet-sized packets.

28.7.15 mbuf Chains and Scatter-Gather

Because a single mbuf can hold only limited bytes, many packets span several mbufs chained through `m_next`. The `m_pkthdr.len` field on the head mbuf holds the total packet length; the `m_len` on each mbuf in the chain holds that mbuf's contribution. Their relationship is `m_pkthdr.len == sum(m_len across chain)`, and any mismatch is a bug.

This chaining has several advantages. It lets the stack prepend headers cheaply: to add an Ethernet header, the stack can allocate a new mbuf, fill in the header, and link it as the new head. It lets the stack split packets

cheaply: TCP can segment a large payload by walking a chain rather than copying data. It lets the hardware use scatter-gather DMA: a NIC can transmit a chain by issuing multiple DMA descriptors, one per mbuf.

The cost is that drivers must walk chains carefully. If you cast `mtod(m, struct ip *)` and the IP header is split across the first and second mbufs, you read garbage. `m_pullup` is the defence against that mistake, and every serious driver uses it when it needs to inspect headers.

28.7.16 mbuf Types and What They Mean

The `m_type` field on every mbuf classifies its purpose:

- `MT_DATA`: ordinary packet data. This is what you use for network packets.
- `MT_HEADER`: a mbuf dedicated to holding protocol headers.
- `MT_SONAME`: a socket address structure. Used by socket-layer code.
- `MT_CONTROL`: ancillary socket control data.
- `MT_NOINIT`: an uninitialised mbuf. Never seen by drivers.

For driver code, `MT_DATA` is almost always correct. The stack handles the others internally.

28.7.17 Packet Header Fields

The `m_pkthdr` structure on a header mbuf carries fields that travel with the packet through the stack. Some of the most relevant for driver authors:

- `len`: total length of the mbuf chain.
- `rcvif`: the interface on which the packet was received. Drivers set this when constructing a received mbuf.
- `flowid` and `rsstype`: hash of the packet's flow, used for multi-queue dispatch.
- `csum_flags` and `csum_data`: hardware checksum state. Drivers with TX checksum offload read these; drivers with RX checksum offload write them.
- `ether_vtag` and `M_VLANTAG` flag in `m_flags`: hardware-extracted VLAN tag, if VLAN hardware tagging is in use.
- `vt_nrecs` and other VLAN fields: for more elaborate VLAN configurations.
- `tso_segsz`: segment size for TSO frames.

Most of these fields are set by higher layers before the packet reaches the driver. For our purposes, setting `rcvif` during receive and reading `len` during transmit is enough. The other fields are hooks that `iflib` and its predecessors use for offload coordination; a pseudo-driver can safely ignore them.

28.7.18 Reference-Counted External Buffers

When a cluster is attached to a mbuf, the cluster is reference-counted. This allows packet duplication (via `m_copypacket`) without copying the payload: two mbufs can share the same cluster, and the cluster is freed only when both mbufs release their reference. BPF uses this mechanism to tap a packet without forcing a copy.

For driver code this is mostly transparent. You call `m_freem` on your mbuf, and if the mbuf has an external cluster, the cluster's reference count is decremented; if it reaches zero, the cluster is freed. You do not have

to think about the reference counts explicitly. But you should know that they exist, because they explain why BPF_MTAP can be cheap: it does not copy the packet, it merely grabs an additional reference.

28.7.19 The Receive Allocation Pattern

A real NIC driver usually allocates mbufs and attaches clusters to them at initialisation time, fills the receive ring with those mbufs, and lets the hardware DMA into them. The pattern is:

```
for (i = 0; i < RX_RING_SIZE; i++) {
    struct mbuf *m = m_getcl(M_WAITOK, MT_DATA, M_PKTHDR);
    rx_ring[i].mbuf = m;
    rx_ring[i].dma_addr = pmap_kextract((vm_offset_t)mtod(m, char *));
    rx_ring[i].desc->addr = rx_ring[i].dma_addr;
    rx_ring[i].desc->status = 0;
}
```

When the hardware receives a packet, it writes the packet data into the cluster pointed at by one of the descriptors, sets the status to indicate completion, and raises an interrupt. The driver's receive routine looks at the status, grabs the mbuf, sets `m->m_pkthdr.len` and `m->m_len` from the descriptor's length field, taps BPF, calls `if_input`, and then allocates a replacement mbuf for the descriptor.

Our pseudo-driver uses a much simpler pattern: allocate a fresh mbuf every time the receive timer fires. This is perfectly fine for a teaching driver because the allocation rate is low. At higher rates you would want the pre-allocation pattern, because allocating mbufs in bulk at init time and recycling them is much cheaper than allocating one per packet.

28.7.20 Common mbuf-Related Mistakes

Even with knowledge of the above, a few mistakes keep occurring in driver code:

- Using `m_free` instead of `m_freem` on a chain head. You free the first mbuf and leak the rest.
- Forgetting to set `m_pkthdr.len` correctly when building a packet. The stack reads `m_pkthdr.len` rather than walking the chain, so if the two disagree, decoding silently fails.
- Reading `m_pkthdr.len` after `m_freem`. Always cache the length into a local before freeing.
- Confusing `m->m_len` (length of this mbuf) with `m->m_pkthdr.len` (total length of the chain). For a single-mbuf packet they are equal; for chains they differ.
- Reading past `m_len` without walking the chain. If you need bytes beyond the first mbuf, use `m_pullup` or `m_copydata`.
- Modifying a mbuf that you do not own. Once you have handed a mbuf to `if_input`, it is not yours any more.
- Allocating without checking for NULL. `m_gethdr(M_NOWAIT, ...)` can return NULL under memory pressure, and the driver must handle that gracefully.

These mistakes are easy to avoid if you know the rules, and reading other drivers is the best way to internalise them.

28.7.21 Multi-Queue Transmit in Real Drivers

Modern hardware NICs can transmit on many queues in parallel. A 10-gigabit NIC commonly has eight or sixteen transmit queues, each with its own hardware ring buffer, its own DMA descriptors, and its own completion interrupt. The driver distributes outgoing packets among these queues based on a hash of the packet's source and destination addresses, so that traffic from different flows goes to different queues and can be processed concurrently on different CPU cores.

This is far beyond what our pseudo-driver needs. But the pattern is worth recognising, because it shows up prominently in production drivers. The key pieces are:

- A queue-selection function that takes a mbuf and returns an index into the driver's queue array. `mynet` has only one queue (or zero, depending on how you count), so this step is trivial. Real drivers often use `m->m_pkthdr.flowid` as a precomputed hash.
- A per-queue lock and a per-queue software queue (typically managed by `drbr(9)`) that allows concurrent producers to enqueue packets without contention.
- A transmit kick that drains the software queue into hardware when a producer has enqueued and the hardware is idle.
- A completion callback, usually from a hardware interrupt, that frees the mbufs whose transmission has completed.

The `if_transmit` prototype is designed to fit this pattern naturally. The caller produces a mbuf and hands it to `if_transmit`. The driver either queues it immediately (in a simple case like ours) or dispatches it to the appropriate hardware queue (in a multi-queue case). Either way, the caller sees a single function call and does not need to know how many queues live underneath.

We will return to multi-queue design when we discuss `iflib` in a later chapter. For now, it is enough to know that the single-queue model we are building here is a simplification that real drivers elaborate.

28.7.22 A Digression on the `drbr(9)` Helper

`drbr` stands for “driver ring buffer” and it is a helper library for drivers that want to maintain their own per-queue software queue. The API is defined and implemented as static `__inline` functions in `/usr/src/sys/net/ifq.h`; there is no separate `drbr.c` or `drbr.h` file. The helpers wrap the underlying `buf_ring(9)` ring buffers with explicit enqueue and dequeue operations, plus helpers for tapping BPF, counting packets, and synchronising with the transmit thread. The shape `drbr` is built for is multi-producer, single-consumer, which is the typical shape of a transmit queue where many threads enqueue but a single dequeue thread drains the ring into hardware.

A driver that uses `drbr` typically has a transmit function that looks like this sketch:

```
int
my_transmit(struct ifnet *ifp, struct mbuf *m)
{
    struct mydrv_softc *sc = ifp->if_softc;
    struct mydrv_txqueue *txq = select_queue(sc, m);
    int error;
```

```

    error = drbr_enqueue(ifp, txq->br, m);
    if (error)
        return (error);
    taskqueue_enqueue(txq->tq, &txq->tx_task);
    return (0);
}

```

The producer enqueues into a ring buffer and kicks a taskqueue. The taskqueue consumer then dequeues from the ring buffer and hands frames to hardware. This decouples the producer (which can be any CPU) from the consumer (which runs on a dedicated worker thread per queue), which is exactly the structure that works well on multi-core systems.

mynet does not use `drbr`, because we have neither multiple queues nor hardware to kick. But the pattern is worth seeing once, because it shows up in every performance-conscious driver in the tree.

28.7.23 Testing the Transmit Path

Build, load, and create the interface as in Section 3, then send traffic at it:

```

# kldload ./mynet.ko
# ifconfig mynet create
mynet0
# ifconfig mynet0 inet 192.0.2.1/24 up
# ping -c 1 192.0.2.99
PING 192.0.2.99 (192.0.2.99): 56 data bytes
--- 192.0.2.99 ping statistics ---
1 packets transmitted, 0 packets received, 100.0% packet loss
# netstat -in -I mynet0

```

Name	Mtu	Network	Address	Ipkts	Ierrs	...	Opkts	Oerrs
mynet0	1500	<Link#12>	02:a3:f1:22:bc:0d	0	0		1	0
mynet0	-	192.0.2.0/24	192.0.2.1	0	-		0	-

The key line is `Opkts 1`. Even though the ping received no reply, we can see that one packet was transmitted through our driver. The reason there was no reply is that `mynet0` is a pseudo-interface with nothing on the other side. We will give it a simulated arrival path in Section 5.

Leave `tcpdump -i mynet0 -n` running in another terminal, repeat the ping, and you will see the outgoing ARP request and IPv4 packet being captured. That confirms `BPF_MTAP` is wired up correctly.

28.7.24 Pitfalls

A handful of mistakes appear repeatedly in student code and even in experienced drivers. Let us walk through them so you learn to recognise them.

Freeing the mbuf twice. If your transmit function has multiple exit paths and one of them forgets to skip `m_freem`, the same mbuf ends up freed twice. The kernel usually panics with a message about a corrupted free list. The fix is to structure the function with a single exit that owns the free, or to null out `m` after you free it and check before freeing again.

Not freeing the mbuf at all. The other side of the same mistake. If you return from `if_transmit` without freeing or queuing the mbuf, you leak it. In a low-rate driver this might take hours to notice; in a high-rate driver the machine runs out of mbuf memory quickly. `vmstat -z | grep mbuf` is your best friend for spotting this.

Assuming the mbuf fits in a single memory block. Even a simple Ethernet frame can be spread across multiple mbufs in a chain, especially after IP fragmentation or TCP segmentation. If you need to examine the headers, either use `m_pullup` to pull the headers into the first mbuf, or walk the chain carefully.

Forgetting to tap BPF. `tcpdump -i mynet0` will still work for received packets but will miss transmitted ones, and your debugging will be harder because the two halves of the conversation will appear asymmetric.

Updating counters after `m_freem`. We already mentioned this. Always read `m->m_pkthdr.len` into a local before freeing, or do all your counter updates before freeing.

Calling `if_link_state_change` with the wrong argument. `LINK_STATE_UP`, `LINK_STATE_DOWN`, and `LINK_STATE_UNKNOWN` are the three values defined in `/usr/src/sys/net/if.h`. Passing a random integer like 1 might coincidentally match `LINK_STATE_DOWN` but make the code unreadable and fragile.

28.7.25 Wrapping Up Section 4

The transmit path is the clearest demonstration of how the network stack and the driver cooperate. We accept a mbuf, validate it, count it, let BPF see it, and free it. Real hardware drivers add DMA and hardware rings at the bottom; the skeleton remains the same.

We have one large piece missing: the receive path. Without it, our interface talks but never listens. Section 5 builds that half.

28.8 Section 5: Handling Packet Reception

Reception is the inbound half of packet flow. Packets arrive from the transport, and the driver is responsible for turning them into mbufs, giving them to BPF, and handing them up to the stack through `if_input`. In a real NIC driver the arrival is an interrupt or a descriptor-ring completion. In our pseudo-driver, we will simulate arrival with a callout that fires every second and constructs a synthetic packet. The mechanism is artificial, but the code path is identical to what real drivers do after the initial descriptor-ring dequeue.

28.8.1 The Callback Direction

Transmit flows down: stack calls driver. Reception flows up: driver calls stack. You do not register a receive callback for the stack to invoke. Instead, whenever a packet arrives, you call `if_input(ifp, m)` (or equivalently `(*ifp->if_input)(ifp, m)`) and the stack takes over. `ether_ifattach` arranged for `ifp->if_input`

to point at `ether_input`, so when we call `if_input` the Ethernet layer receives the frame, strips the Ethernet header, dispatches on the `EtherType`, and hands the payload up to IPv4, IPv6, ARP, or wherever it belongs.

This is an important mental shift from `if_transmit`. The stack does not poll your driver. It waits to be called. Your driver is the active party for reception. Whenever you have a frame ready, you make the call. The stack does the rest.

28.8.2 The Simulated Arrival

Let us build a simulated arrival path. The idea: once a second, wake up, build a small mbuf containing a valid Ethernet frame, and feed it to the stack. The frame will be a broadcast ARP request targeting a nonexistent IP address. That is easy to construct, useful for testing because `tcpdump` will clearly display it, and harmless to the rest of the system.

First, the callout handler:

```
static void
mynet_rx_timer(void *arg)
{
    struct mynet_softc *sc = arg;
    struct ifnet *ifp = sc->ifp;

    MYNET_ASSERT(sc);
    if (!sc->running) {
        return;
    }
    callout_reset(&sc->rx_callout, sc->rx_interval_hz,
        mynet_rx_timer, sc);
    MYNET_UNLOCK(sc);

    mynet_rx_fake_arp(sc);

    MYNET_LOCK(sc);
}
```

The callout is initialised with `callout_init_mtx` and the softc mutex, so the system acquires our mutex before calling us. That gives us `MYNET_ASSERT` for free: the lock is already held. We check if we are still running, reschedule the timer for the next tick, drop the lock, do the actual work, and reacquire the lock on the way back. Dropping the lock is important, because `if_input` can take its time and may acquire other locks. Calling up into the stack while holding a driver mutex is a recipe for lock-order reversals.

Next, the packet construction itself:

```
static void
mynet_rx_fake_arp(struct mynet_softc *sc)
{
```

```
struct ifnet *ifp = sc->ifp;
struct mbuf *m;
struct ether_header *eh;
struct arphdr *ah;
uint8_t *payload;
size_t frame_len;

frame_len = sizeof(*eh) + sizeof(*ah) + 2 * (ETHER_ADDR_LEN + 4);
MGETHDR(m, M_NOWAIT, MT_DATA);
if (m == NULL) {
    if_inc_counter(ifp, IFCOUNTER_IQDROPS, 1);
    return;
}

m->m_pkthdr.len = m->m_len = frame_len;
m->m_pkthdr.rcvif = ifp;

eh = mtod(m, struct ether_header *);
memset(eh->ether_dhost, 0xff, ETHER_ADDR_LEN); /* broadcast */
memcpy(eh->ether_shost, sc->hwaddr, ETHER_ADDR_LEN);
eh->ether_type = htons(ETHERTYPE_ARP);

ah = (struct arphdr *)(eh + 1);
ah->ar_hrd = htons(ARPHRD_ETHER);
ah->ar_pro = htons(ETHERTYPE_IP);
ah->ar_hln = ETHER_ADDR_LEN;
ah->ar_pln = 4;
ah->ar_op = htons(ARPOP_REQUEST);

payload = (uint8_t *)(ah + 1);
memcpy(payload, sc->hwaddr, ETHER_ADDR_LEN); /* sender MAC */
payload += ETHER_ADDR_LEN;
memset(payload, 0, 4); /* sender IP 0.0.0.0 */
payload += 4;
memset(payload, 0, ETHER_ADDR_LEN); /* target MAC */
payload += ETHER_ADDR_LEN;
memcpy(payload, "\xc0\x00\x02\x63", 4); /* target IP 192.0.2.99 */

BPF_MTAP(ifp, m);

if_inc_counter(ifp, IFCOUNTER_IPACKETS, 1);
if_inc_counter(ifp, IFCOUNTER_IBYTES, frame_len);

if_input(ifp, m);
```

```
}
```

There is a lot to unpack, but most of it is simple. Let us walk through.

28.8.3 MGETHDR: Allocating the Head of the Chain

`MGETHDR(m, M_NOWAIT, MT_DATA)` allocates a new mbuf and prepares it as the head of a packet chain. It expands to `m_gethdr(M_NOWAIT, MT_DATA)` through the compatibility macro block in `/usr/src/sys/sys/mbuf.h` (the `#define MGETHDR(m, how, type) ((m) = m_gethdr((how), (type)))` entry, right next to `MGET` and `MCLGET`). `M_NOWAIT` tells the allocator to fail rather than sleep, which is appropriate because we may run in contexts where sleeping is forbidden (this particular callback is a callout, which cannot sleep). `MT_DATA` is the mbuf type for generic data.

On allocation failure we increment `IFCOUNTER_IQDROPS` (input queue drops) and return. Drops caused by mbuf starvation are counted this way in most drivers.

28.8.4 Setting Packet Header Fields

Once we have the mbuf, we set three fields in the packet header:

- `m->m_pkthdr.len`: the total length of the packet. This is the sum of `m_len` across the chain. For a single-mbuf packet like ours, `m_pkthdr.len` equals `m_len`.
- `m->m_len`: the length of data in this mbuf. We are storing the whole frame in the first (and only) mbuf.
- `m->m_pkthdr.rcvif`: the interface on which the packet arrived. The stack uses this for routing decisions and for reporting.

A small mbuf (about 256 bytes) holds our 42-byte Ethernet ARP frame comfortably. If we were building a larger frame, we would use `MGET` and external buffers, or `m_getcl` for a cluster-backed mbuf, or chain several mbufs together. We will revisit those patterns in later chapters.

28.8.5 Writing the Ethernet Header

`mtod(m, struct ether_header *)` is a macro from `/usr/src/sys/sys/mbuf.h` that casts `m_data` to a pointer to the requested type. It stands for “mbuf to data”. We use it to get a writeable `struct ether_header` pointer at the start of the packet and fill in the destination MAC (broadcast `ff:ff:ff:ff:ff:ff`), the source MAC (our interface’s MAC), and the EtherType (`ETHERTYPE_ARP`, in network byte order).

The Ethernet header is the minimum layer-2 encapsulation the stack expects on our interface, because we attached with `ether_ifattach`. `ether_input` will strip this header and dispatch on the EtherType.

28.8.6 Writing the ARP Body

Past the Ethernet header comes the ARP header proper, then the ARP payload (sender MAC, sender IP, target MAC, target IP). The field names and constants come from `/usr/src/sys/net/if_arp.h`. We put a real sender MAC (ours), a sender IP of `0.0.0.0`, a zero target MAC, and a target IP of `192.0.2.99`. That last

address is in the TEST-NET-1 range reserved by RFC 5737 for documentation and examples, which is a polite choice for a synthetic packet that will never leave our system.

None of this is production-grade ARP code. We are not trying to resolve anything. We are generating a well-formed frame that the Ethernet input layer will recognise, parse, log in counters, and drop (because the target IP is not ours). It is exactly the right level of realism for a teaching driver.

28.8.7 Handing It to BPF

`BPF_MTAP(ifp, m)` gives `tcpdump` a chance to see the incoming frame. We tap before we call `if_input`, because `if_input` may mutate the mbuf in ways that would make the tap show confusing data. Real drivers always tap before consuming.

28.8.8 Incrementing Input Counters

`IFCOUNTER_IPACKETS` and `IFCOUNTER_IBYTES` count received packets and bytes respectively. If the frame is a broadcast or multicast, we would also increment `IFCOUNTER_IMCASTS`. We omit that here for brevity but the full companion file includes it.

28.8.9 Calling `if_input`

`if_input(ifp, m)` is the final step. It is an inline helper in `/usr/src/sys/net/if_var.h` that dereferences `ifp->if_input` (which `ether_ifattach` set to `ether_input`) and invokes it. From that moment, the mbuf is the stack's responsibility. If the stack accepts the packet, it uses it and eventually frees it. If the stack rejects the packet, it frees it and increments `IFCOUNTER_IERRORS`. Either way, we must not touch `m` again.

This is the complementary rule to transmit: in transmit, the driver owns the mbuf until it is freed or handed to hardware; in receive, the stack takes ownership the moment you call `if_input`. Getting these ownership rules right is the single most important discipline in writing network drivers.

28.8.10 Verifying the Receive Path

Build and load the updated driver, bring up the interface, and watch `tcpdump`:

```
# kldload ./mynet.ko
# ifconfig mynet create
mynet0
# ifconfig mynet0 inet 192.0.2.1/24 up
# tcpdump -i mynet0 -n
tcpdump: verbose output suppressed, use -v or -vv for full protocol decode
listening on mynet0, link-type EN10MB (Ethernet), capture size 262144 bytes
14:22:01.000 02:a3:f1:22:bc:0d > ff:ff:ff:ff:ff:ff, ethertype ARP, Request who-has
↪ 192.0.2.99 tell 0.0.0.0, length 28
14:22:02.000 02:a3:f1:22:bc:0d > ff:ff:ff:ff:ff:ff, ethertype ARP, Request who-has
↪ 192.0.2.99 tell 0.0.0.0, length 28
...
```

Every second, you should see one synthesised ARP request fly by. If you then check `netstat -in -I mynet0`, the `IpKts` counter should be climbing. The stack accepts the packet, inspects the ARP, decides it is not a question addressed to it (because `192.0.2.99` is not assigned to the interface), and silently drops it. That is exactly what we want, and it demonstrates that the full receive path works.

28.8.11 Ownership: A Diagram

Because the ownership rules are so important, it helps to draw them. The following diagram summarises who owns the mbuf at each stage:

Transmit:

```
stack allocates mbuf
stack calls if_transmit(ifp, m)    <-- ownership handed to driver
driver inspects, counts, taps, drops or sends
driver must m_freem(m) exactly once
return 0 to stack
```

Receive:

```
driver allocates mbuf (MGETHDR/MGET)
driver fills in data
driver taps BPF
driver calls if_input(ifp, m)      <-- ownership handed to stack
driver MUST NOT touch m again
```

If you keep these two diagrams in your head, you will not get mbuf ownership wrong in your own drivers.

28.8.12 Keeping Receive Safe Under Contention

A production driver's receive path is usually called from an interrupt handler or a hardware queue completion routine, running on one CPU while another CPU may be transmitting or handling `ioctl`s. The pattern we have shown here is safe because:

- We hold our mutex around the “am I running?” check.
- We drop the mutex before the heavy work of mbuf allocation and packet construction.
- We drop the mutex before calling `if_input`, which may in turn call into the stack and acquire other locks.
- We reacquire our mutex after `if_input` returns, so that the callout framework can see a consistent state.

Real drivers often add per-CPU receive queues, deferred processing via taskqueues, and lock-free counters. All of that is a refinement of the same pattern. The core invariants remain the same: do not call up with a driver lock held, and do not touch an mbuf after it has been handed up.

28.8.13 Alternative: Using `if_epoch`

FreeBSD 12 introduced a network epoch mechanism, `net_epoch`, for accessing certain data structures without long-lived locks. Modern drivers often enter the net epoch around receive code to make their access to the routing table, ARP tables, and some parts of the `ifnet` list safe and fast. You will see `NET_EPOCH_ENTER(et)` and `NET_EPOCH_EXIT(et)` in many drivers. For our simple pseudo-driver, entering `net_epoch` would add complexity we do not need. We mention it here so that you recognise it when you read `if_em.c` or `if_bge.c`, and we will return to it in later chapters.

28.8.14 Receive Paths in Real NIC Drivers

Our simulated receive path is artificial, but the surrounding structure is exactly what real drivers use. The differences are in where the mbuf comes from and who calls the receive routine, not in what the receive routine does afterwards. This subsection walks through the typical real-driver receive path so that you recognise it the next time you open an Ethernet driver in the tree.

On a real NIC, packets arrive as DMA writes to receive descriptors in ring buffers. The hardware populates each descriptor with a pointer to a pre-allocated mbuf (provided by the driver during initialisation), a length, and a status field indicating whether the descriptor is ready for the driver to process. When a descriptor is ready, the hardware either raises an interrupt or sets a bit that the driver will notice through polling, or both.

The driver's receive routine walks the ring starting at the last-processed index. For each ready descriptor, it reads the length and status, fixes up the corresponding mbuf to have the correct `m_len` and `m_pkthdr.len`, sets `m->m_pkthdr.rcvif = ifp`, taps BPF, updates counters, and calls `if_input`. It then allocates a replacement mbuf to put back into the descriptor, so that future packets have somewhere to land, and advances the head pointer.

This loop continues until either the ring is empty or the driver has processed its per-invocation budget. Processing too many packets in one interrupt starves other interrupts and hurts latency for other devices; processing too few wastes context switches. A budget of 32 or 64 packets is typical.

After the receive loop, the driver updates the hardware's tail pointer to reflect the newly-replenished descriptors. If any descriptors are still ready, the driver either re-arms the interrupt or schedules itself to run again through a taskqueue.

The completion routine for transmit is the mirror image: it walks the transmit ring looking for descriptors whose status indicates the hardware has finished with them, frees the corresponding mbufs, and updates the driver's sense of available transmit slots.

You will see all of this in `/usr/src/sys/dev/e1000/em_txrx.c` and its equivalents for other Ethernet hardware. The ring-buffer machinery looks intimidating at first, but its purpose is always the same: produce mbufs from hardware DMA and hand them up through `if_input`. Our pseudo-driver produces mbufs from `malloc` and hands them up through `if_input`. The hand-up is identical; only the source of mbufs differs.

28.8.15 Deferred Receive Processing with Taskqueues

A common refinement in high-rate drivers is to defer the actual receive processing out of the interrupt context and into a taskqueue. The interrupt handler does the minimum amount of work (typically acknowledging the

interrupt to hardware and scheduling the task), and the taskqueue worker thread does the ring walk and the `if_input` calls.

Why defer? Because `if_input` can do significant work inside the stack, including TCP processing, socket-buffer deposition, and sleep operations. Holding a CPU in an interrupt handler for that long is bad for interrupt latency on other devices. Moving receive processing to a taskqueue lets the scheduler interleave it with other work.

FreeBSD's taskqueue subsystem, `/usr/src/sys/kern/subr_taskqueue.c`, provides per-CPU worker threads that can be targeted by drivers. A receive interrupt handler looks like:

```
static void
my_rx_intr(void *arg)
{
    struct mydrv_softc *sc = arg;

    /* Acknowledge the interrupt. */
    write_register(sc, RX_INT_STATUS, RX_READY);

    /* Defer the actual work. */
    taskqueue_enqueue(sc->rx_tq, &sc->rx_task);
}

static void
my_rx_task(void *arg, int pending __unused)
{
    struct mydrv_softc *sc = arg;

    mydrv_rx_drain(sc);      /* walk the ring and if_input each packet */
}
```

Again, `mynet` is a pseudo-driver and does not need this complexity. But seeing the pattern means that when you read `if_em.c` or `if_ixl.c` and see `taskqueue_enqueue`, you know what is being deferred and why.

28.8.16 Understanding `net_epoch`

The `net_epoch` framework in FreeBSD is an implementation of epoch-based reclamation adapted for the networking subsystem. Its purpose is to let readers of networking data structures (routing tables, ARP tables, interface lists, and so on) read those structures without acquiring locks, while ensuring that writers do not free a structure while a reader might still be looking at it.

The API is simple. A reader enters the epoch with `NET_EPOCH_ENTER(et)` and exits with `NET_EPOCH_EXIT(et)`, where `et` is a per-call tracker variable. Between enter and exit, the reader can safely dereference pointers into the protected data structures. Writers that want to free a protected object call `epoch_call` to defer the free until all current readers have exited.

For driver code, the relevance is this: the stack routines you call from your receive path, including `ether_input` and its downstream callers, expect to be invoked while the caller is inside the net epoch. Some drivers therefore wrap their `if_input` calls in `NET_EPOCH_ENTER/NET_EPOCH_EXIT`. Others (and this includes most callout-based pseudo-drivers) rely on the fact that `if_input` itself enters the epoch on entry if not already inside it.

For `mynet`, we do not enter the epoch explicitly. `if_input` handles that for us. If you want to be extra careful or are operating in a context where the epoch is known not to be entered, you can wrap your call like this:

```
struct epoch_tracker et;

NET_EPOCH_ENTER(et);
if_input(ifp, m);
NET_EPOCH_EXIT(et);
```

This is the idiom you will see in more recent drivers. We have omitted it in the main chapter text because it adds noise without changing behaviour for our pseudo-driver. In a driver that may fire `if_input` from unusual contexts (for example, a workqueue or a timer tick scheduled on a non-network CPU), you would want to wrap explicitly.

28.8.17 Receive Backpressure

A driver that receives packets faster than the stack can process them will eventually overrun its ring buffer. Real drivers handle this in one of two ways: they drop the oldest pending packets and update `IFCOUNTER_IQDROPS`, or they stop taking new descriptors and let the hardware itself drop.

In software pseudo-drivers there is no hardware to run out of descriptors, but you should still think about backpressure. If your simulated receive path is generating packets faster than the stack can consume them, you will eventually see mbuf allocation failures, or the system will start queueing packets in socket buffers without ever emptying them. The practical defence is to rate-limit yourself through the callout interval and to watch `vmstat -z | grep mbuf` during long-running tests.

For `mynet`, we generate one synthetic ARP per second. That is several orders of magnitude below any reasonable backpressure threshold. But if you increase `sc->rx_interval_hz` to something aggressive like `hz / 1000` (one packet per millisecond), you are asking the kernel to absorb a thousand ARPs per second from a single driver, and you will see the costs.

28.8.18 Common Mistakes

The most common receive-path mistakes are the following.

Forgetting `M_PKTHDR` discipline. If you construct the mbuf without `MGETHDR`, you do not get a packet header, and the stack will assert or misbehave. Always use `MGETHDR` (or `m_gethdr`) for the head mbuf, and `MGET` (or `m_get`) for subsequent ones.

Forgetting to set `m_len` and `m_pkthdr.len`. The stack uses `m_pkthdr.len` to decide how big the packet is, and it uses `m_len` to walk the chain. If these are wrong, decoding fails silently.

Holding the driver mutex across `if_input`. The stack can take a long time inside `if_input`, and it may attempt to acquire other locks. Releasing the driver lock before calling up is a discipline that avoids deadlocks.

Touching `m` after `if_input`. The stack may have already freed or re-queued the mbuf. Treat `if_input` as a one-way door.

Feeding raw data without a link-layer header. Because we used `ether_ifattach`, `ether_input` expects a full Ethernet frame. If you feed it a bare IPv4 packet, it will reject the frame and increment `IFCOUNTER_IERRORS`.

28.8.19 Wrapping Up Section 5

We now have two-way traffic through our driver. Transmit consumes mbufs from the stack; receive produces mbufs for the stack. In between we have BPF hooks, counter updates, and mutex discipline. What we do not yet have is a careful story for link state, media descriptors, and interface flags. That is Section 6.

28.9 Section 6: Media State, Flags, and Link Events

Up to this point we have focused on packets. But a network interface is more than a packet mover. It is a stateful participant in the network stack. It goes up and it goes down. It has a media type, and that media can change. Its link can come and go. The stack cares about all of those transitions, and userland tools present them to the administrator. In this section we add the state-management layer to mynet.

28.9.1 Interface Flags: `IFF_` and `IFF_DRV_`

You have already met `IFF_UP` and `IFF_DRV_RUNNING`. There are many more, and they divide into two families that work in distinct ways.

The `IFF_` flags, defined in `/usr/src/sys/net/if.h`, are the user-visible flags. They are what `ifconfig` reads and writes. Common ones include:

- `IFF_UP` (0x1): the interface is administratively up.
- `IFF_BROADCAST` (0x2): the interface supports broadcast.
- `IFF_POINTOPOINT` (0x10): the interface is point-to-point.
- `IFF_LOOPBACK` (0x8): the interface is a loopback.
- `IFF_SIMPLEX` (0x800): the interface cannot hear its own transmissions.
- `IFF_MULTICAST` (0x8000): the interface supports multicast.
- `IFF_PROMISC` (0x100): the interface is in promiscuous mode.
- `IFF_ALLMULTI` (0x200): the interface is receiving all multicast.
- `IFF_DEBUG` (0x4): debug tracing is requested by the user.

These flags are set and cleared primarily by userland through `SIOCSIFFLAGS`. Your driver should react to changes in them: when `IFF_UP` goes from clear to set, initialise; when it goes from set to clear, quiesce.

The `IFF_DRV_` flags, also in `if.h`, are driver-private. They live in `ifp->if_drv_flags` (not `if_flags`). Userland cannot see or modify them. The two most important are:

- `IFF_DRV_RUNNING (0x40)`: the driver has allocated its per-interface resources and can move traffic. Identical to the older `IFF_RUNNING` alias.
- `IFF_DRV_OACTIVE (0x400)`: the driver's output queue is full. The stack should not call `if_start` or `if_transmit` again until this flag clears.

Think of `IFF_UP` as the user's intent and `IFF_DRV_RUNNING` as the driver's readiness. Both need to be true for traffic to flow.

28.9.2 The `SIOCSIFFLAGS` `ioctl`

When userland runs `ifconfig mynet0 up`, it sets `IFF_UP` in the interface's flag field and issues `SIOCSIFFLAGS`. The stack dispatches this `ioctl` through our `if_ioctl` callback. Our job is to notice the flag change and react.

Here is the canonical pattern for handling `SIOCSIFFLAGS` in a network driver:

```
case SIOCSIFFLAGS:
    MYNET_LOCK(sc);
    if (ifp->if_flags & IFF_UP) {
        if ((ifp->if_drv_flags & IFF_DRV_RUNNING) == 0) {
            MYNET_UNLOCK(sc);
            mynet_init(sc);
            MYNET_LOCK(sc);
        }
    } else {
        if (ifp->if_drv_flags & IFF_DRV_RUNNING) {
            MYNET_UNLOCK(sc);
            mynet_stop(sc);
            MYNET_LOCK(sc);
        }
    }
    MYNET_UNLOCK(sc);
    break;
```

Let us parse this.

If `IFF_UP` is set, we check whether the driver is already running. If not, we invoke `mynet_init` to initialise. If the driver is already running, we do nothing: the user setting the flag again is a no-op.

If `IFF_UP` is not set, we check whether we were running. If so, we call `mynet_stop` to quiesce. If not, again a no-op.

We drop the lock before calling `mynet_init` or `mynet_stop`, because those functions may take time and may internally reacquire the lock. The pattern of “unlock, call, relock” is a standard idiom for `ioctl` handlers.

28.9.3 Writing `mynet_stop`

`mynet_init` we wrote in Section 4. Its counterpart `mynet_stop` is similar but in reverse:

```
static void
mynet_stop(struct mynet_softc *sc)
{
    struct ifnet *ifp = sc->ifp;

    MYNET_LOCK(sc);
    sc->running = false;
    ifp->if_drv_flags &= ~IFF_DRV_RUNNING;
    callout_stop(&sc->rx_callout);
    MYNET_UNLOCK(sc);

    if_link_state_change(ifp, LINK_STATE_DOWN);
}
```

We clear our running flag, drop the IFF_DRV_RUNNING bit so the stack knows we are not carrying traffic, stop the receive callout, and announce link-down to the stack. This is the symmetric partner to the init function.

28.9.4 Link State: `if_link_state_change`

`if_link_state_change(ifp, state)` is the canonical way for a driver to report link transitions. The values come from `/usr/src/sys/net/if.h`:

- `LINK_STATE_UNKNOWN (0)`: the driver does not know the link state. This is the initial value.
- `LINK_STATE_DOWN (1)`: no carrier, no link partner reachable.
- `LINK_STATE_UP (2)`: link is up, link partner is reachable, carrier is present.

The stack records the new state, sends a routing socket notification, wakes up any sleepers on the interface state, and lets userland know through `ifconfig's status: line`. Real NIC drivers call `if_link_state_change` from the link-state-change interrupt handler, typically in response to PHY autonegotiation completion or loss. For pseudo-drivers, we choose when to call it based on the driver's own logic.

It is worth being deliberate about when you call this function. In `mynet_init` we call it with `LINK_STATE_UP` after we have set `IFF_DRV_RUNNING`. In `mynet_stop` we call it with `LINK_STATE_DOWN` after we have cleared `IFF_DRV_RUNNING`. If you reverse the order, you will briefly be reporting a link up on an interface that is not running, or a link down on an interface that still claims to be running. The stack can cope, but the symptoms of the reversal are confusing.

28.9.5 Media Descriptors

Above link state sits media. Media is the description of what kind of connection is in use: 10BaseT, 100BaseT, 1000BaseT, 10GBaseSR, and so on. It is not the same as link state: a connection can have a known media type even when the link is down.

FreeBSD's media subsystem lives in `/usr/src/sys/net/if_media.c` and its header `/usr/src/sys/net/if_media.h`. Drivers use it through a small API:

- `ifmedia_init(ifm, dontcare_mask, change_fn, status_fn)`: initialise the descriptor.
- `ifmedia_add(ifm, word, data, aux)`: add a media entry.
- `ifmedia_set(ifm, word)`: choose the default entry.
- `ifmedia_ioctl(ifp, ifr, ifm, cmd)`: handle `SIOCGIFMEDIA` and `SIOCSIFMEDIA`.

The “word” is a bitfield combining the media subtype and flags. For Ethernet drivers you combine `IFM_ETHER` with a subtype like `IFM_1000_T` (1000BaseT), `IFM_10G_T` (10GBaseT), or `IFM_AUTO` (autonegotiate). The full set of subtypes is enumerated in `if_media.h`.

We set up the descriptor in Section 3:

```
ifmedia_init(&sc->media, 0, mynet_media_change, mynet_media_status);
ifmedia_add(&sc->media, IFM_ETHER | IFM_1000_T | IFM_FDX, 0, NULL);
ifmedia_add(&sc->media, IFM_ETHER | IFM_AUTO, 0, NULL);
ifmedia_set(&sc->media, IFM_ETHER | IFM_AUTO);
```

The callbacks are what the stack invokes when userland queries or sets the media:

```
static int
mynet_media_change(struct ifnet *ifp __unused)
{
    /* In a real driver, program the PHY here. */
    return (0);
}

static void
mynet_media_status(struct ifnet *ifp, struct ifmediareq *imr)
{
    struct mynet_softc *sc = ifp->if_softc;

    imr->ifm_status = IFM_AVALID;
    if (sc->running)
        imr->ifm_status |= IFM_ACTIVE;
    imr->ifm_active = IFM_ETHER | IFM_1000_T | IFM_FDX;
}
```

`mynet_media_change` is the stub: there is no PHY to reprogram in a pseudo-driver. `mynet_media_status` is what `ifconfig` reports through `SIOCGIFMEDIA`: `ifm_status` gets `IFM_AVALID` (the status fields are valid) and `IFM_ACTIVE` (the link is currently active) when we are running, and `ifm_active` tells the caller which media we are actually using.

The `ioctl` handler routes media requests to `ifmedia_ioctl`:

```
case SIOCGIFMEDIA:
case SIOCSIFMEDIA:
```

```
error = ifmedia_ioctl(ifp, ifr, &sc->media, cmd);  
break;
```

This is exactly the pattern used by the SIOCSIFMEDIA / SIOCGIFMEDIA case inside `epair_ioctl` in `/usr/src/sys/net/if_epair.c`.

With this in place, `ifconfig mynet0` will report something like:

```
mynet0: flags=8843<UP,BROADCAST,RUNNING,SIMPLEX,MULTICAST> metric 0 mtu 1500  
ether 02:a3:f1:22:bc:0d  
inet 192.0.2.1 netmask 0xffffffff broadcast 192.0.2.255  
media: Ethernet autoselect (1000baseT <full-duplex>)  
status: active
```

28.9.6 Handling MTU Changes

SIOCSIFMTU is the `ioctl` the user issues when running `ifconfig mynet0 mtu 1400`. A well-behaved driver checks that the requested value is within its supported range and then updates `if_mtu`. Our code:

```
case SIOCSIFMTU:  
    if (ifr->ifr_mtu < 68 || ifr->ifr_mtu > 9216) {  
        error = EINVAL;  
        break;  
    }  
    ifp->if_mtu = ifr->ifr_mtu;  
    break;
```

The lower limit of 68 bytes matches the smallest IPv4 payload plus headers. The upper limit of 9216 is a generous jumbo-frame bound. Real drivers have narrower ranges that match what their hardware can fragment. We keep the range permissive because this is a pseudo-driver.

28.9.7 Handling Multicast Group Changes

SIOCADDMULTI and SIOCDELMULTI signal that the user has added or removed a multicast group on the interface. For a real NIC that implements hardware multicast filtering, the driver would reprogram the filter each time. Our pseudo-driver has no filter, so we simply acknowledge the request:

```
case SIOCADDMULTI:  
case SIOCDELMULTI:  
    /* Nothing to program. */  
    break;
```

This is good enough for correct operation. The stack will deliver multicast traffic to the interface based on its internal group list, and we do not need to do anything special.

28.9.8 Putting the ioctl Handler Together

With all of the above, the full `mynet_ioctl` looks like this:

```
static int
mynet_ioctl(struct ifnet *ifp, u_long cmd, caddr_t data)
{
    struct mynet_softc *sc = ifp->if_softc;
    struct ifreq *ifr = (struct ifreq *)data;
    int error = 0;

    switch (cmd) {
    case SIOCSIFFLAGS:
        MYNET_LOCK(sc);
        if (ifp->if_flags & IFF_UP) {
            if ((ifp->if_drv_flags & IFF_DRV_RUNNING) == 0) {
                MYNET_UNLOCK(sc);
                mynet_init(sc);
                MYNET_LOCK(sc);
            }
        } else {
            if (ifp->if_drv_flags & IFF_DRV_RUNNING) {
                MYNET_UNLOCK(sc);
                mynet_stop(sc);
                MYNET_LOCK(sc);
            }
        }
        MYNET_UNLOCK(sc);
        break;

    case SIOCSIFMTU:
        if (ifr->ifr_mtu < 68 || ifr->ifr_mtu > 9216) {
            error = EINVAL;
            break;
        }
        ifp->if_mtu = ifr->ifr_mtu;
        break;

    case SIOCADDMULTI:
    case SIOCDELMULTI:
        break;

    case SIOCGIFMEDIA:
    case SIOCSIFMEDIA:
        error = ifmedia_ioctl(ifp, ifr, &sc->media, cmd);
    }
```

```
        break;

    default:
        /* Let the common ethernet handler process this. */
        error = ether_ioctl(ifp, cmd, data);
        break;
    }

    return (error);
}
```

The default case delegates to `ether_ioctl`, which handles the `ioctl`s that every Ethernet driver handles the same way (for example `SIOCSIFADDR`, `SIOCSIFCAP` in the common cases). That saves us writing fifteen lines of boilerplate. `/usr/src/sys/net/if_epair.c` does the same in the default arm of the switch in `epair_ioctl`.

28.9.9 Flag Coherence Rules

There are a few coherence rules you should keep in mind as you write driver state transitions:

1. `IFF_DRV_RUNNING` follows `IFF_UP`, not the other way around. The user sets `IFF_UP`, and the driver sets or clears `IFF_DRV_RUNNING` in response.
2. Link state changes should happen after `IFF_DRV_RUNNING` transitions, not before.
3. Callouts and taskqueues that were started when you set `IFF_DRV_RUNNING` should be stopped or drained when you clear it.
4. `if_input` calls should only happen when `IFF_DRV_RUNNING` is set. Otherwise, you are delivering packets on an interface that the stack has not finished bringing up.
5. `if_transmit` may be called even when `IFF_UP` is clear, because of a race between userland and the stack. Your transmit path should check the flags and drop gracefully if either is clear.

These rules are implicit in the code of every well-written driver. Making them explicit is useful when you are first learning.

28.9.10 Interface Capabilities in Depth

We touched on capabilities in Section 3 when we set `IFCAP_VLAN_MTU`. Capabilities deserve a fuller treatment here, because they are how a driver tells the stack which offloads it can perform, and they are increasingly central to how fast drivers stay fast.

The `if_capabilities` field, defined in `/usr/src/sys/net/if.h`, is a bitmask of capabilities the hardware can perform. The `if_capenable` field is a bitmask of capabilities currently enabled. They are separated because userland can toggle individual offloads at runtime through `ifconfig mynet0 -rxcsu` or `ifconfig mynet0 +tso`, and the driver must honour that choice.

The common capabilities are:

- `IFCAP_RXCSUM` and `IFCAP_RXCSUM_IPV6`: the driver will verify IPv4 and IPv6 checksums in hardware and mark correctly-summed packets with `CSUM_DATA_VALID` in the mbuf's `m_pkthdr.csum_flags`.
- `IFCAP_TXCSUM` and `IFCAP_TXCSUM_IPV6`: the driver will compute TCP, UDP, and IP checksums in hardware for outbound packets whose `m_pkthdr.csum_flags` requests it.
- `IFCAP_TS04` and `IFCAP_TS06`: the driver accepts large TCP segments and the hardware splits them into MTU-sized frames on the wire. This dramatically reduces CPU load for TCP-heavy workloads.
- `IFCAP_LRO`: the driver aggregates multiple received TCP segments into a single large mbuf before handing up. Symmetric to TSO on the receive side.
- `IFCAP_VLAN_HWTAGGING`: the driver will add and strip 802.1Q VLAN tags in hardware rather than in software. This saves a mbuf copy per VLAN frame.
- `IFCAP_VLAN_MTU`: the driver can carry VLAN-tagged frames whose total length slightly exceeds the standard Ethernet MTU because of the extra 4-byte tag.
- `IFCAP_JUMBO_MTU`: the driver supports frames larger than 1500 bytes of payload.
- `IFCAP_WOL_MAGIC`: wake-on-LAN using the magic packet.
- `IFCAP_POLLING`: classic device polling, now rarely used.
- `IFCAP_NETMAP`: the driver supports `netmap(4)` kernel-bypass packet I/O.
- `IFCAP_TOE`: TCP offload engine. Rare, but exists on some high-end NICs.

Advertising a capability makes a promise to the stack that you will honour it. If you claim `IFCAP_TXCSUM` but do not actually compute the TCP checksum for outbound frames, the kernel will happily hand you packets with an uncomputed checksum and expect you to finish the job. The receiver will get corrupt frames and discard them. The symptom is silent data loss, which is painful to debug.

For `mynet`, we honestly advertise only what we can deliver. `IFCAP_VLAN_MTU` is the only capability we claim, and we honour it by accepting frames up to `ifp->if_mtu + sizeof(struct ether_vlan_header)` in our transmit path.

A well-behaved driver also handles `SIOCSIFCAP` in its `ioctl` handler so that the user can toggle specific offloads:

```
case SIOCSIFCAP:
    mask = ifr->ifr_reqcap ^ ifp->if_capenable;
    if (mask & IFCAP_VLAN_MTU)
        ifp->if_capenable ^= IFCAP_VLAN_MTU;
    /* Reprogram hardware if needed. */
    break;
```

For a pseudo-driver there is no hardware to reprogram, but the user-visible toggle still works because the `ioctl` updates `if_capenable` and every subsequent transmit decision reads that field.

28.9.11 The `ether_ioctl` Common Handler

We saw earlier that `mynet_ioctl` delegates unknown `ioctls` to `ether_ioctl`. It is worth peeking at what that function does, because it explains why most drivers can get away with handling only a handful of `ioctls` explicitly.

`ether_ioctl`, defined in `/usr/src/sys/net/if_etherubr.c`, is a generic handler for the `ioctls` that every Ethernet interface treats the same way. Its responsibilities include:

- `SIOCSIFADDR`: the user is assigning an IP address to the interface. `ether_ioctl` handles the ARP probe and the address registration. It invokes the driver's `if_init` callback if the interface is down and should be brought up.
- `SIOCGIFADDR`: return the link-layer address of the interface.
- `SIOCSIFMTU`: if the driver does not provide its own handler, `ether_ioctl` performs the generic MTU change by updating `if_mtu`.
- `SIOCADDMULTI` and `SIOCDELMULTI`: update the driver's multicast filter, if one exists.
- Various capability-related `ioctls`.

Because the default handler handles so much, drivers typically only need to handle `ioctls` that require driver-specific logic: `SIOCSIFFLAGS` for the up/down transition, `SIOCSIFMEDIA` to reprogram media, and `SIOCSIFCAP` to toggle capabilities. Everything else falls through to `ether_ioctl`.

This delegation model is one of the things that makes writing a small Ethernet driver pleasant: you write the code that is specific to your driver, and the common code takes care of the rest.

28.9.12 Hardware Multicast Filtering

For a real NIC, multicast filtering is often done in hardware. The driver programs a set of MAC addresses into a hardware filter table, and the NIC only delivers frames whose destination matches an address in the table. When the user runs `ifconfig mynet0 addm 01:00:5e:00:00:01` to join a multicast group, the stack issues `SIOCADDMULTI`, and the driver must update the filter table.

The typical pattern in a real driver is:

```
case SIOCADDMULTI:
case SIOCDELMULTI:
    if (ifp->if_drv_flags & IFF_DRV_RUNNING) {
        MYDRV_LOCK(sc);
        mydrv_setup_multicast(sc);
        MYDRV_UNLOCK(sc);
    }
    break;
```

`mydrv_setup_multicast` walks the interface's multicast list (accessed through `if_maddr_r` lock and friends) and programs each address into the hardware filter. The code is boring but important; getting it wrong means multicast applications like mDNS (Bonjour, Avahi), IGMP-based routing, and IPv6 neighbour discovery quietly misbehave.

For `mynet` we have no hardware filter, so we simply accept `SIOCADDMULTI` and `SIOCDELMULTI` without doing anything. The stack still tracks the list of multicast groups for us, and our receive path does not filter, so everything works.

If you ever write a driver with hardware multicast filtering, read `/usr/src/sys/dev/e1000/if_em.c`'s `em_multi_set` function for a clear example of the pattern.

28.9.13 Wrapping Up Section 6

We have covered the state half of a network driver. Flags, link state, media descriptors, and the ioctls that tie them all together. Combined with the transmit and receive paths from Sections 4 and 5, we now have a driver that is indistinguishable from a simple real Ethernet driver at the `ifnet` boundary.

Before we can call the driver finished, we need to make sure we can test it thoroughly with the tools the FreeBSD ecosystem provides. That is Section 7.

28.10 Section 7: Testing the Driver With Standard Networking Tools

A driver is only as good as your confidence that it works. Confidence does not come from staring at code. It comes from running the driver, interacting with it from the outside, and observing the results. This section walks through the standard FreeBSD networking tools and shows how to use each one to exercise a specific aspect of `mynet`.

28.10.1 Load, Create, Configure

Start with a clean slate. If the module is loaded, unload it, then load the fresh build and create the first interface:

```
# kldstat | grep mynet
# kldload ./mynet.ko
# ifconfig mynet create
mynet0
```

`ifconfig mynet0` should show the interface with a MAC address, no IP, no flags beyond the default set, and a media descriptor saying “autoselect”. Assign an address and bring it up:

```
# ifconfig mynet0 inet 192.0.2.1/24 up
# ifconfig mynet0
mynet0: flags=8843<UP,BROADCAST,RUNNING,SIMPLEX,MULTICAST> metric 0 mtu 1500
    ether 02:a3:f1:22:bc:0d
    inet 192.0.2.1 netmask 0xffffffff broadcast 192.0.2.255
    media: Ethernet autoselect (1000baseT <full-duplex>)
    status: active
    groups: mynet
```

The `UP` and `RUNNING` flags confirm that the user’s intent and the driver’s readiness are both present. The `status: active` line comes from our media callback. The media description includes `1000baseT` because that is what `mynet_media_status` returned.

28.10.2 Inspecting With netstat

`netstat -in -I mynet0` shows per-interface counters. Initially, everything is zero; wait a few seconds for the receive simulation to kick in and the counter should climb:

```
# netstat -in -I mynet0
```

Name	Mtu	Network	Address	Ipkts	Ierrs	...	Opkts	Oerrs
mynet0	1500	<Link#12>	02:a3:f1:22:bc:0d	3	0		0	0
mynet0	-	192.0.2.0/24	192.0.2.1	0	-		0	-

The first line's `Ipkts` counts the synthetic ARP requests our receive timer produces. It should rise by about one every second. If it does not, the `rx_interval_hz` setting is wrong, or the callout is not being started in `mynet_init`, or `running` is false.

28.10.3 Capturing With tcpdump

`tcpdump -i mynet0 -n` captures all traffic on our interface. You should see the synthetic ARP requests being generated every second, along with any traffic caused by your own ping attempts:

```
# tcpdump -i mynet0 -n
tcpdump: verbose output suppressed, use -v or -vv for full protocol decode
listening on mynet0, link-type EN10MB (Ethernet), capture size 262144 bytes
14:30:12.000 02:a3:f1:22:bc:0d > ff:ff:ff:ff:ff:ff, ethertype ARP, Request who-has
  ↪ 192.0.2.99 tell 0.0.0.0, length 28
14:30:13.000 02:a3:f1:22:bc:0d > ff:ff:ff:ff:ff:ff, ethertype ARP, Request who-has
  ↪ 192.0.2.99 tell 0.0.0.0, length 28
...
```

The “link-type EN10MB (Ethernet)” confirms that BPF saw us as an Ethernet interface, which is the consequence of `ether_ifattach` having called `bpfattach(ifp, DLT_EN10MB, ETHER_HDR_LEN)` for us. Switch to `-v` or `-vv` to see fuller protocol decoding.

28.10.4 Generating Traffic With ping

Trigger outbound traffic by pinging an IP in the subnet we assigned:

```
# ping -c 3 192.0.2.99
PING 192.0.2.99 (192.0.2.99): 56 data bytes
--- 192.0.2.99 ping statistics ---
3 packets transmitted, 0 packets received, 100.0% packet loss
```

All three pings are lost, because our pseudo-driver simulates a wire with nothing at the other end. But the transmit counter moves:

```
# netstat -in -I mynet0
Name      Mtu Network      Address                Ipkts Ierrs ... Opkts Oerrs
mynet0 1500 <Link#12>    02:a3:f1:22:bc:0d      30    0      6    0
```

The 6 transmitted packets are three pings plus three ARP broadcast requests the stack issued trying to resolve 192.0.2.99. You can verify this with `tcpdump`.

28.10.5 `arp -an`

`arp -an` shows the system's ARP cache. Entries for 192.0.2.99 should appear as incomplete while the stack waits for an ARP reply that will never come. After a minute or so they expire.

28.10.6 `sysctl net.link` and `sysctl net.inet`

The network subsystems expose a wealth of per-interface and per-protocol sysctls. `sysctl net.link.ether` controls Ethernet-layer behaviour. `sysctl net.inet.ip` controls IP-layer behaviour. While none of these are specific to `mynet`, they are good to know. A common one when diagnosing pseudo-driver behaviour is `sysctl net.link.ether.inet.log_arp_wrong_iface=0`, which silences log messages about ARP traffic appearing on unexpected interfaces.

28.10.7 Monitoring Link Events With `ifstated` or `devd`

FreeBSD propagates link-state changes through the routing socket. You can observe this live with `route monitor`:

```
# route monitor
```

When you run `ifconfig mynet0 down` followed by `ifconfig mynet0 up`, `route monitor` prints `RTM_IFINFO` messages corresponding to the link-state changes we are announcing through `if_link_state_change`. That is the same mechanism `devd` uses for its notify events, and it is how scripts can react to link flaps.

28.10.8 Testing MTU Changes

```
# ifconfig mynet0 mtu 9000
# ifconfig mynet0
mynet0: ... mtu 9000
```

Change the MTU to something reasonable and watch `ifconfig` reflect the change. Try an out-of-range value and verify that the kernel rejects it:

```
# ifconfig mynet0 mtu 10
ifconfig: ioctl SIOCSIFMTU (set mtu): Invalid argument
```

That error comes from our SIOCSIFMTU handler returning EINVAL.

28.10.9 Testing Media Commands

```
# ifconfig mynet0 media 10baseT/UTP
ifconfig: requested media type not found
```

This fails because we did not register IFM_ETHER | IFM_10_T as an acceptable media type. Register it in mynet_create_unit and rebuild to see the command succeed.

```
# ifconfig mynet0 media 1000baseT
# ifconfig mynet0 | grep media
      media: Ethernet 1000baseT <full-duplex>
```

28.10.10 Comparing Against if_disc

Load if_disc alongside and compare:

```
# kldload if_disc
# ifconfig disc create
disc0
# ifconfig disc0 inet 192.0.2.50/24 up
```

disc0 is a simpler pseudo-driver. It ignores every outbound packet by dropping it in its discoutput function (not discoutput we wrote, but the one in if_disc.c). It has no receive path. Running tcpdump -i disc0 while pinging 192.0.2.50 shows outbound ICMP frames but no inbound ARP activity. Compare that with our mynet0, which still shows its synthetic ARP frames arriving once per second.

The contrast is useful because it shows how small the step is from “drop everything” to “simulate a full Ethernet interface”. We added a MAC address, a media descriptor, a callout, and a packet builder. Everything else, including the interface registration, the BPF hook, the flags, was already in the pattern.

28.10.11 Stress Test With iperf3

iperf3 can saturate a real Ethernet link. On our pseudo-driver it will not produce meaningful throughput numbers (the packets go nowhere), but it exercises if_transmit very hard:

```
# iperf3 -c 192.0.2.99 -t 10
Connecting to host 192.0.2.99, port 5201
iperf3: error - unable to connect to server: Connection refused
```

The connection fails because there is no server, but `netstat -in -I mynet0` will show `Opkts` climbing rapidly with the TCP retransmissions and ARP requests `iperf3` caused. Watch `vmstat 1` in another terminal and make sure the system load remains reasonable. If you see a lot of time spent in the driver, you may have a locking hot spot that is worth investigating.

28.10.12 Scripted Test Runs

You can wrap the above commands into a small shell script that exercises the driver in a known sequence. Here is a minimal example:

```
#!/bin/sh

set -e

echo "== load =="
kldload ./mynet.ko

echo "== create =="
ifconfig mynet create

echo "== configure =="
ifconfig mynet0 inet 192.0.2.1/24 up

echo "== traffic =="
(tcpdump -i mynet0 -nn -c 5 > /tmp/mynet-tcpdump.txt 2>&1) &
sleep 3
ping -c 2 192.0.2.99 || true
wait
cat /tmp/mynet-tcpdump.txt

echo "== counters =="
netstat -in -I mynet0

echo "== teardown =="
ifconfig mynet0 destroy
kldunload mynet
```

Save it under `examples/part-06/ch28-network-driver/lab05-bpf/run.sh`, mark it executable, and run it as root. It walks the driver through its entire lifecycle in under ten seconds. When something breaks later, a scripted baseline like this is priceless for spotting regressions.

28.10.13 What to Watch For

While testing, keep an eye on:

- `dmesg` output during load and unload, for unexpected warnings.
- `netstat -in -I mynet0` before and after operations, to confirm counters move in the expected direction.
- `kldstat` after unload, to confirm the module is gone.
- `ifconfig -a` after destroy, to confirm no orphan interface is left.
- `vmstat -m | grep mynet` to confirm memory is returned on unload.
- `vmstat -z | grep mbuf` across load test runs, to confirm mbuf counts stabilise.

A driver that is correct on a cold load can still leak on unload, or leak under load, or panic the kernel in a rare race. The tools listed above are the first line of defence against all those classes of bugs.

28.10.14 Deeper Observability with DTrace

FreeBSD's DTrace implementation is a formidable tool for driver observability, and once you know a few patterns you will reach for it often. The basic idea is that every function entry and exit in the kernel is a probe point, and every probe point can be instrumented from userland without modifying the code.

To count how often our transmit function is called:

```
# dtrace -n 'fbt::mynet_transmit:entry { @c = count(); }'
```

Run that in one terminal, generate traffic in another, and you will see the count climb. To observe each call with the packet length:

```
# dtrace -n 'fbt::mynet_transmit:entry { printf("len=%d", args[1]->m_pkthdr.len); }'
```

DTrace scripts can be much more elaborate. Here is one that counts transmitted packets grouped by source IP, if the interface is carrying IPv4 traffic:

```
# dtrace -n 'fbt::mynet_transmit:entry /args[1]->m_pkthdr.len > 34/ {  
    this->ip = (struct ip *) (mtod(args[1], struct ether_header *) + 1);  
    @src[this->ip->ip_src.s_addr] = count();  
}'
```

This kind of observability is difficult to add to a driver by hand, but DTrace gives it to you for free. Use it. When you cannot tell why a packet did or did not flow, DTrace probes on your own functions will almost always reveal the answer.

Some additional useful one-liners for network-driver work:

```
# dtrace -n 'fbt::if_input:entry { @ifs[stringof(args[0]->if_xname)] = count(); }'
```

This counts every call to `if_input` across the whole system, grouped by interface name. It is a quick way to verify that your receive path is reaching the stack.

```
# dtrace -n 'fbt::if_inc_counter:entry /args[1] == 1/ {
    @[stringof(args[0]->if_xname)] = count();
}'
```

This counts calls to `if_inc_counter` for `IFCOUNTER_IPACKETS` (which is value 1 in the enum) grouped by interface name. Compared with `netstat -in`, it lets you see the increments in real time.

Do not be afraid of DTrace. It looks intimidating at first because of the script-like syntax, but a driver debugging session with DTrace often takes minutes where the equivalent `printf`-debugging takes hours. Every minute you invest in learning DTrace idioms repays itself many times over.

28.10.15 Kernel Debugger Tips for Drivers

When a network driver panics or hangs, the kernel debugger (`ddb` or `kgdb`) is the tool of last resort. A few tips specific to driver work:

- After a panic, show `mbuf` (or show `pcpu`, show `alltrace`, show `lockchain` depending on what you are investigating) walks the mbuf allocations or the per-CPU data or the blocked-thread chains. Knowing which of these to invoke is a matter of practice.
- `show ifnet <pointer>` prints the contents of an `ifnet` structure given its address. Useful when a panic message says “`ifp = 0xffff...`”. The equivalent for a softc depends on the driver.
- `bt` prints a stack trace. Mostly you want `bt <tid>` where `<tid>` is the thread ID of interest.
- `continue` resumes execution, but after a real panic it is usually not safe. Collect information and then reboot.

For non-panic debugging, `kgdb /boot/kernel/kernel /var/crash/vmcore.0` lets you post-mortem a crash dump. Driver development on a lab VM with a crash dump partition is a comfortable workflow: panic, reboot, look at the dump at leisure.

28.10.16 `systat -if` for Live Counter Views

`systat -if 1` opens an ncurses view that refreshes every second and shows per-interface counter rates. It is a useful complement to `netstat -in` because you can watch traffic rise and fall in real time without reading the terminal log.

	/0	/1	/2	/3	/4	/5	/6	/7	/8	/9	/10
Load Average											
Interface	Traffic					Peak		Total			
mynet0	in	0.000 KB/s				0.041 KB/s		0.123 KB			
	out	0.000 KB/s				0.047 KB/s		0.167 KB			

The rates in this view are computed by `systat` from the counters we increment in `if_transmit` and in our receive path. If the rates do not match what you expect, the first suspicion should be that a counter is being

updated twice, or that it is being updated after `m_freem`, or that it is using `IFCOUNTER_OPACKETS` where it should use `IFCOUNTER_IPACKETS`. `systat -if` makes those mistakes very visible.

28.10.17 Wrapping Up Section 7

You now have a tested driver. It loads, configures, carries traffic both directions, reports its state to userland, cooperates with BPF, and reacts to link events. What remains is the final phase of the lifecycle: clean detachment, module unload, and some refactoring advice. That is Section 8.

28.11 Section 8: Cleanup, Detach, and Refactoring of the Network Driver

Every driver has a beginning and an end. The beginning is the pattern we have built up over the chapter: allocate, configure, register, run. The end is the symmetric teardown: quiesce, deregister, free. A driver that leaks a single byte on unload is not a correct driver, no matter how good it is during its active life. In this section we finalise the cleanup path, review the unload discipline, and offer refactoring advice so that the code stays maintainable as it grows.

28.11.1 The Full Teardown Sequence

Putting everything we have said together, the full teardown of a `mynet` interface looks like this:

```
static void
mynet_destroy(struct mynet_softc *sc)
{
    struct ifnet *ifp = sc->ifp;

    MYNET_LOCK(sc);
    sc->running = false;
    ifp->if_drv_flags &= ~IFF_DRV_RUNNING;
    MYNET_UNLOCK(sc);

    callout_drain(&sc->rx_callout);

    ether_ifdetach(ifp);
    if_free(ifp);

    ifmedia_removeall(&sc->media);
    mtx_destroy(&sc->mtx);
    free(sc, M_MYNET);
}
```

The order matters. Let us walk through it.

Step 1: mark not running. Setting `sc->running = false` and clearing `IFF_DRV_RUNNING` under the mutex means that any concurrent callout invocation sees the update and exits cleanly. This alone is not enough to stop running callouts, but it does stop new work from being scheduled.

Step 2: drain the callout. `callout_drain(&sc->rx_callout)` blocks the calling thread until any in-progress callout invocation has finished and no further invocation will occur. After `callout_drain` returns, it is safe to access the `softc` without worrying that the callout will fire again. This is the cleanest way to synchronise with a callout and is the pattern we recommend in every driver that uses them.

Step 3: detach the interface. `ether_ifdetach(ifp)` undoes what `ether_ifattach` did. It calls `if_detach`, which removes the interface from the global list, revokes its addresses, and invalidates any cached pointers. It also calls `bpfdetach` so that BPF releases its handle. After this call, the interface is no longer visible to userland or to the stack.

Step 4: free the ifnet. `if_free(ifp)` releases the memory. After this call, the `ifp` pointer is invalid and must not be used.

Step 5: clean up driver-private state. `ifmedia_removeall` frees the media entries we added. `mtx_destroy` tears down the mutex. `free` releases the `softc`.

Getting this sequence wrong in any way leads to subtle bugs. Freeing the `softc` before draining the callout produces use-after-free when the callout fires. Freeing the `ifnet` before detaching it produces cascading failures all over the stack. Destroying the mutex before draining the callout (which reacquires the mutex on entry) produces a classic “destroying locked mutex” panic. The discipline of “quiesce, detach, free” is what keeps the teardown clean.

28.11.2 The Cloner Destroy Path

Recall that we registered our cloner with `if_clone_simple`, passing `mynet_clone_create` and `mynet_clone_destroy`. The destroy function is called by the cloner framework when userland runs `ifconfig mynet0 destroy` or when the module is unloaded and the cloner is detached. Our implementation is a trivial wrapper:

```
static void
mynet_clone_destroy(struct ifnet *ifp)
{
    mynet_destroy((struct mynet_softc *)ifp->if_softc);
}
```

The cloner framework walks the list of interfaces it has created and calls the destroy function for each one. It does not do the draining or unlocking itself. That is the driver’s responsibility, and `mynet_destroy` does it correctly.

28.11.3 Module Unload

When `kldunload mynet` is invoked, the kernel calls the module event handler with `MOD_UNLOAD`. Our module handler does nothing interesting; the heavy lifting is done by the VNET sysunit we registered:

```
static void
vnet_mynet_uninit(const void *unused __unused)
{
    if_clone_detach(V_mynet_cloner);
}
```

`if_clone_detach` does two things. First, it destroys every interface that was created through the cloner by calling our `mynet_clone_destroy` for each one. Second, it unregisters the cloner itself so that no new interfaces can be created. After this call, every trace of our driver is gone from the kernel's state.

Try it:

```
# ifconfig mynet create
mynet0
# ifconfig mynet create
mynet1
# kldunload mynet
# ifconfig -a
```

`mynet0` and `mynet1` should be gone. No messages on the console, no stray counters, no leftover cloners. That is a successful unload.

28.11.4 Memory Accounting

`vmstat -m | grep mynet` shows the current allocation of our `M_MYNET` tag:

```
# vmstat -m | grep mynet
      Type InUse MemUse Requests  Size(s)
      mynet    0    0K         7  2048
```

`InUse 0` and `MemUse 0K` after unload confirm that we are not leaking. `Requests` counts the lifetime allocations. If you unload and reload several times, `Requests` climbs but `InUse` returns to zero each time. If `InUse` ever stays above zero after unload, you have a leak.

28.11.5 Dealing With Stuck Callouts

Occasionally during development you will tweak the driver and end up with a callout that does not drain cleanly. The symptom is that `kldunload` hangs, or the system panics with a message about a locked mutex. The root cause is almost always one of:

- The callout handler reacquires the mutex but does not reschedule itself, and `callout_drain` is called before the last scheduled firing completes.
- The callout handler is stuck waiting on a lock that another thread holds.
- The callout itself was never properly stopped before drain.

The first line of defence is `callout_init_mtx` with the softc mutex: this sets up an automatic acquisition pattern that makes drain correct by construction. The second line is to use `callout_stop` or `callout_drain` consistently and to avoid mixing the two on the same callout.

If the unload hangs, use `ps -auxw` to find the offending thread, and `kgdb` on a running kernel (through `/dev/mem` and `bin/kgdb /boot/kernel/kernel`) to see what it is stuck on. The stuck frame is almost always in the callout code, and the fix is almost always to drain before destroying the mutex.

28.11.6 VNET Considerations

FreeBSD's network stack supports VNETs, virtual network stacks associated with a jail or a VNET instance. A driver can be VNET-aware if it wants to allow per-VNET creation of interfaces, or it can be non-VNET-aware if one set of interfaces per system is enough.

We used `VNET_DEFINE_STATIC` and `VNET_SYSINIT/VNET_SYSUNINIT` in our cloner registration. That choice makes our driver implicitly VNET-aware: each VNET gets its own cloner, and `mynet` interfaces can be created in any VNET. For a small pseudo-driver this costs us nothing and gains us flexibility.

The deeper aspects of VNET, including moving an interface between VNETs with `if_vmove` and handling VNET teardown, are beyond the scope of this chapter and will be covered later in the book, in Chapter 30. For now it is enough to know that our driver follows the conventions that make it VNET-compatible.

28.11.7 Refactoring Advice

The driver we have built is a single C file with about 500 lines of code. That is comfortable for a teaching example. In a production driver with more features, the file would grow, and you would want to split it up. Here are the splits that almost every driver eventually makes.

Separate the ifnet glue from the data path. The `ifnet` registration, cloner logic, and `ioctl` handling tend to be stable over time. The data path, transmit and receive, evolves as hardware features change. Splitting them into `mynet_if.c` and `mynet_data.c` keeps most files small and focused.

Isolate the backend. In a real NIC driver, the backend is hardware-specific code: register access, DMA, MSI-X, ring buffers. In a pseudo-driver, the backend is the simulation. Either way, putting the backend in `mynet_backend.c` with a clean interface makes it possible to replace the backend without touching the `ifnet` code.

Separate sysctl and debugging. As your driver grows, you will add `sysctls` for diagnostic controls, counters for debugging, and maybe DTrace SDT probes. These tend to accumulate in messy ways. Keeping them in `mynet_sysctl.c` keeps the main files readable.

Keep the header public. A `mynet_var.h` or `mynet.h` header that declares the softc and the cross-file prototypes is the glue that keeps the split compiling. Treat that header as a mini public API.

Version the driver. `MODULE_VERSION(mynet, 1)` is the bare minimum. When you add a significant feature, increment the version. Downstream consumers who depend on your module can then require a minimum version, and kernel users can tell which version of the driver they have loaded via `kldstat -v`.

28.11.8 Feature Flags and Capabilities

Ethernet drivers advertise capabilities through `if_capabilities` and `if_capenable`. We set `IFCAP_VLAN_MTU`. Other capabilities a real driver might advertise include:

- `IFCAP_HWCSUM`: hardware checksum offload.
- `IFCAP_TS04`, `IFCAP_TS06`: TCP segmentation offload for IPv4 and IPv6.
- `IFCAP_LRO`: large receive offload.
- `IFCAP_VLAN_HWTAGGING`: hardware VLAN tagging.
- `IFCAP_RXCSUM`, `IFCAP_TXCSUM`: receive and transmit checksum offload.
- `IFCAP_JUMBO_MTU`: jumbo frames support.
- `IFCAP_LINKSTATE`: hardware link-state events.
- `IFCAP_NETMAP`: netmap(4) support for high-speed packet I/O.

For a pseudo-driver most of these are not relevant. Advertising them falsely causes problems because the stack will then attempt to use them and expect them to work. Keep the capability set honest: advertise only what your driver actually supports.

28.11.9 Writing a Run Script

One of the most useful artefacts to produce alongside a driver is a small shell script that exercises its entire lifecycle. The skeleton we showed in Section 7 is already 80% of that script. Extend it with:

- Consistency checks after each operation (`ifconfig -a | grep mynet0` or `netstat -in -I mynet0 | ...`).
- Optional logging of each step to a file for after-the-fact inspection.
- A cleanup block at the end that ensures the system is left in a known state even if an earlier step fails.

A good run script is the single most valuable tool for regression-free development. We encourage you to maintain one as you extend the driver in the challenges.

28.11.10 Tidying Up the File

Finally, a word on code style. Real FreeBSD drivers follow KNF (Kernel Normal Form), the coding style documented in `style(9)`. Summarised: tabs for indentation, braces on the same line as function definitions but on the next line for structures and enums, 80-column lines where possible, no spaces before the opening parenthesis of a function call, and so on. Your driver will be easier to merge upstream (and easier to read a year from now) if you follow KNF consistently.

28.11.11 Handling Partial Initialisation Failure

We have focused on the happy path. What happens if `mynet_create_unit` fails partway through? Say `if_alloc` succeeds, `mtx_init` runs, `ifmedia_init` sets up the media, and then `malloc` of some auxiliary buffer returns `NULL`. We need to roll back cleanly, because the user just got `ifconfig mynet create` to fail, and we must leave no trace.

The idiom for rollback is a block of labels near the end of the function, each label undoing one step of the initialisation:

```
static int
mynet_create_unit(int unit)
{
    struct mynet_softc *sc;
    struct ifnet *ifp;
    int error = 0;

    sc = malloc(sizeof(*sc), M_MYNET, M_WAITOK | M_ZERO);
    ifp = if_alloc(IFT_ETHER);
    if (ifp == NULL) {
        error = ENOSPC;
        goto fail_alloc;
    }

    sc->ifp = ifp;
    mtx_init(&sc->mtx, "mynet", NULL, MTX_DEF);
    /* ... other setup ... */

    ether_ifattach(ifp, sc->hwaddr);
    return (0);

fail_alloc:
    free(sc, M_MYNET);
    return (error);
}
```

This pattern, common in kernel code, makes rollback boring. Each label takes responsibility for the step immediately above it. The overall shape is “if something in step N fails, jump to label N-1 and unwind from there”.

For our driver the only realistic failure point early in create is `if_alloc`. If that succeeds, the rest of the setup (mutex init, media init, `ether_ifattach`) is either infallible or sufficiently idempotent that no rollback is needed. But the shape of the rollback matters, because a more complex driver will have more failure points, and the same pattern scales cleanly.

28.11.12 Synchronising With In-Flight Callbacks

Beyond callouts, other asynchronous code might be in flight when we tear down an interface. Taskqueue tasks, interrupt handlers, and timer-based rearm functions all need to be stopped before memory is freed.

The kernel provides `taskqueue_drain(tq, task)` for taskqueue tasks, analogous to `callout_drain` for callouts. For interrupts, `bus_teardown_intr` and `bus_release_resource` ensure the interrupt handler will

not be invoked again. For rearmable callouts where the handler reschedules itself, `callout_drain` still does the right thing: it waits for the current invocation to finish and prevents further rearms.

A general rule for a teardown path:

1. Clear any “running” or “armed” flags that the asynchronous code checks.
2. Drain each asynchronous source in turn (taskqueue, callout, interrupt).
3. Detach from upper layers (`ether_ifdetach`).
4. Free the memory.

Skipping step 1 is usually the cause of “destroying locked mutex” panics, because the asynchronous code is still running when the mutex gets destroyed. Skipping step 2 is the cause of use-after-free. Step 3 and step 4 must happen in that order or the stack may try to call into our callbacks after they have been freed.

28.11.13 A Worked Error Scenario

To make the above concrete, imagine a subtle bug. Suppose that during development we call `mtx_destroy` before `callout_drain`. The callout is scheduled, the user runs `ifconfig mynet0 destroy`, our destroy function destroys the mutex, and then the scheduled callout fires. The callout tries to acquire the mutex (because we registered it with `callout_init_mtx`), sees a destroyed mutex, and triggers an assertion: “acquiring a destroyed mutex”. The system panics with a stack trace pointing into the callout code.

The fix is to reverse the order: `callout_drain` first, `mtx_destroy` later. The general principle is that synchronisation primitives are destroyed last, after all consumers are known to have stopped.

This kind of bug is easy to introduce and hard to diagnose if you have not seen it before. Having an explicit mental model of “quiesce, detach, free” prevents it.

28.11.14 Wrapping Up Section 8

The full lifecycle is now in your hands. Load, cloner registration, per-interface creation, active life with transmit, receive, ioctl, and link events, per-interface destruction, cloner detach, module unload. You can build, test, tear down, and rebuild with confidence that the kernel is returned to a clean state.

The sections that come next are the hands-on part of the chapter: labs that walk you through the milestones we have described, challenges that extend the driver, troubleshooting pointers, and a wrap-up.

28.12 Hands-On Labs

The labs below are ordered to mirror the chapter’s flow. Each one builds on the previous, so do them in sequence. The companion files live under `examples/part-06/ch28-network-driver/`, and each lab has its own README with the specific commands.

Before starting, make sure you are on a FreeBSD 14.3 lab VM with root access, a clean workspace directory where you can build a kernel module, and a freshly-snapshot state you can return to if something goes wrong. A snapshot before beginning the labs is a small investment that pays for itself the first time you need it.

Each lab ends with a brief “checkpoint” block listing the specific observations you should record in your logbook. If your logbook already has those observations, you can move on. If it does not, return to the previous step

and redo it. The cumulative structure of the labs means that a missed observation in Lab 2 will make Lab 4 confusing.

28.12.1 Lab 1: Build and Load the Skeleton

Goal. Build the skeleton driver from Section 3, load it, create an instance, and observe the default state.

Steps.

1. `cd examples/part-06/ch28-network-driver/`
2. `make` and watch for warnings. The build should produce `mynet.ko` without warnings.
3. `kldload ./mynet.ko`. No messages should appear on the console; `kldstat` should list `mynet` as present.
4. `ifconfig mynet create` should print `mynet0`.
5. `ifconfig mynet0` and record the output in your logbook. Note especially the flags, the MAC address, the media line, and the status.
6. `kldstat -v | grep mynet` and verify the module is present and loaded at the expected address.
7. `sysctl net.generic.ifclone` and confirm that `mynet` appears in the list of cloners.
8. `ifconfig mynet0 destroy`. The interface should disappear.
9. `kldunload mynet`. The module should unload cleanly.
10. `kldstat` and `ifconfig -a` to confirm nothing is left.

What to watch for. The `ifconfig mynet0` output should show flags `BROADCAST`, `SIMPLEX`, `MULTICAST`, a MAC address, a media line of “Ethernet autoselect”, and a status of “no carrier”. If any of these is missing, recheck the `mynet_create_unit` function and the `ifmedia_init` call.

Logbook checkpoint.

- Record the exact MAC address assigned to `mynet0`.
- Record the initial value of `if_mtu`.
- Note the flags reported before and after `ifconfig mynet0 up`.
- Note whether status: changes between “no carrier” and “active”.

If things go wrong. The most common Lab 1 failure is a build error caused by a missing header. Make sure your kernel source tree under `/usr/src/sys/` matches the running kernel version. If `kldload` fails with “module already present”, unload any prior instance with `kldunload mynet` and try again. If `ifconfig mynet create` returns “Operation not supported”, the cloner did not register, and you need to re-check the `VNET_SYSINIT` call.

28.12.2 Lab 2: Exercise the Transmit Path

Goal. Verify that `if_transmit` is called when traffic leaves the interface.

Steps.

1. Create the interface and bring it up as in Lab 1.
2. `ifconfig mynet0 inet 192.0.2.1/24 up`. Both `UP` and `RUNNING` flags should now appear.
3. In one terminal, run `tcpdump -i mynet0 -nn`.
4. In another, run `ping -c 3 192.0.2.99`.

5. Observe the ARP and ICMP traffic printed by `tcpdump`.
6. `netstat -in -I mynet0` and record the counters. The `Opkts` column should show at least four (three ICMP requests plus the ARP broadcast attempts).
7. Modify the transmit function to return `ENOBUFS` for every call and rebuild.
8. Unload and reload, repeat the ping, observe that `Opkts` stops climbing and that `Oerrors` increases instead.
9. Revert the modification and rebuild.
10. Optional: run the DTrace one-liner `dtrace -n 'fbt::mynet_transmit:entry { @c = count(); }'` while generating traffic to confirm each call reaches your transmit function.

What to watch for. In step 5, each ping produces one ARP broadcast (because the stack does not know the MAC for 192.0.2.99) and one ICMP echo request per ping attempt, but the ARP reply never comes, so subsequent pings only add ICMP requests. Understanding why that is, and what it looks like in `tcpdump`, is an important part of this lab.

Logbook checkpoint.

- Record the exact `Opkts` count after three pings.
- Record the `Obytes` count and verify that it matches the expected sum of ARP frame (42 bytes) plus three ICMP frames.
- Note what changes in `Oerrors` when you deliberately return `ENOBUFS`.

If things go wrong. If `Opkts` is zero after the pings, your `if_transmit` callback is not being called. Check that `ifp->if_transmit = mynet_transmit` is set during create. If `Obytes` is growing but `Opkts` is not, one of the counter calls is missing or reaching the wrong counter. If `tcpdump` shows no outbound traffic at all, the BPF tap in `transmit` is missing; add `BPF_MTAP(ifp, m)` before the free.

28.12.3 Lab 3: Exercise the Receive Path

Goal. Verify that `if_input` delivers packets into the stack.

Steps.

1. Create the interface and bring it up.
2. `tcpdump -i mynet0 -nn`.
3. Wait five seconds and confirm that one synthesised ARP request per second appears.
4. `netstat -in -I mynet0` and confirm `Ipkts` matches the packet count.
5. Change `sc->rx_interval_hz = hz / 10;` and rebuild.
6. Unload, reload, re-create. Observe that the rate becomes ten packets per second.
7. Revert to one packet per second.
8. Optional: comment out the `BPF_MTAP` call in the receive path, rebuild, and observe that `tcpdump` no longer shows the synthesised ARP but `Ipkts` still increments. This confirms that BPF visibility and counter updates are independent.
9. Optional: comment out the `if_input` call (leave `BPF_MTAP` in place), rebuild, and observe the opposite behaviour: `tcpdump` sees the frame, but `Ipkts` does not move because the stack never actually got the frame.

What to watch for. The `Ipkts` counter should increment exactly once per synthesised frame. If it does not, the BPF tap may be seeing the frame but `if_input` is not being called, or the calls are racing with teardown.

Logbook checkpoint.

- Record the interval between consecutive synthesised ARPs as shown by tcpdump timestamps.
- Record the MAC addresses in the ARP frame and confirm that the source MAC matches the interface's address.
- Observe what `arp -an` shows before and after; entries for `192.0.2.99` should remain incomplete.

If things go wrong. If no synthesised ARP appears in tcpdump, the callout is not firing. Check that `callout_reset` is called in `mynet_init` and that `sc->running` is true at the time. If tcpdump shows the ARP but `Ipkts` is zero, the counter is not being updated (or is being updated after `if_input` which has already freed the mbuf).

28.12.4 Lab 4: Media and Link State

Goal. Observe the difference between link state, media, and interface flags.

Steps.

1. Create and configure the interface.
2. `ifconfig mynet0` and note the status and media lines.
3. `ifconfig mynet0 down`.
4. `ifconfig mynet0` and note that status changes.
5. `ifconfig mynet0 up`.
6. In another terminal, `route monitor` and repeat steps 3 and 5 while watching the output.
7. `ifconfig mynet0 media 1000baseT mediaopt full-duplex` and confirm `ifconfig mynet0` reflects the change.
8. Add a third media entry `IFM_ETHER | IFM_100_TX | IFM_FDX` to `mynet_create_unit`, rebuild, and verify that `ifconfig mynet0 media 100baseTX mediaopt full-duplex` now succeeds.
9. Remove the entry and rebuild. Verify that the same command now fails with “requested media type not found”.

What to watch for. `route monitor` prints `RTM_IFINFO` messages on every link-state transition. The `ifconfig mynet0 status:` line shows `active` when the driver is running and the link is up, and `no carrier` when the driver has called `LINK_STATE_DOWN`.

Logbook checkpoint.

- Record the exact `RTM_IFINFO` message text from `route monitor`.
- Note the difference between `IFF_UP` and `LINK_STATE_UP` by capturing the output of `ifconfig mynet0` in each of the four possible combinations (up or down cross with link up or down).
- Observe whether `status:` and the interface flags stay consistent across all four states.

If things go wrong. If `status:` stays at “no carrier” even after the interface is up, you are not calling `if_link_state_change(ifp, LINK_STATE_UP)` from `mynet_init`. If `ifconfig mynet0 media 1000baseT` fails with “requested media type not found”, you did not register `IFM_ETHER | IFM_1000_T` via `ifmedia_add`, or you registered it with the wrong flags.

28.12.5 Lab 5: tcpdump and BPF

Goal. Confirm that BPF sees both outbound and inbound packets.

Steps.

1. Create and configure the interface with IP 192.0.2.1/24.
2. `tcpdump -i mynet0 -nn > /tmp/dump.txt &`
3. Wait ten seconds.
4. `ping -c 3 192.0.2.99.`
5. Wait another ten seconds.
6. `kill %1.`
7. `cat /tmp/dump.txt` and identify the synthesised ARP requests, the ARP broadcasts generated by your ping, and the ICMP echo requests.
8. Remove the BPF_MTAP call from `mynet_transmit` and rebuild. Repeat. Note that outbound ICMP no longer appears in the `tcpdump` output.
9. Restore the BPF_MTAP call.
10. Experiment with filters: `tcpdump -i mynet0 -nn 'arp'` should show only the synthesised ARPs and ARP from your pings, while `tcpdump -i mynet0 -nn 'icmp'` should show only the ICMP echo requests.
11. Observe the link-type line in `tcpdump`'s startup output. It should say EN10MB (Ethernet), because `ether_ifattach` set that up for us. If it says NULL, the interface was attached without Ethernet semantics.

What to watch for. The exercise demonstrates that BPF visibility is not automatic for every packet. It is the driver's job to tap on both the transmit and receive paths.

Logbook checkpoint.

- Record one complete line of `tcpdump` output for each type of frame you observed: synthesised ARP, outbound ARP, outbound ICMP echo request.
- Record the link-type line as printed by `tcpdump`.
- Note what happens to the output when you remove BPF_MTAP from `transmit`.

If things go wrong. If `tcpdump` never shows any packets at all, `bpfattach` was not called (usually because you forgot `ether_ifattach`). If it shows received packets but not transmitted ones, your transmit tap is missing. If it shows transmitted packets but not received ones, your receive tap is missing. If the link-type is wrong, the interface type or the `bpfattach` call is wrong.

28.12.6 Lab 6: Clean Detach

Goal. Verify that `unload` returns the system to a clean state.

Steps.

1. Create three interfaces: `mynet` create three times.
2. Configure each with a different IP in 192.0.2.0/24 (for example, 192.0.2.1/24, 192.0.2.2/24, 192.0.2.3/24).
3. `vmstat -m | grep mynet` and record the allocation count.
4. `kldunload mynet` (do not destroy first).

5. `ifconfig -a` and confirm none of `mynet0`, `mynet1`, `mynet2` remains.
6. `vmstat -m | grep mynet` and confirm `InUse` returns to zero.
7. Repeat steps 1 through 6 five times in sequence. Each round should leave `InUse` at zero and should not leave any orphaned state.
8. Optional: introduce an artificial bug by removing the `callout_drain` call from `mynet_destroy`. Re-build, load, create an interface, and unload. Observe what happens (it is usually a panic, and it is a dramatic way to learn why `callout_drain` exists).
9. Restore the `callout_drain` call.

What to watch for. The cloner detach path should iterate over all three interfaces, call `mynet_clone_destroy` on each, and free all memory. If any interface remains, or if `InUse` is non-zero, something in the teardown is broken.

Logbook checkpoint.

- Record the `InUse` values before and after each round of load-create-unload.
- Note the `Requests` column in `vmstat -m | grep mynet`; it should climb monotonically because it records lifetime allocations.
- Record any unexpected messages in `dmesg`.

If things go wrong. If `kldunload` hangs, a callout or a taskqueue task is still running. Use `ps -auxw` to find the kernel thread and `procstat -k <pid>` to see its backtrace. If `InUse` stays above zero after unload, you have a memory leak; the usual suspect is that `mynet_destroy` is not being called on one of the interfaces, which means `if_clone_detach` did not find it.

28.12.7 Lab 7: Reading the Real Tree

Goal. Connect what you have built to what lives in `/usr/src/sys/net/`.

Steps.

1. Open `/usr/src/sys/net/if_disc.c` side by side with your `mynet.c`. For each of the following, locate the corresponding code in both files:
 - Cloner registration.
 - Softc allocation.
 - Interface type (`IFT_LOOP` vs `IFT_ETHER`).
 - BPF attach.
 - Transmit path.
 - Ioctl handling.
 - Cloner destroy.
2. Open `/usr/src/sys/net/if_epair.c` and do the same exercise. Note the use of `if_clone_advanced`, the pairing logic, and the use of `ifmedia_init`.
3. Open `/usr/src/sys/net/if_ethersubr.c` and locate `ether_ifattach`. Trace through it line by line, and cross-reference each line with what we said it does in Section 3.
4. Open `/usr/src/sys/net/bpf.c` and locate `bpf_mtap_if`, which is the function `BPF_MTAP` expands to. Note the fast-path check for active peers.

What to watch for. The goal of this lab is recognition, not comprehension. You do not need to understand every line of `epair(4)` or `ether_ifattach`. You just need to see that the same patterns we used in our driver appear in the real tree, and that the new code you might encounter elsewhere is a variation on themes you already know.

Logbook checkpoint.

- Record one function name from each of `if_disc.c`, `if_epair.c`, and `if_ethersubr.c` that you now understand well enough to explain aloud.
- Note any pattern in these files that surprised you or that contradicted an assumption you had built from our chapter.

28.13 Challenge Exercises

The challenges below extend the driver in small, self-contained directions. Each one is meant to be doable in one or two focused sessions and relies only on what the chapter has taught.

28.13.1 Challenge 1: Shared Queue Between Paired Interfaces

Brief. Modify `mynet` so that creating two paired interfaces (`mynet0a` and `mynet0b`) behaves like `epair(4)`: transmitting on one interface causes the frame to appear on the other.

Hints. Use `if_clone_advanced` with a match function, as `epair.c` does. Share a queue between the two `softc` structures. Use a callout or a taskqueue to dequeue on the other side and call `if_input`.

Expected result. When you ping an IP assigned to `mynet0a` from an IP assigned to `mynet0b`, the replies should actually come back. You have built a software simulation of two cables plugged into each other.

Key design questions. Where do you store the shared queue? How do you ensure that a packet sent on one side cannot be seen by the original sender (the `IFF_SIMPLEX` contract)? How do you handle the case where only one side of the pair is up?

Suggested structure. Add a struct `mynet_pair` that owns two `softcs`, and have each `softc` carry a pointer to the pair. The transmit function on side A enqueues the mbuf on side B's input queue and schedules a taskqueue. The taskqueue dequeues and calls `if_input` on side B. Use a mutex in the pair structure to protect the queue.

28.13.2 Challenge 2: Link Flap Simulation

Brief. Add a sysctl `net.mynet.flap_interval` that, when non-zero, causes the driver to flap the link up and down every `flap_interval` seconds.

Hints. Use a callout that calls `if_link_state_change` alternately with `LINK_STATE_UP` and `LINK_STATE_DOWN`. Observe the effect on `route monitor`.

Expected result. While flapping is enabled, `ifconfig mynet0` should alternate between `status: active` and `status: no carrier` at the chosen interval. `route monitor` should print `RTM_IFINFO` messages at each transition.

Extension. Make the flap interval per-interface rather than global. You can do this by creating a sysctl node per interface under `net.mynet.<ifname>`, which requires using `sysctl_add_oid` and similar dynamic-sysctl APIs.

28.13.3 Challenge 3: Error Injection

Brief. Add a sysctl `net.mynet.drop_rate` that sets a percentage of outbound frames to be dropped with an error.

Hints. In `mynet_transmit`, roll a random number via `arc4random`. If it falls below the configured percentage, increment `IFCOUNTER_OERRORS`, free the mbuf, and return. Otherwise continue as before.

Expected result. With `drop_rate` set to 50, ping should show roughly 50% packet loss instead of 100%. (Remember, the “100% loss” without `drop_rate` came from no reply ever returning, not from a transmit drop. So with `drop_rate=50` you still get 100% ping loss; but if you combine this challenge with Challenge 1’s pair, the combined behaviour should be 50% ping loss.)

Extension. Add a separate `rx_drop_rate` that drops synthesised receive frames. Observe how the receive-counter output differs between transmit and receive drops.

28.13.4 Challenge 4: iperf3 Stress

Brief. Use `iperf3` to stress the transmit path and measure how quickly the driver can process frames.

Hints. Run `iperf3 -c 192.0.2.99 -t 10 -u -b 1G` to generate a UDP flood. Observe `netstat -in -I mynet0` before and after. Observe `vmstat 1` for system load. Consider what you would need to change in the driver to support higher rates: per-CPU counters, lock-free transmit paths, taskqueue-based deferred processing.

Expected result. The `iperf3` run will not produce meaningful bandwidth numbers (because there is no server to acknowledge anything), but it will push `0pkts` up rapidly. Watch for any CPU hotspot on the transmit path. If you have combined this with Challenge 1, the paired interface setup should show packets crossing the simulated link.

Measurement tips. Use `pmcstat` or `dtrace` to profile where time is spent. The transmit path is a reasonable place to look for lock contention. If you see a high rate of `mtx_lock` on the `softc` mutex in `mynet_transmit`, that is a sign that you are contending on a lock that real drivers would split per-queue.

28.13.5 Challenge 5: Per-Interface sysctl Tree

Brief. Expose per-interface runtime controls and statistics under `net.mynet.mynet0.*`.

Hints. Use `sysctl_add_oid` to dynamically add per-interface sysctls when the interface is created, and remove them when the interface is destroyed. A common pattern is to create a per-instance context under a static root node, and to attach child leaves for the specific controls and stats.

Expected result. `sysctl net.mynet.mynet0.rx_interval_hz` should read and write the receive interval, overriding the compile-time default. `sysctl net.mynet.mynet0.rx_packets_generated` should read a counter that increments every time the synthetic receive timer fires.

Extension. Add an `rx_enabled` sysctl that pauses and resumes the synthetic receive timer. Verify the behaviour by watching `tcpdump` while toggling the sysctl.

28.13.6 Challenge 6: Netgraph Node

Brief. Expose `mynet` as a netgraph node so that it can be wired into the netgraph framework.

Hints. This is a longer challenge because it requires familiarity with `netgraph(4)`. Read `/usr/src/sys/net-graph/ng_ether.c` for a reference example of an interface exposed as a netgraph node. Add a single hook that provides packet interception before or after our `if_transmit` and `if_input`.

Expected result. After the netgraph node is present, you should be able to use `ngctl` to attach a filter or a redirection node and watch packets flow through the netgraph chain.

This challenge is the most open-ended of the set. If you reach a working skeleton, you have essentially completed the path from “hello world” driver to a driver that participates fully in FreeBSD’s advanced networking infrastructure.

28.14 Troubleshooting and Common Mistakes

Network drivers fail in a handful of characteristic ways. Learn to spot them and you save hours of debugging.

28.14.1 Symptom: `ifconfig mynet create` Returns “Operation not supported”

Likely cause. The cloner is not registered, or the cloner name does not match. Check that `v_mynet_cloner` is initialised in `vnet_mynet_init`, and that the `mynet_name` string is the one the user is typing.

Diagnostic. `sysctl net.generic.ifclone` lists all registered cloners. If `mynet` is absent, the registration did not happen.

28.14.2 Symptom: `ifconfig mynet0 up` Hangs or Panics

Likely cause. The `mynet_init` function is doing something that sleeps while holding the `softc` mutex, or is calling up into the stack with the mutex held.

Diagnostic. If the system hangs, enter the debugger (`Ctrl-Alt-Esc` in a console) and type `ps` to see which thread is stuck, then `trace TID` to get a backtrace. Look for the offending lock acquisition.

28.14.3 Symptom: `tcpdump -i mynet0` Sees No Packets

Likely cause. `BPF_MTAP` is not being called, or `bpfattach` was not called during interface setup.

Diagnostic. `bpf_peers_present(ifp->if_bpf)` should return true when `tcpdump` is running. If it does not, check that `ether_ifattach` was called. If `ether_ifattach` was called but `BPF_MTAP` is not in the data path, add the call in both `transmit` and `receive`.

28.14.4 Symptom: ping Shows 100% Loss (Expected) but Opkts Stays Zero

Likely cause. `if_transmit` is not being called, or it is returning early without incrementing counters.

Diagnostic. `dtrace -n 'fbt::mynet_transmit:entry { @[probefunc] = count(); }'` counts how often the function is called. If it is zero, the stack is not dispatching to us, and the assignment to `ifp->if_transmit` (or, if you switched to the helper, the `if_settransmitfn` call) during setup is suspect.

28.14.5 Symptom: kldunload Panics with “destroying locked mutex”

Likely cause. The mutex is being destroyed while another thread (typically a callout) still holds it.

Diagnostic. Audit the teardown order. `callout_drain` must be called before `mtx_destroy`. `ether_ifdetach` must be called before `if_free`. If the callout locks the softc mutex, `callout_drain` must happen before that mutex goes away.

28.14.6 Symptom: netstat -in -I mynet0 Shows Opkts Higher Than Opkts in systat -if

Likely cause. One of the counters is being incremented twice in the transmit path.

Diagnostic. Inspect the code paths. A common mistake is to increment `IFCOUNTER_OPACKETS` both in the driver and in a helper function.

28.14.7 Symptom: Module Loads But ifconfig mynet create Produces a Kernel Warning

Likely cause. A field of the `ifnet` is not properly initialised, or `ether_ifattach` is called without a valid MAC address.

Diagnostic. Run `dmesg` after the warning. The kernel usually prints enough context to identify the offending field.

28.14.8 Symptom: kldunload Returns But ifconfig -a Still Shows mynet0

Likely cause. The cloner detach did not iterate all interfaces. This is usually a sign that the interface was created outside the cloner path, or that the `if_clone` data structures are out of sync.

Diagnostic. `sysctl net.generic.ifclone` after the unload should not list `mynet`. If it does, `if_clone_detach` did not complete.

28.14.9 Symptom: Intermittent Panics Under iperf3 Load

Likely cause. A race between the transmit path and the `ioctl` path, typically one not locking when the other does.

Diagnostic. Run the kernel with `INVARIANTS` and `WITNESS` enabled. These options add lock-order and assertion checks that catch most races immediately. They are the single best development tool for network drivers.

28.14.10 Symptom: `ifconfig mynet0 mtu 9000` Succeeds But Jumbo Frames Fail

Likely cause. The driver advertises an MTU range it cannot actually transport. Our reference driver uses a wide range for simplicity, but a real driver has a hard upper limit dictated by hardware.

Diagnostic. Send a frame larger than the configured MTU and observe that `IFCOUNTER_OERRORS` increments. Align the advertised upper bound with the actual capability.

28.14.11 Symptom: `dmesg` Shows “acquiring a destroyed mutex”

Likely cause. A callout, taskqueue task, or interrupt handler is acquiring a mutex after `mtx_destroy` has been called. Almost always caused by incorrect teardown ordering.

Diagnostic. Trace through your `mynet_destroy`. `callout_drain` and equivalent drain operations must happen before `mtx_destroy`. The correct order is “quiesce, detach, destroy”, not “destroy, quiesce”.

28.14.12 Symptom: `WITNESS` Reports a Lock-Order Reversal

Likely cause. Two threads acquire the same pair of locks in opposite orders. In a network driver this most commonly happens between the softc mutex and a stack-internal lock like the ARP table lock or the routing table lock.

Diagnostic. Read the `WITNESS` output carefully; it shows both backtraces. The fix is usually to release the driver mutex before calling into the stack (for example, before `if_input` or `if_link_state_change`), which we recommend throughout this chapter.

28.14.13 Symptom: Packet Loss Under Moderate Load

Likely cause. Either mbuf exhaustion (check `vmstat -z | grep mbuf`) or a transmit queue that has no backpressure and silently drops.

Diagnostic. `vmstat -z | grep mbuf` before and after the load. If mbuf or `mbuf_cluster` allocations are climbing but not being returned, you have a mbuf leak. If they are being returned but your driver’s internal queue is dropping, you need to either enlarge the queue or implement backpressure.

28.14.14 Symptom: `ifconfig mynet0 inet6 2001:db8::1/64` Has No Effect

Likely cause. IPv6 is not compiled into your kernel, or the interface does not advertise `IFF_MULTICAST` (which IPv6 requires).

Diagnostic. `sysctl net.inet6.ip6.v6only` and similar tell you whether IPv6 is present. `ifconfig mynet0` shows the flags; ensure `MULTICAST` is one of them.

28.14.15 Symptom: Module Loads But `ifconfig mynet create` Produces No Interface and No Error

Likely cause. The cloner’s create function is returning success but never actually allocating an interface. Easy to cause by returning 0 before calling `if_alloc`.

Diagnostic. Add a `printf("mynet_clone_create called\n")` at the start of your create callback. If the message appears but no interface is created, the bug is between the `printf` and the `if_attach` call.

28.14.16 Symptom: `sysctl net.link.generic` Returns Unexpected Results

Likely cause. The driver has corrupted a field of `ifnet` that the generic `sysctl` handler reads. This is rare but indicative of deeper bugs.

Diagnostic. Run the kernel with `INVARIENTS` and look for assertion failures. The offending write is usually near where `ifnet` fields are being initialised.

28.15 Quick Reference Tables

The tables below summarise the most frequently-used APIs and constants introduced in this chapter. Keep the page open as you work through the labs.

28.15.1 Lifecycle Functions

Function	Purpose
<code>if_alloc(type)</code>	Allocate a new <code>ifnet</code> of the given <code>IFT_</code> type.
<code>if_free(ifp)</code>	Free an <code>ifnet</code> after detach.
<code>if_attach(ifp)</code>	Register the interface with the stack.
<code>if_detach(ifp)</code>	Unregister the interface.
<code>ether_ifattach(ifp, mac)</code>	Register an Ethernet-like interface. Wraps <code>if_attach</code> plus <code>bpfattach</code> and sets Ethernet defaults.
<code>ether_ifdetach(ifp)</code>	Undo <code>ether_ifattach</code> .
<code>if_initname(ifp, family, unit)</code>	Set the interface name.
<code>bpfattach(ifp, dlt, hdrlen)</code>	Register with BPF manually. Done automatically by <code>ether_ifattach</code> .
<code>bpfdetach(ifp)</code>	Unregister from BPF. Done automatically by <code>ether_ifdetach</code> .
<code>if_clone_simple(name, create, destroy, minifs)</code>	Register a simple cloner.
<code>if_clone_advanced(name, minifs, match, create, destroy)</code>	Register a cloner with a custom match function.
<code>if_clone_detach(cloner)</code>	Tear down a cloner and all its interfaces.
<code>callout_init_mtx(co, mtx, flags)</code>	Initialise a callout associated with a mutex.
<code>callout_reset(co, ticks, fn, arg)</code>	Schedule or rearm a callout.

Function	Purpose
<code>callout_stop(co)</code>	Cancel a callout.
<code>callout_drain(co)</code>	Synchronously wait for a callout to finish.
<code>ifmedia_init(ifm, mask, change, status)</code>	Initialise a media descriptor.
<code>ifmedia_add(ifm, word, data, aux)</code>	Add a supported media entry.
<code>ifmedia_set(ifm, word)</code>	Choose the default media.
<code>ifmedia_ioctl(ifp, ifr, ifm, cmd)</code>	Handle SIOCGIFMEDIA and SIOCSIFMEDIA.
<code>ifmedia_removeall(ifm)</code>	Free all media entries on teardown.

28.15.2 Data-Path Functions

Function	Purpose
<code>if_transmit(ifp, m)</code>	The driver's outbound callback.
<code>if_input(ifp, m)</code>	Deliver a mbuf to the stack.
<code>if_qflush(ifp)</code>	Flush any driver-internal queues.
<code>BPF_MTAP(ifp, m)</code>	Tap a frame to BPF if any observers.
<code>bpf_mtap2(bpf, data, dlen, m)</code>	Tap with a prepended header.
<code>m_freem(m)</code>	Free an entire mbuf chain.
<code>m_free(m)</code>	Free a single mbuf.
<code>MGETHDR(m, how, type)</code>	Allocate a mbuf as the head of a packet.
<code>MGET(m, how, type)</code>	Allocate a mbuf as a chain continuation.
<code>m_gethdr(how, type)</code>	Alternative form of MGETHDR.
<code>m_pullup(m, len)</code>	Ensure the first len bytes are contiguous.
<code>m_copydata(m, off, len, buf)</code>	Read bytes from a chain without consuming it.
<code>m_defrag(m, how)</code>	Flatten a chain into a single mbuf.
<code>mtod(m, type)</code>	Cast <code>m_data</code> to the requested type.
<code>if_inc_counter(ifp, ctr, n)</code>	Increment a per-interface counter.
<code>if_link_state_change(ifp, state)</code>	Report a link transition.

28.15.3 Common IFF_ Flags

Flag	Meaning
IFF_UP	Administratively up. User-controlled.
IFF_BROADCAST	Supports broadcast.
IFF_DEBUG	Debug tracing requested.
IFF_LOOPBACK	Loopback interface.
IFF_POINTOPOINT	Point-to-point link.
IFF_RUNNING	Alias for IFF_DRV_RUNNING.
IFF_NOARP	ARP disabled.
IFF_PROMISC	Promiscuous mode.
IFF_ALLMULTI	Receive all multicast.
IFF_SIMPLEX	Cannot hear own transmissions.
IFF_MULTICAST	Supports multicast.
IFF_DRV_RUNNING	Driver-private: resources allocated.
IFF_DRV_OACTIVE	Driver-private: transmit queue full.

28.15.4 Common IFCAP_ Capabilities

Capability	Meaning
IFCAP_RXCSUM	IPv4 receive checksum offload.
IFCAP_TXCSUM	IPv4 transmit checksum offload.
IFCAP_RXCSUM_IPV6	IPv6 receive checksum offload.
IFCAP_TXCSUM_IPV6	IPv6 transmit checksum offload.
IFCAP_TS04	IPv4 TCP segmentation offload.
IFCAP_TS06	IPv6 TCP segmentation offload.
IFCAP_LR0	Large receive offload.
IFCAP_VLAN_HWTAGGING	Hardware VLAN tagging.
IFCAP_VLAN_MTU	VLAN over standard MTU.
IFCAP_JUMBO_MTU	Jumbo frames supported.
IFCAP_POLLING	Polled rather than interrupt-driven.
IFCAP_WOL_MAGIC	Wake-on-LAN magic packet.
IFCAP_NETMAP	netmap(4) support.
IFCAP_TOE	TCP offload engine.
IFCAP_LINKSTATE	Hardware link-state events.

28.15.5 Common IFCOUNTER_ Counters

Counter	Meaning
IFCOUNTER_IPACKETS	Packets received.
IFCOUNTER_IERRORS	Receive errors.
IFCOUNTER_OPACKETS	Packets transmitted.
IFCOUNTER_OERRORS	Transmit errors.
IFCOUNTER_COLLISIONS	Collisions (Ethernet).
IFCOUNTER_IBYTES	Bytes received.
IFCOUNTER_OBYTES	Bytes transmitted.
IFCOUNTER_IMCASTS	Multicast packets received.
IFCOUNTER_OMCASTS	Multicast packets transmitted.
IFCOUNTER_IQDROPS	Receive queue drops.
IFCOUNTER_OQDROPS	Transmit queue drops.
IFCOUNTER_NOPROTO	Packets for unknown protocol.

28.15.6 Common Interface Ioctls

Ioctl	When issued	Driver responsibility
SIOCSIFFLAGS	ifconfig up / down	Bring the driver up or down.
SIOCSIFADDR	ifconfig inet 1.2.3.4	Address assignment. Usually handled by ether_ioctl.
SIOCSIFMTU	ifconfig mtu N	Validate and update if_mtu.
SIOCADDMULTI	Multicast group joined	Reprogram hardware filter.
SIOCDELMULTI	Multicast group left	Reprogram hardware filter.
SIOCGIFMEDIA	ifconfig display	Return current media.
SIOCSIFMEDIA	ifconfig media X	Reprogram PHY or equivalent.
SIOCSIFCAP	ifconfig ±offloads	Toggle offloads.
SIOCSIFNAME	ifconfig name X	Rename the interface.

28.16 Reading Real Network Drivers

One of the best ways to solidify your understanding is to read real drivers in the FreeBSD tree. This section walks you through a handful of drivers that illustrate important patterns, and it suggests a reading order that builds on what this chapter has taught you. You do not need to understand every line in these files. The goal is

recognition: seeing the familiar bones of `ether_ifattach`, `if_transmit`, `if_input`, `ifmedia_init`, and so on inside drivers of very different sizes and purposes.

28.16.1 Reading `/usr/src/sys/net/if_tuntap.c`

The `tun(4)` and `tap(4)` drivers are implemented together in this file. They give userland a file descriptor through which packets can flow in and out of the kernel. Reading `if_tuntap.c` shows you how a driver can bridge the userland-character-device world of Chapter 14 with the network-stack world of this chapter.

Open the file and look for the following landmarks:

- The `cdevsw` declaration at the top, which is how userland opens `/dev/tun0` or `/dev/tap0`.
- The `tunstart` function, which moves packets from the kernel interface queue to userland reads.
- The `tunwrite` function, which moves packets from userland writes into the kernel via `if_input`.
- The `tuncreate` function, which allocates an `ifnet` and registers it.

You will see `ether_ifattach` for `tap` and plain `if_attach` for `tun`, because the two flavours differ in link-layer semantics: `tap` is an Ethernet-looking tunnel, while `tun` is a pure IP tunnel without a link layer. This file is an excellent case study in how the choice of `ether_ifattach` vs `if_attach` ripples through the rest of the driver.

Notice that `tuntap` does not use an interface cloner in the same way `disc` does. It creates interfaces on-demand when userland opens `/dev/tapN`, which shows yet another way interfaces can be brought into being. This is a variant of the cloner pattern, rather than a departure from it.

28.16.2 Reading `/usr/src/sys/net/if_bridge.c`

The bridge driver implements software Ethernet bridging between multiple interfaces. It is a larger file (more than three thousand lines) but its core is the same: it creates an `ifnet` per bridge, receives frames from member interfaces via `if_input` hooks, looks up destinations in a MAC-address-to-port table, and forwards frames through `if_transmit` on the outbound port.

What makes `if_bridge.c` particularly instructive is that it is itself both a client and a provider of the `ifnet` interface. It is a client because it transmits frames to member interfaces. It is a provider because it exposes a bridge interface that other code can use. Reading it shows you how to write a driver that is transparently layered on top of other drivers.

28.16.3 Reading `/usr/src/sys/dev/e1000/if_em.c`

The `em(4)` driver is the canonical example of a PCI Ethernet driver for Intel's e1000-class hardware. It is significantly larger than our pseudo-driver because it does everything real hardware requires: PCI attach, register programming, EEPROM reading, MSI-X allocation, ring-buffer management, DMA, interrupt handling, and so on.

However, if you squint past the hardware-specific parts, you will see our familiar patterns everywhere:

- `em_if_attach_pre` allocates a softc.
- `em_if_attach_post` populates the `ifnet`.

- `em_if_init` is the `if_init` callback.
- `em_if_ioctl` is the `if_ioctl` callback.
- `em_if_tx` is the transmit callback (wrapped through `iflib`).
- `em_if_rx` is the receive callback (wrapped through `iflib`).
- `em_if_detach` is the detach function.

The driver uses `iflib(9)` rather than raw `ifnet` calls, but `iflib` is itself a thin layer over the same APIs we have been using. Reading `em` is a good way to see how a real driver scales up from our small teaching example.

Focus on the transmit function first. You will see descriptor-ring management, DMA mapping, TSO handling, and checksum offload decisions. The amount of state is larger, but each decision has a clear purpose that maps to one of the concepts we discussed.

28.16.4 Reading `/usr/src/sys/dev/virtio/network/if_vtnet.c`

The `vtnet(4)` driver is for VirtIO network adapters used by virtual machines. It is smaller than `em` but still larger than our pseudo-driver. It uses `virtio(9)` as its transport rather than `bus_space(9)` plus DMA rings, which makes the code easier to follow if you are less familiar with PCI hardware.

`vtnet` is a particularly good second real driver to read after `mynet` because:

- It is used in almost every FreeBSD VM.
- Its source is clean and well-commented.
- It demonstrates multi-queue transmit and receive.
- It shows how offloads interact with the transmit path.

Spend an evening reading the transmit path and the receive path. You will probably find yourself recognising 70 to 80 percent of the patterns immediately, and the unfamiliar 20 percent will be things like VirtIO queue management that belong to the transport rather than to the network driver contract.

28.16.5 Reading `/usr/src/sys/net/if_lagg.c`

The link aggregation driver implements 802.3ad LACP, round-robin, failover, and other bonding protocols. It is an `ifnet` itself and aggregates over member `ifnets`. Reading it is an exercise in seeing how aggregate drivers can be layered on top of leaf drivers, and it shows you the full power of the `ifnet` abstraction: a bond interface looks the same to the stack as a single NIC.

28.16.6 Suggested Reading Order

If you have time for a deeper study, read in this order:

1. `if_disc.c`: the smallest pseudo-driver. You will recognise everything.
2. `if_tuntap.c`: pseudo-driver plus userland character-device interface.
3. `if_epair.c`: paired pseudo-drivers with simulated wire.
4. `if_bridge.c`: `ifnet`-layered driver.
5. `if_vtnet.c`: small real driver for VirtIO.
6. `if_em.c`: full-featured real driver using `iflib`.

7. `if_lagg.c`: aggregate driver.
8. `if_wg.c`: WireGuard tunnel driver. Modern, cryptographic, interesting.

After this sequence you will have seen enough drivers that almost any driver in the tree becomes readable. The unfamiliar parts will fall into “this is hardware-specific” or “this is a subsystem I have not studied yet”, both of which are finite and conquerable.

28.16.7 Reading as a Habit

Cultivate the habit of reading one driver per month. Pick one at random, read the attach function, and skim the transmit and receive paths. You will be surprised how quickly your vocabulary and your reading speed grow. By the end of a year, you will recognise patterns in drivers you have never seen before, and the instinct for “where should I look for this feature” becomes sharper.

Reading is also the best preparation for writing. The moment you need to add a new feature to a driver you have never touched, the experience of having read thirty drivers means you know roughly where to look and what to imitate.

28.17 Production Considerations

Most of this chapter has been about understanding. Before we close, a short section on what changes when you move from a teaching driver to a driver that will live in a production environment.

28.17.1 Performance

A production driver is usually measured in packets per second, bytes per second, or latency in microseconds. The pseudo-driver we built in this chapter is not stressed in any of those dimensions. If you try to take `mynet` to a real workload, you will quickly hit the limits of a single-mutex design, synchronous `m_freem`, and single-queue dispatch.

The refinements typically include:

- Per-queue locks rather than a softc-level lock.
- `drbr(9)` for per-CPU transmit rings.
- Taskqueue-based deferred receive processing.
- Pre-allocated mbuf pools with `m_getcl`.
- Bypass of `if_input` via direct dispatch helpers in some paths.
- Flow hashing to pin sockets to specific CPUs.
- Netmap support for kernel-bypass workloads.

Each of these optimisations adds code. A production-quality driver for a 10 Gbps NIC might be 3000 to 10000 lines of C, compared with our 500-line teaching driver.

28.17.2 Reliability

A production driver is expected to survive months of continuous operation without leaking memory, crashing the kernel, or drifting in its counter values. The practices that make this possible include:

- Running the kernel with INVARIANTS and WITNESS in QA, so that assertions catch bugs early.
- Writing regression tests that exercise every lifecycle path.
- Running the driver through stress tests (like `iperf3`, `pktgen`, or `netmap pkt-gen`) for extended periods.
- Instrumenting the driver with counters for every error path, so that operators can diagnose problems in the field.
- Providing clear diagnostics through `dmesg`, `sysctl`, and SDT probes.

These practices are not optional for a driver that will be deployed at scale. They are the cost of entry.

28.17.3 Observability

A well-written production driver exposes enough state through `sysctl`, counters, and DTrace probes that an operator can diagnose most problems without adding `printfs` or rebuilding the kernel. The rule of thumb is that every significant code path should have a counter or a probe point, and every decision that depends on runtime state should be queryable without a kernel rebuild.

For `mynet` we have only the built-in `ifnet` counters. A production version would add per-driver counters for things like transmit-path entries, receive-path drops, and interrupt-handler invocations. These counters are cheap to increment and priceless when a problem arrives.

28.17.4 Backward Compatibility

A driver that ships in a release must work on future releases too, ideally without modification. The FreeBSD kernel evolves its internal APIs over time, and drivers that reach too deep into structures may break when those structures change.

The accessor API we introduced in Section 2 is one of the defences. Using `if_setflagbits` rather than `ifp->if_flags |= flag` insulates you from layout changes. Similarly, `if_inc_counter` rather than direct counter updates insulates you from counter-representation changes.

For production drivers, prefer the accessor style whenever it is readily available.

28.17.5 Licensing and Upstreaming

A driver you intend to merge upstream must be licensed compatibly with the FreeBSD tree, which is typically a two-clause BSD license. It should also follow KNF (`style(9)`), include manual pages under `share/man/man4`, include a module Makefile under `sys/modules`, and be submitted through the FreeBSD contribution process (Phabricator reviews as of this writing).

Teaching drivers like `mynet` do not need to worry about upstreaming, but if you are writing a driver with the intent to ship it to others, these are the additional considerations that turn your C code into a community artefact.

28.18 Wrapping Up

Take a moment to appreciate what you have just done. You have:

- Built your first network driver, from scratch.

- Registered it with the network stack through `ifnet` and `ether_ifattach`.
- Implemented a transmit path that accepts mbufs, taps BPF, updates counters, and cleans up.
- Implemented a receive path that constructs mbufs, hands them to BPF, and delivers them to the stack.
- Handled interface flags, link-state transitions, and media descriptors.
- Tested the driver with `ifconfig`, `netstat`, `tcpdump`, `ping`, and `route monitor`.
- Cleaned up on interface destroy and on module unload, without leaks.

More important than any of these individual accomplishments, you have internalised a mental model. A network driver is a participant in a contract with the kernel's network stack. The contract has a fixed shape: a few callbacks going down, one call going up, a handful of flags, a few counters, a media descriptor, a link state. Once you can see that shape clearly, every network driver in the FreeBSD tree becomes comprehensible. The production drivers are bigger, but they are not fundamentally different.

28.18.1 What This Chapter Did Not Cover

A few topics are within reach but were deliberately deferred to keep this chapter tractable.

iflib(9). The modern NIC driver framework that most production drivers use on FreeBSD 14. `iflib` shares transmit and receive ring buffers across many drivers and provides a simpler callback-oriented model for hardware NICs. The patterns we have written by hand in this chapter are exactly what `iflib` automates, so everything you learned here is still valid. We will look at `iflib` in later chapters when we study specific hardware drivers.

DMA for receive and transmit. Real NICs move packet data through DMA-mapped ring buffers. The `bus_dma(9)` API we introduced in earlier chapters is how that is done. Adding DMA to a driver turns the mbuf construction story into “map the mbuf, hand the mapped address to hardware, wait for the completion interrupt, unmap”. That is a significant amount of additional code, and it deserves its own treatment in a later chapter.

MSI-X and interrupt moderation. Modern NICs have multiple interrupt vectors and support interrupt coalescing. We used a callout because we are a pseudo-driver. Real drivers use interrupt handlers. Interrupt moderation (letting the hardware aggregate several completion events into a single interrupt) is critical for performance.

netmap(4). The kernel-bypass fast path used by some high-performance applications. Drivers opt in by calling `netmap_attach()` and exposing per-queue ring buffers. It is a specialisation for throughput-sensitive use cases.

polling(4). An older technique where the driver is polled for packets by a kernel thread rather than driven by interrupts. Still available but less commonly used than it once was.

VNET in detail. We set up the driver to be VNET-compatible, but we did not explore what it means to move interfaces between VNETs with `if_vmove`, or what a VNET teardown looks like from the driver's perspective. Chapter 30 will visit that territory.

Hardware offloads. Checksum offload, TSO, LRO, VLAN tagging, encryption offload. All of these are capabilities a real NIC might expose. A driver that advertises them has to honour them, and that leads into a rich design space we have not touched.

Wireless. `wlan(4)` drivers are radically different from Ethernet drivers because they deal with 802.11 frame formats, scanning, authentication, and management frames. The `ifnet` is still present, but it sits on top of a very different link layer. We will visit wireless drivers in a later chapter.

Network graph (netgraph(4)). FreeBSD’s packet-filtering and classification framework. It is largely orthogonal to driver writing but worth knowing about for advanced network architectures.

Bridging and VLAN interfaces. Virtual interfaces that aggregate or modify traffic. They are built on top of `ifnet`, exactly like our driver, but their role is quite different.

Each of these topics deserves its own chapter. What you have built here is the stable base camp from which those expeditions set out.

28.18.2 Final Reflection

Network drivers have a reputation as a demanding subfield of kernel engineering. They deserve it: the constraints are tight, the interactions with the stack are many, the performance expectations are high, and the user-facing commands are numerous. But the structure of a network driver is clean once you can see it. That is what this chapter has given you: the ability to see the structure.

Read `if_em.c`, `if_bge.c`, or `if_tuntap.c` now. You will recognise the skeleton. The `softc`. The `ether_ifattach` call. The `if_transmit`. The `if_ioctl` switch. The `if_input` in the receive handler. The `bpfattach` and `BPF_MTAP`. Wherever the code adds complexity, it is adding complexity to a skeleton you have already built in miniature.

Like Chapter 27, this chapter is long because the topic is layered. We have tried to make every layer land softly before the next arrives. If a particular section did not settle, go back and do the corresponding lab again. Kernel learning is strongly cumulative. A second pass through one section often does more than a first pass through the next one.

28.18.3 Further Reading

Manual pages. `ifnet(9)`, `ifmedia(9)`, `mbuf(9)`, `ether(9)`, `bpf(9)`, `polling(9)`, `ifconfig(8)`, `netstat(1)`, `tcpdump(1)`, `route(8)`, `ngctl(8)`. Read them in that order.

The FreeBSD Architecture Handbook. The networking chapters are a good complement.

Kirk McKusick et al., “The Design and Implementation of the FreeBSD Operating System”. The network-stack chapters are especially relevant.

“TCP/IP Illustrated, Volume 2” by Wright and Stevens. A classic walk-through of a BSD-derived network stack. Dated but still unique in its depth.

The FreeBSD source tree. `/usr/src/sys/net/`, `/usr/src/sys/netinet/`, `/usr/src/sys/dev/e1000/`, `/usr/src/sys/dev/bge/`, `/usr/src/sys/dev/mlx5/`. Every pattern discussed in this chapter is grounded in that code.

The mailing list archives. `freebsd-net@` is the most relevant list. Reading historic threads is a great way to pick up idioms that never made it into formal documentation.

Commit history on GitHub mirrors. The FreeBSD repository has an excellent history. `git log --follow sys/net/if_var.h` is a good starting point for seeing how the `ifnet` abstraction evolved.

The FreeBSD Developer Summit slides. When available, these often include networking-focused sessions.

Other BSDs. NetBSD and OpenBSD have slightly different network-driver frameworks, but the core ideas are identical. Reading a driver in another BSD after reading its FreeBSD equivalent is a good way to understand what is universal and what is FreeBSD-specific.

28.19 Field Guide to Related ifnet Subsystems

You have built a driver. You have read a handful of real drivers. Before we close the chapter, let us survey the surrounding subsystems so that you know where to look when you need them.

28.19.1 arp(4) and Neighbour Discovery

ARP for IPv4 lives in `/usr/src/sys/netinet/if_ether.c`. It is the subsystem that maps IP addresses to MAC addresses. Drivers do not usually interact with ARP directly; they carry packets (including ARP requests and replies) through their transmit and receive paths, and the ARP code inside `ether_input` and `arpresolve` does the rest.

The IPv6 equivalent is neighbour discovery, in `/usr/src/sys/netinet6/nd6.c`. It uses ICMPv6 rather than a separate protocol, but the role is the same: map IPv6 addresses to MAC addresses for on-link delivery.

28.19.2 bpf(4)

The Berkeley Packet Filter subsystem lives in `/usr/src/sys/net/bpf.c`. BPF is the userland-visible mechanism for packet capture. `tcpdump(1)`, `libpcap(3)`, and many other tools use BPF. Drivers register with BPF through `bpfattach` (done automatically by `ether_ifattach`) and tap packets to BPF through `BPF_MTAP` (which you do manually).

BPF filters are programs written in the BPF pseudo-machine language, compiled to bytecode in userland and executed in the kernel. They are what allows `tcpdump -i 'port 80'` to work efficiently: the filter runs before the packet is copied to userland, so only matching packets are transferred.

28.19.3 route(4)

The routing subsystem lives in `/usr/src/sys/net/route.c` and is growing over time (the recent `nhop(9)` next-hop abstraction is a notable change). Drivers interact with routing indirectly: when they report link state changes, the routing subsystem updates metrics; when they transmit, the stack has already done the route lookup. `route monitor`, which we used in a lab, subscribes to routing events and displays them.

28.19.4 if_clone(4)

The cloner subsystem in `/usr/src/sys/net/if_clone.c` is what we have been using throughout this chapter. It manages the list of per-driver cloners and dispatches `ifconfig create` and `ifconfig destroy` requests to the correct driver.

28.19.5 pf(4)

The packet filter lives in `/usr/src/sys/net/pfil/pf/`. It is independent of any specific driver and runs as a hook on packet paths through `pfil(9)`. Drivers do not usually interact with `pf` directly; traffic passing through the stack is filtered transparently.

28.19.6 netmap(4)

`netmap(4)` is a kernel-bypass packet-I/O framework in `/usr/src/sys/dev/netmap/`. Drivers that support `netmap` expose their ring buffers directly to userland, bypassing the normal `if_input` and `if_transmit` paths. This allows applications to receive and transmit packets at line rate without kernel involvement. Only a handful of drivers support `netmap` natively; the rest use a shim that emulates `netmap` semantics at the cost of some performance.

28.19.7 netgraph(4)

`netgraph(4)` is FreeBSD's modular packet-processing framework, in `/usr/src/sys/netgraph/`. It lets you build arbitrary graphs of packet-processing nodes in the kernel, configured from userland via `ngctl`. Drivers can expose themselves as `netgraph` nodes (see `ng_ether.c`), and `netgraph` can be used to implement tunnels, PPP over Ethernet, encrypted links, and many other features without modifying the stack itself.

28.19.8 iflib(9)

`iflib(9)` is the modern framework for high-performance Ethernet drivers in `/usr/src/sys/net/iflib.c`. It takes over the rote parts of a NIC driver (ring-buffer management, interrupt handling, TSO fragmentation, LRO aggregation) and leaves the driver writer to provide the hardware-specific callbacks. On the drivers that have been converted to `iflib` to date, driver code typically shrinks by 30 to 50 percent compared with the equivalent plain-`ifnet` implementation. See Appendix F for a reproducible line-count comparison across the `iflib` and non-`iflib` driver corpora. Appendix F's `iflib` section also pins a specific per-driver measurement on the `ixgbe` conversion commit at roughly the lower edge of this range.

For now, `iflib` is beyond the scope of this chapter. Appendix F's `iflib` section offers a reproducible line-count comparison that shows how much code the framework saves on drivers that have been converted to it.

28.19.9 Summary of the Landscape

A network driver lives in a rich environment. Above it are ARP, IP, TCP, UDP, and the socket layer. Alongside it are BPF, `pf`, `netmap`, and `netgraph`. Below it is hardware, or a transport simulation, or a pipe to userland. Each of these components has its own conventions, and learning any of them in depth is a meaningful investment. What this chapter has given you is enough familiarity with the central object, the `ifnet`, that you can approach any of these subsystems without being intimidated.

28.20 Debugging Scenarios: A Worked Example

One of the best ways to close a chapter about driver-writing is to walk through a specific debugging session. The scenario below is composite: it combines symptoms and fixes from several different driver bugs into one narrative, so that the full arc of “something is wrong, let us find it” is visible.

28.20.1 The Problem

You load `mynet`, create an interface, assign an IP, and run `ping`. The ping reports 100% loss, as expected (our pseudo-driver has nothing on the other end). But `netstat -in -I mynet0` shows `Opkts 0` even after several pings. Something in the transmit path is broken.

28.20.2 First Hypothesis: the transmit function is not being called.

You run `dtrace -n 'fbt::mynet_transmit:entry { printf("called"); }'`. No output, even during the ping. That confirms that `if_transmit` is not being invoked.

28.20.3 Investigating Why

You open the source and find that `ifp->if_transmit = mynet_transmit;` is present. You check `ifp->if_transmit` at runtime by grabbing the `ifnet` pointer via `ifconfig`'s reporting (there is no direct way to read function pointers from userland, but a DTrace probe can do it):

```
# dtrace -n 'fbt::ether_output_frame:entry {  
    printf("if_transmit = %p", args[0]->if_transmit);  
}'
```

The output shows a different address than you expected. Closer inspection reveals that `ether_ifattach` overwrote `if_transmit` with its own wrapper. You `grep` for `if_transmit` in `if_ethersubr.c` and confirm that `ether_ifattach` sets `ifp->if_output = ether_output` but does not touch `if_transmit`. So `if_transmit` should still be your function.

You go back to your source and notice that you set `ifp->if_transmit = mynet_transmit;` before `ether_ifattach`, but you inadvertently set it through the legacy `if_start` field in a second assignment that you forgot to remove. The legacy `if_start` mechanism takes precedence under some conditions, and the kernel ends up calling `if_start` instead of `if_transmit`.

You remove the stray `if_start` assignment and rebuild. The transmit function is now called.

28.20.4 Second Problem: counter disagreement

Transmit is now called, and `Opkts` climbs. But `Obytes` is suspiciously low: it is incremented by one per ping, not by the ping's byte length. You re-inspect the counter update code:

```
if_inc_counter(ifp, IFCOUNTER_OBYTES, 1);
```

The constant 1 should be `len`. You typed the wrong argument. You change it to `if_inc_counter(ifp, IFCOUNTER_OBYTES, len)` and rebuild. Obytes now climbs by the expected amount.

28.20.5 Third Problem: the receive path seems intermittent

Synthesised ARPs appear most of the time but occasionally stop for several seconds. You add a DTrace probe to `mynet_rx_timer` and see that the function is being called at regular intervals, but that some calls early-return without generating a frame.

You inspect `mynet_rx_fake_arp` and find that it uses `M_NOWAIT` for its mbuf allocation. Under memory pressure, `M_NOWAIT` returns `NULL`, and the receive path silently drops. You instrument the allocation failure path:

```
if (m == NULL) {
    if_inc_counter(ifp, IFCOUNTER_IQDROPS, 1);
    return;
}
```

And you check the counter: it matches the missing frames. You have found the cause: transient mbuf pressure on your test VM. The fix is to either accept occasional drops (they are legitimate and correctly counted) or to switch to `M_WAITOK` if the callout can tolerate sleeping (it cannot, because callouts run in a non-sleepable context).

In this case, accepting the drops is correct. The fix is therefore to make the behaviour visible in a dashboard: you add a sysctl that exposes `IFCOUNTER_IQDROPS` on this specific interface, and note it in the driver documentation.

28.20.6 What This Scenario Teaches

Three separate bugs. None of them was catastrophic. Each one required a different combination of tools to diagnose: DTrace for function tracing, code reading for understanding the API, and counters for observing the runtime effect.

The lesson is that driver bugs tend to hide in plain sight. The first rule of driver debugging is “do not trust, verify”. The second rule is “the counters and the tools will tell you”. The third rule is “if the counters do not tell you what you need, add more counters or more probes”.

With practice, debugging sessions like this become faster. You develop an instinct for which tool to reach for first, and the difference between a driver that works on the first load and a driver that took six iterations becomes a shorter debugging cycle.

28.21 A Note on Testing Discipline

Before we truly close the chapter, a few paragraphs on testing discipline. A teaching driver can be tested casually. A driver you intend to maintain over time deserves a more rigorous approach.

28.21.1 Unit-Level Thinking

Every callback in your driver has a small, well-defined contract. `mynet_transmit` takes an `ifnet` and a `mbuf`, validates, counts, taps, and frees. `mynet_ioctl` takes an `ifnet` and an `ioctl` code, dispatches, and returns an `errno`. Each of these can be exercised independently.

In practice, unit testing kernel code is hard because the kernel is not easy to embed in a userland test harness. But you can approximate the discipline by designing the code so that most of each callback is pure: given inputs, produce outputs, without touching global state. The validation block in `mynet_transmit` is a good example: it does not touch anything except `ifp->if_mtu` and local variables.

A mental model of “this callback has a contract; here are the cases that exercise the contract; here are the expected behaviours for each case” is the foundation of good testing.

28.21.2 Lifecycle Tests

Every driver should be tested across its full lifecycle: load, create, configure, carry traffic, stop, destroy, unload. The Lab 6 script is a minimum version of such a test. A more rigorous version would include:

- Multiple interfaces created concurrently.
- Unload while traffic is flowing (at low rate, to be safe).
- Repeated load/unload cycles to catch leaks.
- Tests with `INVARIANTS` and `WITNESS` enabled.

28.21.3 Error-Path Tests

Every error-path in the driver needs to be exercisable. If `if_alloc` fails, does the create function roll back cleanly? If an `ioctl` returns an error, does the caller cope? If the callout fails to allocate a `mbuf`, does the driver stay consistent?

One useful technique is fault injection: add a `sysctl` that probabilistically fails specific operations (`if_alloc`, `m_gethdr`, and so on), and run your lifecycle tests with the fault injection enabled. This exposes error paths that almost never fire in production but can still happen under load.

28.21.4 Regression Tests

Whenever you fix a bug, add a test that would have caught it. Even a simple shell script that loads the driver, exercises a specific feature, and checks a counter is a regression test.

Over time, a regression-test suite becomes a guardrail against reintroducing bugs. It also documents the behaviour you guarantee. A new contributor reading the test suite gains a clearer picture of what the driver promises than any amount of code reading could provide.

28.21.5 Watching for Latent Issues

Some issues only manifest after hours or days of operation: slow memory leaks, counter drift, rare race conditions. Long-running tests are the only way to find these. A driver deployed to production without at least a 24-hour soak under representative load is not ready.

For `mynet` the soak might be as simple as “leave the driver loaded for a day and check `vmstat -m` and `vmstat -z` at the end”. For a real driver, the soak might involve terabyte-hours of traffic under a real workload. The scale differs; the principle is the same.

28.22 A Complete Walkthrough of `mynet.c`

Before we close the chapter, it is worth showing a concise end-to-end walkthrough of the reference driver. The goal is to see the entire driver once in one place, with short annotations at each step, so that you can visualise the full shape without having to jump between Sections 3 through 6.

28.22.1 File-Level Preamble

The driver opens with a license header, the copyright notice, and the include block we described in Section 3. After the includes, the file declares the memory type, the cloner variable, and the `softc` structure:

```
static const char mynet_name[] = "mynet";
static MALLOC_DEFINE(M_MYNET, "mynet", "mynet pseudo Ethernet driver");

VNET_DEFINE_STATIC(struct if_clone *, mynet_cloner);
#define V_mynet_cloner VNET(mynet_cloner)

struct mynet_softc {
    struct ifnet      *ifp;
    struct mtx        mtx;
    uint8_t           hwaddr[ETHER_ADDR_LEN];
    struct ifmedia     media;
    struct callout     rx_callout;
    int               rx_interval_hz;
    bool              running;
};

#define MYNET_LOCK(sc)      mtx_lock(&(sc)->mtx)
#define MYNET_UNLOCK(sc)   mtx_unlock(&(sc)->mtx)
#define MYNET_ASSERT(sc)   mtx_assert(&(sc)->mtx, MA_OWNED)
```

Every field and macro here has a purpose we discussed earlier. The `softc` carries the per-instance state; the locking macros document when the mutex should be held; the VNET-aware cloner is the mechanism by which `ifconfig mynet create` produces new interfaces.

28.22.2 Forward Declarations

A small block of forward declarations for the static functions the driver exposes as callbacks:

```

static int      mynet_clone_create(struct if_clone *, int, caddr_t);
static void     mynet_clone_destroy(struct ifnet *);
static int      mynet_create_unit(int unit);
static void     mynet_destroy(struct mynet_softc *);
static void     mynet_init(void *);
static void     mynet_stop(struct mynet_softc *);
static int      mynet_transmit(struct ifnet *, struct mbuf *);
static void     mynet_qflush(struct ifnet *);
static int      mynet_ioctl(struct ifnet *, u_long, caddr_t);
static int      mynet_media_change(struct ifnet *);
static void     mynet_media_status(struct ifnet *, struct ifmediareq *);
static void     mynet_rx_timer(void *);
static void     mynet_rx_fake_arp(struct mynet_softc *);
static int      mynet_modevent(module_t, int, void *);
static void     vnet_mynet_init(const void *);
static void     vnet_mynet_uninit(const void *);

```

Forward declarations are a courtesy to the reader. They let you scan the top of the file and see every named function the driver exports, without searching for definitions.

28.22.3 Cloner Dispatch

The cloner create and destroy functions are thin wrappers that delegate the real work to the per-unit helpers:

```

static int
mynet_clone_create(struct if_clone *ifc __unused, int unit, caddr_t params __unused)
{
    return (mynet_create_unit(unit));
}

static void
mynet_clone_destroy(struct ifnet *ifp)
{
    mynet_destroy((struct mynet_softc *)ifp->if_softc);
}

```

Keeping the cloner callbacks small is a convention worth following. It makes it easy to test the real work functions (`mynet_create_unit`, `mynet_destroy`) in isolation and it makes the cloner glue boring.

28.22.4 Per-Unit Creation

The per-unit creation function is where the real setup happens:

```

static int
mynet_create_unit(int unit)
{
    struct mynet_softc *sc;
    struct ifnet *ifp;

    sc = malloc(sizeof(*sc), M_MYNET, M_WAITOK | M_ZERO);
    ifp = if_alloc(IFT_ETHER);
    if (ifp == NULL) {
        free(sc, M_MYNET);
        return (ENOSPC);
    }
    sc->ifp = ifp;
    mtx_init(&sc->mtx, "mynet", NULL, MTX_DEF);

    arc4rand(sc->hwaddr, ETHER_ADDR_LEN, 0);
    sc->hwaddr[0] = 0x02; /* locally administered, unicast */

    if_initname(ifp, mynet_name, unit);
    ifp->if_softc = sc;
    ifp->if_flags = IFF_BROADCAST | IFF_SIMPLEX | IFF_MULTICAST;
    ifp->if_capabilities = IFCAP_VLAN_MTU;
    ifp->if_capenable = IFCAP_VLAN_MTU;
    ifp->if_transmit = mynet_transmit;
    ifp->if_qflush = mynet_qflush;
    ifp->if_ioctl = mynet_ioctl;
    ifp->if_init = mynet_init;
    ifp->if_baudrate = IF_Gbps(1);

    ifmedia_init(&sc->media, 0, mynet_media_change, mynet_media_status);
    ifmedia_add(&sc->media, IFM_ETHER | IFM_1000_T | IFM_FDX, 0, NULL);
    ifmedia_add(&sc->media, IFM_ETHER | IFM_AUTO, 0, NULL);
    ifmedia_set(&sc->media, IFM_ETHER | IFM_AUTO);

    callout_init_mtx(&sc->rx_callout, &sc->mtx, 0);
    sc->rx_interval_hz = hz;

    ether_ifattach(ifp, sc->hwaddr);
    return (0);
}

```

You can see every concept from Section 3 in one place: softc and ifnet allocation, MAC fabrication, field configuration, media setup, callout initialisation, and the final `ether_ifattach` that registers the interface with the stack.

28.22.5 Destruction

Destruction mirrors creation in reverse:

```
static void
mynet_destroy(struct mynet_softc *sc)
{
    struct ifnet *ifp = sc->ifp;

    MYNET_LOCK(sc);
    sc->running = false;
    ifp->if_drv_flags &= ~IFF_DRV_RUNNING;
    MYNET_UNLOCK(sc);

    callout_drain(&sc->rx_callout);

    ether_ifdetach(ifp);
    if_free(ifp);

    ifmedia_removeall(&sc->media);
    mtx_destroy(&sc->mtx);
    free(sc, M_MYNET);
}
```

Again, every step is one we discussed. The order is quiesce, detach, free.

28.22.6 Init and Stop

The transitions between “not running” and “running” are handled by two small functions:

```
static void
mynet_init(void *arg)
{
    struct mynet_softc *sc = arg;

    MYNET_LOCK(sc);
    sc->running = true;
    sc->ifp->if_drv_flags |= IFF_DRV_RUNNING;
    sc->ifp->if_drv_flags &= ~IFF_DRV_OACTIVE;
    callout_reset(&sc->rx_callout, sc->rx_interval_hz,
        mynet_rx_timer, sc);
    MYNET_UNLOCK(sc);

    if_link_state_change(sc->ifp, LINK_STATE_UP);
}
```

```
}

static void
mynet_stop(struct mynet_softc *sc)
{
    MYNET_LOCK(sc);
    sc->running = false;
    sc->ifp->if_drv_flags &= ~IFF_DRV_RUNNING;
    callout_stop(&sc->rx_callout);
    MYNET_UNLOCK(sc);

    if_link_state_change(sc->ifp, LINK_STATE_DOWN);
}
```

Both are symmetric, both honour the rule about dropping the lock before `if_link_state_change`, and both maintain the coherence rules we described in Section 6.

28.22.7 The Data Path

Transmit and the simulated receive are the heart of the driver:

```
static int
mynet_transmit(struct ifnet *ifp, struct mbuf *m)
{
    struct mynet_softc *sc = ifp->if_softc;
    int len;

    if (m == NULL)
        return (0);
    M_ASSERTPKTHDR(m);

    if (m->m_pkthdr.len > (ifp->if_mtu + sizeof(struct ether_vlan_header))) {
        m_freem(m);
        if_inc_counter(ifp, IFCOUNTER_OERRORS, 1);
        return (E2BIG);
    }

    if ((ifp->if_flags & IFF_UP) == 0 ||
        (ifp->if_drv_flags & IFF_DRV_RUNNING) == 0) {
        m_freem(m);
        if_inc_counter(ifp, IFCOUNTER_OERRORS, 1);
        return (ENETDOWN);
    }
}
```

```

    BPF_MTAP(ifp, m);

    len = m->m_pkthdr.len;
    if_inc_counter(ifp, IFCOUNTER_OPACKETS, 1);
    if_inc_counter(ifp, IFCOUNTER_OBYTES, len);
    if (m->m_flags & (M_BCAST | M_MCAST))
        if_inc_counter(ifp, IFCOUNTER_OMCASTS, 1);

    m_freem(m);
    return (0);
}

static void
mynet_qflush(struct ifnet *ifp __unused)
{
}

static void
mynet_rx_timer(void *arg)
{
    struct mynet_softc *sc = arg;

    MYNET_ASSERT(sc);
    if (!sc->running)
        return;
    callout_reset(&sc->rx_callout, sc->rx_interval_hz,
        mynet_rx_timer, sc);
    MYNET_UNLOCK(sc);

    mynet_rx_fake_arp(sc);

    MYNET_LOCK(sc);
}

```

The fake-ARP helper builds the synthetic frame and hands it to the stack:

```

static void
mynet_rx_fake_arp(struct mynet_softc *sc)
{
    struct ifnet *ifp = sc->ifp;
    struct mbuf *m;
    struct ether_header *eh;
    struct arphdr *ah;
    uint8_t *payload;

```

```

size_t frame_len;

frame_len = sizeof(*eh) + sizeof(*ah) + 2 * (ETHER_ADDR_LEN + 4);
MGETHDR(m, M_NOWAIT, MT_DATA);
if (m == NULL) {
    if_inc_counter(ifp, IFCOUNTER_IQDROPS, 1);
    return;
}
m->m_pkthdr.len = m->m_len = frame_len;
m->m_pkthdr.rcvif = ifp;

eh = mtod(m, struct ether_header *);
memset(eh->ether_dhost, 0xff, ETHER_ADDR_LEN);
memcpy(eh->ether_shost, sc->hwaddr, ETHER_ADDR_LEN);
eh->ether_type = htons(ETHERTYPE_ARP);

ah = (struct arphdr *)(eh + 1);
ah->ar_hrd = htons(ARPHRD_ETHER);
ah->ar_pro = htons(ETHERTYPE_IP);
ah->ar_hln = ETHER_ADDR_LEN;
ah->ar_pln = 4;
ah->ar_op = htons(ARPOP_REQUEST);

payload = (uint8_t *)(ah + 1);
memcpy(payload, sc->hwaddr, ETHER_ADDR_LEN);
payload += ETHER_ADDR_LEN;
memset(payload, 0, 4);
payload += 4;
memset(payload, 0, ETHER_ADDR_LEN);
payload += ETHER_ADDR_LEN;
memcpy(payload, "\xc0\x00\x02\x63", 4);

BPF_MTAP(ifp, m);
if_inc_counter(ifp, IFCOUNTER_IPACKETS, 1);
if_inc_counter(ifp, IFCOUNTER_IBYTES, frame_len);
if_inc_counter(ifp, IFCOUNTER_IMCASTS, 1); /* broadcast counts as multicast */

if_input(ifp, m);
}

```

28.22.8 Ioctl and Media Callbacks

The ioctl handler and the two media callbacks:

```
static int
mynet_ioctl(struct ifnet *ifp, u_long cmd, caddr_t data)
{
    struct mynet_softc *sc = ifp->if_softc;
    struct ifreq *ifr = (struct ifreq *)data;
    int error = 0;

    switch (cmd) {
    case SIOCSIFFLAGS:
        MYNET_LOCK(sc);
        if (ifp->if_flags & IFF_UP) {
            if ((ifp->if_drv_flags & IFF_DRV_RUNNING) == 0) {
                MYNET_UNLOCK(sc);
                mynet_init(sc);
                MYNET_LOCK(sc);
            }
        } else {
            if (ifp->if_drv_flags & IFF_DRV_RUNNING) {
                MYNET_UNLOCK(sc);
                mynet_stop(sc);
                MYNET_LOCK(sc);
            }
        }
        MYNET_UNLOCK(sc);
        break;

    case SIOCSIFMTU:
        if (ifr->ifr_mtu < 68 || ifr->ifr_mtu > 9216) {
            error = EINVAL;
            break;
        }
        ifp->if_mtu = ifr->ifr_mtu;
        break;

    case SIOCADDMULTI:
    case SIOCDELMULTI:
        break;

    case SIOCGIFMEDIA:
    case SIOCSIFMEDIA:
        error = ifmedia_ioctl(ifp, ifr, &sc->media, cmd);
        break;

    default:
```

```

        error = ether_ioctl(ifp, cmd, data);
        break;
    }

    return (error);
}

static int
mynet_media_change(struct ifnet *ifp __unused)
{
    return (0);
}

static void
mynet_media_status(struct ifnet *ifp, struct ifmediareq *imr)
{
    struct mynet_softc *sc = ifp->if_softc;

    imr->ifm_status = IFM_AVALID;
    if (sc->running)
        imr->ifm_status |= IFM_ACTIVE;
    imr->ifm_active = IFM_ETHER | IFM_1000_T | IFM_FDX;
}

```

28.22.9 Module Glue and Cloner Registration

The bottom of the file holds the module handler, the VNET sysinit/sysuninit functions, and the module declarations:

```

static void
vnet_mynet_init(const void *unused __unused)
{
    V_mynet_cloner = if_clone_simple(mynet_name, mynet_clone_create,
        mynet_clone_destroy, 0);
}

VNET_SYSINIT(vnet_mynet_init, SI_SUB_PSEUDO, SI_ORDER_ANY,
    vnet_mynet_init, NULL);

static void
vnet_mynet_uninit(const void *unused __unused)
{
    if_clone_detach(V_mynet_cloner);
}

VNET_SYSUNINIT(vnet_mynet_uninit, SI_SUB_INIT_IF, SI_ORDER_ANY,

```

```
vnet_mynet_uninit, NULL);

static int
mynet_modevent(module_t mod __unused, int type, void *data __unused)
{
    switch (type) {
        case MOD_LOAD:
        case MOD_UNLOAD:
            return (0);
        default:
            return (EOPNOTSUPP);
    }
}

static moduledata_t mynet_mod = {
    "mynet",
    mynet_modevent,
    NULL
};

DECLARE_MODULE(mynet, mynet_mod, SI_SUB_PSEUDO, SI_ORDER_ANY);
MODULE_DEPEND(mynet, ether, 1, 1, 1);
MODULE_VERSION(mynet, 1);
```

28.22.10 Line Count and Density

The complete `mynet.c` is about 500 lines of C code. The entire teaching driver, from the license header at the top to the `MODULE_VERSION` at the bottom, is shorter than many single functions in production drivers. That compactness is not a coincidence: pseudo-drivers have no hardware to talk to, so they can focus on the `ifnet` contract and nothing else.

Read through the complete file in the companion materials. Type your own copy if you have not already done so. Build it. Load it. Mutate it. Until you have internalised the shape, do not move on to the next chapter.

28.23 A Complete Lifecycle Trace

It helps to see, end to end, the sequence of events that happens when the reader runs the ordinary commands from a shell. The trace below follows the mental model we have built up, but stitches it together into one continuous story. Read it as an animated flipbook rather than as a reference table.

28.23.1 Trace 1: From `kldload` to `ifconfig up`

Imagine you are sitting at the keyboard with a fresh FreeBSD 14.3 machine. You have never loaded `mynet` before. You type the first command:

```
# kldload ./mynet.ko
```

What happens next? The loader reads the ELF header of `mynet.ko`, relocates the module into kernel memory, and walks the module's `modmetadata_set` linker set. It finds the `DECLARE_MODULE` record for `mynet` and calls `mynet_modevent(mod, MOD_LOAD, data)`. Our handler returns zero without doing any work. The loader also processes the `MODULE_DEPEND` records, and because `ether` is already part of the base kernel, the dependency is satisfied immediately.

Then the linker set for `VNET_SYSINIT` is walked. Our `vnet_mynet_init()` fires. It calls `if_clone_simple()` with the name `mynet` and the two callbacks `mynet_clone_create` and `mynet_clone_destroy`. The kernel registers a new cloner in the `VNET` cloner list. At this point, no interface exists yet: the cloner is only a factory.

The shell prompt returns. You type:

```
# ifconfig mynet create
```

`ifconfig(8)` opens a datagram socket and issues the `SIOCIFCREATE2` ioctl on it, passing the name `mynet`. The kernel's clone dispatcher finds the `mynet` cloner and calls `mynet_clone_create(cloner, unit, params, params_len)` with the first available unit number, which is zero. Our callback allocates a `mynet_softc`, locks its mutex, calls `if_alloc(IFT_ETHER)`, fills in the callbacks, initialises the media table, generates a MAC address, calls `ether_ifattach()`, and returns zero. Inside `ether_ifattach()`, the kernel calls `if_attach()` which links the interface into the global interface list, calls `bpfattach()` so `tcpdump(8)` can observe it, publishes the device to userland through `devd(8)`, and runs any registered `ifnet_arrival_event` handlers.

The shell prompt returns again. You type:

```
# ifconfig mynet0 up
```

Same socket, same kind of ioctl, different command: `SIOCSIFFLAGS`. The kernel looks up the interface by name, finds `mynet0`, and calls `mynet_ioctl(ifp, SIOCSIFFLAGS, data)`. Our handler observes that `IFF_UP` is set but `IFF_DRV_RUNNING` is not, so it calls `mynet_init()`. That function flips `running` to true, sets `IFF_DRV_RUNNING` on the interface, schedules the first callout tick, and returns. The ioctl returns zero. The shell prompt returns.

You type:

```
# ping -c 1 -t 1 192.0.2.99
```

At this point the network stack attempts ARP resolution. It builds an ARP request packet, formatted as Ethernet + ARP, and calls `ether_output()` for the interface. `ether_output()` prepends the Ethernet header, calls `if_transmit()`, which is a macro that calls our `mynet_transmit()` function. Our transmit function increments counters, taps BPF, frees the mbuf, and returns zero. `tcpdump -i mynet0` would have seen the ARP request in flight.

Meanwhile, because our driver is also generating fake inbound ARP responses on its callout timer, the next callout tick synthesises an ARP reply, calls `if_input()`, and the stack believes it has heard from `192.0.2.99`.

ping sends the ICMP echo request, our driver taps it, frees the mbuf, and records success. ping never gets a reply, because our driver only fakes ARP; but the lifecycle worked exactly as expected, and nothing crashed.

This sequence, trivial as it looks, exercises almost every code path in your driver. Internalise it.

28.23.2 Trace 2: From ifconfig down to kldunload

Now you are cleaning up. You type:

```
# ifconfig mynet0 down
```

SIOCSIFFLAGS again, this time with IFF_UP cleared. Our ioctl handler sees IFF_DRV_RUNNING set but IFF_UP unset, so it calls mynet_stop(). That function flips running to false, clears IFF_DRV_RUNNING, drains the callout, and returns. Subsequent transmit attempts will be refused by mynet_transmit() because of the running check.

```
# ifconfig mynet0 destroy
```

SIOCIFDESTROY ioctl. The kernel finds the cloner that owns this interface, and calls mynet_clone_destroy(cloner, ifp). Our callback calls mynet_stop() (belt and braces: the interface was already down), then ether_ifdetach(), which calls if_detach() internally. if_detach() unlinks the interface from the global list, drains any references, calls bpfdetach(), notifies devd(8), and runs the ifnet_departure_event handlers. Our callback then calls ifmedia_removeall() to free the media list, destroys the mutex, frees the ifnet with if_free(), and frees the softc with free().

```
# kldunload mynet
```

The loader walks VNET_SYSUNINIT and calls vnet_mynet_uninit(), which detaches the cloner with if_clone_detach(). Then mynet_modevent(mod, MOD_UNLOAD, data) runs and returns zero. The loader unmaps the module from kernel memory. The system is clean.

Each command in the sequence corresponds to a specific callback in your driver. If a command hangs, the broken callback is usually obvious. If a command crashes, the stack trace points directly at it. Practise this trace until it feels mechanical; you will spend the rest of your career as a driver author walking variants of it.

28.24 Common Misconceptions About Network Drivers

Beginners arrive at this chapter with a handful of recurring misconceptions. Naming them explicitly helps you avoid subtle bugs later.

“The driver parses Ethernet headers.” Not quite. For reception, the driver does not parse the Ethernet header at all: it hands the raw frame to ether_input() (called from if_input() under the Ethernet framework), and ether_input() does the parsing. For transmission, ether_output() in the generic layer prepends the Ethernet header; your transmit callback usually sees the complete frame and simply moves its bytes out to the wire. The driver’s job is to move frames, not to understand protocols.

“The driver must know about IP addresses.” No. An Ethernet driver operates below IP entirely. It handles MAC addresses, frame sizes, multicast filters, and link state, but it never looks at IP headers. When you attach a network driver to an address using `ifconfig mynet0 192.0.2.1/24`, the assignment is stored in a protocol-family-specific structure (a `struct in_ifaddr`) which the driver never touches. The driver only sees outbound frames and only produces inbound frames: whether those frames carry IPv4, IPv6, ARP, or something exotic is above its pay grade.

“IFF_UP means the interface can send packets.” Partially true. `IFF_UP` means the administrator has said, “I want this interface to be active.” The driver responds by initialising hardware (or, in our case, flipping `running` to `true`) and setting `IFF_DRV_RUNNING`. The distinction matters. `IFF_UP` is user intent; `IFF_DRV_RUNNING` is driver state. Only the latter reliably indicates that the driver is prepared to send frames. If you check `IFF_UP` alone before transmitting, you will occasionally send frames into a half-initialised hardware state and watch the machine panic.

“BPF is something you enable for debugging.” BPF is always on for every network driver. The `bpfattach()` call inside `ether_ifattach()` registers the interface with the Berkeley Packet Filter framework unconditionally. When no BPF listeners exist, `BPF_MTAP()` is cheap; it checks an atomic counter and returns. When listeners exist, the mbuf is cloned and delivered to each one. You do not need to do anything special to make `tcpdump` work on your driver; you only need to call `BPF_MTAP()` on both paths. Forgetting that single call is the most common reason a new driver shows packets in counters but nothing in `tcpdump`.

“The kernel will clean up if my driver crashes.” False. A crash inside a driver is a crash inside the kernel. There is no process boundary to contain the damage. If your transmit function dereferences a null pointer, the machine panics. If your callback leaks a mutex, every subsequent call that touches the interface will hang. Write defensively. Test under load. Use `INVARIANTS` and `WITNESS` builds.

“Network drivers are slower than storage drivers.” Not inherently. Modern NICs process tens of millions of packets per second, and a well-written driver using `iflib(9)` can keep pace. The confusion comes from the fact that each individual packet is tiny compared to a storage request, so the per-packet overhead of clumsy designs becomes visible immediately. A sloppy storage driver might still hit 80% of line rate because a single I/O moves 64 KiB; a sloppy network driver will fall apart at 10% of line rate because each frame is 1.5 KiB and the per-frame overhead dominates.

“Once my driver passes `ifconfig`, I’m done.” Not even close. A driver that passes `ifconfig` up but fails under `jail`, `vnet`, or module unload can still break production systems. The rigorous test matrix you built in the testing section is the real bar. Many production bugs are discovered only at the intersection of features: VLAN plus TSO, jumbo frames plus checksum offload, promiscuous mode plus multicast filtering, rapid up/down cycles plus BPF listeners.

Each misconception can trace back to a piece of earlier reading that was technically accurate but incomplete. Now that you have written a driver, these edges come into focus.

28.25 How Packets Actually Reach and Leave Your Driver

It is worth slowing down and tracing the exact path a packet takes. The geography of the FreeBSD network stack is older than you might think, and much of it is invisible from the driver’s perspective. Knowing the geography makes the bugs you encounter easier to diagnose.

28.25.1 The outbound path

When a userland process calls `send()` on a UDP socket, the path looks like this:

1. The system call enters the kernel and reaches the socket layer. The data is copied from userland into kernel mbufs using `sosend()`.
2. The socket layer hands the mbufs to the protocol layer, which in this case is UDP. UDP prepends a UDP header and hands the packet to IP.
3. IP prepends the IP header, selects an output route using the routing table, and hands the packet to the interface-specific output function via the route's `rt_ifp` pointer. For an Ethernet interface, that function is `ether_output()`.
4. `ether_output()` calls `arpresolve()` to find the destination MAC address. If the ARP cache has an entry, execution continues. If not, the packet is queued inside ARP and an ARP request is transmitted; the queued packet will be released later when the reply arrives.
5. `ether_output()` prepends the Ethernet header and calls `if_transmit(ifp, m)`, which is a thin macro over the driver's `if_transmit` callback.
6. Your `mynet_transmit()` runs. It may queue the mbuf onto hardware, tap BPF, update counters, and free or retain the mbuf depending on whether it owns it.

Six layers, and only one of them is your driver. The rest is scenery you never have to touch. But when a bug occurs, understanding which layer might be responsible is the difference between a two-hour fix and a two-day fix.

28.25.2 The inbound path

For the receive side, the path runs in the opposite direction:

1. A frame arrives on the wire (or, in our case, is synthesised by the driver).
2. The driver builds an mbuf with `m_gethdr()`, populates `m_pkthdr.rcvif`, taps BPF with `BPF_MTAP()`, and calls `if_input(ifp, m)`.
3. `if_input()` is a thin wrapper that calls the interface's `if_input` callback. For Ethernet interfaces, `ether_ifattach()` sets this callback to `ether_input()`.
4. `ether_input()` examines the Ethernet header, looks up the Ethernet type (IPv4, IPv6, ARP, etc.), and calls the appropriate demux routine: `netisr_dispatch(NETISR_IP, m)` for IPv4, `netisr_dispatch(NETISR_ARP, m)` for ARP, and so on.
5. The netisr framework optionally defers the packet to a worker thread, then delivers it to the protocol-specific input routine. For IPv4, this is `ip_input()`.
6. IP parses the header, performs source/destination checks, consults the routing table to decide whether the packet is local or transit, and either delivers it up to the transport layer or sends it back down for forwarding.
7. If the packet is for the local host and the protocol is UDP, `udp_input()` validates the UDP checksum and delivers the payload to the matching socket's receive buffer.
8. The userland process that called `recv()` wakes up and reads the data.

Eight layers on reception, and again, only one of them is your driver. But look at how many places `m_pullup()` might be called to make a header contiguous in memory, how many places the mbuf might be freed, how many places a counter might be bumped. If you see `ifconfig mynet0` reporting packets received but `tcpdump -i`

mynet0 showing nothing, the gap is most likely between step 2 and step 3 (your `BPF_MTAP()` is missing or wrong). If `tcpdump` shows the packets but `netstat -s` shows them being dropped, the gap is most likely between step 6 and step 7 (the routing table doesn't think the interface owns the destination address).

28.25.3 Why this geography matters for driver authors

Understanding the geography gives you diagnostic power. When something breaks, you can ask focused questions. Is the counter incrementing? Step 6 in the outbound path fired. Is BPF seeing the packet? Your `BPF_MTAP()` call is present and the interface is marked running. Is the packet reaching the peer? The hardware actually transmitted it. Each question corresponds to a specific checkpoint in the geography, and each checkpoint narrows the range of possible bugs.

Production drivers extend this geography with transmit and receive rings, batch processing, hardware offloads, and interrupt moderation. Each optimisation changes the path; none of them changes the overall shape. The shape is worth memorising now, before the optimisations confuse it.

28.26 Things This Chapter Did Not Cover

An honest list of omissions helps you know what to learn next, and it sets up Chapter 29 more precisely than an artificial summary would.

Real hardware initialisation. We did not touch PCI enumeration, bus resource allocation, interrupt setup, or DMA ring construction. For that, read drivers like `/usr/src/sys/dev/e1000/if_em.c` carefully, especially `em_attach()` and `em_allocate_transmit_structures()`. You will see `bus_alloc_resource_any()`, `bus_setup_intr()`, `bus_dma_tag_create()`, and `bus_dmamap_create()` in action. Those are the functions that make a physical NIC actually move bits.

iflib. The `iflib(9)` framework abstracts most of the fiddly parts of a modern Ethernet driver. As a rough order-of-magnitude figure, a new NIC driver in FreeBSD 14.3 often consists of around 1,500 lines of hardware-specific code plus calls into `iflib`, rather than the roughly 10,000 lines of open-coded ring management a fully hand-written driver would need. We mentioned `iflib` without teaching it, because the teaching driver is simpler without it. A real driver in production in 2026 probably uses `iflib`.

Checksum offload. Modern NICs compute TCP, UDP, and IP checksums in hardware. Setting up `IFCAP_RXCSUM`, `IFCAP_TXCSUM`, and their IPv6 counterparts requires both driver support and mbuf flag manipulation (`CSUM_DATA_VALID`, `CSUM_PSEUDO_HDR`, etc.). Get it wrong and you silently corrupt traffic for some users only. The best introduction is `if_em.c`'s `em_transmit_checksum_setup()` function, paired with `ether_input()` to see how the flags propagate up.

Segmentation offload. TSO (transmit), LRO (receive), and GSO (generic segmentation offload) let the host hand the NIC multi-segment frames that the hardware (or a driver-level helper) breaks into MTU-sized fragments. For a primer, read `tcp_output()` and trace how it cooperates with `if_hwt_somax` and `IFCAP_TS04`.

Multicast filtering. Real drivers program hardware multicast hash tables based on the memberships advertised through `SIOCADDMULTI`. We stubbed the ioctls; a real implementation walks `ifp->if_multiaddrs` and pokes a hash register on the NIC.

VLAN processing. Real drivers set `IFCAP_VLAN_HWTAGGING` and allow `vlan(4)` to hand off tagging and untagging to the hardware. Without it, every VLAN-tagged frame goes through software `vlan_input()` and `vlan_output()`, slower but simpler. Our driver is VLAN-transparent: it carries tagged frames as-is.

Offload negotiation via SIOCSIFCAP. `ifconfig mynet0 -rxcsom` toggles capabilities at runtime. Real drivers must gracefully handle the capability changing mid-flight: flush rings, reconfigure hardware, then accept traffic again.

SR-IOV. Single-root I/O virtualisation lets a physical NIC present multiple virtual functions to a hypervisor. The FreeBSD support (`iovt(9)`) is non-trivial. We did not go near it.

Wireless. Wireless drivers use `net80211(4)`, a separate framework layered on top of `ifnet`. They have a rich state machine, complex rate control, encryption offload, and a completely different regulatory compliance story. Reading `/usr/src/sys/dev/ath/if_ath.c` is a worthwhile afternoon, but most of what it teaches is orthogonal to what we built here.

InfiniBand and RDMA. Out of scope entirely. These use `/usr/src/sys/ofed/` and a separate OS-agnostic verb framework.

Virtualisation-specific acceleration. `netmap(4)`, `vhost(4)`, and DPDK-style user-space fastpaths exist and matter in 2026 production environments. They are later-career topics.

We cover none of these in full. We gave you pointers to each, so that when your job demands one of them, you know where to begin reading.

28.27 Historical Context: Why ifnet Looks the Way It Does

A last stop before the bridge: a short history lesson. Understanding where `ifnet` came from makes some of its rough edges less surprising.

The earliest UNIX network stacks, in the late 1970s, had no `ifnet` structure at all. Each driver provided an ad hoc set of callbacks registered through patchy conventions. When 4.2BSD introduced the sockets API and the modern TCP/IP stack in 1983, the BSD team also introduced `struct ifnet` as a uniform interface between the protocol code and the driver code. The early version had about a dozen fields: a name, a unit number, a set of flags, an output callback, and a handful of counters. Compared to modern `struct ifnet`, it looks almost empty.

Over the next four decades, `struct ifnet` grew. BPF was added in the late 1980s. Multicast support arrived in the early 1990s. IPv6 support bolted on in the late 1990s. Interface cloning, media layer, and link-state events arrived through the 2000s. Offload capabilities, VNets, checksum offload flags, TSO, LRO, and VLAN offload appeared through the 2010s. By the time FreeBSD 11 arrived in 2016, the structure had become unwieldy enough that the project introduced the `if_t` opaque type and the `if_get*/if_set*` accessor functions, so that the structure's layout could change without breaking binary compatibility for modules.

That history explains several things. It explains why `ifnet` has both `if_ioctl1` and `if_ioctl2`; why some fields are accessed through macros and others directly; why `IFF_*` and `IFCAP_*` exist as parallel flag spaces; why the cloner API has both `if_clone_simple()` and `if_clone_advanced()`; why `ether_ifattach()` exists as a wrapper over `if_attach()`. Each addition solved a real problem. The accumulated weight is the cost of living inside a running system that never had the luxury of a clean slate.

For you, the practical takeaway is that `ifnet`'s surface area is large and a little inconsistent. Read it as geology, not as architecture. The strata record real events in the history of UNIX networking. Once you know they are strata, the inconsistencies become navigable.

28.28 Self-Assessment: Do You Really Know This Material?

Before moving on, measure your own understanding against a concrete rubric. A network driver author should be able to answer every question below without looking at the chapter. Work through them honestly. If you cannot answer one, re-read the relevant section; do not just skim until the answer looks familiar.

Conceptual questions.

1. What is the difference between `IFF_UP` and `IFF_DRV_RUNNING`, and which one decides whether a frame is actually sent?
2. Name three callbacks your driver must provide, and for each one, describe what failing to implement it correctly would cause.
3. Why does the kernel generate a random locally-administered MAC address for pseudo-interfaces, and what bit must be set to mark an address locally administered?
4. When `ether_input()` receives an Ethernet frame, which field of `m_pkthdr` tells the stack which interface the frame came from, and why does every inbound mbuf need it set correctly?
5. What does `net_epoch` protect, and why is it considered lighter weight than a traditional read lock?

Mechanical questions.

6. Write, from memory, the sequence of function calls from `if_alloc()` through `ether_ifattach()` that creates a minimum viable interface. You do not need to remember argument lists; just the names and the order.
7. Write the exact macro call that feeds an outbound mbuf to BPF. Write the exact macro call for inbound.
8. Given an mbuf chain that might be fragmented, which helper gives you a single flat buffer suitable for DMA? Which helper ensures at least the first *n* bytes are contiguous?
9. Which ioctl does `ifconfig mynet0 192.0.2.1/24` produce? Which layer in the kernel actually processes it: the generic `ifioctl()` dispatcher, `ether_ioctl()`, or your driver's `if_ioctl` callback? Why?
10. Your driver uses `callout_init_mtx(&sc->tick, &sc->mtx, 0)`. What is the purpose of the mutex argument, and what bug would arise if you passed `NULL`?

Debugging questions.

11. `ifconfig mynet0 up` returns instantly, but `netstat -in` shows the interface with zero packets after ten minutes of ping. Describe the three most likely causes and the commands you would run to distinguish between them.
12. The module loads cleanly. `ifconfig mynet create` succeeds. `ifconfig mynet0 destroy` panics with a "locking assertion" message. What is the most likely bug? How would you fix it?
13. `tcpdump -i mynet0` shows outbound packets but never inbound, even though `netstat -in` shows RX counters incrementing. Which function call is almost certainly missing, and on which code path?
14. You run `kldunload mynet` while an interface still exists. What happens? What safe sequence should the user have followed? How might a production driver refuse to unload under these conditions?

15. Running `ifconfig mynet0 up` followed immediately by `ifconfig mynet0 down` a hundred times in a loop causes the machine to panic on the fiftieth iteration with a corrupted mbuf queue. Walk through the likely class of bug and the fix.

Advanced questions.

16. Explain in your own words what `net_epoch` provides that a mutex does not, and when you would use one versus the other inside a network driver.
17. If your driver advertises `IFCAP_VLAN_HWTAGGING`, how does that change the mbufs your transmit callback sees compared to the default?
18. The kernel has two distinct delivery paths for inbound frames: one via `netisr_dispatch()`, one via direct dispatch. What are they, and when would a driver care which one is used?
19. What is the difference between `if_transmit` and the older `if_start/if_output` pair, and which should a new driver use?
20. Describe the lifecycle of a VNET on a FreeBSD 14.3 system, and explain why a cloner registered with `VNET_SYSINIT` produces a cloner in every VNET rather than a single global cloner.

If you answered every question without hesitation, you are ready for Chapter 29. If five or more questions gave you trouble, spend another session with this chapter before moving forward. The next chapter builds on the assumption that you know this material cold.

28.29 Further Reading and Source Code Study

The bibliography below is small, targeted, and ordered by usefulness for a driver author at your current stage. Treat it as a reading list for the weeks after you finish Chapter 28, not an overwhelming bookshelf.

Must read, in order.

- `/usr/src/sys/net/if.c`: the generic interface machinery. Start with `if_alloc()`, `if_attach()`, `if_detach()`, and the ioctl dispatcher `ifioctl()`. This is the file that actually runs the lifecycle functions you call in your driver.
- `/usr/src/sys/net/if_etherubr.c`: Ethernet framing. Read `ether_ifattach()`, `ether_ifdetach()`, `ether_output()`, `ether_input()`, and `ether_ioctl()`. These four functions form the contract between your driver and the Ethernet layer.
- `/usr/src/sys/net/if_disc.c`: the minimal pseudo-driver. Less than 200 lines. A reference for the absolute minimum viable `ifnet`.
- `/usr/src/sys/net/if_epair.c`: the paired pseudo-driver. The cleanest reference for writing a cloner with a shared structure between two instances.
- `/usr/src/sys/dev/virtio/network/if_vtnet.c`: a modern paravirtual driver. Small enough to read fully, realistic enough to teach you about rings, checksum offload, multiqueue, and hardware-like resource management.

Read next, when the time comes.

- `/usr/src/sys/dev/e1000/if_em.c` and the accompanying `em_txrx.c`, `if_em.h`: a production Intel NIC driver. Larger and more elaborate, but representative of real-world driver complexity.
- `/usr/src/sys/net/iflib.c` and `/usr/src/sys/net/iflib.h`: the `iflib` framework. Read after you have studied `if_em.c` so you can recognise the structures `iflib` takes over.

- `/usr/src/sys/net/if_lagg.c`: the link aggregation driver. A detailed study of multi-interface orchestration, failover, and mode selection.
- `/usr/src/sys/net/if_bridge.c`: software bridging. Excellent for learning multicast forwarding, learning bridges, and the STP state machine.

Worthwhile manual pages.

- `ifnet(9)`: the interface framework.
- `mbuf(9)`: the packet buffer system.
- `bpf(9)` and `bpf(4)`: the Berkeley Packet Filter.
- `ifmedia(9)`: the media framework.
- `ether(9)`: Ethernet helpers.
- `vnet(9)`: virtualised network stacks.
- `net_epoch(9)`: the network epoch synchronisation primitive.
- `iflib(9)`: the `iflib` framework.
- `netmap(4)`: high-speed user-space packet I/O.
- `netgraph(4)` and `netgraph(3)`: the `netgraph` framework.
- `if_clone(9)`: interface cloning.

Books and papers.

The 4.4BSD design books (particularly “The Design and Implementation of the 4.4BSD Operating System” by McKusick, Bostic, Karels, and Quarterman) remain the best long-form explanation of how the sockets and interface layers came to exist. The FreeBSD Developer’s Handbook sections on kernel programming and loadable modules are the next stop for general background. For packet processing at speed, the `netmap` papers by Luigi Rizzo are foundational; they explain both the techniques and the rationale behind modern high-performance packet pipelines.

Keep a reading journal. When you finish a file, write a paragraph summarising what surprised you, what you want to revisit, and what you think you might steal for your own drivers. Over six months of this practice, your intuition for how production drivers are structured will grow faster than you expect.

28.30 Frequently Asked Questions

New driver authors tend to ask the same questions as they work through their first `ifnet` driver. Here are the most common ones, with short, pointed answers. Each answer is a signpost, not an exhaustive treatment; follow the bread crumbs back to the relevant section of the chapter if you want more detail.

Q: Can I write an Ethernet driver without using `ether_ifattach`?

Technically yes; practically no. `ether_ifattach()` sets `if_input` to `ether_input()`, hooks BPF with `bpfattach()`, and configures a dozen small default behaviours. Skipping it means reimplementing every one of those defaults by hand. The only reason to bypass `ether_ifattach()` is if your driver is not actually Ethernet, in which case you will use `if_attach()` directly and supply your own framing callbacks.

Q: What is the difference between `if_transmit` and `if_output`?

`if_output` is the older, protocol-agnostic output callback. For Ethernet drivers, it is set to `ether_output()` by `ether_ifattach()`, and it handles ARP resolution and Ethernet framing before calling `if_transmit`.

`if_transmit` is the driver-specific callback you write. In short: `if_output` is what the stack calls; `if_transmit` is what `if_output` calls; your driver supplies the latter.

Q: Do I need to handle `SIOCSIFADDR` in my `ioctl` callback?

Not directly. `ether_ioctl()` handles address configuration for Ethernet interfaces. Your callback should delegate unrecognised `ioctls` to `ether_ioctl()` via the default: arm of its switch statement, and address-related `ioctls` will flow through that path correctly.

Q: How do I know when a frame has actually been transmitted by the hardware?

For our pseudo-driver, “transmit” is synchronous: `mynet_transmit()` frees the mbuf immediately. For a real NIC driver, the hardware signals completion via an interrupt or a ring descriptor flag; the driver’s transmit completion handler (sometimes called the “tx reaper”) walks the ring, releases the mbufs, and updates counters. Read `if_em.c`’s `em_txeof()` for a concrete example.

Q: Why does `ifconfig mynet0 delete` not call my driver?

Because address configuration lives in the protocol layer, not the interface layer. Removing an address from an Ethernet interface is handled by `in_control()` (for IPv4) or `in6_control()` (for IPv6). Your driver is unaware of these operations; it only sees them indirectly through route changes and ARP table updates.

Q: Why is my driver panicking when I call `if_inc_counter()` from a callout?

Almost certainly because you are holding a non-recursive mutex that was acquired elsewhere. `if_inc_counter()` is safe from any context on modern FreeBSD, but if your callout acquires a lock that the callout infrastructure already holds, you deadlock. The safest pattern is to call `if_inc_counter()` without holding any driver-specific locks, and to update your own counters separately inside the lock.

Q: How do I make my driver show up in `sysctl net.link.generic.ifdata.mynet0.link`?

You do not. That `sysctl` tree is populated automatically by the generic `ifnet` layer. Every interface registered via `if_attach()` (directly or via `ether_ifattach()`) receives a `sysctl` node. If yours is missing, your interface did not attach correctly.

Q: My driver works on FreeBSD 14.3 but fails to build on FreeBSD 13.x. Why?

The `if_t` opaque type and the associated accessor functions were stabilised across FreeBSD 13 and 14, but several helper APIs only arrived in 14. For example, `if_clone_simple()` has existed for years, but some of the counter accessor helpers are new. Either use `__FreeBSD_version` guards to compile cleanly on both, or state clearly in your driver that FreeBSD 14.0 or later is required.

Q: I want to write a driver that accepts packets on one interface and retransmits them on another. Is that a network driver?

Not quite. That is a bridge or a forwarder. The FreeBSD kernel has `if_bridge(4)` for bridging, `netgraph(4)` for arbitrary packet pipelines, and `pf(4)` for filtering and policy. Writing your own forwarding code from scratch is almost never the right answer in 2026; the existing frameworks are better-maintained, faster, and more flexible. Read them and configure them before writing a new driver.

Q: Do I need to worry about endianness inside my network driver?

Only at specific boundaries. Ethernet frames are network byte order (big-endian) by convention; if you parse an Ethernet header yourself, the `ether_type` field needs `ntohs()`. Inside the mbuf, the data is stored in network byte order, not the host’s native order. The `ether_input()` and `ether_output()` functions handle the conversions for you, so most driver code does not touch endianness directly.

Q: When do I use `m_pullup()` versus `m_copydata()`?

`m_pullup(m, n)` mutates the mbuf chain so that the first `n` bytes are stored contiguously in memory, making them safe to access with a pointer cast. `m_copydata(m, off, len, buf)` copies bytes out of the mbuf chain into a separate buffer you provide. Use `m_pullup()` when you want to read and potentially modify header fields in place. Use `m_copydata()` when you want a snapshot for inspection without disturbing the mbuf.

Q: Why does `netstat -I mynet0 1` sometimes show zero bytes even when packets are being exchanged?

You may be incrementing `IFCOUNTER_IPACKETS` or `IFCOUNTER_OPACKETS` without also incrementing `IFCOUNTER_IBYTES` or `IFCOUNTER_OBYTES`. The per-second display shows bytes separately; if the byte counters never move, `netstat -I` reports zero throughput. Always update packet count and byte count together.

Q: How do I destroy all cloned interfaces on module unload?

The simplest approach is to let `if_clone_detach()` do it for you; the clone detach helper walks the cloner's interface list and destroys each one. If you want to defend against leaks, you can also enumerate the interfaces belonging to the cloner and destroy them explicitly before calling `if_clone_detach()`. The shorter path is usually the better one, because the helper is tested and yours probably is not.

Q: My driver works under ping but crashes during a large iperf3 run. What is typical?

At high packet rates, all the subtle concurrency bugs in a driver become exposed. Common causes include: a counter updated outside a lock that runs on multiple CPUs, a mbuf queue that is not properly drained before free, a callout that fires during shutdown, a `BPF_MTAP()` call after the interface was detached. Run with `WITNESS` and `INVARIANTS` enabled; the locking assertions almost always catch it.

28.31 A Short Closing Note on Craft

We have spent many pages on mechanics: callbacks, locks, mbufs, ioctls, counters. The mechanics are necessary, but they are not sufficient. A good network driver is the product of a disciplined author, not merely a correct set of callbacks.

That discipline shows up in small places. It shows up in the decision to drain a callout on detach even though the test suite never catches a leak. It shows up in the decision to update a counter in the right order so that `netstat -s` adds up across a long run. It shows up in the decision to log once, clearly, when a resource cannot be allocated, rather than either staying silent or flooding the log. It shows up in the decision to use `M_ZERO` when allocating a softc, so that any future field added to the structure starts at a known zero even if the explicit initialisation is forgotten.

Each decision is small. The accumulated effect is the difference between a driver that works on the first day and a driver that works on the thousandth day. You are training a habit, not memorising a syntax. Be patient with yourself while the habit forms; it takes years.

The great FreeBSD driver authors, the ones whose names you see in the `$FreeBSD$` tags and the commit logs, did not become great by knowing the API better than you. They became great by reviewing their own work as if someone else wrote it, and fixing every small flaw they found. That practice scales. Pick it up early.

28.32 Mini-Glossary of Network Driver Terms

A short glossary follows, aimed at the reader who wants to revisit the chapter's core vocabulary in one place. Use it as a refresher, not as a replacement for the explanations in the main text.

- **ifnet.** The kernel data structure representing a network interface. Each attached interface has exactly one `ifnet`. The opaque handle `if_t` is used by most modern code.
- **ether_ifattach.** The wrapper over `if_attach()` that sets up Ethernet-specific defaults, including BPF hooks and the standard `if_input` function.
- **cloner.** A factory for pseudo-interfaces. Registered with `if_clone_simple()` or `if_clone_advanced()`. Responsible for creating and destroying interfaces in response to `ifconfig name create` and `ifconfig name0 destroy`.
- **mbuf.** The kernel's packet buffer. A small struct with metadata, an optional embedded payload, and pointers to additional buffers for chained data. Allocated with `m_gethdr()`, freed with `m_freem()`.
- **softc.** Per-instance driver state. Allocated with `malloc(M_ZERO)` in the cloner create callback and freed in the cloner destroy callback. Traditionally points to mutex, media descriptor, callout, and the interface.
- **BPF.** The Berkeley Packet Filter, a framework for userland tools like `tcpdump` to observe the traffic on an interface. Drivers hook into it with `BPF_MTAP()` on both transmit and receive paths.
- **IFF_UP.** The administrative flag set by `ifconfig name0 up`. Indicates user intent to activate the interface.
- **IFF_DRV_RUNNING.** The driver-controlled flag indicating the driver is prepared to send and receive packets. Set inside the driver after hardware (or pseudo-hardware) initialisation completes.
- **Media.** The abstraction for link speed, duplex, autonegotiation, and related physical-layer properties. Managed through the `ifmedia(9)` framework.
- **Link state.** A three-valued indicator (`LINK_STATE_UP`, `LINK_STATE_DOWN`, `LINK_STATE_UNKNOWN`) reported via `if_link_state_change()`. Used by routing daemons and userland tools.
- **VNET.** FreeBSD's virtualised network stack. Each VNET has its own interface list, routing table, and sockets. Pseudo-drivers typically use `VNET_SYSINIT` to register cloners in every VNET.
- **net_epoch.** A lightweight synchronisation primitive used to delimit read-side critical sections in the network stack. Faster than a traditional read lock.
- **IFCAP.** A bitfield of capabilities (`IFCAP_RXCSUM`, `IFCAP_TS04`, etc.) negotiated between the driver and the stack. Controls which offloads are active on a given interface.
- **IFCOUNTER.** A named counter (`IFCOUNTER_IPACKETS`, `IFCOUNTER_OBYTES`, etc.) displayed by `net-stat`. Updated by drivers via `if_inc_counter()`.
- **Ethernet type.** The 16-bit field in an Ethernet frame header identifying the encapsulated protocol. Values are defined in `net/ethernet.h`, with `ETHERTYPE_IP` and `ETHERTYPE_ARP` being the most common.
- **Jumbo frame.** An Ethernet frame larger than the standard 1500-byte MTU, typically 9000 bytes. Drivers advertise support through `ifp->if_capabilities |= IFCAP_JUMBO_MTU`.
- **Promiscuous mode.** A mode in which the interface delivers every observed frame to the stack, not only those addressed to its own MAC. Controlled via `IFF_PROMISC`. Used by network analysis tools.
- **Multicast.** Frames addressed to a group of receivers rather than a single destination. Drivers track group memberships through `SIOCADDMULTI` and `SIOCDELMULTI`, typically programming a hardware hash filter.
- **Checksum offload.** A capability where the NIC computes TCP, UDP, and IP header checksums in hardware. Negotiated through `IFCAP_RXCSUM` and `IFCAP_TXCSUM`; flagged per mbuf via `m_pkthdr.csum_flags`.

- **TSO (TCP Segmentation Offload).** A capability where the host hands the NIC a large TCP segment and the NIC splits it into MTU-sized fragments. Negotiated via `IFCAP_TS04` and `IFCAP_TS06`.
- **LRO (Large Receive Offload).** The receive-side counterpart to TSO. The NIC or software layer aggregates sequential inbound segments into a single large mbuf chain before handing it to the stack.
- **VLAN tagging.** A four-byte shim in the Ethernet frame that identifies the VLAN membership. Drivers may advertise `IFCAP_VLAN_HWTAGGING` to offload the insertion and removal to hardware.
- **MSI-X.** Message-signalled interrupts, the modern replacement for wired IRQs. Allows the NIC to raise separate interrupts per queue.
- **Interrupt moderation.** A technique where the NIC coalesces multiple completion events into fewer interrupts, reducing overhead at high packet rates.
- **Ring buffer.** A circular queue of descriptors shared between the driver and the NIC. Transmit rings feed packets to hardware; receive rings deliver packets from hardware.
- **iflib.** FreeBSD's modern NIC driver framework. Abstracts ring management, interrupt handling, and mbuf flow so the driver author can focus on hardware-specific code.
- **netmap.** A high-performance packet I/O framework that gives userland direct access to driver rings, bypassing most of the network stack.
- **netgraph.** A flexible framework for composing packet-processing pipelines out of reusable nodes. Largely orthogonal to driver writing but often relevant to network architecture.
- **pf.** FreeBSD's packet filter. A firewall and NAT engine that sits inline with `ether_input()` and `ether_output()` via `pf1l(9)` hooks. Drivers do not interact with it directly; the hooks are inserted by the generic layers.
- **pfil.** The packet filter interface through which firewalls attach to the forwarding path. Gives frameworks like `pf` and `ipfw` a stable place to observe and modify packets.
- **if_transmit.** The per-driver outbound callback, set during interface allocation. Receives an mbuf chain, is responsible for queueing it for hardware or discarding it.
- **if_input.** The per-interface inbound callback. For Ethernet drivers, set to `ether_input()` by `ether_ifattach()`. The driver calls it via the `if_input(ifp, m)` helper to hand received frames up to the stack.
- **if_ioctl.** The per-driver ioctl callback. Handles interface-level ioctls such as `SIOCSIFFLAGS`, `SIOC-SIFMTU`, and `SIOCSIFMEDIA`. Delegates unknown ioctls to `ether_ioctl()` for Ethernet drivers.

Keep this glossary nearby as you read Chapter 29 and the chapters that follow. Each term recurs often enough that a quick reference pays for itself.

28.33 Part 6 Checkpoint

Part 6 put the discipline of Parts 1 through 5 under three very different transports: USB, GEOM-backed storage, and `ifnet`-based network. Before Part 7 returns to the cumulative `myfirst` arc and starts pushing on portability, security, performance, and craft, confirm that the three transport vocabularies have settled into the same underlying model.

By the end of Part 6 you should be able to do each of the following:

- Attach to a USB device through the `usb_request_methods` framework: configure transfers for control, bulk, interrupt, and isochronous endpoints; dispatch read and write through the transfer callbacks; and survive hot-plug and hot-unplug as normal operating conditions.

- Write a storage driver that plugs into GEOM: provision a provider through `g_new_providerf`, service BIO requests in the class's start routine, walk the `g_down/g_up` threads in your head, and tear down cleanly under mounted load.
- Write a network driver that presents an `ifnet` through `ether_ifattach`: implement `if_transmit` for the outbound path, call `if_input` for the inbound path, integrate with `bpf` and media state, and clean up through `ether_ifdetach`.
- Explain why the three transports look so different at the surface but share the same underlying discipline from Parts 1 through 5: Newbus attach, softc management, resource allocation, locking, detach ordering, observability, production discipline.

If any of those still feels unsteady, the labs to revisit are:

- USB path: Lab 2 (Building and Loading the USB Driver Skeleton), Lab 3 (A Bulk Loopback Test), Lab 6 (Observing Hot-Plug Lifecycle), and Lab 7 (Building a `ucom(4)` Skeleton from Scratch) in Chapter 26.
- GEOM storage path: Lab 2 (Build the Skeleton Driver), Lab 3 (Implement the BIO Handler), Lab 4 (Increase Size and Mount UFS), and Lab 10 (Break It On Purpose) in Chapter 27.
- Network path: Lab 1 (Build and Load the Skeleton), Lab 2 (Exercise the Transmit Path), Lab 3 (Exercise the Receive Path), Lab 5 (`tcpdump` and `BPF`), and Lab 6 (Clean Detach) in Chapter 28.

Part 7 expects the following as a baseline:

- Comfort switching between `cdevsw`, GEOM, and `ifnet` as three idioms over the same Newbus-and-softc core, rather than as three disconnected subjects.
- Understanding that Part 7 returns to the single-thread `myfirst` arc for the final polish on portability, security, performance, tracing, kernel-debugger work, and the craft of engaging with the community. The transport-specific demos of Part 6 do not continue; their lessons do.
- A mental library of three real transports you have touched with your own hands, so that when Chapter 29 talks about abstraction across backends, you are drawing on experience rather than on examples you have only read about.

If those hold, Part 7 is ready for you. The final nine chapters are the part of the book that turns a capable driver author into a craftsperson; the groundwork Parts 1 through 6 have laid is what makes that transition possible.

28.34 Looking Ahead: Bridge to Chapter 29

You have just written a network driver. The next chapter, **Portability and Driver Abstraction**, zooms out from the concrete details you have mastered and asks: how do we write drivers that work well across FreeBSD's many supported architectures, and how do we structure driver code so that parts of it can be reused across different hardware backends?

That question is sharper after Chapter 28 than it was before. You have now written drivers for three very different subsystems: character devices on top of `cdevsw`, storage devices on top of GEOM, and network devices on top of `ifnet`. The three look different on the surface, but they share a surprising amount of plumbing: probe and attach, softc allocation, resource management, lifecycle control, unloading cleanliness. Chapter 29 will turn that observation into a practical refactoring: isolating the hardware-dependent code, separating backends behind a common API, preparing the driver to compile on x86, ARM, and RISC-V alike.

You will not be writing a new kind of driver in Chapter 29. You will be learning how to make the drivers you already wrote more robust, more portable, and more maintainable. That is a different kind of progress, one that matters the moment you start working on a driver that will live for years.

Before you move on, unload every module you created in this chapter, destroy every interface, and make sure `netstat -in` is back to a boring baseline. Close your lab logbook with a brief note on what worked and what puzzled you. Rest your eyes for a minute. Then, when you are ready, turn the page.

You have earned the step.

29 Portability and Driver Abstraction

29.1 Introduction

You arrive at Chapter 29 with a particular kind of experience. You have written three drivers that look very different on the surface. In Chapter 26 you connected a character device to `cdevsw` and taught `/dev` how to reach your code. In Chapter 27 you fed blocks into GEOM and let a filesystem sit on top. In Chapter 28 you shaped a network interface, registered it with the stack, and watched packets flow back and forth. Each of those drivers was cut to fit a specific subsystem, and each one taught you a specific contract with the FreeBSD kernel. If you read the three side by side, you would notice that they also share a great deal: a `softc`, a probe and attach path, resource allocation, teardown, careful handling of concurrency, and attention to the load and unload lifecycle.

This chapter is about that shared skeleton. More importantly, it is about what happens to that skeleton when the rest of the world changes around it. The machine you built your driver on today is unlikely to be the only machine that ever runs it. A driver written for an x86 workstation in 2026 might be compiled for an ARM server in 2027, for a RISC-V embedded board in 2028, and for a FreeBSD 15 release in 2029. Along the way, the hardware it talks to might change from a PCI card to a USB dongle to a simulated device in `bhyve`. The kernel API might evolve. The surrounding system might change from FreeBSD to NetBSD for one downstream consumer. The code that started small and single-purpose has to become something that survives that turbulence with minimal surgery.

That survival is what we mean by **portability**. Portability is not one property. It is a small family of related properties. It includes the ability to be compiled on a CPU architecture that you did not originally target. It includes the ability to attach to a different physical bus, such as PCI one day and USB another. It includes the ability to switch between a real device and a simulated stand-in during testing without rewriting half the file. It includes the ability to coexist with kernel API churn, so that a rename or a deprecation in a future release of FreeBSD does not force you to throw away your driver. And, occasionally, it includes the ability to share code with cousins of FreeBSD like NetBSD and OpenBSD without turning the whole codebase into a compatibility maze.

Chapter 29 teaches you how to design, structure, and refactor a driver so that each of those kinds of change becomes a local problem rather than a global rewrite. The chapter is not about a new subsystem. You have already met them. It is about the engineering discipline that allows a driver to age gracefully. It is the part of driver authorship that does not show up on the first day, when the module loads cleanly and the device responds, but that matters enormously on day one thousand, when the same module has to ship on three architectures, two buses, and four FreeBSD releases while staying readable to new contributors.

We will not invent a new driver from scratch. Instead, we will take a driver shape that is familiar to you and evolve it. You will learn how to separate hardware-dependent code from logic that does not care about hardware. You will learn how to hide a physical bus behind a backend interface, so that a PCI variant and a USB variant can share the same core. You will learn how to split a single `.c` file into a small family of files that

each have a clear responsibility. You will learn how to use the kernel's endian helpers, fixed-width types, and `bus_space/bus_dma` abstractions so that your register accesses work on little-endian and big-endian machines alike, and on 32-bit as well as 64-bit word sizes. You will learn how to use conditional compilation without turning the source into a thicket of `#ifdef`. And you will learn how to step back and version the driver so that users of your code know what it supports and what it does not.

Through all of this, the tone remains the same as in earlier chapters. Portability looks abstract when you read about it in a textbook, but it is concrete when you sit in front of a driver source file and decide which function goes where. We will stay close to that second view. Every pattern you meet will be tied to a real FreeBSD practice, and often to a real file under `/usr/src/` that you can open and read alongside the text.

Before you begin, resist the temptation to read this chapter as a set of rules. It is not. It is a set of **habits**. Each habit exists because a future version of you will thank the current version of you for having formed it. A driver that never has to be ported will still benefit from being written as if it might be, because the same habits that help portability also help readability, testability, and long-term maintenance. Do not treat this chapter as optional polish. Treat it as the part of craft that separates a driver that works from a driver that keeps working.

29.2 Reader Guidance: How to Use This Chapter

This chapter is a little different from the three that came before it. Chapters 26, 27, and 28 were each built around a concrete subsystem with a concrete API. Chapter 29 is built around a way of thinking. You will still read code, and you will still do labs, but the subject is how driver code is **organised**, not which kernel function it calls. That distinction affects the best way to study it.

If you choose the **reading-only path**, plan for roughly two to three focused hours. By the end you will recognise the common structural patterns that mature FreeBSD drivers use to stay portable and will know what to look for when you open an unfamiliar driver source tree. This is a legitimate way to use the chapter on a first pass, because the ideas here become more useful once you have seen them in action in your own work.

If you choose the **reading-plus-labs path**, plan for about five to eight hours across one or two sessions. You will take a small reference driver and progressively refactor it into a portable, multi-backend shape. You will split a single file into a core and two backend files, you will introduce a backend interface, and you will make the driver compile cleanly with and without optional backends enabled. The labs are deliberately incremental so that each step stands on its own and leaves you with a working module rather than a broken one.

If you choose the **reading-plus-labs-plus-challenges path**, plan for a weekend or a few evenings. The challenges push the refactoring further: adding a third backend, exposing version metadata to userland, simulating a big-endian environment, and writing a build matrix that proves the driver compiles in every documented configuration. Each challenge stands alone and uses only material from this chapter and the earlier ones.

You should continue to work on a throwaway FreeBSD 14.3 machine, as in earlier chapters. The labs do not require special hardware, a complicated bus, or a particular NIC. They work on a plain virtual machine with the source tree installed, a working compiler, and the usual kernel module build tools. A snapshot before you begin is cheap, and the only thing you need to undo a mistake is the ability to reboot.

A word on prerequisites. You should be comfortable with everything from Chapters 26, 27, and 28: writing a kernel module, allocating a softc, managing the probe and attach lifecycle, registering with `cdevsw`, `GEOM`, or `ifnet` as appropriate, and reasoning about the load and unload path. You should also be comfortable with `make`

and with the FreeBSD `bsd.kmod.mk` build system, since a good deal of the chapter is about how to split and compile a multi-file driver. If any of that feels uncertain, a quick skim of the earlier chapters will save you time here.

Finally, do not skip the troubleshooting section near the end. Portability refactors fail in a handful of characteristic ways, and learning to recognise those patterns early is more useful than memorising which macro lives in which header. A portable driver that mostly works is worse than a non-portable one that definitely works, because the portability gives you a false sense of confidence. Treat the troubleshooting material as part of the lesson.

29.2.1 Work Section by Section

The chapter is structured as a deliberate progression. Section 1 defines what portability really means for a driver, and why we care. Section 2 walks through isolating hardware-dependent code from logic that is not. Section 3 teaches how to hide backends behind an interface so that the core driver does not need to know whether it is talking to a PCI card or a USB dongle. Section 4 organises those pieces into a clear file layout. Section 5 deals with architectural portability: endianness, alignment, and word size. Section 6 teaches disciplined use of conditional compilation and build-time feature selection. Section 7 takes a brief look at cross-BSD compatibility, enough to be useful without turning the chapter into a NetBSD porting manual. Section 8 steps back and addresses refactoring and versioning for long-term maintenance.

You are meant to read these sections in order. Each one assumes the previous ones are fresh in your mind, and each lab builds on the results of the one before it.

29.2.2 A Gentle Warning About Over-Engineering

Before we dive in, a word of caution. Portability patterns can become an end in themselves if you are not careful. It is possible to build a driver so layered, so abstracted, and so wrapped that no one, including you, can follow what actually happens on a given code path. The goal of this chapter is not to maximise abstraction; it is to choose the right level of abstraction for the driver at hand.

For a small driver with one backend and no prospect of a second one, the simplest portable design is a single `.c` file that uses `bus_read_*`, endian helpers, and fixed-width types throughout. No backend interface. No file split. The investment stops there, and that is enough. The refactor to a multi-backend layout can happen later, when the need appears.

For a driver that already supports two or three variants, the full multi-file layout earns its keep, and the refactor to get there saves more time than it costs. For a driver that might one day support additional variants but does not yet, the middle ground is a single file with clean internal separation (a backend interface as a struct, even if only one backend is instantiated), ready to be split into multiple files when the second backend arrives.

Matching the complexity of the design to the complexity of the problem is the craft. Read this chapter with that in mind. Not every pattern in it belongs in every driver. The patterns belong where they pay for themselves.

29.2.3 Keep the Reference Driver Close

The labs in this chapter centre on a small reference driver called `portdrv`. You will find it under `examples/part-07/ch29-portability/`, staged in the same way as the examples from earlier chap-

ters. Each lab directory contains the state of the driver at that step, along with the Makefile and any support files needed to compile and test it. Do not just read the lab; type the changes, build the module, and load it. The feedback loop is tight because refactoring either compiles or it does not, and running the module after each step confirms that you did not accidentally break the driver while moving code around.

29.2.4 Open the FreeBSD Source Tree

Several sections in this chapter point to real FreeBSD drivers as concrete examples of portable structure. The files of interest include `/usr/src/sys/dev/uart/uart_core.c`, `/usr/src/sys/dev/uart/uart_bus_pci.c`, `/usr/src/sys/dev/uart/uart_bus_fdt.c`, `/usr/src/sys/dev/uart/uart_bus_acpi.c`, `/usr/src/sys/dev/uart/uart_bus.h`, `/usr/src/sys/modules/uart/Makefile`, `/usr/src/sys/sys/_endian.h`, `/usr/src/sys/sys/bus_dma.h`, and the per-architecture bus headers under `/usr/src/sys/amd64/include/_bus.h`, `/usr/src/sys/arm64/include/_bus.h`, `/usr/src/sys/arm/include/_bus.h`, and `/usr/src/sys/riscv/include/_bus.h`. Open them as the text points to them. Their shape is half the lesson.

29.2.5 Keep the Lab Logbook

Continue the lab logbook you started in Chapter 26. For this chapter, log a short entry at the end of each lab: which files you edited, which build options you enabled, which backends compiled, and any warnings the compiler produced. Portability is easy to claim and hard to verify, and a paper trail of your experiments is the fastest way to notice when you have quietly regressed.

29.2.6 Pace Yourself

If your understanding blurs during a particular section, stop. Re-read the previous subsection. Try a small experiment, for example recompiling the driver with one backend disabled and confirming that it still builds. Portability refactors reward slow, deliberate steps. A hurried split that leaves a function in the wrong file is harder to fix than an unhurried one that places it correctly the first time.

29.3 How to Get the Most Out of This Chapter

Chapter 29 is not a reference list. It is a workshop about structure. The most effective way to use it is to keep the driver under your hands while you read, and to ask of every pattern you meet: what problem does this solve, and what would happen if the problem did not exist? That question is the fastest path to internalising the habits.

29.3.1 Refactor in Small Steps

Do not try to go from a single-file driver to a fully portable, multi-backend, cross-BSD-compatible architecture in one sitting. The labs are broken into discrete steps for a reason. Each step makes exactly one change to the code and confirms that the module still loads cleanly after it. That discipline mirrors real-world practice. Professional driver refactors are rarely large, dramatic rewrites; they are a long sequence of small, reviewable moves, each of which can be reverted if something goes wrong.

29.3.2 Read the Compiler Output

The compiler is your collaborator during a portability refactor. A missed include, a stale prototype, a function moved to a file that does not list it in SRCS, these become compiler errors the moment you build, and the messages are precise if you read them carefully. When the build fails, resist the urge to guess; open the file the compiler is pointing at and fix the specific symbol it cannot find. Over a chapter's worth of labs, you will develop a feel for how the build system reacts to different kinds of reorganisation.

29.3.3 Use Version Control as a Safety Net

Commit before each refactoring step. The project's git history gives you a zero-cost way to step back to a known good state. If a split goes wrong, reverting the change is a single command, not an hour of hunting for what you broke. You do not need to push these commits anywhere; they are for you.

29.3.4 Compare Against Real FreeBSD Drivers

When the chapter points to a real file under `/usr/src/sys/`, open it. The `uart(4)` driver in particular is a superb study in backend abstraction: its core logic in `uart_core.c` knows nothing about the bus, and its backend files add PCI, FDT, and ACPI attachment with a small amount of code each. Reading those files alongside this chapter will teach you what "good" looks like far better than any synthetic example could.

29.3.5 Take Notes on Patterns, Not Syntax

The specific macros and function names in this chapter are less important than the patterns behind them. A backend interface defined as a struct of function pointers is a pattern you will use for the rest of your career; the particular spelling of the functions in `portdrv` is a one-time lesson. Write down the patterns in your logbook. Revisit them when you design your own drivers.

29.3.6 Trust the Build System

FreeBSD's `bsd.kmod.mk` is mature, and it does a great deal of work for you. A multi-file driver is not significantly more complicated to build than a single-file driver; you add a line to SRCS and the build keeps working. Lean on that. Do not write your own Makefile machinery when the existing one does the job.

29.3.7 Take Breaks

Refactoring work has a particular cognitive cost. You are holding two versions of the code in your head at once, the one before the move and the one after, and your mind gets fatigued more quickly than during new development. Two or three focused hours are usually more productive than an uninterrupted seven-hour sprint. If you notice yourself copy-pasting without reading, stand up for ten minutes.

With those habits in place, let us begin.

29.4 Section 1: What Does “Portable” Mean for a Device Driver?

Portability is one of those words that everyone uses and few people pin down. When someone says a driver is portable, they might mean any of half a dozen different things. Before we can talk about how to achieve it, we need to be clear about what we are actually trying to achieve. This section takes that step carefully, because every later section depends on sharing the same vocabulary.

29.4.1 A Working Definition

For this book, a driver is portable when changing one of the following does not force a change in the driver’s core logic:

- the CPU architecture it is compiled for
- the bus through which it reaches the hardware
- the specific revision of the hardware behind the bus
- the version of FreeBSD it is running on, within reasonable limits
- the physical deployment, such as real hardware versus a simulator

Notice that this definition is negative. It does not say that a portable driver runs everywhere without modification, because no driver does. It says that when any of these elements change, the change is **local**. The core logic stays where it was. The hardware-specific or platform-specific code absorbs the change. That locality is the practical meaning of portability, and everything in this chapter is about how to arrange the code so that change is local.

A driver that is not portable will usually reveal itself in three ways. First, a small change in the environment produces diffs scattered across the entire file. Second, the author has to read the whole file to know where to make a change, because information about the bus or the architecture is sprinkled throughout the logic. Third, adding support for a new backend requires either duplicating the entire driver or carving `#ifdef` blocks through every function. If you have ever tried to support a second variant of a device this way, you already know how fragile the result becomes.

29.4.2 Portability Across Architectures

FreeBSD runs on a wide variety of CPU architectures, and all of them can load kernel modules. The ones you are most likely to encounter in practice are `amd64` (the 64-bit x86 family), `i386` (legacy 32-bit x86), `arm64` (the 64-bit ARM family), `armv7` (the 32-bit ARM family), `riscv` (both 32-bit and 64-bit RISC-V), and `powerpc` and `powerpc64` for older and server-class PowerPC systems. A driver that is portable across architectures compiles and runs correctly on all of those without the author having to know anything specific about, say, `amd64`’s calling conventions or `arm64`’s alignment rules.

The CPU architectures differ along several axes that a driver author must take seriously. They differ in **endianness**: most of the common ones today are little-endian, but `powerpc` and `powerpc64` can be configured as big-endian and are historically big-endian. They differ in **word size**: 32-bit and 64-bit systems have different natural integer widths, which matters when you store an address in a variable. They differ in **alignment**: `amd64` will forgive an unaligned 32-bit access, but `arm` on some cores will fault. They differ in the physical layout of memory and the behaviour of memory barriers, but those are issues that the kernel’s synchronisation primitives already solve for you if you use them correctly.

A driver written carelessly will not compile at all on some of these architectures, or worse, will compile but misbehave. A driver written with a little care compiles cleanly everywhere and does the same thing everywhere. The difference between those two outcomes is almost always a matter of using the right types, the right endian helpers, and the right accessor functions, rather than a matter of deep kernel knowledge.

29.4.3 Portability Across Buses

The second axis of portability is the bus through which the driver talks to the hardware. The classical FreeBSD driver talks to a PCI device. But the same hardware function can appear behind other buses too: on USB, on a platform-specific memory-mapped region attached via Device Tree (FDT) on embedded systems, on a Low Pin Count or SMBus interface, or on nothing at all when the device is simulated in software. The `/usr/src/sys/dev/uart/` tree is a lovely example: `uart_bus_pci.c`, `uart_bus_fdt.c`, `uart_bus_acpi.c`, and several smaller files each teach the shared UART core how to be reached over a particular bus, and the core itself, in `uart_core.c`, does not care which one was used.

When a driver is portable across buses, adding a new bus is a matter of writing one small file that translates between the bus API and the driver's internal API, then listing that file in the kernel's build system. The core does not need to change. If you have a PCI-based variant of a device today and the same silicon turns up soldered to a board tomorrow, your driver picks up the new attachment in a few hundred lines rather than a few thousand.

29.4.4 Portability Across Systems

The third axis of portability is cross-system: can your driver be shared with other operating systems, especially the other BSDs? This is the form of portability that matters least for most FreeBSD-only projects and the one that consumes the most effort when it does matter, which is why we will treat it lightly in this chapter. The short answer is that NetBSD and OpenBSD share a great deal of history with FreeBSD, and a driver that is carefully written in the FreeBSD dialect can often be translated to those systems with a modest amount of work. A driver written carelessly, with FreeBSD assumptions scattered throughout, usually cannot be translated without a major rewrite.

For our purposes, cross-BSD compatibility means writing your driver so that FreeBSD-specific conventions are introduced in a small number of well-known places and can be wrapped or replaced when needed. You will see that pattern in Section 7.

29.4.5 Portability Across Time

A fourth form of portability is subtler but matters enormously over the life of a project: portability across time. FreeBSD is a living system. APIs evolve, macros are renamed, and older conventions give way to new ones. The `if_t` opaque handle for network interfaces, for example, replaced the raw `struct ifnet *` pointer across FreeBSD 13 and 14; drivers that used the opaque API continued to compile, while drivers that used the raw structure had to be updated. A driver that is careful about which APIs it uses, which headers it includes, and how it detects the kernel version it is compiled against, will survive those evolutions with little more than a version check at the top of a few files.

You will meet the `__FreeBSD_version` macro shortly. Think of it as a version stamp that the kernel itself carries, and that your driver can test against to adapt to the API surface of the specific release it is built on. Used sparingly, it is a quiet, effective tool. Used profligately, it turns the source into a patchwork.

29.4.6 Portability Across Deployments

A final, often forgotten, form of portability is portability between real hardware and a simulator. In Chapter 17 you learned how valuable it is to be able to test a driver without the real device present. A driver whose backend can be switched at build time between “the real device” and “a simulated stand-in” is much easier to develop, review, and test than one that can only run against the true hardware. This form of portability is the cheapest to achieve, because it costs only a small amount of up-front design, and it pays for itself every time a bug is caught on a CI runner that does not have the hardware.

29.4.7 Why Portability Matters

It is tempting to treat portability as a nice-to-have, something you will address “later” when the driver stabilises. In practice, portability is cheapest when it is designed in from the start, and most painful when it is bolted on after the driver has grown to ten thousand lines. There are three concrete reasons portability earns its keep.

First, hardware varies. The device you support today is rarely the only device you will ever support. Silicon vendors produce variants. A sensor that lived on I2C last year may appear over USB this year and over PCIe the year after, with the same programming model underneath. If your core logic is hardware-independent, those variants are cheap to support. If it is not, they are expensive.

Second, platforms evolve. A driver that ships on amd64 this year may need to run on arm64 next year as embedded deployments grow. A driver that assumes little-endian memory will misbehave on a big-endian target, and the bugs will be subtle because most of the time the code looks right. Arranging the driver so that endianness is handled in a small number of obvious places means the move to a new architecture is a one-afternoon exercise, not a one-month forensic investigation.

Third, time passes. A long-lived driver outlives its author. A driver that is structured cleanly can be maintained by a newcomer who has no context. A driver that is a tangle of conditional blocks and hardware assumptions cannot, and tends to be rewritten from scratch by the next maintainer. The accumulated cost of those rewrites, measured over the life of a project, is far higher than the cost of writing the original driver in a portable style.

29.4.8 Code Duplication vs Modular Design

Before we go further, it is worth naming a temptation that every driver author faces: duplication. When a second variant of a device appears, the fastest way to support it is to copy the existing driver and change the parts that are different. This works, in the short term. It is also one of the most expensive decisions a project can make, because every bug found in one copy must be found in the other, every improvement must be duplicated, and every security issue must be patched twice. After the third or fourth variant, the project has become unmaintainable.

The alternative is modular design. The parts that are the same live in one place. The parts that are different live in small, backend-specific files. The core is compiled once. Each backend is compiled separately and linked against the core. When a bug is fixed in the core, all variants benefit. When a new variant appears, only a small

file needs to be added. This is the approach FreeBSD drivers in the mainline tree overwhelmingly adopt, for the same reasons.

Chapter 29 teaches you to recognise where duplication is creeping in and how to pull it apart before it calcifies. That skill pays dividends for the rest of your career in systems programming.

29.4.9 A Tale of Two Drivers

Before closing this section, it helps to compare two hypothetical drivers that a team might write for the same device, one with portability in mind from the start and one without. The story is composite, but every scenario in it has occurred in real FreeBSD projects, usually more than once.

Driver A is written in a hurry to support a single PCI card on amd64. The author writes every register access as a direct call to `bus_read_4(sc->sc_res, offset)`. The PCI probe, the attach function, the ioctl switch, and the register dumping code all live in a single file of about twelve hundred lines. The author knows about endianness in theory but assumes the host is little-endian because the target is amd64. The driver ships, works, and passes its first round of customer testing. The team declares victory.

Six months later, a second customer requests support for a USB variant of the same device. The programming model is identical; the mechanism is different. The author opens Driver A and considers the options. Option one is to add a second attach path and scatter `if (sc->sc_is_usb)` branches through the file; the author quickly sees that this means touching more than a hundred functions, each of which would grow a new branch. Option two is to copy Driver A to Driver A'-USB and change the parts that differ. The author takes option two because it is faster. Now there are two drivers. Every bug fix must be applied twice, once to each copy, and after the third such fix the team notices they have already forgotten one of them. A maintenance tax quietly begins to accumulate.

A year after that, a third customer wants the same silicon supported on an arm64 board. The PCI driver is almost correct on arm64, but the endianness of a specific register was wrong, and the author did not notice because they had never built on a big-endian platform. The USB driver works, but only after the author realises that a structure they had cast a `volatile` pointer to was not aligned on arm64 and was producing bus faults. They add a third copy, Driver A''-USB-ARM, with fixes for the alignment and the endianness. The team now maintains three drivers. The ratio of bugs to fixes has climbed. The total lines of code have tripled, but the shared behaviour has not.

Driver B is written by a different team at the same time, for the same device. The author begins by drawing the line between hardware-dependent and hardware-independent code in the first hour, before writing any logic. They create a backend interface with four operations: `attach`, `detach`, `read_reg`, and `write_reg`. They implement a PCI backend first, and write the core against the interface. They also implement a simulation backend during development, because it is easier to test the core without needing a real card. The driver ships at about eighteen hundred lines, spread across six files.

Six months later, the USB request arrives. The author writes a `portdrv_usb.c` file of about three hundred lines, adds one line to the Makefile, and ships. The core is unchanged. The USB backend is reviewed in isolation, because it does not touch any other file. The bug fixes to the core benefit both backends automatically.

A year after that, the arm64 request arrives. The author builds on arm64, notices one warning from the compiler about a signed comparison with `uint32_t`, fixes the warning, and ships. The endianness is handled because every multi-byte value on a register boundary went through `le32toh` or `htole32` from day one. The alignment

is handled because the author used `bus_read_*` and `memcpy` rather than raw pointers. The arm64 port is a one-day job, not a month.

Two different teams, same device, same time, same customers. At the end of eighteen months, Driver A has three copies, two thousand lines of drift between them, and a steady trickle of bugs that affect one copy and not the others. Driver B has one copy, one backend interface, and a changelog that reads like a straight line. The teams that wrote them are by now worth different amounts to the project.

The moral is simple but easy to forget: **the cheap path at the start of a driver is often the expensive path over its lifetime**. Portability is an investment that pays dividends, but only if you make the investment early. Retrofitting portability into a driver that has already grown to several thousand lines is possible and sometimes necessary, but it takes more time than writing the driver from scratch in the portable style. This is not an argument for over-engineering; it is an argument for making the right small moves in the first week, before the driver has time to calcify.

29.4.10 The Cost of Deferring Portability

The “we’ll add portability later” argument sounds reasonable and is almost always wrong. There are three specific costs that a late refactor pays and an early design does not.

The detection cost. Portability bugs in a driver that was never tested portably are invisible. They lie in wait until the day someone tries to build on a new platform or a new release. By that time, other work depends on the driver, and a fix that touches a core assumption can cascade through the project. An early investment in portable patterns means the bugs are caught in the first week, not the third year.

The reviewer cost. A driver that mixes hardware-dependent code with core logic is harder to review, because every change is potentially a change to the architectural abstraction. Reviewers either slow down or, more commonly, start approving patches without fully understanding them. The project’s quality silently decays. A cleanly split driver gives reviewers a clear signal: a patch in the core deserves scrutiny because it affects every backend; a patch in a backend file is local and can be approved more quickly.

The contributor cost. New contributors are scared by tangled code. A driver that has obvious structure, where new features look like additions to an existing pattern, attracts contributions. A driver that is a wall of nested conditions repels them. Over the life of a project, this is the difference between a healthy community and a lone maintainer struggling to keep up.

None of these costs are visible in the first week. All three appear by the end of the first year. By the third year they dominate the project. That is why portability, discussed in the abstract, sounds optional and, discussed with real projects in mind, is nothing of the sort.

29.4.11 Why FreeBSD Makes This Easier Than Most

A final note, and a slightly optimistic one. Among mainstream kernels, FreeBSD is one of the easier to target for portability, because the project has taken the portable abstractions seriously from the beginning. `bus_space(9)` exists so that driver authors do not have to write architecture-specific register access. `bus_dma(9)` exists so that DMA behaves identically across platforms. Newbus exists so that bus-specific probe logic is separable from core driver logic. The endian helpers in `/usr/src/sys/sys/endian.h` exist so that a single expression works

on little-endian and big-endian hosts. The fixed-width types in `/usr/src/sys/sys/types.h` exist so that “how wide is an int on this platform” never matters.

Contrast this with projects that grew organically across architectures without a plan, and you will find drivers littered with `#ifdef CONFIG_ARM`, with raw pointer casts to device memory, and with ad hoc byte-swap code inlined at every register access. FreeBSD could have ended up that way and did not, because the core maintainers cared about portability from early on. Your drivers can inherit that discipline for free; the cost is learning which abstractions to use and using them consistently.

This is the spirit in which the rest of the chapter is written. The tools are in place. The patterns are clear. The investment is small if you make it early. Let us begin.

29.4.12 Wrapping Up Section 1

You now have a working definition of portability and a set of axes along which it varies: architecture, bus, operating system, time, and deployment. You also have a sense of why portability matters as a practical engineering concern, not a theoretical nicety, illustrated by the contrast between a careless driver and a careful one over a span of eighteen months. The next sections turn from definition to method. In Section 2, we begin the practical work of portability by isolating the parts of a driver that depend on hardware details from the parts that do not. That distinction is the first structural move every portable driver makes, and it is the move that pays the biggest dividends for the smallest cost.

29.5 Section 2: Isolating Hardware-Dependent Code

The first concrete move toward a portable driver is to separate code that depends on specific hardware details from code that does not. This sounds obvious when stated in the abstract, and it is surprisingly easy to get wrong in practice. Hardware-dependent code tends to leak into unexpected places, because the path from a piece of data to the hardware is long, and every step along the way has the potential to encode an assumption that should have stayed elsewhere.

This section introduces the idea in concrete terms, shows you the kinds of code that count as hardware-dependent, and then walks through the two most common mechanisms FreeBSD gives you for putting that code behind an abstraction: the `bus_space(9)` family of macros for register access, and the `bus_dma(9)` family for buffers that the device reads and writes directly. By the end of this section, you will recognise the pattern of hardware isolation when you see it in real drivers and know how to apply it to your own.

29.5.1 What Counts as Hardware-Dependent?

Let us be precise about what we mean. Hardware-dependent code is code whose correctness depends on facts that are specific to a particular piece of silicon or to the bus it sits on. Classic examples include:

- the numeric offset of a register within the device’s memory-mapped region
- the exact bit layout of a status word
- the width of a FIFO in bytes
- the required sequence of register writes to initialise the device
- the endianness in which the device expects to see multi-byte values

- the alignment constraints of DMA buffers for a particular DMA engine

Note that none of these facts are true across every device your driver might ever have to handle. If tomorrow the hardware vendor releases a revision with a different FIFO depth, every line that assumed the old depth must change. If the same silicon appears on USB instead of PCI, every `bus_space_read_*` call must become something else. Those are the seams where portability either holds or breaks.

By contrast, code is hardware-**independent** when it deals with the data once it is out of the device's grip. A function that walks a queue of pending requests, assigns sequence numbers, manages timeouts, or coordinates with the upper half of the kernel (like GEOM, `ifnet`, or `cdevsw`) does not need to know whether the data came in over PCI, USB, or a simulator. As long as the hardware-dependent layer has lifted the data up into a clean, uniform representation, the rest of the driver does not care.

The goal, then, is to draw a line down through the driver. Above the line lives hardware-independent logic. Below the line lives everything that knows about registers, DMA, or bus-specific APIs. The higher the line can be drawn without distorting the code, the more portable the driver becomes.

29.5.2 A Small Thought Experiment

Before we introduce tools, try a thought experiment. Imagine a driver for a made-up “widget” device that performs some simple I/O. The device has two registers: a control register at offset 0x00 and a data register at offset 0x04. Your driver writes a byte to the data register, sets a bit in the control register to start a transfer, polls another bit in the control register until it clears, and then reads a status from the data register.

Now imagine the same widget is produced in two physical forms. One form is a PCI card where both registers are reached through a memory-mapped BAR. Another form is a USB dongle where both registers are reached by USB control transfers. The programming model is identical, but the mechanism for actually reading and writing the registers is completely different.

How do you write the core of the driver, the part that performs transfers and polls for completion, so that it works with both forms?

The answer, which drives the rest of this section, is to stop writing register accesses directly. Instead, write accessors. The core logic calls `widget_read_reg(sc, offset)` and `widget_write_reg(sc, offset, value)`. Those accessors are backend-specific: the PCI backend maps them to `bus_space_read_4` and `bus_space_write_4`, and the USB backend maps them to USB control transfers. The core logic does not know, and does not need to know, which backend is in use.

This is the fundamental move of hardware isolation, and it scales. Once your driver reads and writes registers only through accessors, swapping the backend becomes a local change. Add a third backend for a simulated device? Write a third set of accessors that read and write an in-memory buffer. Nothing else in the driver changes.

29.5.3 A Closer Look at the `uart` Driver

Before we get to the FreeBSD primitives, it helps to trace the shape of a real, mature driver so you can see the ideas in situ. Open `/usr/src/sys/dev/uart/uart_core.c` and scroll slowly. You will see that the file contains the state machine for a UART: the TTY integration, the transmit and receive paths, the interrupt routing, and the lifecycle hooks. You will not find `bus_space_read_4` anywhere in this file (or rather, you will find it

only in helpers that are themselves abstracted behind class-specific methods), and you will not find any mention of PCI, FDT, or ACPI. The core does not know which bus the UART is sitting on. It knows only the programming model of a UART.

Now open `/usr/src/sys/dev/uart/uart_bus_pci.c`. This file is short. It declares a table of vendor and device IDs, implements a PCI probe that matches against the table, implements a PCI attach that allocates a BAR and wires it into the class, and registers the driver with Newbus via `DRIVER_MODULE`. It is the PCI backend for the UART. Compare with `/usr/src/sys/dev/uart/uart_bus_fdt.c`, which does the same job for Device Tree platforms, and `/usr/src/sys/dev/uart/uart_bus_acpi.c` for ACPI platforms.

Finally, open `/usr/src/sys/dev/uart/uart_bus.h`. This is the header that ties the pieces together. It defines `struct uart_class`, which is essentially the UART's backend interface: a set of function pointers plus some configuration fields. Each hardware variant of the UART provides a `struct uart_class` instance. The core calls through the class rather than calling any variant directly.

This is the same pattern we will build in Section 3, only in the specific dialect that FreeBSD uses for UARTs. Reading the UART driver alongside this chapter will cement the ideas much better than reading the chapter alone. Keep `/usr/src/sys/dev/uart/uart_bus.h` open in a second window as you read the rest of Section 2 and the whole of Section 3.

29.5.4 The `bus_space(9)` Abstraction

FreeBSD already gives you a tool that solves this problem for memory-mapped and I/O-port devices: the `bus_space(9)` API. You have encountered it before in Chapter 16, so this is a recap rather than a fresh introduction. The purpose of `bus_space` is to let you write a single register access that works correctly regardless of the CPU architecture, regardless of whether the device is reached through memory-mapped I/O or I/O ports, and regardless of the specific machine's bus topology.

At the programming model level, you hold two opaque values for each device: a `bus_space_tag_t` and a `bus_space_handle_t`. Once you have them, you access the device through calls such as:

```
uint32_t value = bus_space_read_4(sc->sc_tag, sc->sc_handle, REG_CONTROL);
bus_space_write_4(sc->sc_tag, sc->sc_handle, REG_CONTROL, value | CTRL_START);
```

On amd64, the tag and the handle are simple integers. You can confirm this by opening `/usr/src/sys/amd64/include/_bus.h`, where both are defined as `uint64_t`. On arm64, the tag is a pointer to a structure of function pointers and the handle is a `u_long`. You can see this in `/usr/src/sys/arm64/include/_bus.h`. The ARM family needs the indirection because different platforms within ARM can map memory differently, and a function-pointer dispatch handles all of them uniformly.

This architectural difference is essential to portability. If you bypass `bus_space` and use a raw volatile `uint32_t *` pointer to the device's memory, your code will work on amd64 and will fail silently or loudly on some ARM platforms. If you use `bus_space`, the same code works on both. That is the single most important portability gain you can get from this chapter with the smallest effort.

The `bus_space` functions come in a family that varies along three axes. First, the width: `bus_space_read_1`, `bus_space_read_2`, `bus_space_read_4`, and on 64-bit architectures `bus_space_read_8`. Second, the direction: read or write. Third, the multiplicity: the plain variant accesses a single value, the `_multi_` variants

access a buffer of values, and the `_region_` variants access a contiguous region with an implied increment. For most drivers the single-value variants are the workhorses, and you will reach for the others when you have FIFOs or packet buffers to move in bulk.

You can confirm the presence of these functions by opening `/usr/src/sys/sys/bus.h`. The header has a long series of macro definitions for `bus_space_read_1`, `bus_space_write_1`, `bus_space_read_2`, and so on, each defined in terms of the architecture-specific primitives.

29.5.5 Wrapping `bus_space` for Clarity

Even when you are committed to using `bus_space`, you should go one step further and wrap the calls in driver-specific accessors. Why? Because raw `bus_space_read_4(sc->sc_tag, sc->sc_handle, REG_CONTROL)` appears dozens of times in a growing driver, and each appearance is three arguments of visual noise when the only thing that matters is the offset and the value. More importantly, the raw call hardcodes the idea that the device is reached through `bus_space`. If you ever want to add a different backend, every one of those calls must change.

A driver-local wrapper gives you both a cleaner call site and a single place to change. The wrapper looks like this:

```
static inline uint32_t
widget_read_reg(struct widget_softc *sc, bus_size_t off)
{
    return (bus_space_read_4(sc->sc_btag, sc->sc_bhandle, off));
}

static inline void
widget_write_reg(struct widget_softc *sc, bus_size_t off, uint32_t val)
{
    bus_space_write_4(sc->sc_btag, sc->sc_bhandle, off, val);
}
```

Now the rest of the driver calls `widget_read_reg(sc, REG_CONTROL)` and `widget_write_reg(sc, REG_CONTROL, val)`. The call sites read like specifications of intent rather than like plumbing. And when you add a USB backend in the next section, you can change the body of these two functions to dispatch on the backend type without touching any of the hundreds of callers.

This pattern, *wrap the primitive, then call the wrapper*, is the first and most common tool of driver portability. Make it a habit. Whenever you find yourself typing `bus_space_read_*` or `bus_space_write_*` in a file other than the backend-specific one, stop and ask whether a wrapper would serve you better.

29.5.6 Conditional Register Access by Bus

Once wrappers are in place, the next question is what to do when the same driver must support multiple buses. There are two common approaches.

The first approach is **compile-time selection**. The driver is built once per bus, and the wrappers are implemented differently in each build. This is the approach `uart(4)` takes in some contexts. Each bus backend file builds its own set of attach helpers and calls the core's API. The wrappers do not need runtime dispatch because each backend compiles against its own specialisation. This approach produces the smallest, fastest binary, but it requires you to build the driver once per bus backend you want to support.

The second approach is **runtime dispatch**. The driver is built once and includes support for all enabled backends. At attach time, the driver detects which backend is actually in use and stores a function pointer in the `softc`. Each call through the wrapper costs one indirection. This approach is slightly more flexible at the cost of a small runtime overhead.

For most drivers, especially beginner-level ones, the clearest approach is a hybrid: build the core once, build each backend as a separately compiled source file, and use a small backend table per-instance that the core uses to dispatch. The wrappers are inline functions that read the backend table and call through it. You will see exactly this pattern in Section 3 when we introduce the backend interface formally.

29.5.7 The `bus_dma(9)` Abstraction

For devices that perform direct memory access (DMA) to transfer data between system memory and the device, the analogous abstraction is `bus_dma(9)`. DMA is hardware-dependent in ways that register access is not: the physical address that the device sees is not always the same as the kernel virtual address your code holds, alignment requirements vary by device and by bus, and some architectures need explicit cache-flush or cache-invalidate operations between the CPU and the DMA engine to maintain consistency.

Open `/usr/src/sys/sys/bus_dma.h` and look at the core API. Without going into the full depth of `bus_dma`, the shape of the interface is:

```
int bus_dma_tag_create(bus_dma_tag_t parent, bus_size_t alignment,
    bus_addr_t boundary, bus_addr_t lowaddr, bus_addr_t highaddr,
    bus_dma_filter_t *filtfunc, void *filtfuncarg,
    bus_size_t maxsize, int nsegments, bus_size_t maxsegsz,
    int flags, bus_dma_lock_t *lockfunc, void *lockfuncarg,
    bus_dma_tag_t *dmat);

int bus_dmamem_alloc(bus_dma_tag_t dmat, void **vaddr, int flags,
    bus_dmamap_t *mapp);

int bus_dmamap_load(bus_dma_tag_t dmat, bus_dmamap_t map, void *buf,
    bus_size_t buflen, bus_dmamap_callback_t *callback,
    void *callback_arg, int flags);

void bus_dmamap_sync(bus_dma_tag_t dmat, bus_dmamap_t dmamap,
    bus_dmasync_op_t op);

void bus_dmamap_unload(bus_dma_tag_t dmat, bus_dmamap_t dmamap);
void bus_dmamem_free(bus_dma_tag_t dmat, void *vaddr, bus_dmamap_t map);
```

The full mechanics of `bus_dma` are covered in depth in later chapters. For the purpose of this chapter you need only the portability consequence: **use `bus_dma` for all device-visible buffers**, and hide the use behind driver-local helpers just as you did for register access. The reason is identical. A direct `bus_dmamap_load` call encodes the assumption that you are using `bus_dma` and makes it hard to substitute an in-memory buffer for simulated testing, or a different DMA framework for an unusual platform. A wrapper function such as `widget_dma_load(sc, buf, len)` hides the assumption.

The callback-based nature of `bus_dmamap_load` is itself a portability feature worth pausing on. The callback is invoked with the list of physical segments the buffer was mapped into. On a system with a simple 1:1 virtual-to-physical mapping, that list will have one entry. On a system that needs bounce buffers to reach limited address ranges, the list might have several entries. Your driver writes one callback, and that callback handles both cases uniformly. That is `bus_dma`'s portability contribution: the callback sees a simple model, and the complexity lives under `bus_dma` itself.

29.5.8 A Practical Header-Per-Backend Pattern

Putting these ideas together, a portable driver often uses a small family of header files and source files to make the separation visible in the filesystem layout. The core includes `widget_common.h` for types and prototypes that are not tied to any bus. The core source, typically `widget_core.c`, contains the hardware-independent logic. Each bus backend lives in its own `.c` file, such as `widget_pci.c` or `widget_usb.c`, and includes `widget_backend.h` for the definitions of the backend interface. The Makefile lists the core and whichever backends are enabled in `SRCS`, and the kernel build does the rest.

You will see this layout applied step by step in Section 4 with the `portdrv` reference driver. Before we get there, we need to formalise what a “backend interface” looks like. That is the subject of the next section.

29.5.9 Common Mistakes When Isolating Hardware Code

A handful of mistakes recur often enough to be worth calling out. Each one is small in isolation but damaging in aggregate.

The first mistake is **hidden access**. A helper function somewhere deep in the driver reaches into the softc and performs a register access directly instead of going through the accessor. The result is a single leak, but the leak can be enough to defeat the abstraction. When you read a driver, look for calls to `bus_space_*` outside the designated backend files; they are warning signs.

The second mistake is **offset leakage**. The driver writes `bus_space_read_4(tag, handle, 0x20)` with a literal offset. Literal offsets are fine as constants named `REG_CONTROL` in a header, but they are dangerous as bare integers. A bare offset tells you nothing about what the register does, and renumbering the register on a future hardware revision becomes a search-and-replace exercise. Always define register names as macros or enumerations in the header, and use the names in the code.

The third mistake is **type confusion**. A register returns a 32-bit value, but the code stores the result in an `int` or an `unsigned long`. On a 64-bit system this often works by accident, because the value fits. On a 32-bit system with a signed `int`, a register whose top bit is set becomes negative, and comparisons break. Always match the type to the register width, using `uint8_t`, `uint16_t`, `uint32_t`, or `uint64_t` as appropriate.

The fourth mistake is **endianness assumptions at the accessor layer**. The `bus_space` functions return the value as the host sees it, in host byte order. If the device uses a specific byte order in its registers, the conversion

happens elsewhere in the code, using `htole32` or `be32toh` as needed. Do not bake the conversion into the accessor, because other parts of the driver may be accessing the same register for administrative purposes and do not want the conversion applied.

The fifth mistake is **no accessor at all**. The driver uses raw volatile `uint32_t *` pointers to map registers. This works on some architectures and fails on others. It defeats the entire point of `bus_space`. If you are reading a driver that does this, assume it is broken on at least one architecture even if you cannot immediately say which one.

29.5.10 Subregions, Barriers, and Burst Operations

Three `bus_space` features are worth a short tour, because they come up often enough in real drivers that you will meet them even in small code bases.

The **subregion** feature lets you split a mapped region into logical parts and hand each part to a different piece of code. If your device's BAR is 64 KB and the driver conceptually has three separate register banks at offsets 0, 0x4000, and 0x8000, you can create three subregions with `bus_space_subregion` and give each to the function that cares about it. Each subregion has its own tag and handle, and accesses to it naturally carry offsets from the start of the subregion, not from the start of the whole BAR. The result is code that reads `bus_space_read_4(bank_tag, bank_handle, REG_CONTROL)` rather than `bus_space_read_4(whole_tag, whole_handle, BANK_B_BASE + REG_CONTROL)`. The offsets become local to the bank and do not carry the whole BAR's address arithmetic in every call site.

The **barrier** feature is about ordering. When you write to a device register, the kernel has two separate guarantees to provide. First, that the write actually reaches the device, rather than sitting in a CPU write buffer or a bus bridge. Second, that writes happen in the order the programmer expected. On most common amd64 configurations, these guarantees come for free; on arm64 and some other platforms, they do not. The primitive is `bus_space_barrier(tag, handle, offset, length, flags)`, where `flags` is a combination of `BUS_SPACE_BARRIER_READ` and `BUS_SPACE_BARRIER_WRITE`. The call says: "all reads or writes in the specified range before this point must complete before any after it." You use it when your driver depends on the order in which the device sees register accesses, for example when arming an interrupt after setting up a DMA descriptor.

The **burst** feature handles fast moves to or from device memory. When you need to copy a packet into a FIFO or out of a DMA buffer, calling `bus_space_write_4` in a loop is correct but slow. The `bus_space_write_multi_4` and `bus_space_read_multi_4` functions do the whole burst in one call, and on architectures that have specialised move instructions they use them. For a network driver transferring frames at high rates, burst helpers can be the difference between wire speed and half wire speed, and the cost of using them is only a slightly different call signature.

None of these features is mandatory for a small driver. All of them are worth knowing about, because their absence in a growing driver leads to workarounds that are harder to read and slower to run than the primitive they were avoiding.

29.5.11 Layered Wrapping: From Primitive to Domain

The accessors shown earlier in this section are the first layer of wrapping around `bus_space`. Real drivers sometimes benefit from a second layer that lifts the accessors into a domain-specific vocabulary. The idea is

simple: once you have `portdrv_read_reg(sc, off)`, you can build on top of it with functions like `portdrv_read_status(sc)`, `portdrv_arm_interrupt(sc)`, or `portdrv_load_descriptor(sc, idx, addr, len)`. The core of the driver then speaks in the device’s vocabulary rather than in raw register accesses.

```
static inline uint32_t
portdrv_read_status(struct portdrv_softc *sc)
{
    return (portdrv_read_reg(sc, REG_STATUS));
}

static inline bool
portdrv_is_ready(struct portdrv_softc *sc)
{
    return ((portdrv_read_status(sc) & STATUS_READY) != 0);
}

static inline void
portdrv_arm_interrupt(struct portdrv_softc *sc, uint32_t mask)
{
    portdrv_write_reg(sc, REG_INTR_MASK, mask);
}
```

Code that calls `portdrv_is_ready(sc)` instead of `(portdrv_read_reg(sc, REG_STATUS) & STATUS_READY) != 0` reads like intent rather than plumbing. When the definition of “ready” changes on a newer revision of the device, the change happens in one inline function rather than at every call site. This is the same pattern as the primitive accessors, only applied to the next layer up.

Do not overdo it. A wrapper per trivial register read is wrappering for its own sake. Add a domain-level wrapper when its name is meaningfully more informative than the register access, or when the operation is non-trivial enough that the reader benefits from a name. For a single register read, the primitive wrapper is usually enough.

29.5.12 Accessor Layering Inside the FreeBSD Tree

You can see this layered approach used in mature FreeBSD drivers. Look at `/usr/src/sys/dev/e1000/` for the Intel Gigabit Ethernet driver. The file `e1000_api.c` exposes dispatch functions like `e1000_reset_hw`, `e1000_init_hw`, and `e1000_check_for_link`, each of which forwards to a chip-family helper (for example, the 82571 helpers live in `e1000_82571.c`, the 82575 helpers live in `e1000_82575.c`, and so on). Those chip-specific helpers do their register work through `E1000_READ_REG` and `E1000_WRITE_REG`, which are defined in `/usr/src/sys/dev/e1000/e1000_osdep.h` as macros that expand to `bus_space_read_4` and `bus_space_write_4` on the tag and handle carried inside the driver’s struct `e1000_osdep`. Four layers: bus primitive, register accessor macro, chip-family helper, and driver-facing API in `if_em.c`. Each layer adds a little more meaning, and each layer can be changed without disturbing the others.

For your own drivers, two layers is usually the right target: a primitive accessor that wraps `bus_read_*` or dispatches through the backend, and a set of domain helpers that lift the primitive into the vocabulary of the

device. Three layers, if the driver is large and spans multiple subsystems. More than three, and the layering is probably obscuring rather than clarifying.

29.5.13 When the Line Between HW-Dependent and HW-Independent Blurs

The line between hardware-dependent and hardware-independent code is usually clear, but there are edge cases worth naming.

One edge case is **timing logic**. Suppose the driver must wait up to 50 microseconds for a status bit to appear after writing a register. The wait itself is hardware-dependent, because the 50-microsecond figure comes from the device's datasheet. But the scaffolding, the loop that polls, the timeout that gives up, and the error return, is hardware-independent. The right design is to have a small helper in the core that takes the poll predicate as a function pointer or inline expression, and a hardware-specific constant for the timeout. The core owns the polling loop; the backend owns the constant.

```
/* Core. */
static int
portdrv_wait_for(struct portdrv_softc *sc,
    bool (*predicate)(struct portdrv_softc *sc),
    int timeout_us)
{
    int i;

    for (i = 0; i < timeout_us; i += 10) {
        if (predicate(sc))
            return (0);
        DELAY(10);
    }
    return (ETIMEDOUT);
}
```

The backend provides the predicate (which may be trivial, such as reading a status register) and the timeout. This keeps the loop structure in one place and lets the individual device details live where they belong.

Another edge case is **state machines**. The state machine of a typical request processing loop is hardware-independent: idle, pending, in-flight, complete. The transitions, however, may depend on hardware events. A common pattern is to keep the state machine in the core and invoke backend methods for the operations that might differ between backends. The core says “start the transfer”; the backend does whatever that means. The state transitions happen in the core based on the backend's return values.

A third edge case is **logging and telemetry**. You want one `device_printf` in the core when a transfer fails, not one per backend. But the `printf` may want to include backend-specific information such as the register that caused the error. The solution is to expose a backend method like `describe_error(sc, buf, buflen)` that fills a buffer with a human-readable summary, and have the core call it. The core owns the log line; the backend owns the vocabulary.

The common theme in all these edge cases is the same: **put structure in the core, and put details in the backend**. When you are unsure where a piece of code belongs, ask which category it is, structure or detail. Structure is about what happens. Details are about exactly how the hardware is touched to make it happen.

29.5.14 Wrapping Up Section 2

You have now seen the first structural move every portable driver makes: draw a clean line between hardware-dependent and hardware-independent code, and express the line in actual files and accessor functions rather than in comments. The `bus_space(9)` and `bus_dma(9)` abstractions are FreeBSD's gifts to that effort, because they already hide most architecture-specific complexity. Wrapping them in driver-local accessors gives you the final piece: a single place to change when the backend changes. Layered wrapping, disciplined use of subregions and barriers, and careful placement of edge-case code between core and backend make the line between them stable rather than fragile.

The next section takes the step beyond accessors. If the driver has to support multiple backends in the same binary, what does the interface between the core and the backends look like? That is where the idea of a **backend interface**, expressed as a struct of function pointers, becomes essential.

29.6 Section 3: Abstracting Device Behavior

In Section 2 we drew a line between hardware-dependent and hardware-independent code, and wrapped the primitive bus operations behind driver-local accessors. That move handles the simple case, where the driver talks to one kind of device over one kind of bus. In this section we handle the harder and more interesting case: a driver that supports multiple backends in the same build.

The technique that makes this manageable is straightforward to describe and profoundly useful in practice. The driver's core defines an **interface**: a struct of function pointers that describes what operations a backend must provide. Each backend provides an instance of that struct, filled in with its own implementations. The core calls through the struct rather than calling any backend directly. Adding a new backend is a matter of writing one more struct instance and one more set of functions; the core is untouched.

This pattern is everywhere in FreeBSD. The Newbus framework itself is built on a more elaborate version of it, called `kobj`, and you have been using `kobj` indirectly every time you filled in a `device_method_t` array in earlier chapters. In this chapter we introduce a lighter version that you can apply to your own drivers without the full ceremony of `kobj`.

29.6.1 Why a Formal Interface Beats If-Else Chains

The first instinct of a programmer who needs to support two backends is often to branch on a backend type at each call site. Something like this:

```
static void
widget_start_transfer(struct widget_softc *sc)
{
    if (sc->sc_backend == BACKEND_PCI) {
```

```

        bus_space_write_4(sc->sc_btag, sc->sc_bhandle,
            REG_CONTROL, CTRL_START);
    } else if (sc->sc_backend == BACKEND_USB) {
        widget_usb_ctrl_write(sc, REG_CONTROL, CTRL_START);
    } else if (sc->sc_backend == BACKEND_SIM) {
        sc->sc_sim_state.control |= CTRL_START;
    }
}

```

This works for one function. It becomes unbearable by the tenth. Every function acquires a switch statement. Every new backend adds another branch to every switch. The number of edits grows as the product of functions and backends. After the third backend the driver is barely readable, and any change to the shape of a backend operation requires visits to a dozen files.

The structural fix is to replace the chain with a single indirection. Define a struct of function pointers:

```

struct widget_backend {
    const char *name;
    int (*attach)(struct widget_softc *sc);
    void (*detach)(struct widget_softc *sc);
    uint32_t (*read_reg)(struct widget_softc *sc, bus_size_t off);
    void (*write_reg)(struct widget_softc *sc, bus_size_t off, uint32_t val);
    int (*start_transfer)(struct widget_softc *sc,
        const void *buf, size_t len);
    int (*poll_done)(struct widget_softc *sc);
};

```

Each backend provides an instance of this struct. The PCI backend defines `widget_pci_read_reg`, `widget_pci_write_reg`, and the rest, and then fills in a struct `widget_backend` with those function pointers:

```

const struct widget_backend widget_pci_backend = {
    .name          = "pci",
    .attach        = widget_pci_attach,
    .detach        = widget_pci_detach,
    .read_reg      = widget_pci_read_reg,
    .write_reg     = widget_pci_write_reg,
    .start_transfer = widget_pci_start_transfer,
    .poll_done     = widget_pci_poll_done,
};

```

The USB backend does the same, the simulation backend does the same, and so on. The `softc` carries a pointer to whichever backend this instance is using:

```

struct widget_softc {
    device_t    sc_dev;
    const struct widget_backend *sc_be;
    /* ... bus-specific fields, kept opaque to the core ... */
    void        *sc_backend_priv;
};

```

And the core calls through the pointer:

```

static void
widget_start_transfer(struct widget_softc *sc, const void *buf, size_t len)
{
    (void)sc->sc_be->start_transfer(sc, buf, len);
}

```

The core does not branch. The core does not mention pci, usb, or sim. The core calls an operation, and the operation is looked up through a pointer. This is the fundamental move. Read it a few times and let it settle; the rest of the section is elaboration and concrete detail.

29.6.2 Setting Up the Backend at Attach Time

Each attach path installs the right backend into the_softc. The PCI attach code looks roughly like this:

```

static int
widget_pci_attach(device_t dev)
{
    struct widget_softc *sc = device_get_softc(dev);
    int err;

    sc->sc_dev = dev;
    sc->sc_be = &widget_pci_backend;

    /* Allocate bus resources, store them in sc->sc_backend_priv. */
    err = widget_pci_alloc_resources(sc);
    if (err != 0)
        return (err);

    /* Hand off to the core, which will use the backend through sc->sc_be. */
    return (widget_core_attach(sc));
}

```

The USB attach is structurally identical: allocate its bus resources, install widget_usb_backend, and call widget_core_attach. The simulation attach is identical too: install widget_sim_backend, which does not allocate anything real, and call widget_core_attach.

The lesson is that **the per-backend attach path is small, and its job is to prepare the softc for the core**. Once the softc has a valid backend and valid backend-private state, the core takes over and does the universal work of wiring the driver into the rest of the kernel.

29.6.3 How the Real UART Driver Does This

Open `/usr/src/sys/dev/uart/uart_bus.h` and jump to the struct `uart_class` definition. You will see the pattern we have just described, with a FreeBSD-specific twist. The twist is that the UART driver uses the `kobj(9)` framework, which adds a layer of compile-time dispatch on top of function pointers, but the essence is the same. A struct `uart_class` carries a `uc_ops` pointer to an operations struct, along with some configuration fields, and each hardware-specific variant of the driver provides its own `uart_class` instance.

Now open `/usr/src/sys/dev/uart/uart_bus_pci.c`. The `device_method_t uart_pci_methods[]` array at the top of the file declares which functions implement the PCI-specific device methods. Compare with `/usr/src/sys/dev/uart/uart_bus_fdt.c`, which does the same job for Device Tree-based platforms. Both files are short because they do very little: they install the right class, allocate resources, and hand off to the core in `uart_core.c`.

This is exactly the pattern you are learning in this section, only dressed in the formal `kobj` idiom that FreeBSD uses for bus drivers. When you write your own lighter-weight abstraction for a smaller driver, you can use a plain struct of function pointers, and the result is easier to read and reason about than a full `kobj`. For a driver with a handful of backends and a simple method set, the plain struct is the right choice.

29.6.4 Choosing the Set of Operations

Designing a backend interface is a matter of taste and judgement. There is no mechanical formula, but a few principles help.

First, **every operation that varies by backend belongs in the interface; every operation that does not varies does not**. If the same code is correct regardless of whether the backend is PCI or USB, put that code in the core. Do not put it in the interface, because each backend would then have to implement it, and the implementations would be identical, which defeats the point.

Second, **keep the interface narrow**. The fewer operations, the less work to implement a new backend and the less surface area to maintain. If two operations always appear together at call sites, consider merging them into one operation that does both.

Third, **prefer coarse operations over fine ones**. An operation like `start_transfer(sc, buf, len)` is coarse: it captures the intent of a transfer in one call. An equivalent pair like `write_reg(sc, DATA, ...)` followed by `write_reg(sc, CONTROL, CTRL_START)` is fine-grained, and it forces the core to know the register layout. Coarse operations let the backends implement the sequence however they need to, including in ways the core cannot know. This is also the key to backend simulation: a simulator can “perform” a transfer without actually writing any registers.

Fourth, **leave room for private state**. Each backend may need its own per-instance data that the core does not care about. A `void *sc_backend_priv` in the softc, owned by the backend, is the usual pattern. The PCI backend stores its bus resources there. The USB backend stores its USB device handles. The simulation

backend stores its in-memory register map. The core never reads or writes this field; it simply passes the softc through.

Fifth, **define a versioned struct if you want to evolve the interface over time**. When the interface is small and the number of backends is also small, you can add a field and update all backends in one commit. When the backends are external to your tree or maintained separately, you may want a version field in the struct, so a backend can refuse to attach if the core expects a newer shape. This is the same trick FreeBSD itself uses in some of its KPIs.

29.6.5 Avoiding If-Else Creep

Once the interface is in place, keep watch for a subtle form of regression: the reintroduction of backend-specific branches. This can happen innocently. A new feature is added that only makes sense on one backend, and rather than extend the interface, the developer writes `if (sc->sc_be == &widget_pci_backend) { ... }` somewhere in the core. This works, once. Repeat it three or four times and the driver is no longer cleanly abstracted; the backend is leaking back into the core through tag comparisons.

The right fix for a feature that only one backend supports is to add an operation to the interface that the other backends implement trivially. If only the PCI backend supports, say, interrupt coalescing, add `set_coalesce(sc, usec)` to the interface and implement it as a no-op in the USB and simulation backends. The core calls it unconditionally. This keeps the core ignorant of backend identity while still allowing per-backend specialisation.

29.6.6 Backend Discovery and Registration

A last practical question: how does a backend get attached in the first place? The answer varies by bus. On PCI, the kernel's Newbus machinery walks the PCI tree and calls each candidate driver's probe function. You write `widget_pci_probe` and register it with `DRIVER_MODULE(widget_pci, ...)`; the kernel does the rest. On USB, the `usbd` framework performs an analogous walk over USB devices and calls each candidate driver's probe. On a purely virtual or simulated backend, there is no bus to walk, and the backend is usually attached through a module init hook that creates a single instance.

The important portability point is this: **each bus's registration machinery is part of the backend, not the core**. The core never calls `DRIVER_MODULE` or `USB_PNP_HOST_INFO` or any bus-specific registration macro. The core exports a clean entry point (`widget_core_attach`) that each backend calls when its own attach logic is ready. Everything bus-specific happens in the backend file. This is what keeps the core clean enough to move unchanged to a new bus.

29.6.7 Common Mistakes When Designing an Interface

A few pitfalls recur often enough to call out.

Over-abstracting. Not every operation belongs in the interface. An operation that only one backend ever needs should live in that backend's private code, not be forced into the struct. An interface full of stub `return 0;` implementations has grown too wide.

Under-abstracting. Conversely, an interface that forces each backend to replicate the same five lines of setup logic has grown too narrow. If three backends all begin their `start_transfer` with the same two lines, move those two lines into the core and have the interface operation receive already-validated input.

Exposing backend types. If the core has a switch on backend identity, the abstraction is broken. The core should know which operations to call, not which backend is providing them.

Mixing synchronisation policies. Each backend must honour the core's locking policy. If the core calls `start_transfer` with the softc lock held, every backend must respect that and not sleep. If the core calls `attach` without a lock, the backend must not assume one is held. An interface is not just a set of signatures; it is also a contract about the surrounding context.

Ignoring lifetime. If the core calls `backend->attach` and gets back a non-zero error code, it must not call `backend->detach` afterwards, because nothing was attached. Document the contract, and write the backends to honour it. Confusion here leads to double frees and use-after-free bugs.

29.6.8 A Closer Look at `kobj(9)`

Because Newbus itself uses `kobj(9)`, it is worth taking a moment to look at what the kernel does for you when you write `device_method_t`. The mechanism may look intimidating, but the underlying idea is the same function-pointer dispatch we have been discussing, only formalised.

Open `/usr/src/sys/kern/subr_kobj.c` and look at how classes are registered. A `kobj_class` holds a name, a list of method pointers, an ops table that the kernel builds at module load time, and a size for instance data. When you write:

```
static device_method_t portdrv_pci_methods[] = {
    DEVMETHOD(device_probe,   portdrv_pci_probe),
    DEVMETHOD(device_attach,  portdrv_pci_attach),
    DEVMETHOD(device_detach,  portdrv_pci_detach),
    DEVMETHOD_END
};
```

you are building one of these method lists. The kernel compiles the list into a dispatch table at runtime, and every call such as `DEVICE_PROBE(dev)` becomes a lookup into the table followed by a call through a function pointer. From the programmer's perspective, the call site is a single macro; from the machine's perspective, it is one indirection.

For a small backend abstraction, the plain struct-of-function-pointers pattern we showed earlier is enough and is easier to read. When the interface grows beyond about eight methods and begins to accumulate default implementations, `kobj` starts to earn its keep. The ability to have a subclass inherit methods from a base class, to default a method to a no-op when a class does not provide it, and to be statically checked via the `method-ID` header is worth the additional machinery. For most drivers in this book, you will not need `kobj` directly, but recognising that it is doing the same thing your plain struct does makes the Newbus machinery feel less magical.

29.6.9 Stacked Backends and Delegation

A related, more advanced pattern is the **stacked** or **delegating** backend. Sometimes a backend is naturally a thin wrapper over another backend, with some small transformation applied. Imagine a backend that forces all

register writes to be logged for debugging, or one that adds a delay before every read to simulate a slow bus, or one that records register traffic into a ring buffer for later replay. Each of these is functionally a wrapper around a real backend.

The pattern is straightforward. The wrapping backend's struct includes a pointer to an inner backend:

```
struct portdrv_debug_priv {
    const struct portdrv_backend *inner;
    void *inner_priv;
    /* logging state, statistics, etc. */
};

static uint32_t
portdrv_debug_read_reg(struct portdrv_softc *sc, bus_size_t off)
{
    struct portdrv_debug_priv *dp = sc->sc_backend_priv;
    void *saved_priv = sc->sc_backend_priv;
    uint32_t val;

    sc->sc_backend_priv = dp->inner_priv;
    val = dp->inner->read_reg(sc, off);
    sc->sc_backend_priv = saved_priv;

    device_printf(sc->sc_dev, "read 0x%04jx -> 0x%08x\n",
        (uintmax_t)off, val);
    return (val);
}
```

The debug backend borrows the real backend's implementation for the actual register read, and adds logging around it. The core does not know it is talking to a wrapper. At attach time, the driver can install either the plain PCI backend or the debug backend that wraps it. This is a useful pattern for development, for recording a trace of a boot failure, or for building a simulator that replays a recorded trace.

Not every driver needs stacked backends. When you do need them, the pattern above is the template. The interface stays the same; a backend instance simply has the flexibility to delegate to another instance rather than doing the work itself.

29.6.10 Making the Interface Contract Explicit

A good backend interface is not just a struct; it is a contract about what each method does, what preconditions it has, and what side effects it produces. The contract lives in a comment at the top of the header:

```
/*
 * portdrv_backend.h - backend interface contract.
 */
```

```

* The core acquires sc->sc_mtx (a MTX_DEF) before calling any method
* except attach and detach. Methods must not sleep while holding this
* lock. The core releases the lock before calling attach and detach,
* because those methods may allocate memory with M_WAITOK or perform
* other sleepable operations.
*
* read_reg and write_reg must be side-effect-free from the core's
* point of view, other than the corresponding register access.
* start_transfer may record pending work but must not block; it
* returns 0 on success or an errno on failure. poll_done returns
* non-zero when the transfer has completed and zero otherwise.
*
* Backends may return EOPNOTSUPP for an operation they do not
* support. The core treats EOPNOTSUPP as "feature not present",
* and its callers degrade gracefully.
*/

```

This kind of comment is not decoration. It is the body of knowledge that a new contributor needs to implement a new backend correctly. Without it, the author of the third backend must reverse-engineer the contract from the existing two, and usually gets it slightly wrong. With it, the third backend is a straightforward exercise.

Include in the contract at least: the locking rules (which locks the core holds at each method call), the sleep rules (which methods may sleep), the return-value conventions, and any side effects the core depends on. If the contract allows methods to be NULL, state it. If some methods are required and some are optional, state that too.

29.6.11 Minimal vs. Rich Interfaces

A recurring design question is how rich the interface should be. Should the backend expose a single `do_transfer` method that covers every transfer type, or a family of specialised methods for read, write, command, and status? Should the core do high-level request queuing and ask the backend to perform each step, or should the backend own the queue and report completions upward?

There is no universal answer, but two principles help.

If the operation differs only in the vocabulary, unify it. `read_reg` and `write_reg` differ only in whether the access is outbound or inbound. They are naturally two methods, but one could reasonably be a single `access_reg(sc, off, direction, valp)`. In practice, having two methods is clearer than a direction flag, because the call sites read better. Split when the split is obvious.

If the operations differ in content, keep them separate. A device might support both “command” transfers and “data” transfers that look completely different at the register level. Fold them into one method and you force the backend to dispatch on a flag inside. Keep them as two methods and the backend’s job becomes obvious. Split when the split is substantive.

A useful test: write the documentation for the method you are considering. If the documentation needs to describe two behaviours distinguished by a parameter, split. If it describes one behaviour with parameters that

vary the value, keep.

29.6.12 The “Soft” Contract of a Backend

Beyond the explicit contract, there is a soft contract about resource management. Each backend should be consistent in who allocates what, when each piece of state is valid, and who frees it at shutdown. The usual convention is:

- The backend’s per-attach code allocates its private state in `sc_backend_priv` and any bus resources it needs. It returns before the core begins using the interface.
- The core allocates its own state (locks, queues, character devices) after the backend is installed, in `port_drv_core_attach`.
- On detach, the core tears down its own state first, then calls the backend’s `detach` method, which releases the backend’s resources and frees `sc_backend_priv`.

This ordering matters. If the core tears down its character device before the backend stops DMA, an in-flight transfer might fire a callback into a destroyed object. If the backend frees `sc_backend_priv` before the core finishes a write, the core’s access panics with a use-after-free. Document the teardown order in the backend contract, and honour it in every backend.

Double-checking the soft contract is an excellent activity to perform when you write a new backend. Walk through the attach and detach paths mentally, keeping track of which object is alive and which is being torn down. Most bugs in a well-written backend are life-cycle bugs, and they are easiest to catch before the code runs than after.

29.6.13 Wrapping Up Section 3

The backend interface is the conceptual spine of a portable driver. Accessors handle small-scale variation like register width and architecture, but the backend interface handles large-scale variation like the entire bus. Once you have an interface, adding a backend is a one-file change, and the core is inoculated against bus-specific concerns. The first time you experience this, you will understand why the pattern is so universal in kernel code. Understanding `kobj(9)` as a more elaborate form of the same idea, and recognising when stacked backends or a careful contract are worth the effort, are the next steps toward writing drivers that scale beyond a single variant.

In Section 4 we turn the backend interface into a concrete file layout: which functions live in which file, which header each file includes, and how the build system pulls everything together. The ideas are the same; the payoff is a working multi-file driver you can build and load.

29.7 Section 4: Splitting Code Into Logical Modules

A portable driver is not usually one file. It is a small family of files, each with a clear responsibility, and a build system that knows how to assemble them. This section takes the backend interface from Section 3 and expresses it as a concrete directory layout that you can type, build, and load. The file layout is not sacred, but it is a well-established convention in FreeBSD, and following it will make your driver look familiar to anyone else who reads it.

The goal is a layout in which each file answers exactly one question. A reader picking up the driver for the first time should be able to guess which file to open based on what they are looking for, without having to `grep`. That is what “logical modules” means in this chapter: not module in the `.ko` sense, but module in the structural sense, a unit of code with one purpose.

29.7.1 The Canonical Layout

Start with the reference driver `portdrv`. After refactoring, it looks like this on disk:

```
portdrv/
├─ Makefile
├─ portdrv.h           # cross-file public prototypes and types
├─ portdrv_common.h   # types shared between core and backends
├─ portdrv_backend.h  # the backend interface struct
├─ portdrv_core.c     # hardware-independent logic
├─ portdrv_pci.c      # PCI backend
├─ portdrv_usb.c      # USB backend (optional, conditional)
├─ portdrv_sim.c      # simulation backend (optional, conditional)
├─ portdrv_sysctl.c   # sysctl tree, helpers
├─ portdrv_ioctl.c    # ioctl handlers, if the driver exposes them
└─ portdrv_dma.c      # DMA helpers, if the driver uses DMA
```

That is the target. Not every driver needs every file. A small driver that does not do DMA has no `portdrv_dma.c`. A driver that has only one backend has no separate backend files and may keep the hardware-specific code in a single `portdrv_pci.c` alongside the core. The layout scales up as the driver grows, and the key idea is that **new responsibilities get new files rather than new sections in an existing file**.

29.7.2 Responsibilities Per File

Let us walk through the intended job of each file, so that the layout feels less abstract.

- **`portdrv.h`**: the public header for the driver. This is what `portdrv_sysctl.c` and other internal files include to see the `softc` and the core entry points. It pulls in common types, forward declares the `softc`, and exposes the functions each file needs to call across file boundaries.
- **`portdrv_common.h`**: the subset of types that the backends also need. Splitting this out from `portdrv.h` is useful because the backend files should not need to see every internal detail of the core. If the `softc` has, say, a field that is only relevant to `ioctl` handling, that field’s type can stay in `portdrv.h`, while the pointer to the backend interface is exposed in `portdrv_common.h`. In smaller drivers you can merge the two headers if the split feels forced.
- **`portdrv_backend.h`**: the single authoritative definition of the backend interface: the struct of function pointers, the constants for backend identification, and the declarations of any helpers shared among backends. Every backend file includes it. The core also includes it. This is the file you open when you want to know what the core expects from a backend.

- **portdrv_core.c**: the hardware-independent logic. Attach and detach for the driver as a whole, the request queue, the softc allocation, the character device or interface registration, the callback invocation path. The core does not include any bus-specific header like `dev/pci/pcivar.h` or `dev/usb/usb.h`. If you find yourself including such a header in `portdrv_core.c`, something has gone wrong.
- **portdrv_pci.c**: everything that knows about PCI. The `device_method_t` array for PCI, the PCI probe, the PCI-specific allocator, the PCI interrupt handler if the driver uses one, and the `DRIVER_MODULE` registration. The PCI backend's implementation of each function in the backend interface lives here. This file includes `dev/pci/pcivar.h` and the other PCI headers; the core does not.
- **portdrv_usb.c**: the USB backend, with its own attach, its own registration through the USB framework, and its own implementation of the backend interface. Parallel in structure to the PCI backend, but reaching the hardware over a completely different API.
- **portdrv_sim.c**: the simulation backend. A pure software implementation that honours the same interface but stores register state in memory and synthesises completions. Useful for testing and CI; essential for development when the real hardware is not available.
- **portdrv_sysctl.c**: the driver's sysctl tree and the helper functions that read and set its variables. Keeping sysctl out of the core has two benefits. First, the core file stays focused on I/O. Second, the sysctl tree becomes easy to extend without adding noise to the core.
- **portdrv_ioctl.c**: the switch statement that dispatches ioctl commands, one helper per command. Large drivers accumulate many ioctls, and moving them to their own file keeps the main flow of the core readable. A small driver with two ioctls can keep them in the core.
- **portdrv_dma.c**: helpers for DMA setup and teardown. The functions `portdrv_dma_create_tag`, `portdrv_dma_alloc_buffer`, `portdrv_dma_free_buffer`, and so on, each of which wraps a `bus_dma` primitive. These helpers are used by the backends but do not depend on any specific bus. Isolating them into their own file makes it obvious what the DMA surface of the driver is.

29.7.3 A Minimal Core File

The core file is where most of your non-trivial logic will live. Here is a sketch of what `portdrv_core.c` looks like, showing just the structural elements. Type it in, build it, and load it; the details are filled out in the lab at the end of the chapter.

```
/*
 * portdrv_core.c - hardware-independent core for the portdrv driver.
 *
 * This file knows about the backend interface and the softc, but
 * does not include any bus-specific header. Backends are installed
 * by per-bus attach paths in portdrv_pci.c, portdrv_usb.c, etc.
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
```

```
#include <sys/module.h>
#include <sys/conf.h>
#include <sys/malloc.h>
#include <sys/mutex.h>

#include "portdrv.h"
#include "portdrv_common.h"
#include "portdrv_backend.h"

static MALLOC_DEFINE(M_PORTDRV, "portdrv", "portdrv driver state");

int
portdrv_core_attach(struct portdrv_softc *sc)
{
    KASSERT(sc != NULL, ("portdrv_core_attach: NULL softc"));
    KASSERT(sc->sc_be != NULL,
        ("portdrv_core_attach: backend not installed"));

    mtx_init(&sc->sc_mtx, "portdrv", NULL, MTX_DEF);

    /* Call the backend-specific attach step. */
    if (sc->sc_be->attach != NULL) {
        int err = sc->sc_be->attach(sc);
        if (err != 0) {
            mtx_destroy(&sc->sc_mtx);
            return (err);
        }
    }

    /* Hardware is up; register with the upper half of the kernel
     * (cdev, ifnet, GEOM, etc. as appropriate). */
    return (portdrv_core_register_cdev(sc));
}

void
portdrv_core_detach(struct portdrv_softc *sc)
{
    portdrv_core_unregister_cdev(sc);
    if (sc->sc_be->detach != NULL)
        sc->sc_be->detach(sc);
    mtx_destroy(&sc->sc_mtx);
}

int
```

```
portdrv_core_submit(struct portdrv_softc *sc, const void *buf, size_t len)
{
    /* All of this logic is hardware-independent. */
    return (sc->sc_be->start_transfer(sc, buf, len));
}
```

Notice what is not in this file. No `#include <dev/pci/pcivar.h>`. No PCI probe. No USB descriptors. No register offsets. The core is pure logic and delegation. It is small enough that a reader can hold the whole file in their head, and it does not change when a new backend is added.

29.7.4 A Minimal Backend File

The per-backend file is the only place where bus-specific headers appear. A sketch of `portdrv_pci.c`:

```
/*
 * portdrv_pci.c - PCI backend for the portdrv driver.
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/bus.h>
#include <sys/rman.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/pci/pcivar.h>
#include <dev/pci/pcireg.h>

#include "portdrv.h"
#include "portdrv_common.h"
#include "portdrv_backend.h"

struct portdrv_pci_softc {
    struct resource *pci_bar;
    int pci_bar_rid;
    struct resource *pci_irq;
    int pci_irq_rid;
    void *pci_ih;
};

static uint32_t
```

```
portdrv_pci_read_reg(struct portdrv_softc *sc, bus_size_t off)
{
    struct portdrv_pci_softc *psc = sc->sc_backend_priv;

    return (bus_read_4(psc->pci_bar, off));
}

static void
portdrv_pci_write_reg(struct portdrv_softc *sc, bus_size_t off, uint32_t val)
{
    struct portdrv_pci_softc *psc = sc->sc_backend_priv;

    bus_write_4(psc->pci_bar, off, val);
}

static int
portdrv_pci_attach_be(struct portdrv_softc *sc)
{
    /* Finish any backend-specific setup after resources are claimed. */
    return (0);
}

static void
portdrv_pci_detach_be(struct portdrv_softc *sc)
{
    /* Tear down any backend-specific state. */
}

const struct portdrv_backend portdrv_pci_backend = {
    .name          = "pci",
    .attach        = portdrv_pci_attach_be,
    .detach        = portdrv_pci_detach_be,
    .read_reg      = portdrv_pci_read_reg,
    .write_reg     = portdrv_pci_write_reg,
    .start_transfer = portdrv_pci_start_transfer,
    .poll_done     = portdrv_pci_poll_done,
};

static int
portdrv_pci_probe(device_t dev)
{
    if (pci_get_vendor(dev) != PORTDRV_VENDOR ||
        pci_get_device(dev) != PORTDRV_DEVICE)
        return (ENXIO);
}
```

```
device_set_desc(dev, "portdrv (PCI backend)");
return (BUS_PROBE_DEFAULT);
}

static int
portdrv_pci_attach(device_t dev)
{
    struct portdrv_softc *sc = device_get_softc(dev);
    struct portdrv_pci_softc *psc;
    int err;

    psc = malloc(sizeof(*psc), M_PORTDRV, M_WAITOK | M_ZERO);
    sc->sc_dev = dev;
    sc->sc_be = &portdrv_pci_backend;
    sc->sc_backend_priv = psc;

    psc->pci_bar_rid = PCIR_BAR(0);
    psc->pci_bar = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &psc->pci_bar_rid, RF_ACTIVE);
    if (psc->pci_bar == NULL) {
        free(psc, M_PORTDRV);
        sc->sc_backend_priv = NULL;
        return (ENXIO);
    }

    err = portdrv_core_attach(sc);
    if (err != 0) {
        bus_release_resource(dev, SYS_RES_MEMORY, psc->pci_bar_rid,
            psc->pci_bar);
        free(psc, M_PORTDRV);
        sc->sc_backend_priv = NULL;
    }
    return (err);
}

static int
portdrv_pci_detach(device_t dev)
{
    struct portdrv_softc *sc = device_get_softc(dev);
    struct portdrv_pci_softc *psc = sc->sc_backend_priv;

    portdrv_core_detach(sc);
    if (psc != NULL) {
        if (psc->pci_bar != NULL)
```

```

        bus_release_resource(dev, SYS_RES_MEMORY,
            psc->pci_bar_rid, psc->pci_bar);
    free(psc, M_PORTDRV);
    sc->sc_backend_priv = NULL;
}
return (0);
}

static device_method_t portdrv_pci_methods[] = {
    DEVMETHOD(device_probe,   portdrv_pci_probe),
    DEVMETHOD(device_attach, portdrv_pci_attach),
    DEVMETHOD(device_detach, portdrv_pci_detach),
    DEVMETHOD_END
};

static driver_t portdrv_pci_driver = {
    "portdrv_pci",
    portdrv_pci_methods,
    sizeof(struct portdrv_softc)
};

DRIVER_MODULE(portdrv_pci, pci, portdrv_pci_driver, 0, 0);
MODULE_VERSION(portdrv_pci, 1);
MODULE_DEPEND(portdrv_pci, portdrv_core, 1, 1, 1);

```

Again, notice what is present and what is not. The PCI-specific header includes are all here. The PCI probe is here. The `DRIVER_MODULE` macro is here. None of it is in the core. If you are writing a USB backend next, that file looks structurally identical but includes USB headers instead and registers with the USB subsystem.

29.7.5 Header Organisation

The three headers `portdrv.h`, `portdrv_common.h`, and `portdrv_backend.h` look like this in miniature.

`portdrv.h` is the driver's public face within the driver's files:

```

#ifndef _PORTDRV_H_
#define _PORTDRV_H_

#include <sys/malloc.h>

/* Softc, opaque to anything outside the core. */
struct portdrv_softc;

/* Core entry points called by backends. */

```

```

int  portdrv_core_attach(struct portdrv_softc *sc);
void portdrv_core_detach(struct portdrv_softc *sc);
int  portdrv_core_submit(struct portdrv_softc *sc,
                        const void *buf, size_t len);

MALLOC_DECLARE(M_PORTDRV);

#endif /* !_PORTDRV_H_ */

```

portdrv_common.h contains the types that backends and the core share:

```

#ifndef _PORTDRV_COMMON_H_
#define _PORTDRV_COMMON_H_

#include <sys/param.h>
#include <sys/lock.h>
#include <sys/mutex.h>

/* Forward declaration of the backend interface. */
struct portdrv_backend;

/* The_softc, visible to the backends so they can install sc_be, etc. */
struct portdrv_softc {
    device_t          sc_dev;
    const struct portdrv_backend *sc_be;
    void             *sc_backend_priv;

    struct mtx        sc_mtx;
    struct cdev        sc_cdev;

    /* other common fields ... */
};

#endif /* !_PORTDRV_COMMON_H_ */

```

portdrv_backend.h contains the interface and the declarations of each backend's canonical instance:

```

#ifndef _PORTDRV_BACKEND_H_
#define _PORTDRV_BACKEND_H_

#include <sys/types.h>
#include <machine/bus.h>

```

```
#include "portdrv_common.h"

struct portdrv_backend {
    const char *name;
    int  (*attach)(struct portdrv_softc *sc);
    void (*detach)(struct portdrv_softc *sc);
    uint32_t (*read_reg)(struct portdrv_softc *sc, bus_size_t off);
    void     (*write_reg)(struct portdrv_softc *sc, bus_size_t off,
                        uint32_t val);
    int  (*start_transfer)(struct portdrv_softc *sc,
                        const void *buf, size_t len);
    int  (*poll_done)(struct portdrv_softc *sc);
};

extern const struct portdrv_backend portdrv_pci_backend;
extern const struct portdrv_backend portdrv_usb_backend;
extern const struct portdrv_backend portdrv_sim_backend;

#endif /* !_PORTDRV_BACKEND_H_ */
```

These headers are short on purpose. A header that takes a page to read is a header that is hiding something. Split the types where they are used, and keep each header free of unnecessary prototypes.

29.7.6 The Makefile

The build side of this layout is pleasantly simple in FreeBSD. `bsd.kmod.mk` handles multi-file modules naturally. The Makefile looks like this:

```
# Makefile for portdrv - Chapter 29 reference driver.

KMOD=    portdrv
SRCS=    portdrv_core.c \
        portdrv_sysctl.c \
        portdrv_ioctl.c \
        portdrv_dma.c

# Backends are selected at build time.
.if defined(PORTDRV_WITH_PCI) && ${PORTDRV_WITH_PCI} == "yes"
SRCS+=   portdrv_pci.c
CFLAGS+= -DPORTRV_WITH_PCI
.endif

.if defined(PORTDRV_WITH_USB) && ${PORTDRV_WITH_USB} == "yes"
SRCS+=   portdrv_usb.c
```

```
CFLAGS+= -DPORTDRV_WITH_USB
#endif

.if defined(PORTDRV_WITH_SIM) && ${PORTDRV_WITH_SIM} == "yes"
SRCS+= portdrv_sim.c
CFLAGS+= -DPORTDRV_WITH_SIM
#endif

# If no backend was explicitly selected, enable the simulation
# backend so that the driver still builds and loads.
.if !defined(PORTDRV_WITH_PCI) && \
    !defined(PORTDRV_WITH_USB) && \
    !defined(PORTDRV_WITH_SIM)
SRCS+= portdrv_sim.c
CFLAGS+= -DPORTDRV_WITH_SIM
#endif

SYSDIR?=    /usr/src/sys

#include <bsd.kmod.mk>
```

Build it with any combination of backends:

```
make clean
make PORTDRV_WITH_PCI=yes PORTDRV_WITH_SIM=yes
```

The resulting `portdrv.ko` contains only the files you asked for. Dropping a backend is as easy as removing its make variable. This is the compile-time selection approach, and it works well for drivers whose backend set is known at build time.

29.7.7 Compare with `/usr/src/sys/modules/uart/Makefile`

Open `/usr/src/sys/modules/uart/Makefile` and compare. The structure is similar in spirit: a `SRCS` list that names each file, plus conditional blocks that select backends and hardware-specific helpers based on architecture. The UART build is more elaborate than ours because the driver supports many backends and many hardware variants, but the shape is recognisable. Studying this file alongside the one in the reference driver will make both more understandable.

Take a few minutes to walk through the UART Makefile from the top. Notice how the `SRCS` list is built up through additions, not a single assignment: `SRCS+= uart_tty.c`, `SRCS+= uart_dev_ns8250.c`, and so on. Each addition can be guarded by a conditional that checks an architecture macro or a feature flag. The result is a single Makefile that produces different builds on `amd64`, `arm64`, and `riscv`, with different sets of backends enabled on each. That is the structure you want your own drivers to have once they grow to cover more than one platform.

29.7.8 Makefile Idioms for Portable Drivers

A few Makefile idioms recur so often that they deserve explicit naming. You will see each of these in real FreeBSD module Makefiles and in the reference driver.

The **unconditional core list**:

```
KMOD=    portdrv
SRCS=    portdrv_core.c portdrv_ioctl.c portdrv_sysctl.c
```

This is always the starting point: the files that are always compiled, regardless of configuration.

The **conditional backend list**:

```
.if ${MACHINE_CPUARCH} == "amd64" || ${MACHINE_CPUARCH} == "i386"
SRCS+=    portdrv_x86_helpers.c
.endif

.if ${MACHINE} == "arm64"
SRCS+=    portdrv_arm64_helpers.c
.endif
```

This pattern lets a file be included only on a specific architecture. It is less common in drivers than in kernel subsystems, but it is the right tool when genuinely architecture-specific code exists.

The **per-feature block**:

```
.if defined(PORTDRV_WITH_DMA) && ${PORTDRV_WITH_DMA} == "yes"
SRCS+=    portdrv_dma.c
CFLAGS+=    -DPORTDRV_WITH_DMA
.endif
```

Each feature that can be toggled has one block. The block adds a source file and a preprocessor flag. This is the pattern you will use most often.

The **header dependency**:

```
beforebuild: genheader
genheader:
    sh ${.CURDIR}/gen_registers.sh > ${.OBJDIR}/portdrv_regs.h
```

When a header is generated from a data file (for example, from a vendor-provided register description), this pattern ensures the header is up to date before the main build runs. Use it sparingly; each generated artefact is a maintenance point.

The **CFLAGS discipline block**:

```
CFLAGS+=      -Wall
CFLAGS+=      -Wmissing-prototypes
CFLAGS+=      -Wno-sign-compare
CFLAGS+=      -Werror=implicit-function-declaration
```

This turns on warnings that catch common portability bugs. Treat new warnings as bugs, and fix them as they appear. The `-Werror=implicit-function-declaration` flag in particular catches the class of bug where a file calls a function without including the appropriate header; on some platforms the compiler would silently assume an `int` return type and proceed, producing a latent bug.

The **include-path addition**:

```
CFLAGS+=      -I${.CURDIR}
CFLAGS+=      -I${.CURDIR}/include
CFLAGS+=      -I${SYSDIR}/contrib/portdrv_vendor_headers
```

When the driver has its own header directory, or when it depends on vendor-supplied headers checked into a contrib area, these `-I` additions are how you tell the compiler where to look. Keep the list short; each additional path increases the surface for header conflicts.

29.7.9 When Multiple Modules Share Code

A question that arises as drivers proliferate is how to share helper code among them. The two approaches are:

Library module. A separate `.ko` file provides helper functions, and the dependent drivers declare `MODULE_DEPEND` on it. This is clean when the helpers are substantial, but each module load now requires loading the helper module first.

Shared source file. Multiple drivers list the same `.c` file in their `SRCS`. Each driver gets its own copy of the functions, compiled into its own `.ko`. This is simpler but duplicates code in every driver's binary.

For helpers under a few hundred lines, the shared source approach is usually right. The duplication is small and the build is simpler. For helpers over a thousand lines, the library module pays for itself because updates to the helper affect only one module, not every driver that uses it.

A third approach is to move the helper into the base kernel and have it exported. This is the right choice when the helper is genuinely general-purpose and belongs to the kernel ABI. For driver-specific helpers, it is overkill.

29.7.10 Benefits of the Split

Why go to this much trouble? The benefits are not cosmetic.

Faster builds. A change to `portdrv_ioctl.c` recompiles one file and relinks the module. A monolithic driver recompiles everything every time.

Easier testing. The simulation backend can be loaded alone, without any hardware, and the core can be exercised completely. Unit-testing a driver this way changes what is possible.

Cleaner API surface. Each file exposes only what the others need. When a function is declared in `portdrv.h`, that declaration is a promise that the function is part of the driver's internal API. Functions that are not declared there are implicitly private to their file.

Easier review. A code reviewer who knows the layout can skim a patch by looking at which files changed. A patch that touches `portdrv_pci.c` only is doing PCI-specific work. A patch that touches `portdrv_core.c` is doing something that affects all backends, and deserves closer scrutiny.

Lower cost to add a backend. Once the layout is in place, a new backend is a single new file. In a monolithic driver, a new backend is a rewrite of half the file.

29.7.11 Common Mistakes When Splitting a Driver

Some pitfalls are easy to blunder into.

Moving too little. A split that leaves bus-specific headers in the “core” file has not moved far enough. The core should include only subsystem headers (`sys/bus.h`, `sys/conf.h`, etc.), not bus-specific ones. If you catch yourself including `dev/pci/pcivar.h` in the core, you have left PCI-specific logic behind.

Moving too much. A split that moves every helper into its own file creates a dozen tiny files and a mesh of cross-dependencies. Balance is the goal. If three functions are always used together and are meaningful only together, they belong in the same file.

Circular includes. When header A includes header B and header B includes header A, the compiler complains about incomplete types. The fix is almost always a forward declaration in one of the headers, so the other header can include it safely.

Silent API breakage. When you move a function from `portdrv.c` to `portdrv_sysctl.c`, its declaration must be visible to anyone who calls it. Check the compiler warnings; a missing declaration usually shows up as an implicit function declaration warning before it turns into a link-time error.

Forgotten entries in SRCS. A new file that is not listed in SRCS is not compiled. The driver will compile and link if you are unlucky and all its symbols are already available elsewhere, or it will fail to link with a mysterious undefined-symbol error. When you add a file, always add it to SRCS in the same commit.

29.7.12 Header Hygiene and Include Graphs

A source file's `#include` lines are a window on its dependencies. A file that includes `dev/pci/pcivar.h` is declaring, in the cleanest way a C programmer can, that it knows about PCI. A file that only includes `sys/param.h`, `sys/bus.h`, `sys/malloc.h`, and the driver's own headers is declaring independence from any specific bus. The discipline of keeping include lists small and focused is called header hygiene, and it is the quiet partner of the backend interface.

Three rules keep include graphs clean.

Rule one: include what you use, declare what you do not. If a file uses `bus_dma_tag_create`, it must include `<sys/bus.h>` and `<machine/bus.h>`. If it merely takes a pointer to a `bus_dma_tag_t` but does not dereference it, a forward declaration in a header may be enough. Over-including pulls in dependencies; under-including causes implicit function declaration warnings. Both are fixable, but the right target is exactly what is needed.

Rule two: include the smallest header that gives you what you need. `<sys/param.h>` is a fine catch-all, but it pulls in a large transitive graph. If you only need fixed-width integer types, `<sys/types.h>` may be enough. The build succeeds either way; the compilation time and the dependency graph shrink when you are disciplined.

Rule three: never rely on transitive includes. If your `.c` file uses `memset`, it must include `<sys/libkern.h>` (or `<string.h>` in userland), even if another header has already pulled it in for you. Transitive includes are not part of the contract; they change when another header is refactored. An explicit include is robust; an implicit one is a ticking bug.

When you split a driver according to the layout in this section, re-inspect every `.c` file's includes. Delete the ones you do not need; add the ones you were getting transitively. After the sweep, each file should have an includes list that matches what it actually does. The result is a source tree where a change to one header does not cascade unexpectedly through the rest.

A useful mental model is that the include graph is the **build-time equivalent of the backend interface**. Both declare what depends on what. Both are kept clean by discipline. Both pay for themselves when the driver is refactored. If the backend interface is the dependency graph of the running code, the include graph is the dependency graph of the source code, and both deserve the same care.

29.7.13 Managing CFLAGS and Symbol Visibility

A multi-file driver eventually needs some build-time knobs for its own compilation. These usually take the form of additions to CFLAGS in the Makefile:

```
CFLAGS+=      -I${.CURDIR}
CFLAGS+=      -Wall -Wmissing-prototypes
CFLAGS+=      -DPORTDRV_VERSION='"2.0"'
```

The first line makes the driver's own headers discoverable; the second turns on warnings that catch common portability mistakes; the third embeds a version string directly into the compiled module. Each flag is small; together they give the driver a small surface of control that does not leak into the source.

Be careful with symbol visibility. In a kernel module, every non-static function is a potentially exported symbol. If two drivers both define a function named `portdrv_helper`, the kernel will accept whichever loads first and reject the second, producing a confusing error. Prefix your symbols: name functions `portdrv_core_attach`, not `attach`; name functions `portdrv_pci_probe`, not `probe`. Static functions never become symbols and can be named more tersely.

This is not just a style issue. On FreeBSD, a kernel module's symbol table is shared with every other loaded module. An unprefixed name collides with everything else the kernel has ever loaded. Use a consistent prefix, and prefer `static` whenever the function does not need to be visible outside its file.

29.7.14 A Dependency Graph on Paper

A good exercise when you first split a driver is to draw its include graph on paper. A box for each file; an arrow from file A to file B when A includes B. The graph should be acyclic, flow downward from source files to the most primitive headers, and contain no surprising edges.

For the reference driver `portdrv`, the graph looks roughly like this:

```
portdrv_core.c
|
+--> portdrv.h
+--> portdrv_common.h
+--> portdrv_backend.h ---> portdrv_common.h
+--> <sys/param.h>, <sys/bus.h>, <sys/malloc.h>, ...

portdrv_pci.c
|
+--> portdrv.h
+--> portdrv_common.h
+--> portdrv_backend.h
+--> <dev/pci/pcivar.h>, <dev/pci/pci.h>
+--> <sys/bus.h>, <machine/bus.h>, <sys/rman.h>, ...

portdrv_sim.c
|
+--> portdrv.h
+--> portdrv_common.h
+--> portdrv_backend.h
+--> <sys/malloc.h>
```

The PCI backend is the only file that reaches into `dev/pci/`. The core is the only file that pulls in the universal subsystem headers. The simulation backend is the lightest of the three because it talks to no real hardware.

Draw this graph before you commit a new file layout. If an arrow goes the wrong way, fix the includes before you write any more code. A graph that flows downward is a sign of healthy layering; a graph with cycles is a sign of a design that wants rethinking.

29.7.15 Static Analysis and Continuous Reviews

Multi-file drivers benefit from a small amount of static analysis. The two tools that pay for themselves almost immediately are:

make -k -j buildkernel with warnings turned on. The FreeBSD build is usually clean, but a new file will often expose a forgotten prototype, an unused variable, or a signed/unsigned mismatch. Read every warning; fix every warning.

cppcheck or **scan-build** on the driver sources. Neither is perfect, but each catches a class of bug that the compiler does not. A missing free, a dereference of a possibly-NULL pointer, a dead branch, and a use-after-free are all common hits. Run one of them periodically, not necessarily on every commit.

For a large driver, consider running `clang-tidy` with a moderate check set. For a small driver, the compiler's warnings plus occasional human review are usually enough.

A multi-file driver is easier to review than a monolithic one precisely because each file has a small scope. Reviewers can take a file at a time, understand its responsibility, and check its conformance to the layout. A reviewer who knows the conventions can move through a large patch quickly because each file's role is obvious from its place in the layout. This is the review-cost payoff mentioned earlier, and it compounds over the life of the driver.

29.7.16 Wrapping Up Section 4

You now have a concrete file layout you can apply to any driver: a core file, a small family of backend files, a header per concern, and a Makefile that lets you select backends at build time. The layout is not mandatory, but it matches what real FreeBSD drivers use in the wild, and it scales from small drivers to large ones without reorganisation. Disciplined header hygiene, a clean include graph, and consistent symbol prefixing are the companions of the layout; together they make the driver's source tree a pleasure to navigate.

The layout also teaches the reader where to look. A new maintainer who knows the conventions can navigate the driver on the first day rather than the tenth. Over the life of a long-lived project, that is worth more than it looks.

Section 5 turns from file organisation to the topic that is easiest to get subtly wrong: supporting multiple CPU architectures. The same driver must compile on amd64, arm64, riscv, and the rest of FreeBSD's ports, and it must behave correctly on each one. The tools are almost all about endianness, alignment, and word size, and using them properly is less effort than it looks.

29.8 Section 5: Supporting Multiple Architectures

Architectural portability is the form of portability that requires the least code and the most attention. The kernel and the compiler already do most of the work for you; your job as a driver author is not to add cleverness but to avoid adding bugs. Every common architectural bug in driver code has a corresponding FreeBSD idiom that prevents it. This section introduces those idioms and shows how to use them.

The three axes along which architectures differ in ways that drivers can feel directly are endianness, alignment, and word size. We will take them in order, then look at how to test architectural portability without owning hardware for every architecture.

29.8.1 How `bus_space` Varies Across Platforms

To understand why the abstraction matters, it helps to look briefly at how it is implemented on each of the architectures FreeBSD supports. The mechanism is different on each one, but the interface you program against is the same.

On amd64, the tag is simply a type tag that distinguishes memory-mapped I/O from I/O ports, and the handle is the virtual address of the mapped region. A `bus_space_read_4` call on amd64 becomes, under the covers, a load instruction to the mapped address. The call is a thin wrapper over a raw load; there is essentially no indirection cost.

On arm64, the tag is a pointer to a table of function pointers, and the handle is the base address of the mapped region. A `bus_space_read_4` call on arm64 becomes an indirect call through the function pointer table. The

indirection is necessary because different ARM platforms can map memory with different cacheability and ordering attributes, and the function table encodes those details per platform. The cost is a single indirect call, which is measurable in tight loops but negligible in a typical driver.

On `riscv`, the mechanism is close to `arm64`, with similar rationale. On older `powerpc`, the tag and handle encode endianness configuration, so that a `bus_space_read_4` on a big-endian bus attached to a little-endian CPU does the right byte swap without the driver knowing.

All of this is invisible to the driver. Your code calls `bus_read_4(res, offset)` and gets the right value, on every architecture, at every bus configuration. The price is that you cannot shortcut the API; the moment you drop to a raw pointer, you lose all of this machinery, and your driver works on exactly one platform.

29.8.2 Endianness in Three Questions

Endianness is the order in which the bytes of a multi-byte value are stored in memory. On a little-endian system like `amd64`, `arm64`, or `riscv`, the least significant byte of a 32-bit value comes first in memory, and the most significant byte comes last. On a big-endian system like some configurations of `powerpc`, the order is reversed. The CPU does not see the bytes individually in either case; it reads the word as a whole and interprets it according to the system's endianness. The problem for drivers is that hardware does not always share the CPU's view.

There are three questions a driver author must ask, and three classes of answer.

Question 1: Does the device have a native byte order? Many devices do. A PCI device may specify that a particular register contains a 32-bit value in little-endian order. Ethernet frames, by contrast, are big-endian. When the device's byte order differs from the CPU's byte order, the driver must convert between them explicitly.

Question 2: Does the bus perform any implicit conversion? Usually not. `bus_space_read_4` returns the 32-bit value as the host sees it, in host byte order. If the device stored that value in a different byte order, the conversion is the driver's responsibility. The same is true for DMA buffers read and written through `bus_dma`. The bytes in the buffer are the bytes the device wrote, in whatever order the device prefers; your code has to interpret them correctly.

Question 3: Which direction am I converting? Going from the device to the host, use `le32toh`, `be32toh`, and their 16-bit and 64-bit companions. Going from the host to the device, use `htole32`, `htobe32`, and their companions. The name convention is simple: the first form is the source, the second form is the destination, and `h` stands for host.

29.8.3 The Endian Helpers in Detail

Open `/usr/src/sys/sys/_endian.h` and look at how the helpers are defined. On a little-endian host, `htole32(x)` is just `(uint32_t)(x)` because no swap is needed, and `htobe32(x)` is `__bswap32(x)` because the device expects the opposite order. On a big-endian host, the pattern is reversed: `htobe32(x)` is the identity and `htole32(x)` performs the swap. This means that your code can call the same helper on every architecture, and the right thing happens under the covers.

The full set of helpers you will use in driver code is:

```
htole16(x), htole32(x), htole64(x)
htobe16(x), htobe32(x), htobe64(x)
le16toh(x), le32toh(x), le64toh(x)
be16toh(x), be32toh(x), be64toh(x)
```

Plus the network-byte-order shortcuts `htons`, `htonl`, `ntohs`, `ntohl`, which are equivalent to the `htobe/betoh` family for 16-bit and 32-bit values.

Use them whenever you store a multi-byte value in a device register or DMA buffer, or whenever you read one. Never write:

```
sc->sc_regs->control = 0x12345678; /* Wrong if the device expects LE. */
```

Write instead:

```
widget_write_reg(sc, REG_CONTROL, htole32(0x12345678));
```

The cost at runtime is zero on a little-endian host, because the compiler inlines the helper to a no-op. The benefit on a big-endian host is correctness.

29.8.4 A Simple Mental Rule

When I am teaching this pattern to new driver authors, I use one rule that catches most mistakes before they happen: **every multi-byte value that leaves the CPU or enters it through hardware must pass through an endian helper**. Registers. DMA buffers. Packet headers. Descriptor rings. Every single one. If you see a `*ptr = value` or `value = *ptr` pattern on a multi-byte quantity that is device-visible, and the endpoints do not use an endian helper, that is a bug or a lucky accident, and the only way to tell which is to know the architecture you are running on.

The same rule, applied consistently, means that moving a driver to a big-endian platform becomes almost free. If the endian helpers were in place from the start, the platform change does nothing to the code. If they were not, the move is a hunt through the entire driver for every read and write that touched device memory, and every one of them is a potential bug.

29.8.5 Alignment and the `NO_STRICT_ALIGNMENT` Macro

The second architectural axis is alignment. A 32-bit value is *aligned* at an address that is a multiple of four. On amd64, unaligned accesses are permitted and only slightly slower than aligned ones. On some ARM cores, an unaligned access can produce a bus fault or silently corrupt data depending on the specific instruction and configuration.

The kernel's policy is that driver code should produce aligned accesses. If you cast a buffer pointer to `uint32_t *` and dereference it, the buffer had better be aligned to four bytes. Most kernel allocators give you naturally aligned memory, so this usually happens for free. It becomes tricky when parsing a wire protocol that does

not align its fields, like an Ethernet frame whose IP header is misaligned by two bytes because of the Ethernet header's odd size.

FreeBSD exposes the macro `__NO_STRICT_ALIGNMENT`, defined in `/usr/src/sys/x86/include/_types.h` and its architecture peers, which drivers occasionally check to see whether the platform tolerates unaligned accesses. For general-purpose driver code, you should not rely on it. Instead, use byte-at-a-time accessors, or `memcpy`, to copy multi-byte values out of unaligned memory before interpreting them. The compiler is good at optimising `memcpy(&val, ptr, sizeof(val))` into a single aligned load on architectures that support it, and a byte-at-a-time load on architectures that need it.

A typical pattern for safely reading an unaligned 32-bit value from a byte buffer is:

```
static inline uint32_t
load_unaligned_le32(const uint8_t *p)
{
    uint32_t v;
    memcpy(&v, p, sizeof(v));
    return (le32toh(v));
}
```

This works on every architecture. The `memcpy` handles alignment; the `le32toh` handles endianness. Use this kind of helper whenever you pull a multi-byte value from a wire format or an on-device buffer that may not be aligned.

29.8.6 Word Size: 32 vs 64 Bits

The third architectural axis is word size. On a 32-bit platform, a pointer is four bytes and `long` is typically four bytes. On a 64-bit platform, both are eight bytes. Most of the FreeBSD kernel and all of the common architectures today are 64-bit, but not all of them, and even 64-bit platforms sometimes run 32-bit compatibility code.

The failure mode to watch for is writing `int` or `long` where the size matters. A register value is a specific number of bits, not “whatever `int` happens to be.” If a register is 32 bits, write `uint32_t`. If it is 16 bits, write `uint16_t`. This rule is easy to remember and completely eliminates a whole class of bugs.

FreeBSD exposes these types through `/usr/src/sys/types.h` and its indirect includes. The standard fixed-width typedefs are:

```
int8_t,    uint8_t
int16_t,   uint16_t
int32_t,   uint32_t
int64_t,   uint64_t
```

And the kernel also exposes `intmax_t`, `uintmax_t`, `intptr_t`, and `uintptr_t` when you need to store an integer that must be at least as wide as any other integer, or that must be the width of a pointer.

Do not use `u_int32_t` or `u_char` in new code. They are legacy names that still exist for backward compatibility but are not the preferred style. The convention in modern FreeBSD driver code is the `uint32_t` family.

29.8.7 Bus Address Types

A related family of types governs addresses that the device and the bus use. These are defined per architecture in `/usr/src/sys/amd64/include/_bus.h`, `/usr/src/sys/arm64/include/_bus.h`, and the rest. The key types are:

- `bus_addr_t`: a bus address, typically `uint64_t` on 64-bit platforms.
- `bus_size_t`: a size on the bus, the same underlying width as `bus_addr_t`.
- `bus_space_tag_t`: the opaque tag handed to `bus_space_*` functions.
- `bus_space_handle_t`: the opaque handle into the mapped region.
- `bus_dma_tag_t`: the opaque tag used by `bus_dma`.
- `bus_dmamap_t`: the opaque DMA map handle.

Using these types instead of bare `uint64_t` or `void *` is how the kernel enforces the architectural abstraction. On `amd64`, they may be simple integers; on `arm64`, some are pointers to structures. Your code compiles the same way everywhere and does the right thing on each platform.

29.8.8 Testing on Emulated Architectures

One of the most practical questions is: if you only have an `amd64` machine, how do you test that the driver works on `arm64` or on a big-endian system? The answer is emulation.

QEMU, which FreeBSD supports well, can run `arm64` guests on an `amd64` host. The performance is slower than native, but enough for functional testing. A simple workflow is:

1. Install the FreeBSD `arm64` release into a QEMU image.
2. Boot the image under QEMU with enough disk and RAM.
3. Cross-build the driver (or build it inside the guest).
4. Load the module and run your tests.

FreeBSD's build infrastructure supports cross-building via `make buildkernel TARGET=arm64 TARGET_ARCH=aarch64`. For kernel modules, the same `TARGET` and `TARGET_ARCH` variables apply. You end up with an `arm64` module that you can copy into the `arm64` guest and test there.

For big-endian testing, QEMU's `powerpc64` and `powerpc` targets exist, and FreeBSD has releases for both. Big-endian PowerPC testing is particularly valuable because it is the fastest way to find hidden endianness bugs: the driver that works perfectly on `amd64` but mangles every register on PowerPC has almost certainly missed an `htole32` somewhere.

For everyday work, it is enough to run the driver once on a cross-architecture guest as part of your release process. You do not need to do it on every commit. But you should not skip it entirely, because the bugs it finds are the bugs your users would otherwise find for you.

29.8.9 Case Study: A DMA Descriptor Ring

A concrete example of how these idioms combine is a DMA descriptor ring. Many devices expose a ring of descriptors in shared memory: each descriptor describes one transfer, and the device walks the ring autonomously

as it services transfers. The ring is a prime example of a shared structure where endianness, alignment, word size, and cache coherency all interact.

A typical descriptor might look like this in C:

```
struct portdrv_desc {
    uint64_t addr;      /* bus address of the payload */
    uint32_t len;       /* payload length in bytes */
    uint16_t flags;     /* control bits */
    uint16_t status;    /* completion status */
};
```

Four considerations apply to this structure.

Endianness. The device reads and writes these fields. The byte order in which it interprets them comes from the datasheet. If the device expects little-endian, every write from the CPU must pass through `htole64` or `htole32` as appropriate, and every read from the device must pass through `le64toh` or `le32toh`.

Alignment. The device reads the whole descriptor in one transaction, so the descriptor must be aligned on at least its natural boundary. For this layout, that is 8 bytes because of the 64-bit `addr` field. The `bus_dma_tag_create` call that allocates the ring must set `alignment` to at least 8.

Word size. The `addr` field is 64 bits because the device may need to reach any physical address on a 64-bit system. On a 32-bit system with a 32-bit-only device, you could declare it `uint32_t`, but the portable choice is `uint64_t` with the upper bits zero when unused.

Cache coherency. After the CPU writes a descriptor and before the device reads it, the CPU's caches must be flushed to memory so the device sees the update. After the device writes the status field and before the CPU reads it, the CPU's caches for the ring memory must be invalidated so it does not read a stale value. The `bus_dmamap_sync` call with `BUS_DMASYNC_PREWRITE` handles the first case; with `BUS_DMASYNC_POSTREAD` handles the second.

Putting these together, the code to enqueue a descriptor looks roughly like this:

```
static int
portdrv_enqueue(struct portdrv_softc *sc, bus_addr_t payload_addr, size_t len)
{
    struct portdrv_desc *d;
    int idx;

    /* Pick a ring slot. */
    idx = sc->sc_tx_head;
    d = &sc->sc_tx_ring[idx];

    /* Populate the descriptor in device byte order. */
    d->addr = htole64(payload_addr);
    d->len = htole32((uint32_t)len);
    d->flags = htole16(DESC_FLAG_VALID);
}
```

```

d->status = 0;

/* Ensure the CPU's writes reach memory before the device reads. */
bus_dmamap_sync(sc->sc_ring_tag, sc->sc_ring_map,
    BUS_DMASYNC_PREWRITE);

/* Notify the device. Use a barrier to ensure the notification
 * is seen after the descriptor writes. */
bus_barrier(sc->sc_bar, 0, 0,
    BUS_SPACE_BARRIER_READ | BUS_SPACE_BARRIER_WRITE);
portdrv_write_reg(sc, REG_TX_DOORBELL, (uint32_t)idx);

sc->sc_tx_head = (idx + 1) % sc->sc_ring_size;
return (0);
}

```

Every one of the four considerations is visible in these few lines. The `htole*` calls handle endianness. The `bus_dmamap_sync` call handles cache coherency. The `bus_barrier` call handles ordering. The `uint64_t` for `addr` handles word size.

And, crucially, this code is identical on `amd64`, `arm64`, and `powerpc64`. The helpers become the right operation on each platform under the covers. The driver author writes one version and it works everywhere.

29.8.10 A Register Layout Worth Doing Carefully

Here is a register layout from a hypothetical device, written as a C structure:

```

struct widget_regs {
    uint32_t control;      /* offset 0x00 */
    uint32_t status;      /* offset 0x04 */
    uint32_t data;        /* offset 0x08 */
    uint8_t pad[4];        /* offset 0x0C: padding */
    uint64_t dma_addr;     /* offset 0x10 */
    uint16_t len;         /* offset 0x18 */
    uint16_t flags;       /* offset 0x1A */
};

```

Two things about this are worth noticing. First, padding is explicit. If the register block has a hole between `data` and `dma_addr`, write a `pad[]` member. Do not rely on the compiler to insert padding of the right size, because the compiler does not know about the device. Second, the types match the register widths exactly. A 16-bit `len` field is `uint16_t`, not `int` or `u_int`.

Do not, however, read and write these registers by casting a pointer to the structure. The pattern

```
struct widget_regs *r = (void *)sc->sc_regs_vaddr;  
r->control = htobe32(value);
```

is a portability trap. On amd64 it works. On arm64 it may work or may fault depending on the alignment of the mapping. On some ARM cores it may produce implementation-specific behaviour. The kernel provides `bus_space` for a reason; use it.

The structure above is useful for documentation and for constant names, but the code should access the registers through accessors that use `bus_space` or `bus_read_*/bus_write_*`.

29.8.11 Using the Newer `bus_read_*/bus_write_*` Helpers

FreeBSD provides a slightly friendlier family of functions, `bus_read_1`, `bus_read_2`, `bus_read_4`, `bus_read_8`, and their `bus_write_*` counterparts. They take a `struct resource *` rather than the pair (tag, handle), so they are shorter at the call site. Internally they use `bus_space` under the covers. For modern drivers they are the preferred idiom.

```
uint32_t v = bus_read_4(sc->sc_bar, REG_CONTROL);  
bus_write_4(sc->sc_bar, REG_CONTROL, v | CTRL_START);
```

These functions are defined in `/usr/src/sys/sys/bus.h`. Use them in preference to the older `bus_space_*` forms when you are writing new code; both work correctly on all supported architectures.

29.8.12 Common Mistakes When Supporting Multiple Architectures

A short list of pitfalls, each of which would bite a naive driver on at least one FreeBSD platform.

Using `int` for a register width. If the register is 32 bits, use `uint32_t`. An `int` is the right size on every FreeBSD architecture today, but it is signed, and bit patterns with the top bit set become negative numbers. That bites when you compare the value or shift it.

Casting pointers to device memory. Writing through a volatile `uint32_t *` pointer to a mapped region works on some architectures and not others. Use `bus_read_*/bus_write_*`. Always.

Packing without packing attributes. If you really must use a struct to describe a wire-format layout, use `__packed` to make sure the compiler does not insert alignment padding. But be aware that accessing fields of a packed struct is itself subject to alignment hazards on strict-alignment architectures. A safer pattern is to read fields out of a byte buffer with `memcpy` and endian helpers, as shown earlier.

Assuming `sizeof(long) == 4` or `sizeof(long) == 8`. On 32-bit platforms, `long` is 4; on 64-bit platforms, it is 8. If the size matters, use `uint32_t` or `uint64_t` explicitly.

Forgetting about 32-bit platforms. Even when the mainline FreeBSD world is largely 64-bit, there are still 32-bit ARM deployments, 32-bit MIPS deployments, and legacy i386 deployments. Testing only on amd64 is not a portability guarantee. At minimum, cross-build on a 32-bit target periodically.

29.8.13 Memory Barriers and Ordering

Register and memory accesses do not always reach their targets in the order your code writes them. Modern CPUs reorder loads and stores as an optimisation, and so do bus bridges and memory controllers. On most common amd64 configurations, the hardware's reordering is conservative enough that drivers rarely notice. On arm64, riscv, and other weakly-ordered architectures, the reordering is more aggressive, and a driver that depends on a specific order of register accesses can fail in mysterious ways if it does not tell the hardware about that dependency.

The tool for expressing ordering is the **memory barrier**. FreeBSD provides two families:

- `bus_space_barrier(tag, handle, offset, length, flags)` for ordering with respect to device accesses. The `flags` argument is a combination of `BUS_SPACE_BARRIER_READ` and `BUS_SPACE_BARRIER_WRITE`.
- `atomic_thread_fence_rel`, `atomic_thread_fence_acq`, and friends for ordering with respect to normal memory. These are found in `/usr/src/sys/sys/atomic_common.h` and the per-architecture `atomic` files.

A typical use of `bus_space_barrier` occurs when you arm an interrupt after setting up a DMA descriptor:

```
/* Program the DMA descriptor. */
portdrv_write_reg(sc, REG_DMA_ADDR_LO, htobe32((uint32_t)addr));
portdrv_write_reg(sc, REG_DMA_ADDR_HI, htobe32((uint32_t)(addr >> 32)));
portdrv_write_reg(sc, REG_DMA_LEN, htobe32(len));

/* Ensure the descriptor writes are visible before we arm the IRQ. */
bus_barrier(sc->sc_bar, 0, 0,
    BUS_SPACE_BARRIER_READ | BUS_SPACE_BARRIER_WRITE);

/* Now it is safe to tell the device to start. */
portdrv_write_reg(sc, REG_DMA_CTL, DMA_CTL_START);
```

On a strongly ordered architecture such as amd64, the `bus_barrier` call is essentially free and the barrier is implicit in most cases. On arm64, the barrier is a real instruction that prevents the CPU from reordering the register writes, and without it the device could see the `DMA_CTL_START` register written before the address registers, which is almost certainly a bug.

Use barriers whenever your code depends on a specific order of register accesses, particularly across the handoff between the CPU and the device. Read your datasheet for the cases where a specific write order is required, and bracket those sections with barriers. Omitting them is the fastest way to write a driver that works on your desk and fails in production on a different machine.

29.8.14 Cache Coherency and `bus_dmamap_sync`

The third ordering issue is cache coherency. On some architectures, the CPU has caches that are not automatically coherent with DMA. If you write to a DMA buffer from the CPU and then tell the device to read it, the

device may see stale data that is still in the CPU cache. Conversely, if the device writes into a DMA buffer, the CPU may read stale data that was cached before the write.

FreeBSD handles this through `bus_dmamap_sync`. After writing to a buffer that the device will read, you call:

```
bus_dmamap_sync(sc->sc_dmat, sc->sc_dmap, BUS_DMASYNC_PREWRITE);
```

After the device has written to a buffer that the CPU will read, you call:

```
bus_dmamap_sync(sc->sc_dmat, sc->sc_dmap, BUS_DMASYNC_POSTREAD);
```

On amd64, where the caches are coherent with DMA, these calls are usually no-ops. On architectures where they are not coherent, `bus_dmamap_sync` emits the right cache-flush or cache-invalidate operation. A driver that uses `bus_dma` but skips these sync calls works on amd64 and fails on other architectures.

As with endian helpers, the rule is uniform: every DMA buffer that is shared between the CPU and the device must pass through `bus_dmamap_sync` at the handoff. The buffer goes from CPU to device: `BUS_DMASYNC_PREWRITE`. The buffer comes back from device to CPU: `BUS_DMASYNC_POSTREAD`. The sync calls cost nothing on coherent systems and are essential on non-coherent ones. Use them consistently, and architectural portability for DMA buffers is largely free.

29.8.15 Bounce Buffers and Address Limits

Some devices cannot reach every address in the system's physical memory. A 32-bit device on a 64-bit system can only address the first four gigabytes of physical memory; anything above that is unreachable. FreeBSD's `bus_dma` handles this through **bounce buffers**: if the physical address of a buffer is outside the device's reach, `bus_dma` allocates a temporary buffer that is within reach, copies data between the real buffer and the bounce buffer, and presents the device with the bounce buffer's address.

Bounce buffers are invisible to the driver if the driver uses `bus_dma` correctly. The `lowaddr` and `highaddr` fields of `bus_dma_tag_create` tell the kernel what the device can and cannot reach. If the driver sets `lowaddr` to `BUS_SPACE_MAXADDR_32BIT`, the kernel will use bounce buffers for any buffer above 4 GB. The `bus_dmamap_sync` calls handle the copy automatically.

Bounce buffers are not free. They cost memory, they cost a copy per operation, and they cost some latency. Well-designed devices avoid them by supporting 64-bit addressing. But a driver author has no control over the device's address width; the only portability-relevant decision is to declare the limits correctly and let `bus_dma` handle the rest. A driver that lies about the device's limits will corrupt memory silently on a large system. A driver that tells the truth will work on every system, with bounce buffers when needed.

29.8.16 Architectural Smoke Tests

Architectural portability is verified by running the driver on a different architecture. Even one such test, once, catches a surprising amount of latent bugs. The minimum viable smoke test is:

1. Build or download a FreeBSD release for a different architecture, typically `arm64` or `powerpc64`.

2. Install the release into a QEMU guest.
3. Build the driver inside the guest, or cross-build it on the host.
4. Load the module.
5. Exercise the driver's main features.
6. Observe whether the driver behaves as expected.

Even this minimum is revealing. The first time you run your driver on a big-endian host, any missing `htole32` or `be32toh` will manifest as obviously wrong register values. The first time you run it on `arm64`, any raw pointer cast to device memory will usually cause an alignment fault on the first access. The first time you build it on `riscv`, any hard-coded assumption about instruction set extensions will fail at compile time. Each bug takes minutes to find because its symptom is immediate.

You do not need to do this on every commit. Once per release is enough for most drivers. The cost is low (a QEMU guest and an hour of your time), and the bugs you catch are the bugs your users would otherwise report.

29.8.17 The Realities of Non-x86 FreeBSD

A practical note on which architectures matter in the FreeBSD world today. At the time of writing, `amd64` is the overwhelmingly dominant production architecture, followed by `arm64` (growing rapidly in embedded and server deployments), `riscv` (growing in research and specific embedded niches), and `powerpc64` (used in certain HPC and legacy environments). The older `i386` platform is still supported for legacy deployments. The ARM 32-bit family (`armv7`) is supported but less common than `arm64`.

For a driver that is expected to live in the mainline tree, working correctly on `amd64`, `arm64`, and at least compiling on `riscv` is usually sufficient. The `powerpc64` port is a useful test for big-endian issues even if you do not have end users on the platform. The `i386` port is a useful test for 32-bit word-size issues. Supporting all of these is the project-wide default; dropping support for any of them is a decision that needs a specific reason.

For a driver that is maintained outside the tree, the question is whose hardware you are supporting. If your users are on `amd64` only, you can legitimately target only that platform. But the habit of writing portable code costs little and protects against surprise, and you will often find that the same driver turns out to be useful on a platform you did not originally target.

29.8.18 Aside: CHERI-BSD and Morello

One corner of the FreeBSD universe sits outside the production architectures and deserves a brief note for curious readers. If you ever encounter a board called **Morello**, or an operating system tree called **CHERI-BSD**, you are looking at a research platform rather than a mainline target. It is worth knowing what these names mean, because they change assumptions that this chapter has otherwise treated as universal.

What CHERI is. CHERI stands for Capability Hardware Enhanced RISC Instructions. It is an instruction-set extension developed jointly by the University of Cambridge Computer Laboratory and SRI International. The goal is to replace the plain pointer model that C has used since the 1970s with **capability pointers**: pointers that carry their own bounds, permissions, and a hardware-checked validity tag. A capability is not just an integer address. It is a small object that the processor knows how to dereference, and it traps if the program tries to use it outside the region it was granted access to.

The practical effect is that many classes of memory-safety bug become hardware-detectable. A buffer overflow that walks off the end of an array no longer corrupts adjacent memory; it traps. A use-after-free no longer quietly reads whatever lives at the old address; the freed capability can be revoked so its tag bit becomes invalid, and any attempt to dereference it traps. Pointer forgery in the classical sense becomes impossible, because capabilities cannot be synthesised from plain integers.

What Morello is. Morello is Arm's prototype implementation of CHERI on top of the Armv8.2-A instruction set. The Morello Program, announced by Arm together with UK Research and Innovation in 2019, produced the first widely available CHERI-capable hardware: development boards and a reference system-on-chip that researchers, universities, and some industry partners could obtain and program. The Morello board is the closest thing the world currently has to a production-grade CHERI machine, but it is explicitly a research prototype. It is not sold as a general-purpose server platform, and it is not expected to become one in its current form.

What CHERI-BSD is. CHERI-BSD is a fork of FreeBSD maintained by the Cambridge CHERI project that targets CHERI hardware, including Morello. It is the operating system in which most of the practical work of porting userland and kernel code to a capability architecture takes place. CHERI-BSD is a research platform. It tracks FreeBSD closely but is not a mainline FreeBSD release, it is not supported by the FreeBSD Project in the same sense as amd64 or arm64, and it is not a target that a typical driver author needs to ship for today. Its purpose is to let researchers and early adopters study what happens to a real operating system kernel when the pointer model changes beneath it.

What a driver author needs to know. Even if you never touch CHERI-BSD, it is useful to know the shape of the assumptions it breaks, because those assumptions appear in ordinary driver code without anyone noticing. Three points stand out.

First, **capability pointers carry sub-object bounds**. A pointer into the middle of a `struct softc` is not merely a byte address; it is bounded to whatever subrange the allocator or language construct gave it. If a driver uses pointer arithmetic to walk from one field to another without going through the enclosing pointer, that arithmetic can trap on CHERI even when it appeared harmless on amd64. The remedy is usually to derive pointers from the structure's base pointer using proper C idioms and to avoid casts that erase type information. This is the same discipline this chapter has been recommending for non-CHERI portability; CHERI simply makes the failure mode immediate rather than occasional.

Second, **freed capabilities can be revoked**. CHERI-BSD can sweep memory to invalidate capabilities whose backing allocation has been released, so that dangling pointers cannot be used even indirectly. A driver that stashes a pointer in a `sysctl` node, a device-tree entry, or some cross-subsystem handle, and then frees the underlying allocation without telling the kernel, can leave behind a revoked capability. On amd64 the use-after-free might simply read garbage; on CHERI it traps deterministically. That is generally a good thing, but it means the driver's lifecycle discipline has to be honest about every reference it hands out.

Third, **kernel APIs look similar but carry capability semantics underneath**. The `bus_space(9)` and `bus_dma(9)` interfaces look the same at the source level on CHERI-BSD as on mainline FreeBSD, but the values they return are capabilities rather than plain addresses. A driver that uses these APIs through the intended accessors will usually port with little change. A driver that casts a `bus_space_handle_t` to a `uintptr_t` and then back, or that manufactures pointers to device memory by integer arithmetic, will break, because the capability metadata is lost in the integer round-trip.

Some drivers port to CHERI-BSD with minimal changes because they already stayed inside the accessors this chapter has been recommending. Others need explicit **capability discipline**: reviewing every cast, every hand-

rolled pointer arithmetic, and every place where a pointer is stored in a non-pointer type. The CHERI-BSD project publishes porting experience reports for various subsystems, and reading one or two of them is a fast way to see what that discipline looks like in practice. The volume of change needed varies widely by driver, and no one should assume either that a given driver is trivially CHERI-clean or that it needs a total rewrite, without actually trying.

Where to look. The foundational technical description is the 2014 ISCA paper *The CHERI Capability Model: Revisiting RISC in an Age of Risk*, which is listed in the FreeBSD documentation tree at `/usr/src/share/doc/papers/bsdreferences.bib`. Subsequent papers from the same group describe the Morello implementation, capability revocation, compiler support, and real-world porting experience. For practical materials, the CHERI-BSD project and the Cambridge Computer Laboratory’s CHERI research group maintain documentation, build instructions, and porting notes; search for the project names rather than relying on a URL printed here, because research project sites move over time.

The point of mentioning CHERI-BSD in a portability chapter is not to push you toward it. It is to tell you that the habits this chapter has been teaching, using accessors rather than raw pointers, respecting the distinction between addresses and opaque handles, and avoiding gratuitous casts, pay dividends on more than one architecture. They are the same habits that make a driver survive on `arm64`, on `riscv`, and on experimental capability machines. The further you stay from clever pointer tricks, the smaller your driver’s CHERI surprise surface becomes, even if you never compile for CHERI at all.

29.8.19 Wrapping Up Section 5

You have met the three axes along which architectures differ, and the FreeBSD idioms that address each. Endianness is handled by the endian helpers; alignment by `bus_read_*` and `memcpy`; word size by fixed-width types. Memory barriers handle the ordering of accesses that are visible to the device, and `bus_dmamap_sync` handles the coherency between CPU caches and DMA buffers. Used consistently, these idioms reduce architectural portability to almost no extra work per driver and almost no extra risk. A driver that uses them well on `amd64` will usually compile cleanly and run correctly on `arm64`, `riscv`, `powerpc`, and the others with nothing more than a recompile and a smoke test.

In Section 6, we turn from architectural portability to build-time flexibility: how to use conditional compilation and kernel build options to select features, enable debugging, and switch between real and simulated backends without cluttering the source with `#ifdef` soup.

29.9 Section 6: Conditional Compilation and Build-time Flexibility

Conditional compilation is the art of making one source tree produce different binaries depending on what was requested at build time. It is tempting, it is sometimes necessary, and it is spectacularly easy to abuse. A driver that uses `#ifdef` thoughtfully is cleaner and more maintainable than one that does not. A driver that reaches for `#ifdef` at every decision becomes a thicket that no one wants to touch.

This section explains when conditional compilation is the right tool, which forms of it are preferred in FreeBSD, and how to keep the source readable in the presence of real build-time variation.

29.9.1 The Three Levels of Conditional Compilation

Conditional compilation in a FreeBSD driver happens at three distinct levels. Each has a different purpose, and choosing the right level for a given problem prevents most of the ugliness that conditional compilation is infamous for.

Level one: architecture-specific code. Sometimes you must write different code for different CPU architectures. An example is a specific byte-swapping inline assembly for a platform that lacks a general compiler builtin. FreeBSD handles this by putting the per-architecture code in a per-architecture file. Look at how `/usr/src/sys/amd64/include/_bus.h` differs from `/usr/src/sys/arm64/include/_bus.h`. Each file contains the definitions appropriate for its architecture. The core source does not use `#ifdef __amd64__` to select between them; it includes `<machine/bus.h>`, and the kernel build picks the right concrete file via include paths. This mechanism is called the **machine-specific header**, and you should prefer it whenever you need more than a few lines of per-architecture code. If you put a large block of `#ifdef __arm64__` in a driver source file, you are probably reinventing this mechanism badly.

Level two: optional features. Optional features are things that your driver can be built with or without, and whose presence is a choice, not an architectural necessity. Simulation backends, debug tracing, sysctl nodes, optional protocol support. FreeBSD handles these through the kernel options system: you add options `PORTDRV_DEBUG` to the kernel configuration or pass `-DPORTDRV_DEBUG` to make. Inside the code, you guard the relevant blocks with `#ifdef PORTDRV_DEBUG`. Because the flag is yours, you control it cleanly, and the feature is either compiled in or not.

Level three: API compatibility. FreeBSD evolves. A macro gets renamed, a function signature changes, a behaviour that used to be implicit becomes explicit. A driver that wants to compile on both an older release and a newer release uses `__FreeBSD_version` to branch on the kernel version. This is the most subtle form of conditional compilation, because the same logical operation is expressed two ways and you must maintain both until the older version is no longer supported. The right approach is to keep these branches small and to refactor them into short helper functions or macros.

29.9.2 The `__FreeBSD_version` Macro

Every FreeBSD kernel defines `__FreeBSD_version` in `/usr/src/sys/sys/param.h`. It is a single integer that encodes the release number: for example, 1403000 corresponds to FreeBSD 14.3-RELEASE. You can use it to guard code that depends on a specific API change:

```
#if __FreeBSD_version >= 1400000
    /* Use the new if_t API. */
    if_setflags(ifp, flags);
#else
    /* Use the older direct struct access. */
    ifp->if_flags = flags;
#endif
```

Two rules about `__FreeBSD_version`. First, use it sparingly; every guard is a branch that must be tested in both configurations. Second, abstract the branch into a helper as soon as it appears more than twice. If you need

`if_setflags` in ten places, write a helper macro in a compatibility header and use it everywhere, rather than duplicating the `#if` at every call site.

Compatibility is a compounding cost. Two `#if` blocks are manageable, and twenty are a maintenance burden. Make every one count, and retire them as soon as the old release drops out of support.

For a feel of what this looks like in tree, open `/usr/src/sys/dev/gve/gve_main.c`. The Google Virtual Ethernet driver is current, in-tree, and supports several releases at once, so its `__FreeBSD_version` guards document recent API migrations with minimum ceremony. Two short examples stand out. The first is in the attach path, where the driver sets the interface flags:

```
#if __FreeBSD_version >= 1400086
    if_setflags(ifp, IFF_BROADCAST | IFF_SIMPLEX | IFF_MULTICAST);
#else
    if_setflags(ifp, IFF_BROADCAST | IFF_SIMPLEX | IFF_MULTICAST | IFF_KNOWSEPOCH);
#endif
```

Older releases required drivers to set `IFF_KNOWSEPOCH` to declare that they used the network epoch correctly. From 1400086 onward the kernel no longer needs that opt-in, and drivers stop setting the flag. The branch is small, the accessor call (`if_setflags`) is the same on both sides, and only the flag list differs. This is the minimal shape these guards should take.

The second example is in the module declaration, at the end of the same file:

```
#if __FreeBSD_version < 1301503
static devclass_t gve_devclass;

DRIVER_MODULE(gve, pci, gve_driver, gve_devclass, 0, 0);
#else
DRIVER_MODULE(gve, pci, gve_driver, 0, 0);
#endif
```

At 1301503, the `DRIVER_MODULE` macro stopped taking a `devclass_t` argument; newer releases pass `0` in its place and older releases still need a real `devclass_t`. Both branches still register the driver with `DRIVER_MODULE`; the difference is a single argument and the static variable that feeds it. When your own driver needs to span this boundary, your guards should look as plain as these. If they do not, it is usually a sign that the compatibility shim wants to live in a small helper macro rather than at every call site.

29.9.3 The Kernel Options Mechanism

For driver-specific options, FreeBSD's kernel options machinery gives you a clean way to expose feature flags. The mechanism has three parts:

1. The option is declared in a per-driver options file that lives alongside the driver's source, for in-tree drivers. For out-of-tree drivers like your reference driver, you define the option via a `CFLAGS+= -DPORTDRV_SOMETHING` in the Makefile and guard code with `#ifdef PORTDRV_SOMETHING`.

2. The option is set or unset at build time. For kernel builds, it goes into the kernel configuration file (`/usr/src/sys/amd64/conf/GENERIC` or a custom file) as options `PORTDRV_SOMETHING`. For module builds, it goes into the Makefile or on the make command line as `-DPORTDRV_SOMETHING`.
3. The code reads the option with `#ifdef PORTDRV_SOMETHING`.

This is a slim mechanism, but it is enough for most needs. A driver that uses it carefully has a handful of options, each guarding a small, well-defined piece of functionality, and each with a plain-English description in the README.

29.9.4 Simulated Mode as a Build Option

A good example of the kernel-options pattern is a simulated mode. The idea is to let the driver be built and loaded without any real hardware, by selecting a software backend that mimics the device. You have already seen this pattern in Section 3; now we express it as a compile-time flag.

The Makefile adds:

```
.if defined(PORTDRV_WITH_SIM) && ${PORTDRV_WITH_SIM} == "yes"
SRCS+= portdrv_sim.c
CFLAGS+= -DPORTDRV_WITH_SIM
.endif
```

The core registers the simulated backend in its module load if the flag is set:

```
static int
portdrv_modevent(module_t mod, int type, void *arg)
{
    switch (type) {
        case MOD_LOAD:
#ifdef PORTDRV_WITH_SIM
            /* Create a single simulated instance. */
            portdrv_sim_create();
#endif
            return (0);
        case MOD_UNLOAD:
#ifdef PORTDRV_WITH_SIM
            portdrv_sim_destroy();
#endif
            return (0);
    }
    return (0);
}
```

And `portdrv_sim.c` is only compiled if the flag is set.

This pattern has several benefits at once. The driver can be developed on a machine without the real hardware. The test suite can be run on any FreeBSD VM. Reviewers can load the driver and exercise the core logic, which is usually where the interesting bugs are, without needing the hardware. And the production builds, which do not pass `PORTDRV_WITH_SIM=yes`, exclude the simulation code entirely so that no stub backend is present in shipping binaries.

29.9.5 Debug Builds

The second typical option is a debug build. Real drivers usually have a `PORTDRV_DEBUG` option that turns on verbose logging, additional assertions, and sometimes slower paths that validate invariants more aggressively. The pattern is:

```
#ifdef PORTDRV_DEBUG
#define PD_DBG(sc, fmt, ...) \
    device_printf((sc)->sc_dev, "DEBUG: " fmt "\n", ##__VA_ARGS__)
#else
#define PD_DBG(sc, fmt, ...) do { (void)(sc); } while (0)
#endif
```

Everywhere in the source that needs a conditional debug message uses `PD_DBG(sc, "got %u bytes", len)`. In a release build, the macro evaluates to nothing, so the message is compiled away entirely. In a debug build, the macro prints. The call sites are not guarded with `#ifdef`; the macro is.

This is the key trick for keeping conditional compilation readable: **hide the `#ifdef` inside a macro, and expose a uniform call at the use site**. The source reads the same way in both configurations, and the reader does not have to mentally unroll half a dozen `#if` branches to understand the code.

29.9.6 Feature Flags Through `sysctl` and `dmesg`

A related but distinct question is: how does the user or an operator discover what features this driver was built with? A production driver typically answers this with a `sysctl` tree and a printed banner at module load.

At module load, the driver prints a short message that identifies itself and the features it supports:

```
printf("portdrv: version %s loaded; backends:"
#ifdef PORTDRV_WITH_PCI
    " pci"
#endif
#ifdef PORTDRV_WITH_USB
    " usb"
#endif
#ifdef PORTDRV_WITH_SIM
    " sim"
#endif
    "\n", PORTDRV_VERSION);
```

The output in the kernel log tells an operator exactly which backends are compiled in. A build that is supposed to have USB support but whose dmesg shows only backends: `pci` reveals the misconfiguration at a glance.

At runtime, a `sysctl` tree exposes the same information machine-readably:

```
dev.portdrv.0.version: 2.0
dev.portdrv.0.backend: pci
dev.portdrv.0.features.dma: 1
dev.portdrv.0.features.debug: 0
```

A script can read these, a monitoring system can alert on them, and a bug report can include them without the reporter having to guess.

29.9.7 Avoiding `#ifdef` Sprawl

The biggest single pitfall of conditional compilation is its tendency to sprawl. A feature is added and guarded with `#ifdef FEATURE_A`. A month later another feature is added and guarded with `#ifdef FEATURE_B`. Six months later a maintainer adds a bug fix that touches both features, and it acquires `#if defined(FEATURE_A) && defined(FEATURE_B)`. Soon every function has five guards, each guarding a handful of lines, and the reader cannot trace a single path through the code without mentally resolving a cross-product of `#if` branches.

Three rules keep sprawl in check.

Keep the guards coarse. Guard an entire function, or an entire file, rather than scattered lines in the middle of a function. If you find yourself adding `#ifdef` inside the body of a function more than once, the function should probably be split: one version for `FEATURE_A`, one for `!FEATURE_A`, and a small dispatcher at the call site.

Hide the guards in macros. If you need a conditional operation in many places, wrap it in a macro or inline function that has an empty form in the `#else` branch. The call sites then do not have guards at all.

Review the guard set periodically. A feature flag that no one has disabled for two years is effectively mandatory. Delete it. A flag that guards a feature that was removed is dead code. Delete that too. A flag that means something different now than when it was introduced should be renamed.

29.9.8 Architecture-Specific Conditionals

There are situations where the right tool truly is an `#if` on the architecture macro. An example from real code, from `/usr/src/sys/dev/vnic/nicvf_queues.c`:

```
#if BYTE_ORDER == BIG_ENDIAN
    return ((i & ~3) + 3 - (i & 3));
#else
    return (i);
#endif
```

This function computes an index whose layout depends on the byte order of the host. There is no way to hide this in a macro because the two forms are genuinely different. The right thing to do is exactly what the real driver does: guard the minimum possible, comment what the two branches do, and move on. Do not try to eliminate every `#if`.

The key is discipline. Use `#if BYTE_ORDER` only where a real architectural difference exists, and keep the conditional block as small as possible. A five-line `#if` block is readable. A fifty-line one usually is not.

29.9.9 Optional Subsystem Support

Sometimes a driver supports features that depend on optional subsystems. For example, a network driver might support checksum offload only if the kernel was built with options `INET`. The idiom is:

```
#ifdef INET
    /* Set up IPv4 checksum offload. */
#endif
#ifdef INET6
    /* Set up IPv6 checksum offload. */
#endif
```

These guards are provided by the kernel build system automatically; you do not need to define them yourself. But you do need to respect them. A driver that uses `struct ip` unconditionally will fail to build when options `INET` is not set, even though the kernel supports compiling without IPv4. Check the build in the configuration your users might use; it is usually just a matter of adding a guard.

29.9.10 Avoiding Runtime Feature Checks That Should Be Compile-Time

A subtle mistake is to implement what ought to be a compile-time decision at runtime. If your driver has a simulation backend and a PCI backend, and the user picks one at build time, there is no reason to carry both in the binary. Making the choice at runtime, for example through a `sysctl` that toggles which backend is used, wastes memory and complicates testing. Make the choice at build time, exclude the unused backend from the build, and the driver is smaller and simpler.

The converse error is also possible: turning a runtime choice into a compile-time one. If the same binary must support multiple pieces of hardware simultaneously, the choice is genuinely runtime, and a compile-time flag is the wrong tool. The right question to ask each time is: “Do I need both behaviours in the same loaded driver?” If yes, runtime. If no, build-time.

29.9.11 Options Files and Kernel Configuration

For drivers that ship with the kernel tree itself, FreeBSD provides a more structured way to expose build options: the options file. Each options file sits next to the driver’s source and lists the options the driver recognises, along with a short description and a default value. The file is named `options` and follows a simple format:

```
# options - portdrv options
PORTDRV_DEBUG
PORTDRV_WITH_SIM
PORTDRV_WITH_PCI
```

Options listed this way can be enabled in the kernel configuration file, typically in `/usr/src/sys/amd64/conf/GENERIC` or a custom kernel config, as:

```
options PORTDRV_DEBUG
options PORTDRV_WITH_SIM
```

The kernel build system takes care of propagating the `-D` flags to the compiler. Inside the driver, the code guards with `#ifdef PORTDRV_DEBUG` exactly as it would for a Makefile-defined option. The difference is organisational: options files live in the source tree next to the driver, so a reader picking up an unfamiliar driver knows exactly which options it recognises.

For out-of-tree drivers, the Makefile-based approach is simpler and is what we have used in this chapter. For in-tree drivers that expect to be built as part of a kernel configuration, the options file is the canonical mechanism.

29.9.12 Module Load Hints and `device.hints`

A related but distinct topic is the `device.hints` mechanism. Hints are a way to configure devices at boot time, before the driver has fully initialised. They live in `/boot/device.hints` and take the form:

```
hint.portdrv.0.mode="simulation"
hint.portdrv.0.debug="1"
```

Inside the driver, these are read with `resource_string_value` or `resource_int_value`:

```
int mode;
const char *mode_str;

if (resource_string_value("portdrv", 0, "mode", &mode_str) == 0) {
    /* Apply the hint. */
}
```

Hints are a way to configure the driver at runtime without recompilation. They are especially useful for embedded systems where the device parameters are known at system design time but not at driver compile time. For a driver that is portable across hardware variants, hints can be the mechanism by which each variant is recognised.

Hints are not a replacement for compile-time feature selection. They are complementary. Compile-time flags decide what the driver can do; hints decide what it actually does at a given boot. A driver can have both, and most mature drivers do.

29.9.13 Feature Flags Through `MODULE_PNP_INFO`

For drivers that attach to hardware identified by vendor and device IDs, `MODULE_PNP_INFO` is a way to declare that identification in the module's metadata. The kernel and userland tools read this metadata to decide which driver to load when a specific piece of hardware is present, and `devd(8)` uses it to match devices to modules.

A typical declaration looks like this:

```
MODULE_PNP_INFO("U32:vendor;U32:device", pci, portdrv_pci,  
    portdrv_pci_ids, nitems(portdrv_pci_ids));
```

where `portdrv_pci_ids` is an array of identification records that the driver's probe function also consults. The metadata is embedded in the `.ko` file and is read by `kldxref(8)` to build an index used at boot and at device attachment.

For a portable driver with multiple backends, each backend declares its own `MODULE_PNP_INFO`. The PCI backend declares PCI IDs; the USB backend declares USB IDs; the simulation backend declares nothing because it has no hardware. The kernel picks up the right backend automatically when the matching hardware is present.

29.9.14 The Limits of `__FreeBSD_version`

`__FreeBSD_version` is valuable, but it has a limit. It tells you what release of the kernel you are compiling against, not what release is actually running. Since kernel modules are tightly coupled to the kernel they load into, these are usually the same, but there are edge cases: modules built on a slightly older tree and loaded into a slightly newer one, or modules built with a custom patch set. In these cases, `__FreeBSD_version` may mislead you.

The more robust approach for runtime decisions is to query the kernel directly through a `sysctl`:

```
int major = 0;  
size_t sz = sizeof(major);  
  
sysctlbyname("kern.osreldate", &major, &sz, NULL, 0);  
if (major < 1400000) {  
    /* Older kernel. Use the legacy code path. */  
}
```

This reads the actual running kernel's version. For most drivers it is overkill; for drivers that must adapt at runtime, it is the right tool. The usual compile-time `__FreeBSD_version` is a statement about the kernel at build time; `kern.osreldate` is a statement about the kernel at run time.

For driver code specifically, the compile-time check is almost always what you want. The module is almost always loaded into the kernel it was built against, and the kernel's ABI check via `MODULE_DEPEND` catches the rare mismatches.

29.9.15 Organising Compatibility Shims

When `__FreeBSD_version` guards begin to appear in more than a few places, the right move is to centralise them in a compatibility header. The typical layout is:

```
/* portdrv_compat.h - compatibility shims for FreeBSD API changes. */

#ifndef _PORTDRV_COMPAT_H_
#define _PORTDRV_COMPAT_H_

#include <sys/param.h>

#if __FreeBSD_version >= 1400000
#include <net/if.h>
#include <net/if_var.h>
#define PD_IF_SETFLAGS(ifp, flags)  if_setflags((ifp), (flags))
#define PD_IF_GETFLAGS(ifp)        if_getflags(ifp)
#else
#define PD_IF_SETFLAGS(ifp, flags)  ((ifp)->if_flags = (flags))
#define PD_IF_GETFLAGS(ifp)        ((ifp)->if_flags)
#endif

#if __FreeBSD_version >= 1300000
#define PD_CV_WAIT(cvp, mtxp)  cv_wait_unlock((cvp), (mtxp))
#else
#define PD_CV_WAIT(cvp, mtxp)  cv_wait((cvp), (mtxp))
#endif

#endif /* !_PORTDRV_COMPAT_H_ */
```

The core code uses `PD_IF_SETFLAGS(ifp, flags)` and `PD_CV_WAIT(cvp, mtxp)` in place of the bare kernel calls. The compatibility header is the one place where `__FreeBSD_version` appears, and the guards are close to each other rather than scattered. When the oldest supported release is dropped, you delete the `else` branches and leave the modern names in place.

This pattern is especially valuable for drivers that must support a range of kernel releases, such as out-of-tree drivers consumed by users on different systems. An in-tree driver typically only has to support the current release plus whichever earlier ones the project promises to support, which is usually one or two.

29.9.16 Build-Time Telemetry

A small but useful trick is to embed build-time telemetry in the module. A single line in the Makefile:

```
CFLAGS+=      -DPORTDRV_BUILD_DATE='"${:!date "+%Y-%m-%dT%H:%M:%S"!}'"
```

captures the build timestamp into a string the driver can print at load time. Combined with a version string and a list of enabled backends, the module's load banner becomes a small diagnostic artefact:

```
portdrv: version 2.0 built 2026-04-19T14:32:17 loaded, backends: pci sim
```

When a user reports a bug, they can paste the banner into the bug report, and you know exactly which version they are running. This is trivial to add and immensely valuable over the life of the driver.

29.9.17 Wrapping Up Section 6

Conditional compilation is a power tool. Used with restraint, it keeps optional features clean, lets you support multiple FreeBSD releases, and enables simulation backends without polluting production builds. Used carelessly, it turns source into a maze. The rules for restraint are: prefer machine-specific headers over `#ifdef __arch__`, keep option flags coarse, hide guards inside macros, and delete flags that have outlived their purpose. Options files, device hints, `MODULE_PNP_INFO`, and a compatibility header give you a small family of tools for managing build-time variation without cluttering the core logic.

Section 7 takes a brief detour outside FreeBSD. Drivers sometimes need to share code with NetBSD or OpenBSD, and while that is not a primary goal of this book, knowing the lay of the land saves you from design choices that would hurt cross-BSD portability even when you do not immediately need it.

29.10 Section 7: Adapting for Cross-BSD Compatibility

The three open-source BSDs, FreeBSD, NetBSD, and OpenBSD, share a long history. At the source-code level they diverged from a common ancestor, and although each has evolved in its own direction, they still recognise one another. A device driver that is carefully written in the FreeBSD style can often be ported to NetBSD or OpenBSD with meaningful but bounded effort, and a driver that is casually written cannot.

This section is deliberately short. This is a FreeBSD book, and turning Chapter 29 into a cross-BSD porting manual would crowd out material that belongs in later chapters. What we will do here is enough to let you recognise which parts of a FreeBSD driver travel well and which parts need translation. You will not learn how to port; you will learn what to design against, so that porting becomes a possibility rather than an impossibility.

29.10.1 Where the BSDs Agree

The areas where FreeBSD, NetBSD, and OpenBSD agree most strongly are the ones your driver leans on most heavily:

- **C language and toolchain.** All three use the same C standards and similar compilers (clang on FreeBSD and OpenBSD; gcc on NetBSD with clang available).
- **The general shape of kernel modules.** All three support loadable kernel modules with a similar life cycle: load, init, attach, detach, unload.

- **The general shape of device drivers.** Probe, attach, detach. Per-instance state. Resource allocation. Interrupt handlers. Newbus-style device trees (NetBSD has `config`; FreeBSD has `Newbus`; OpenBSD has `autoconf`).
- **Standard C library and POSIX.** Even in userland, the three systems share enough that most userland helpers port trivially.
- **Many device-specific protocols and wire formats.** An Ethernet frame is an Ethernet frame, and an NVMe command is an NVMe command, on any of the three.

A driver whose interesting logic is above the kernel API layer, parsing protocols, managing state machines, and coordinating transfers, is largely portable. The interesting logic typically doesn't know about `bus_dma` or `device_t`; it knows about the hardware's programming model.

29.10.2 Where the BSDs Differ

The areas where the three BSDs differ are concentrated in the kernel APIs:

- **Bus framework.** FreeBSD's `Newbus`, NetBSD's `autoconf(9)`, and OpenBSD's `autoconf(9)` (same name, different machinery) are not source compatible. The callbacks are similar in spirit but have different signatures.
- **DMA abstraction.** FreeBSD's `bus_dma(9)` has close cousins in NetBSD and OpenBSD called `bus_dma(9)` as well, but the types and some of the function signatures differ. The general model is shared; the exact API is not.
- **Memory allocation.** `malloc(9)` exists on all three with the same idea but slightly different function families and flags.
- **Synchronisation primitives.** Mutexes, condition variables, and epochs exist in all three, but the specific names and flags differ.
- **Network interfaces.** FreeBSD's `ifnet` and `if_t` opaque handle, NetBSD's `struct ifnet`, and OpenBSD's `struct ifnet` look similar but have diverged in the details.
- **Character devices.** FreeBSD's `cdev` framework, NetBSD's `cdevsw`, and OpenBSD's character-device machinery differ in how they register and dispatch.

This is not a complete list, but it captures the usual sources of porting pain.

29.10.3 The Cross-BSD-Friendly Style

If you want your driver to be portable across BSDs without committing to maintaining three versions, the cheapest long-term strategy is to write it in a style that isolates the FreeBSD-specific parts. The patterns are the ones you have already learned in this chapter:

- **Isolate hardware-dependent code.** A backend interface hides the bus APIs. Swapping FreeBSD's `bus_dma` for NetBSD's involves changing the backend implementation, not the core.
- **Wrap kernel primitives you use often.** If `malloc(M_TYPE, size, M_NOWAIT)` is replaced in NetBSD by a subtly different spelling, wrapping it in `portdrv_alloc(size)` means one place to change, not a hundred.
- **Keep core logic free of kernel subsystem dependencies.** The request queue, the state machine, and the protocol parsing do not need to include `sys/bus.h` or `net/if_var.h`.

- **Separate registration from logic.** The `DRIVER_MODULE` macro and its equivalents are a small, localised piece of code per driver. Putting it in a dedicated file per BSD is easier than sprinkling it through the driver.
- **Use standard types.** `uint32_t` and `size_t` exist on all three BSDs. `u_int32_t` and `int32` are older spellings that are more portable in the narrow sense but less idiomatic on FreeBSD.

If you have followed the file layout in Section 4, much of this is already in place. The core in `portdrv_core.c` is kernel-subsystem-agnostic. The backends in `portdrv_pci.c` and `portdrv_usb.c` are where the FreeBSD-specific code lives. A hypothetical NetBSD port would add `portdrv_pci_netbsd.c` and keep the core unchanged, up to small type mismatches.

29.10.4 Compatibility Wrappers

For the cases where you really do need the same source to compile on multiple BSDs, the standard technique is a compatibility header. Something like:

```
/* portdrv_os.h - OS-specific wrappers */
#ifdef __FreeBSD__
#include <sys/malloc.h>
#define PD_MALLOC(sz, flags) malloc((sz), M_PORTDRV, (flags))
#define PD_FREE(p)          free((p), M_PORTDRV)
#endif

#ifdef __NetBSD__
#include <sys/malloc.h>
#define PD_MALLOC(sz, flags) kmem_alloc((sz), (flags))
#define PD_FREE(p)          kmem_free((p), sz)
#endif

#ifdef __OpenBSD__
#include <sys/malloc.h>
#define PD_MALLOC(sz, flags) malloc((sz), M_DEVBUF, (flags))
#define PD_FREE(p)          free((p), M_DEVBUF, sz)
#endif
```

The core uses `PD_MALLOC` and `PD_FREE` everywhere. One header changes per new OS; the core never changes. Apply the same technique to locks, to DMA, to printing, to any FreeBSD primitive that differs in the other BSDs. The result is a driver whose OS-specific surface is a single file and whose core is shared.

Keep in mind the tradeoff. Writing the driver in this style costs you a little upfront: you cannot simply call `malloc` the FreeBSD way; you have to call your wrapper. If you do not actually need cross-BSD portability, the cost buys you nothing. If you do need it, the cost is far less than the alternative of maintaining three drivers.

29.10.5 Listing the FreeBSD-Specific APIs You Use

A useful exercise before you even consider cross-BSD work is to catalogue the FreeBSD-specific APIs your driver relies on. Go through the source and list every function, macro, and structure name that is unique to FreeBSD. The list typically includes:

- `bus_alloc_resource_any`, `bus_release_resource`
- `bus_setup_intr`, `bus_teardown_intr`
- `bus_read_1`, `bus_read_2`, `bus_read_4`, and the write variants
- `bus_dma_tag_create`, `bus_dmamap_load`, `bus_dmamap_sync`, `bus_dmamap_unload`
- `callout_init_mtx`, `callout_reset`, `callout_stop`, `callout_drain`
- `malloc`, `free`, `MALLOC_DEFINE`
- `mtx_init`, `mtx_lock`, `mtx_unlock`, `mtx_destroy`
- `sx_init`, `sx_slock`, `sx_xlock`
- `device_printf`, `device_get_softc`, `device_set_desc`
- `DRIVER_MODULE`, `MODULE_VERSION`, `MODULE_DEPEND`
- `DEVMETHOD`, `DEVMETHOD_END`
- `SYSCTL_ADD_NODE`, `SYSCTL_ADD_UINT`, etc.
- `if_alloc`, `if_free`, `ether_ifattach`, `if_attach`
- `cdevsw`, `make_dev`, `destroy_dev`

Each entry in this list is a candidate for a wrapper. Not every one needs to be wrapped, and a driver that wraps everything is overengineered. But the list tells you where the porting work would happen if it ever needed to, and it is a useful artifact for maintenance even without any cross-BSD plans.

29.10.6 When to Commit to Cross-BSD Support

Cross-BSD support is not free. It imposes an ongoing cost on development, because every feature must be tested on every supported BSD. It imposes a cost on readability, because wrappers replace direct API calls. It imposes a cost on performance, though usually a small one, because the wrappers add indirection.

That cost is worth paying when there is a clear reason. Examples:

- **You have users on multiple BSDs.** A device vendor that wants their product supported on both FreeBSD and NetBSD has a business reason to absorb the complexity.
- **The driver is community-developed across BSDs.** Open-source projects sometimes have contributors on all three BSDs, and unifying the code base reduces duplicate work.
- **The driver is funded by a project with cross-BSD requirements.** Some academic projects, research infrastructures, or embedded deployments have mixed-OS requirements built into their plans.

If none of these apply, do not preemptively engineer for cross-BSD support. Follow the patterns in this chapter, because they are good FreeBSD practice in their own right, and stay within FreeBSD. If the need for cross-BSD support appears later, the patterns already in place will make the eventual port cheaper than it would have been otherwise.

29.10.7 A Concrete Wrapping Example

To make the cross-BSD wrapping approach feel concrete, consider a driver that uses a callout timer. On FreeBSD, the API is the callout family. The code might look like:

```
callout_init_mtx(&sc->sc_timer, &sc->sc_mtx, 0);
callout_reset(&sc->sc_timer, hz / 10, portdrv_timer_cb, sc);
/* ... later ... */
callout_stop(&sc->sc_timer);
callout_drain(&sc->sc_timer);
```

On NetBSD, the analogous API is the callout family too, but the signatures differ slightly. On OpenBSD, timeout is the equivalent name. A cross-BSD driver wraps the usage:

```
/* portdrv_os.h */
#ifdef __FreeBSD__
typedef struct callout portdrv_timer_t;
#define PD_TIMER_INIT(t, m)    callout_init_mtx((t), (m), 0)
#define PD_TIMER_ARM(t, ticks, cb, arg) \
    callout_reset((t), (ticks), (cb), (arg))
#define PD_TIMER_STOP(t)      callout_stop(t)
#define PD_TIMER_DRAIN(t)     callout_drain(t)
#endif

#ifdef __NetBSD__
typedef struct callout portdrv_timer_t;
/* ... NetBSD-specific definitions ... */
#endif

#ifdef __OpenBSD__
typedef struct timeout portdrv_timer_t;
#define PD_TIMER_INIT(t, m)    timeout_set((t), (cb), (arg))
#define PD_TIMER_ARM(t, ticks, cb, arg) \
    timeout_add((t), (ticks))
/* ... */
#endif
```

The core code uses the PD_TIMER_* macros. The per-OS branches in the header translate between the abstract name and each OS's concrete API. This is the wrapper approach in miniature: one abstraction, many implementations.

Notice that the wrapper does more than rename calls. It also papers over genuine differences in how the APIs work. FreeBSD's callout_init_mtx binds the callout to a mutex so the callback runs with the mutex held. OpenBSD's timeout_set does not have this binding; the callback must acquire the mutex itself. The wrapper macros absorb this difference in the core's favour, by presenting the FreeBSD semantics as the canonical shape.

On OpenBSD, the implementation of `PD_TIMER_INIT` can register a shim callback that acquires the mutex before calling the user's callback.

This shows both the power and the cost of wrapping. The power is that the core code does not need to know about the difference. The cost is that the wrapper layer has non-trivial logic of its own, which must be maintained and tested. Wrapping is not free, and the wrapper layer grows as the set of wrapped APIs grows.

29.10.8 What “Porting” Actually Involves

A realistic cross-BSD port is rarely a single commit. It is a sequence of small steps, each of which makes the driver a little more portable before the final move to the target OS:

1. **Audit.** List every FreeBSD-specific API the driver uses. The list becomes the work plan.
2. **Wrap.** Introduce wrappers, one API at a time. For each wrapper, replace every call in the driver with the wrapper. Commit after each API.
3. **Test on FreeBSD.** Confirm the wrappers do not change behaviour on FreeBSD. This step matters: a bug introduced during wrapping must be caught before the port, not during it.
4. **Build on the target.** Add the target-specific header file. Implement the wrappers for the target OS. Build and fix compile errors until the driver links.
5. **Load on the target.** Load the module. Fix any missing symbols or dependencies.
6. **Test on the target.** Exercise the driver's features. Fix the bugs that appear.
7. **Iterate.** Each bug fix should flow back into the FreeBSD driver if it exposes a real issue, not a platform-specific quirk.

This is far from a one-day task. For a medium-sized driver, it is often a week or two of focused work. The cost pays off when the port is successful and the shared codebase becomes easier to maintain than two separate drivers.

29.10.9 When Cross-BSD Means Cross-Platform Generally

Some drivers benefit from running not just on other BSDs but on other operating systems entirely. Linux is the obvious target, but also macOS, Windows, and even user-space reimplementations of kernel services. A driver written with a clean backend interface and a core that speaks only in its own vocabulary is usable as a building block in any of these environments; only the backend and the wrapper layer change.

This is the deep reason the patterns in this chapter matter. They are not just about FreeBSD; they are about how to structure any driver so that the OS is a detail. The specific tools (`bus_dma`, `bus_space`, `__FreeBSD_version`) are FreeBSD's, but the patterns they embody are universal.

29.10.10 NetBSD and OpenBSD Pointers for the Curious

If you become curious about NetBSD or OpenBSD, a few pointers will save you time.

NetBSD's driver documentation lives in its tree, and the equivalent of `/usr/src/sys` is the same on NetBSD; you can compare the two trees directly. NetBSD's `bus_dma(9)` manual page explains its API with great care. The `config(8)` infrastructure is NetBSD's answer to Newbus and has its own manual.

OpenBSD's driver style is more conservative than FreeBSD's. OpenBSD values simplicity over flexibility, and its drivers tend to be smaller and more direct than FreeBSD's equivalents. If you read OpenBSD driver source, you will see fewer layers of abstraction and fewer build options. This is a design choice; it is neither inherently better nor worse than FreeBSD's style.

Both projects have excellent mailing lists and IRC channels. If you port a driver, asking for review from the community saves time. Both communities are generally welcoming to FreeBSD developers who approach them respectfully.

29.10.11 Wrapping Up Section 7

Cross-BSD portability is a deep topic, but its essentials are simple: isolate kernel-subsystem dependencies behind wrappers, keep the core logic OS-agnostic, and list the FreeBSD-specific APIs you use so you know where the borders are. If you ever need to port to NetBSD or OpenBSD, you will have only the border to translate; the core goes across unchanged. The wrapping itself is non-trivial work, but the wrapping layer grows slowly and is proportional to the breadth of APIs the driver uses, not to the driver's overall size. For most FreeBSD-only drivers, cross-BSD preparation is not justified; the patterns that support it are worth knowing because they make the driver better even when it stays FreeBSD-only.

In Section 8, we step back and address a different question: how do you package, document, and version a portable driver so that others can build, test, and consume it safely? Good code is not enough; good practice around the code matters too.

29.11 Section 8: Refactoring and Versioning for Portability

A portable driver is an artefact, but portability is also a practice. The code is one part; the way the code is organised, documented, and versioned is the rest. This section addresses that rest. It assumes you have refactored the driver into the shape laid out in Sections 2 through 7, and asks: what more should you do so that your work survives contact with other people and other systems?

The answers involve documentation, versioning, build validation, and a small amount of housekeeping. None of it is glamorous. All of it pays off the first time someone new tries to use your driver.

29.11.1 A Short README.portability.md

Every portable driver benefits from a short document that states its supported platforms, supported backends, build options, and known limitations. In the `portdrv` reference driver, that document is `README.portability.md`. A reader who picks up the driver for the first time should be able to read it in a few minutes and know whether their environment is supported.

A good portability README has four sections.

Supported platforms. List the FreeBSD versions and CPU architectures the driver is tested on, and the ones it is known or expected to work on even if not tested. For example:

Tested on:

- FreeBSD 14.3-RELEASE, amd64
- FreeBSD 14.3-RELEASE, arm64 (QEMU guest)

Expected to work but not regularly tested:

- FreeBSD 14.2-RELEASE and later, amd64
- FreeBSD 14.3-RELEASE, riscv64

Not supported:

- FreeBSD 13.x and earlier (API changes required)
- NetBSD / OpenBSD (see Section 7; see compatibility file portdrv_os.h)

Supported backends. List each backend, what hardware or software environment it targets, and any constraints. For example:

pci: PCI variant, requires a device with vendor 0x1234, device 0x5678.

usb: USB variant, requires a USB 2.0 or later host controller.

sim: Pure software simulation. No hardware required. Useful for tests.

Build options. List every -D flag that the Makefile recognises and what each one does. Mention which combinations are expected to work:

PORTDRV_WITH_PCI=yes	Enable the PCI backend.
PORTDRV_WITH_USB=yes	Enable the USB backend.
PORTDRV_WITH_SIM=yes	Enable the simulation backend.
PORTDRV_DEBUG=yes	Enable verbose debug logging.

If no backend flag is set, PORTDRV_WITH_SIM is enabled by default so that a plain "make" produces a loadable module.

Known limitations. State honestly what the driver does not support. A short, honest list is more useful than a long or evasive one.

The simulation backend does not attempt to emulate interrupt latency or DMA bandwidth limits. It completes transfers synchronously. Do not use it as a substitute for performance testing against real hardware.

A portability README lives alongside the driver's source. Update it whenever the supported set changes. If you pick up a driver that lacks one, writing one is the most valuable review activity you can perform.

29.11.2 Versioning the Driver

Kernel modules carry a version via `MODULE_VERSION`. A portable driver should version three things: the driver as a whole, each backend, and the backend interface.

The driver version is a single integer passed to `MODULE_VERSION`:

```
MODULE_VERSION(portdrv, 2);
```

Bump it whenever you change something a dependent consumer can observe, for instance when you add a new ioctl, change the semantics of an existing one, or rename a sysctl.

Each backend has its own module registration. Version each one independently:

```
MODULE_VERSION(portdrv_pci, 1);  
MODULE_DEPEND(portdrv_pci, portdrv_core, 1, 2, 2);
```

The `MODULE_DEPEND` call expresses that `portdrv_pci` depends on `portdrv_core` with a version in the range [1, 2] where 2 is the preferred value. The kernel refuses to load the backend against a core it does not understand, which prevents a mismatch from producing mysterious crashes.

The backend interface itself can be versioned in the struct. A version field at the top of struct `portdrv_backend` lets the core check that each backend was compiled against the right shape:

```
struct portdrv_backend {  
    uint32_t    version;  
    const char  *name;  
    int         (*attach)(struct portdrv_softc *sc);  
    /* ... */  
};  
  
#define PORTDRV_BACKEND_VERSION 2
```

When the core's `portdrv_core_attach` sees `sc->sc_be->version != PORTDRV_BACKEND_VERSION`, it refuses to attach and logs a clear message. This catches the case where someone updates the core but forgets to rebuild a backend, without requiring the kernel to crash to make the point.

Use these mechanisms lightly. Each one imposes a cost at maintenance time, because a version bump must be coordinated. The reward is that when something does go wrong, the error is immediate and clear instead of vague and delayed.

29.11.3 Document Supported Build Configurations

Alongside the `README.portability.md`, maintain a short **build matrix** that records which combinations of backends and options are expected to compile and which have been recently tested. This is a project-management artefact, not a runtime one, but it is invaluable when a new maintainer takes over or when a reviewer wants to know whether a specific configuration will still work after a change.

A practical build matrix looks like this:

Config	Compiles	Tested	Notes
-----	-----	-----	-----
(default: SIM only)	yes	yes	Baseline CI.
PCI only	yes	yes	
USB only	yes	yes	
PCI + USB	yes	yes	
PCI + USB + SIM	yes	yes	Full build.
PCI + DEBUG	yes	yes	
PCI + USB + DEBUG	yes	no	Should be OK.
None of PCI/USB/SIM (no backend)	yes	yes	SIM auto-enabled

Regenerate the matrix before a release. It is a small chore that saves a large amount of time later. When users file bugs against specific configurations, you can tell at a glance whether the configuration was claimed to work, and if so, whether it was in fact tested at the last release.

29.11.4 Validating the Build Before a Release

A good release discipline for a portable driver is to validate every documented configuration automatically before each release. Automation makes this cheap. A short shell script that loops over the build matrix, invokes `make clean` and `make`, and reports success or failure, is typically enough:

```
#!/bin/sh
# Validate portdrv builds in every supported configuration.

set -e

configs="
    PORTDRV_WITH_SIM=yes
    PORTDRV_WITH_PCI=yes
    PORTDRV_WITH_USB=yes
    PORTDRV_WITH_PCI=yes PORTDRV_WITH_USB=yes
    PORTDRV_WITH_PCI=yes PORTDRV_WITH_USB=yes PORTDRV_WITH_SIM=yes
    PORTDRV_WITH_PCI=yes PORTDRV_DEBUG=yes
"

OLDIFS="$IFS"
echo "$configs" | while read cfg; do
    [ -z "$cfg" ] && continue
    echo "==> Building with: $cfg"
    make clean > /dev/null
    if env $cfg make > build.log 2>&1; then
        echo "    OK"
```

```
    else
        echo "      FAIL (see build.log)"
        tail -n 20 build.log
        exit 1
    fi
done
```

Run this before you tag a release. When it passes, you know that every configuration you document as supported actually builds. When it fails, you know the exact configuration that broke and can fix it before shipping. This is the cheapest and most valuable quality practice a portable driver can adopt.

29.11.5 When to Version Bump

A frequent question from new driver authors is: “When should I bump the module version number?” The short answer is that you bump it when anything observable to consumers changes. The longer answer distinguishes three kinds of change:

Backwards-compatible additions. Adding a new ioctl command, a new sysctl, a new module option, without changing the behaviour of existing commands. Bump the minor version. Existing consumers continue to work.

Backwards-incompatible changes. Renaming an ioctl, changing the meaning of an existing sysctl, or breaking a previously documented behaviour. Bump the major version. Update the `MODULE_DEPEND` in dependent modules. Document the break in a release note.

Internal refactoring that users cannot observe. Moving functions between files, renaming private variables, reformatting. Do not bump the version. Internal changes are internal.

Keep in mind that `MODULE_VERSION` is an integer, and consumers decide how to interpret it. For a driver with a small user base, one version number per observable change is fine. For a driver with a larger community and more dependents, establishing a convention such as “major * 100 + minor” lets you encode more information in a single integer. Either way, document what your version numbers mean so that future maintainers and consumers can interpret them.

29.11.6 Refactoring for Portability as an Ongoing Discipline

A portable driver is not a finished artefact. Even after the initial refactor, the driver continues to evolve: new features, new hardware variants, new kernel APIs, new bug fixes. Keeping the driver portable is an ongoing discipline, not a one-time achievement.

Three habits help.

Review new patches for portability hazards. When a contributor adds a new register access, does it go through the accessor? When they add a new backend-specific function, does it fit the interface, or does it force an `if (sc->sc_be == pci)` in the core? When they add a new type, is it fixed-width? These questions take a few seconds per patch and catch most regressions.

Re-run the build matrix regularly. A monthly or weekly automated build of every supported configuration catches silent regressions the moment they appear. If CI resources are limited, run the matrix on pull requests and nightly on the main branch.

Re-test on a non-amd64 platform periodically. Even a single arm64 guest booted under QEMU once a quarter catches a surprising number of architectural bugs. The test does not have to be exhaustive; even just loading the driver and running the simulation backend is enough to reveal many endian and alignment issues.

29.11.7 The Final Shape of a Portable Driver

After all of this, a portable driver has a recognisable shape. The core is small and does not know about specific buses. Each backend is a thin file that implements a clean interface. The headers are short and each has a clear purpose. The Makefile uses feature flags to select backends and options. The driver uses `uint32_t` and its family for sizes, `bus_read_*` and `bus_write_*` for register access, `bus_dma_*` for DMA, and endian helpers whenever multi-byte values cross the hardware boundary. The driver documents its supported platforms and build options. The driver has a build matrix and a validation script.

A reader opening the source for the first time can find what they need in minutes. A new contributor can add a backend in an afternoon. A reviewer can audit a patch without reading the entire driver. That is the shape.

29.11.8 ABI vs. API Stability

A subtle distinction is often missed when drivers are versioned: the difference between the **application programming interface** (API) and the **application binary interface** (ABI). The API is what a programmer sees: function names, parameter types, expected behaviour. The ABI is what a linker sees: symbol names, structure layouts, calling conventions, alignment.

A change that leaves the API unchanged can still break the ABI. Adding a field to the middle of a structure is a classic example: source files that use the structure compile unchanged, but binary modules compiled against the old layout will read the wrong fields at runtime because the offsets have shifted.

For kernel modules, ABI stability matters because modules are loaded into a running kernel, and the kernel and the module must agree on the layout of the structures they share. This is the reason `MODULE_DEPEND` includes version numbers: an older module refusing to load against a newer kernel, or vice versa, is safer than silently reading wrong fields.

Two rules help preserve ABI stability over time.

Rule one: add fields only at the end of structures. The existing fields retain their offsets, and older consumers read them correctly. Newer consumers, which know about the added field, can access it at the end.

Rule two: never change the type or size of an existing field. If you need to widen a field, add a new field and leave the old one for compatibility. This is awkward, but it is the price of ABI stability.

Drivers with a small audience can ignore ABI stability most of the time, because each release rebuilds everything. Drivers whose consumers cannot rebuild everything, such as out-of-tree modules that users compile against their own kernel, must be more careful.

29.11.9 Upgrade and Downgrade Paths

A mature driver must be usable through upgrade and downgrade. Upgrades are straightforward: install the new module, unload the old one, load the new one. Downgrades are sometimes harder, because the new module may have saved state that the old module cannot read.

For most drivers, state is not persistent, so downgrade is easy. For drivers that store state in a character device's data, in filesystem metadata, or in a database the device itself maintains, downgrade paths deserve thought. Your state format should include a version field; older versions should refuse to read newer formats and produce a clear error; newer versions should read older formats when possible.

Release notes are the simplest rollout mechanism. A release note that says “this version changes the state format; downgrade is not possible without loss of data” is worth more than a sophisticated state-migration system that nobody uses. Communicate the upgrade impact clearly and let your users decide.

29.11.10 Telemetry and Observability

A portable driver that is deployed widely benefits from lightweight telemetry. Not intrusive logging that floods the kernel log, but unobtrusive counters that an operator can query to see whether the driver is healthy. The usual FreeBSD mechanism is a sysctl tree:

```
SYSCTL_ADD_UQUAD(ctx, tree, OID_AUTO, "transfers_ok",  
    CTLFLAG_RD, &sc->sc_stats.transfers_ok,  
    "Successful transfers");  
SYSCTL_ADD_UQUAD(ctx, tree, OID_AUTO, "transfers_err",  
    CTLFLAG_RD, &sc->sc_stats.transfers_err,  
    "Failed transfers");  
SYSCTL_ADD_UQUAD(ctx, tree, OID_AUTO, "queue_depth",  
    CTLFLAG_RD, &sc->sc_stats.queue_depth,  
    "Current queue depth");
```

Operators can query these with `sysctl dev.portdrv.0`, monitoring systems can scrape them at intervals, and bug reports can include their values without requiring the reporter to do anything special. The cost to the driver is one field per counter and one sysctl registration per field. For a mature driver, the telemetry tree grows naturally as questions arise.

Add the telemetry first, debug second. When a bug report arrives and the sysctl values show what happened, the debugging is much faster than when the values are missing.

29.11.11 A Post-Refactor Checklist

After a portability refactor, it is worth running through a short checklist before declaring the work complete. The checklist is deliberately terse; each item stands for a subtlety you should confirm.

1. Does the core file include any bus-specific header? If yes, move the include or the using code.

2. Does every register access go through an accessor or a backend method? Grep for `bus_read_`, `bus_write_`, `bus_space_read_`, and `bus_space_write_` in the core file; each occurrence is a candidate for attention.
3. Does the driver use fixed-width types for every value whose size matters? Look for `int`, `long`, `unsigned`, and `size_t` in register access contexts; replace with `uint32_t`, `uint64_t`, and so on as appropriate.
4. Does every multi-byte value that crosses the hardware boundary pass through an endian helper? Look for `raw *(uint32_t *)` casts on DMA buffers and register images.
5. Does the build succeed in every documented configuration? Run the build matrix script.
6. Does the module load cleanly, with the expected banner? Load each configuration in turn and check `dmesg`.
7. Does the driver detach cleanly? Unload it and confirm no panics and no leaked resources.
8. Is the documentation up to date? Re-read `README.portability.md` and ensure it matches reality.
9. Is the lab logbook current? Note what was done, what surprised you, and what you expect to change in the future.

Running the checklist takes about an hour. Finding a problem during the checklist is cheaper than finding it in production.

29.11.12 Rollouts and Rollbacks

When a refactored driver is ready to ship, consider the rollout strategy. For a small user base, a single release is enough. For a larger one, a staged rollout reduces risk:

1. **Internal staging.** Deploy to internal test systems first. Run the driver for at least a day before exposing it to external users.
2. **Early adopters.** Release to a small group of external users who have opted in. Collect feedback for a week.
3. **General release.** Ship to all users. Announce the release with a changelog.
4. **Rollback plan.** Document how to revert to the prior version. A driver that can be unloaded and replaced by the previous version is safer than one that is entangled with the rest of the system.

The granularity of the rollout depends on your project. A hobby project does not need staged rollouts. A commercial driver serving hundreds of users does. Think about the balance and choose deliberately.

29.11.13 Wrapping Up Section 8

You now know not only how to write portable code but how to package it so that others can consume it safely. Versioning, documentation, a build matrix, and a validation script are the small, unglamorous practices that separate a hobbyist driver from a production-ready one. They cost little to adopt and pay off the first time someone else touches the code, including future you. ABI stability, upgrade paths, telemetry, a post-refactor checklist, and a rollout strategy are the companion practices that mature a driver over the long term.

The chapter's remaining material gives you hands-on labs, challenge exercises, and a troubleshooting guide. The labs let you apply every technique in this chapter to the reference driver. The challenges push further, so you can practice the patterns on variations of the same problem. The troubleshooting guide catalogues the failures you are likeliest to meet along the way.

29.12 Hands-On Labs

The labs in this chapter walk you through transforming a small single-file driver into a portable, multi-backend, multi-file driver. The reference implementation, `portdrv`, lives in `examples/part-07/ch29-portability/`. Each lab is self-contained and leaves you with a working module that loads cleanly. You can do them all, or stop at any point; each one is useful on its own.

Before you begin, change into the examples directory and inspect its current state:

```
cd /path/to/FDD-book/examples/part-07/ch29-portability
ls
```

You should see a `lab01-monolithic/` directory that contains the starting-point driver, along with `lab02` through `lab07` directories that contain the successive refactoring steps. Each lab directory has its own `Makefile` and `README`. Work in `lab01-monolithic` first; when a lab is complete, move on to the next directory, which contains the state of the driver after that step.

A quick workflow tip: make a local working copy of the directory for each lab so you can compare your version against the reference afterwards.

```
cp -r lab01-monolithic mywork
cd mywork
```

Then follow the instructions.

29.12.1 Setting Up the Lab Environment

Before you start any of the labs, set up the working environment. A few minutes of preparation saves hours of friction later.

Create a working directory outside the repository, so you do not accidentally commit lab output:

```
mkdir -p ~/fdd-labs/ch29
cd ~/fdd-labs/ch29
cp -r /path/to/FDD-book/examples/part-07/ch29-portability/* .
```

Confirm that `make` works with the default lab files before making any changes:

```
cd lab01-monolithic
make clean && make
ls *.ko
```

If the build fails, stop and debug now. A lab is not useful if the starting state is broken.

Next, verify you can load and unload the reference driver:

```
sudo kldload ./portdrv.ko
dmesg | tail
sudo kldunload portdrv
```

If the load fails, check dmesg for an error message. The usual suspects are a missing module dependency or a conflict with another driver. Fix these before beginning the labs.

Finally, start a simple logbook. A plain text file or a Markdown file in your working directory is enough:

```
=== Chapter 29 Lab Logbook ===
Date: 2026-04-19
System: FreeBSD 14.3-RELEASE, amd64
```

Every lab will add an entry. The logbook is not for public consumption; it is a record for future you.

29.12.2 Lab 1: Audit the Monolithic Driver

The starting-point driver is a single file that compiles and loads but mixes every concern in one place. The goal of this lab is to **notice** the portability problems without fixing them yet. Training your eye is the first step.

```
cd lab01-monolithic
less portdrv.c
```

As you read, make notes in your lab logbook for each of the following:

1. Which lines perform register access? Mark every `bus_space_read_*`, `bus_space_write_*`, `bus_read_*`, `bus_write_*`, and any raw pointer dereferences to device memory.
2. Which lines allocate or manipulate DMA buffers? Mark every `bus_dma_*` call.
3. Which lines include bus-specific headers such as `dev/pci/pcivar.h`?
4. Which lines hardcode specific vendor or device IDs?
5. Which lines use types that might be wrong on a 32-bit platform (`int`, `long`, `size_t`)?
6. Which lines use `htons`, `htonl`, or a related endian helper?
7. Which lines are guarded with `#ifdef`?

Now build and load the driver:

```
make clean
make
sudo kldload ./portdrv.ko
dmesg | tail -5
sudo kldunload portdrv
```

Confirm that the module loads cleanly. If it does not, fix the build before moving on.

Reflection. At the end of the lab, your logbook should have a short paragraph describing the driver's current portability state. Something like: "The register accesses go through `bus_read_*`, so architectural portability is acceptable, but they are spread across the file without accessors. PCI-specific code is interleaved with core logic. No endian helpers are used anywhere. There is no simulation backend. The driver compiles on amd64 only; I have not tried arm64."

This paragraph is the baseline against which every later lab measures progress.

29.12.3 Lab 2: Introduce Register Accessors

The first structural change is to centralise register access in accessors, as described in Section 2. You are not yet splitting the file; you are only adding a layer of indirection.

Add two static inline functions at the top of `portdrv.c`:

```
static inline uint32_t
portdrv_read_reg(struct portdrv_softc *sc, bus_size_t off)
{
    return (bus_read_4(sc->sc_bar, off));
}

static inline void
portdrv_write_reg(struct portdrv_softc *sc, bus_size_t off, uint32_t val)
{
    bus_write_4(sc->sc_bar, off, val);
}
```

Then, throughout the file, replace every `bus_read_4(sc->sc_bar, X)` with `portdrv_read_reg(sc, X)`, and every `bus_write_4(sc->sc_bar, X, V)` with `portdrv_write_reg(sc, X, V)`. Do this carefully. After every small batch of replacements, rebuild:

```
make clean && make
```

And reload:

```
sudo kldunload portdrv 2>/dev/null
sudo kldload ./portdrv.ko
dmesg | tail -5
```

Confirm that the driver still works. The accessor layer is functionally invisible; the binary behaviour should be unchanged.

Checkpoint. Count the number of `bus_read_*` and `bus_write_*` occurrences in the file after the change. They should all be inside the accessors. If any are outside, find and replace them. That sweep is the whole point of the lab.

29.12.4 Lab 3: Extract the Backend Interface

Now that accessors exist, add a backend interface. Create a new file `portdrv_backend.h` with the struct definition from Section 3:

```
#ifndef _PORTDRV_BACKEND_H_
#define _PORTDRV_BACKEND_H_

struct portdrv_softc;

struct portdrv_backend {
    const char *name;
    int  (*attach)(struct portdrv_softc *sc);
    void (*detach)(struct portdrv_softc *sc);
    uint32_t (*read_reg)(struct portdrv_softc *sc, bus_size_t off);
    void      (*write_reg)(struct portdrv_softc *sc, bus_size_t off,
                          uint32_t val);
};

extern const struct portdrv_backend portdrv_pci_backend;

#endif
```

In `portdrv.c`, add the `softc` field:

```
struct portdrv_softc {
    device_t sc_dev;
    struct resource *sc_bar;
    int sc_bar_rid;
    const struct portdrv_backend *sc_be;    /* new */
    /* ... */
};
```

Rewrite the existing accessor functions to dispatch through the backend:

```
static inline uint32_t
portdrv_read_reg(struct portdrv_softc *sc, bus_size_t off)
{
    return (sc->sc_be->read_reg(sc, off));
}

static inline void
portdrv_write_reg(struct portdrv_softc *sc, bus_size_t off, uint32_t val)
{
    return (sc->sc_be->write_reg(sc, off, val));
}
```

```
    sc->sc_be->write_reg(sc, off, val);  
}
```

Define a first instance of the interface:

```
static uint32_t  
portdrv_pci_read_reg_impl(struct portdrv_softc *sc, bus_size_t off)  
{  
    return (bus_read_4(sc->sc_bar, off));  
}  
  
static void  
portdrv_pci_write_reg_impl(struct portdrv_softc *sc, bus_size_t off, uint32_t val)  
{  
    bus_write_4(sc->sc_bar, off, val);  
}  
  
const struct portdrv_backend portdrv_pci_backend = {  
    .name      = "pci",  
    .read_reg  = portdrv_pci_read_reg_impl,  
    .write_reg = portdrv_pci_write_reg_impl,  
    /* attach and detach stay NULL for now. */  
};
```

In the existing `portdrv_attach` function, install the backend:

```
sc->sc_be = &portdrv_pci_backend;
```

Rebuild, load, and confirm the driver still works.

Checkpoint. The core logic now never touches `bus_read_*` or `bus_write_*` directly. Every register access goes through the backend. Verify this by grepping for `bus_read_` and `bus_write_` in the file; they should all be inside the `_impl` functions.

29.12.5 Lab 4: Split the Core and the Backend into Separate Files

Now that the interface is in place, split the file.

Create three files:

- `portdrv_core.c`: contains the `softc` definition, the register accessors, the attach/detach logic that is not PCI-specific, and the module registration for the core.
- `portdrv_pci.c`: contains the PCI probe, the PCI-specific attach and detach, the `_impl` functions, and the backend struct.
- `portdrv_backend.h`: contains the backend interface.

The details of the split are in the reference implementation under `lab04-split`. Study it after you have done your own split, and compare.

Update the `Makefile` to list both source files:

```
SRCS= portdrv_core.c portdrv_pci.c
```

Rebuild and load. The driver should load identically to before, but the source is now organised.

Checkpoint. Open `portdrv_core.c` and search for `#include <dev/pci/pcivar.h>`. It should not appear. The core is free of PCI-specific includes. That is the milestone.

29.12.6 Lab 5: Add a Simulation Backend

Add a second backend that does not require any hardware. Create `portdrv_sim.c` with its own implementation of the backend interface:

```
/* portdrv_sim.c - simulation backend for portdrv */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/bus.h>
#include <sys/malloc.h>

#include "portdrv.h"
#include "portdrv_common.h"
#include "portdrv_backend.h"

struct portdrv_sim_priv {
    uint32_t regs[256]; /* simulated register file */
};

static uint32_t
portdrv_sim_read_reg(struct portdrv_softc *sc, bus_size_t off)
{
    struct portdrv_sim_priv *psp = sc->sc_backend_priv;
    if (off / 4 >= nitems(psp->regs))
        return (0);
    return (psp->regs[off / 4]);
}

static void
portdrv_sim_write_reg(struct portdrv_softc *sc, bus_size_t off, uint32_t val)
```

```

{
    struct portdrv_sim_priv *psp = sc->sc_backend_priv;
    if (off / 4 < nitems(psp->regs))
        psp->regs[off / 4] = val;
}

static int
portdrv_sim_attach_be(struct portdrv_softc *sc)
{
    return (0);
}

static void
portdrv_sim_detach_be(struct portdrv_softc *sc)
{
}

const struct portdrv_backend portdrv_sim_backend = {
    .name      = "sim",
    .attach    = portdrv_sim_attach_be,
    .detach    = portdrv_sim_detach_be,
    .read_reg  = portdrv_sim_read_reg,
    .write_reg = portdrv_sim_write_reg,
};

```

Add a module-load hook that creates a simulated instance when the driver is loaded without any real hardware:

```

static int
portdrv_sim_modevent(module_t mod, int type, void *arg)
{
    static struct portdrv_softc *sim_sc;
    static struct portdrv_sim_priv *sim_priv;

    switch (type) {
    case MOD_LOAD:
        sim_sc = malloc(sizeof(*sim_sc), M_PORTDRV, M_WAITOK | M_ZERO);
        sim_priv = malloc(sizeof(*sim_priv), M_PORTDRV,
            M_WAITOK | M_ZERO);
        sim_sc->sc_be = &portdrv_sim_backend;
        sim_sc->sc_backend_priv = sim_priv;
        return (portdrv_core_attach(sim_sc));
    case MOD_UNLOAD:
        if (sim_sc != NULL) {
            portdrv_core_detach(sim_sc);

```

```
        free(sim_priv, M_PORTDRV);
        free(sim_sc, M_PORTDRV);
    }
    return (0);
}
return (0);
}

static moduledata_t portdrv_sim_mod = {
    "portdrv_sim",
    portdrv_sim_modevent,
    NULL
};

DECLARE_MODULE(portdrv_sim, portdrv_sim_mod, SI_SUB_DRIVERS, SI_ORDER_ANY);
MODULE_VERSION(portdrv_sim, 1);
MODULE_DEPEND(portdrv_sim, portdrv_core, 1, 1, 1);
```

Update the Makefile to include the new file:

```
SRCS= portdrv_core.c portdrv_pci.c portdrv_sim.c
```

Rebuild and load:

```
make clean && make
sudo kldload ./portdrv.ko
dmesg | tail -10
```

You should see both the PCI backend registering with the bus and a simulated instance created by the sim backend's module hook. Interact with the simulated instance through its character device (if any) and confirm that register writes and reads behave as stored integers.

Checkpoint. You now have a driver that compiles with two backends and runs both simultaneously. The PCI backend manages any real hardware the kernel discovers; the simulation backend gives you a software instance for testing.

29.12.7 Lab 6: Conditional Compilation of Backends

Make each backend conditional on a build-time flag. Edit the Makefile:

```
KMOD= portdrv
SRCS= portdrv_core.c
```

```
.if defined(PORTDRV_WITH_PCI) && ${PORTDRV_WITH_PCI} == "yes"
SRCS+= portdrv_pci.c
CFLAGS+= -DPORTDRV_WITH_PCI
.endif

.if defined(PORTDRV_WITH_SIM) && ${PORTDRV_WITH_SIM} == "yes"
SRCS+= portdrv_sim.c
CFLAGS+= -DPORTDRV_WITH_SIM
.endif

.if !defined(PORTDRV_WITH_PCI) && !defined(PORTDRV_WITH_SIM)
SRCS+= portdrv_sim.c
CFLAGS+= -DPORTDRV_WITH_SIM
.endif

SYSDIR?= /usr/src/sys
.include <bsd.kmod.mk>
```

Build with various combinations:

```
make clean && make PORTDRV_WITH_PCI=yes
make clean && make PORTDRV_WITH_SIM=yes
make clean && make PORTDRV_WITH_PCI=yes PORTDRV_WITH_SIM=yes
make clean && make
```

Confirm that each build succeeds and produces a module. Load each module in turn and watch the dmesg output. The message at load time should identify which backends are present.

Add a banner to the core's module load event:

```
static int
portdrv_core_modevent(module_t mod, int type, void *arg)
{
    switch (type) {
        case MOD_LOAD:
            printf("portdrv: version %d loaded, backends:"
#ifdef PORTDRV_WITH_PCI
                " pci"
#endif
#ifdef PORTDRV_WITH_SIM
                " sim"
#endif
                "\n", PORTDRV_VERSION);
            return (0);
    }
}
```

```
    /* ... */  
}  
return (0);  
}
```

Now `dmesg` at load time tells you exactly what this build supports.

Checkpoint. You can now select, at build time, which backends are present in the module. The source is not polluted with `#ifdef` inside function bodies; the selection happens at the Makefile level, and the banner hides its `#ifdef` chain in a controlled location.

29.12.8 Lab 7: Endian-Safe Register Access

Pick one register in the driver that represents a multi-byte value in a specific byte order. Most real devices document this in the datasheet; for the reference driver, assume that register `REG_DATA` at offset `0x08` is little-endian.

Modify the accessors to apply endian conversion explicitly. Do **not** bake the conversion into the general register accessor; the hardware registers themselves are in host order through `bus_read_4`. The conversion applies to the **interpretation** of the value.

Add a higher-level helper:

```
static uint32_t  
portdrv_read_data_le(struct portdrv_softc *sc)  
{  
    uint32_t raw = portdrv_read_reg(sc, REG_DATA);  
    return (le32toh(raw));  
}  
  
static void  
portdrv_write_data_le(struct portdrv_softc *sc, uint32_t val)  
{  
    portdrv_write_reg(sc, REG_DATA, htole32(val));  
}
```

Use these in the core whenever the code is manipulating a value that is stored in little-endian form in the register.

Checkpoint. On amd64 the endian helpers are no-ops, so behaviour does not change. On a big-endian platform, the helpers perform byte swaps that would have been missing before. You are now prepared for architectural portability even if you have not yet tested on a big-endian host.

29.12.9 Lab 8: Build Matrix Script

Write a short script that builds the driver in every supported configuration and reports success or failure. Save it as `validate-build.sh` in the chapter directory.

```
#!/bin/sh
set -e

configs="
PORTDRV_WITH_SIM=yes
PORTDRV_WITH_PCI=yes
PORTDRV_WITH_PCI=yes PORTDRV_WITH_SIM=yes
"

echo "$configs" | while read cfg; do
    [ -z "$cfg" ] && continue
    printf "==> %s ... " "$cfg"
    make clean > /dev/null 2>&1
    if env $cfg make > build.log 2>&1; then
        echo "OK"
    else
        echo "FAIL"
        tail -n 20 build.log
        exit 1
    fi
done
```

Run it:

```
chmod +x validate-build.sh
./validate-build.sh
```

If all three configurations build, you have a minimal build matrix in place. Every future change to the driver can be checked against the matrix with a single invocation.

Checkpoint. The driver builds in every configuration you have advertised. You have a machine-readable way to confirm that fact. This is the last structural piece of a portable driver.

29.12.10 Lab 9: Exercising the Simulation Backend from Userland

A refactor is only as good as the tests you can run against it. Once the simulation backend is in place, you can exercise the driver's core logic from a small userland program without needing any hardware. This lab walks through a lightweight test harness.

Create a userland program, `portdrv_test.c`, that opens `/dev/portdrv0` (or whatever character device the driver creates for the simulated instance), writes a known value, reads it back, and prints the result:

```
#include <sys/types.h>
#include <sys/stat.h>
```

```
#include <fcntl.h>
#include <unistd.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

int
main(int argc, char *argv[])
{
    const char *dev = (argc > 1) ? argv[1] : "/dev/portdrv0";
    int fd;
    char buf[64];

    fd = open(dev, O_RDWR);
    if (fd < 0) {
        perror(dev);
        return (1);
    }

    memset(buf, 0, sizeof(buf));
    snprintf(buf, sizeof(buf), "hello from userland\n");
    if (write(fd, buf, strlen(buf)) < 0) {
        perror("write");
        close(fd);
        return (1);
    }

    memset(buf, 0, sizeof(buf));
    if (read(fd, buf, sizeof(buf) - 1) < 0) {
        perror("read");
        close(fd);
        return (1);
    }

    printf("Read back: %s", buf);
    close(fd);
    return (0);
}
```

Compile it with `cc -o portdrv_test portdrv_test.c`. Load the driver with the simulation backend enabled, then run the test program:

```
sudo kldload ./portdrv.ko
./portdrv_test
```

If the simulation backend stores and retrieves data correctly, the output should confirm a successful round trip. If the test fails, the simulation backend is the isolated place to debug: no hardware, no driver lifecycle surprises, just the core logic plus the simulated backend.

Checkpoint. You have a reproducible end-to-end test that exercises the driver's character-device path, its I/O handling, and its simulation backend without touching any real hardware. This test can run in CI, on a developer's laptop, or inside a bhyve guest with no PCI cards.

29.12.11 Lab 10: Add a Basic sysctl Tree

Introduce a sysctl tree rooted at `dev.portdrv.<unit>` that exposes a handful of runtime-visible values. The goal of this lab is not to wire every statistic into sysctl; it is to establish the structure so that later features can extend it cheaply.

In `portdrv_core.c`, add a pair of helpers:

```
static void
portdrv_sysctl_init(struct portdrv_softc *sc)
{
    struct sysctl_ctx_list *ctx;
    struct sysctl_oid *tree;

    ctx = device_get_sysctl_ctx(sc->sc_dev);
    tree = device_get_sysctl_tree(sc->sc_dev);

    SYSCTL_ADD_STRING(ctx, SYSCTL_CHILDREN(tree),
        OID_AUTO, "backend", CTLFLAG_RD,
        __DECONST(char *, sc->sc_be->name), 0,
        "Backend name");

    SYSCTL_ADD_INT(ctx, SYSCTL_CHILDREN(tree),
        OID_AUTO, "version", CTLFLAG_RD,
        NULL, PORTDRV_VERSION,
        "Driver version");

    SYSCTL_ADD_UQUAD(ctx, SYSCTL_CHILDREN(tree),
        OID_AUTO, "transfers_ok", CTLFLAG_RD,
        &sc->sc_stats.transfers_ok,
        "Successful transfers");
}
```

Call `portdrv_sysctl_init(sc)` at the end of `portdrv_core_attach`. After loading the driver, inspect the tree:

```
sysctl dev.portdrv.0
```

You should see:

```
dev.portdrv.0.%desc: portdrv (PCI backend)
dev.portdrv.0.%parent: pci0
dev.portdrv.0.backend: pci
dev.portdrv.0.version: 2
dev.portdrv.0.transfers_ok: 0
```

Exercise the driver and watch the `transfers_ok` counter increase. If it does not, the core is not updating it; that is a bug to fix.

Checkpoint. The driver's runtime state is now observable from userland without parsing `dmesg`. Monitoring systems and ad-hoc bug reports can include a snapshot of the `sysctl` tree, and you know the driver's health at a glance.

29.12.12 Lab 11: Runtime Backend Selection

For advanced use, let the driver's simulation backend be enabled or disabled at runtime via a `sysctl` or a module parameter. This lab introduces the idea of making backend selection flexible at module load time, useful for CI pipelines that want the same module to behave differently depending on the environment.

Add a tunable to the module:

```
static int portdrv_sim_instances = 0;
SYSCTL_INT(_debug_portdrv, OID_AUTO, sim_instances,
    CTLFLAG_RD, &portdrv_sim_instances, 0,
    "Number of simulation backend instances to create at load time");
TUNABLE_INT("debug.portdrv.sim_instances", &portdrv_sim_instances);
```

In the module's load hook, create the number of simulation instances requested by the tunable:

```
for (i = 0; i < portdrv_sim_instances; i++)
    portdrv_sim_create_instance(i);
```

At load time, the operator can set the tunable from `/boot/loader.conf`:

```
debug.portdrv.sim_instances="2"
```

Load the module and confirm two simulated instances appear. The PCI backend, if compiled in, still attaches to any real hardware it finds. The two kinds of instance coexist in the same module, with no conflict between them.

Checkpoint. The driver is controllable at load time via a tunable, which means the same binary can behave differently in different deployments without recompilation. This is the kind of runtime flexibility that a single-file driver would find awkward and that a well-structured multi-backend driver handles as a natural extension.

29.12.13 Lab 12: Write a Minimal CI Harness

Combine the build matrix script from Lab 8 with a basic load test. The goal is a single command that validates the driver in every supported configuration and confirms it loads cleanly in each. Automate this into a CI-like loop that you can run before committing changes.

```
#!/bin/sh
# ci-check.sh - validate portdrv in every supported configuration.
set -e

configs="
PORTDRV_WITH_SIM=yes
PORTDRV_WITH_PCI=yes
PORTDRV_WITH_PCI=yes PORTDRV_WITH_SIM=yes
"

echo "$configs" | while read cfg; do
    [ -z "$cfg" ] && continue
    printf "==> Build: %s ... " "$cfg"
    make clean > /dev/null 2>&1
    if env $cfg make > build.log 2>&1; then
        echo "OK"
    else
        echo "FAIL"
        tail -n 20 build.log
        exit 1
    fi
    printf "==> Load : %s ... " "$cfg"
    if sudo kldload ./portdrv.ko > load.log 2>&1; then
        sudo kldunload portdrv > /dev/null 2>&1
        echo "OK"
    else
        echo "FAIL"
        cat load.log
        exit 1
    fi
done
echo "All configurations passed."
```

Run it:

```
chmod +x ci-check.sh
./ci-check.sh
```

Checkpoint. A single script confirms that every configuration you document as supported actually builds and

loads. You can invoke this before every commit, or wire it into a CI system that runs it on every pull request. The cost is a minute or two per run; the reward is catching regressions within minutes of making them.

29.13 Challenge Exercises

The following challenges push the refactoring further and give you room to practice the chapter's patterns on variations of the same problem. Each challenge is independent and draws only on material from this chapter and the earlier ones. Take them at your own pace; they are designed to consolidate mastery rather than to introduce new foundations.

29.13.1 Challenge 1: Add a Third Backend

Add a third backend to the reference driver. The specifics depend on your interests:

- An MMIO backend that reaches the device through a Device Tree node on an embedded platform.
- A child of an I2C or SPI bus.
- A backend that uses bhyve's virtio framework as a guest.

The structural requirement is the same in each case: a new `portdrv_XXX.c` file, a new implementation of the backend interface, a new entry in the Makefile and a new build-time flag. After the work is done, confirm that the driver still builds in every previously supported configuration and additionally in the new one.

29.13.2 Challenge 2: Expose Version Metadata via sysctl

Create a sysctl subtree at `dev.portdrv.<unit>.version` that exposes:

- the driver version
- the backend name
- the backend version
- the flags that were set at build time

The sysctl tree should be populated in `portdrv_sysctl.c` (create it if it does not exist) and should read its values from constants defined in the individual backend files. At runtime, the operator can learn everything they need to know about the build by running `sysctl dev.portdrv.0`.

29.13.3 Challenge 3: Simulate a Big-Endian Host

You probably do not have a big-endian machine. Simulate the experience.

Write a one-time debugging mode, controlled by a build flag `PORTDRV_FAKE_BE`, in which all endian helpers are replaced by macros that assume a big-endian host. The code must still compile and run on amd64, but any multi-byte value that should have been converted will now be converted (the wrong way, for correctness, but that is the point). Load the driver with this flag on and exercise the simulation backend. If the driver works, congratulations: your use of endian helpers is consistent enough to survive an endianness flip. If it does not, the places where it fails are the places you missed an `htole` or `be32toh`.

This is a laboratory exercise, not a production pattern. The knowledge you gain, however, is exactly the knowledge that would protect you on a real big-endian platform.

29.13.4 Challenge 4: Cross-Build for arm64

Install or boot an arm64 FreeBSD guest in QEMU. Build the driver inside the guest, or cross-build it on your amd64 host using:

```
make TARGET=arm64 TARGET_ARCH=aarch64
```

Copy the resulting `.ko` into the guest and load it. Run the simulation backend and confirm the driver behaves identically. Note any warnings the arm64 compiler emits that the amd64 compiler did not; these are often alignment or size mismatches that deserve a fix.

29.13.5 Challenge 5: Write a README.portability.md

Author a `README.portability.md` that documents:

- the platforms on which the driver has been tested
- the backends it supports
- the build options the Makefile recognises
- any limitations, bugs, or known issues

This challenge is about writing, not coding. The artefact is as important to the driver's portability as the code itself. Keep it short; keep it honest.

29.13.6 Challenge 6: Create a Versioned Backend Interface

Add a version field to `struct portdrv_backend` and have the core reject a backend whose version does not match the core's expected version. Add a second version with a small additional field (for example, `configure_dma`), and confirm that a backend compiled against the older version still loads against a core that tolerates both, while a backend compiled against the newer version refuses to load against an older core.

This challenge is deeper than it looks. Versioning an interface requires careful thought about compatibility. The mechanics are worth practising once in an isolated context so that you know how to reach for them when your own drivers need them.

29.13.7 Challenge 7: Audit a Real FreeBSD Driver

Pick one of the drivers referenced in this chapter, for example `/usr/src/sys/dev/uart/`, and audit it against the patterns here. Answer:

- How is the core separated from the backends?
- Where are the register accessors, and do they use `bus_read_*`?
- What backends does the driver support, and how is each registered?

- Are there `#ifdef` chains, and are they well-justified?
- How is the Makefile structured, and what options does it expose?
- What could you change to make the driver more portable, in your judgement?

Write a short report in your lab logbook. The exercise is for you; the aim is to train your eye on real code.

29.13.8 Challenge 8: Measure the Cost of Backend Dispatch

The backend interface introduces one function-pointer indirection per register access. On a driver that performs millions of accesses per second, that indirection might or might not be measurable. Design an experiment to find out.

Use the simulation backend, so the measurement is not muddled by hardware latency. Modify the driver so it performs a tight loop of `portdrv_read_reg` calls in response to an `ioctl`. Time the loop with `clock_gettime(CLOCK_MONOTONIC)`. Compare two builds: one where the accessor dispatches through the backend, and one where the accessor calls `bus_read_4` directly.

Report your findings in your lab logbook. On a modern amd64 CPU, you will likely find the difference is in the single-digit percentage range or smaller. On an older or simpler CPU, it may be larger. Understanding the cost empirically, rather than guessing, is the right way to inform future design decisions.

29.13.9 Challenge 9: Add a Second FreeBSD Version Target

Take the driver and make it build on both FreeBSD 14.3 and FreeBSD 14.2. Identify one API difference between the two releases that your driver uses, wrap it in `__FreeBSD_version` guards, and confirm the module builds cleanly against both release headers.

Document the difference and your wrapping approach in a short note at the top of the file where the guard lives. This exercise introduces you to the practical side of multi-release compatibility, which you will need if you ever maintain an out-of-tree driver against a range of FreeBSD releases.

29.13.10 Challenge 10: Design a New Driver from Scratch

Starting from the patterns in this chapter, design a portable driver for a hypothetical device of your choice. The device should have at least two hardware variants (for example, PCI and USB), should have a simple register model, and should be amenable to simulation. Write:

- A one-page design document describing the driver's structure.
- The header file `mydev_backend.h` that defines the backend interface.
- A skeleton implementation of the core that compiles and links with placeholder functions.
- The Makefile with conditional backend selection.

You do not need to implement the full driver. The exercise is to practice the design phase, which is where most of the portability decisions are made. Share your design with a colleague or a mentor and listen for their questions; the questions reveal the parts of the design that were not yet obvious to a fresh reader.

29.14 Troubleshooting and Common Mistakes

Portability refactors fail in characteristic ways. This section catalogues the failures you are likeliest to meet, with concrete symptoms and concrete fixes.

29.14.1 Symptom: Build Fails with “Undefined Reference” After Splitting a File

A function that was static in the original file is now called from a different file. The compiler does not see it.

Fix. Remove the `static` qualifier from the function’s definition and add a declaration for it in the appropriate header. If the function should remain private to one file, find the caller in the other file and restructure so that the call crosses a proper interface rather than a private symbol.

29.14.2 Symptom: Build Fails with “Implicit Function Declaration” After Splitting

A file calls a function whose prototype it has not seen. This is the classic “I moved the definition but forgot the declaration” mistake.

Fix. Add `#include "portdrv.h"` or the appropriate header at the top of the calling file. If the header does not declare the function, add the declaration. Treat the prototype as part of the API surface; every function that crosses files must have a declaration in a shared header.

29.14.3 Symptom: Build Succeeds, but Load Fails with a Dependency Error

The module registration declares a `MODULE_DEPEND` on a module that is not loaded, or loads a version outside the expected range.

Fix. Use `kldstat` to see what is loaded. Load the required module first, then load yours. Check that the `MODULE_VERSION` in the dependency matches the range in `MODULE_DEPEND`. If you are in the middle of a refactor and the dependency chain is unstable, temporarily relax the version range or remove the dependency until the refactor settles.

29.14.4 Symptom: The Driver Loads, but `dmesg` Shows Only One Backend

The Makefile flags were not set as you expected. The banner reports only the backends whose `#ifdef` was satisfied.

Fix. Check the flags on the make command line. Look at the actual Makefile expansion:

```
make -n
```

The `-n` option prints what make would do without executing, and you can see whether `-DPORTDRV_WITH_PCI` actually made it into the compilation command. If not, something in the Makefile conditional is wrong.

29.14.5 Symptom: Register Reads Return Zero on ARM but Work on x86

You are reaching the device through raw pointer dereference instead of `bus_read_*`.

Fix. Replace every raw pointer dereference of device memory with a call to `bus_read_*` or `bus_space_read_*`. On amd64 the difference is invisible; on ARM it is the difference between working and broken.

29.14.6 Symptom: The Simulation Backend Works but the PCI Backend Hangs at Attach

The PCI resources were not allocated properly, or the backend-private data structure was not initialised correctly.

Fix. Add a `device_printf` trace at each step of the PCI attach function to narrow down where the hang happens. Check that `bus_alloc_resource_any` returned a non-NULL resource. Check that the backend's attach callback is called after `sc->sc_backend_priv` is installed; a NULL deref in the callback is easy to cause and obvious once seen.

29.14.7 Symptom: Build Fails on a Different FreeBSD Release

An API changed between the release you developed on and the release you tried to build on. The compiler complains about a missing function or a mismatched signature.

Fix. Bracket the affected code with `#if __FreeBSD_version >= N ... #else ... #endif` where N is the version at which the API took its current form. If the change is used in many places, abstract it into a helper in a compatibility header so the `#if` appears in only one place.

29.14.8 Symptom: The Driver Panics with “Locking Assertion Failed” After a Backend Split

The core and the backend are disagreeing about which lock is held at the call to the backend method.

Fix. Document, in a comment at the top of `portdrv_backend.h`, which lock the core holds at each method call. For each backend operation, either the core holds the softc mutex across the call or it does not, consistently. Audit every backend for conformance. The usual cause is a backend that acquires a lock the core already holds, or vice versa.

29.14.9 Symptom: The Driver Builds but `make clean` Leaves Stale Object Files

`bsd.kmod.mk` knows how to clean the KMOD's own files but may miss extras you added. The consequence is stale `.o` files that link into the next build and cause odd behaviour.

Fix. Delete the build directory and restart:

```
rm -f *.o *.ko
make clean
```

Then rebuild. Add the stale files to a `CLEANFILES` variable in the Makefile if they are generated by the build.

29.14.10 Symptom: Cross-Architecture Build Fails with “Cannot Find <machine/bus.h>”

The cross-compile environment is incomplete or the target architecture is not installed.

Fix. Follow the FreeBSD handbook on cross-compilation. Typically, you need to install the source tree for the target architecture and run `make TARGET=arm64 TARGET_ARCH=aarch64` from the top of the source tree. Building a single out-of-tree module requires the base system’s cross-build support, and the documentation for that is at the top of `/usr/src/Makefile` and in the “Cross-Build” handbook chapter.

29.14.11 Symptom: A `sysctl` You Just Added Does Not Appear

The `sysctl` was registered in a file that is not compiled into the module, or the registration code is not called.

Fix. Confirm that `portdrv_sysctl.c` is in `SRCS`. Confirm that the `sysctl` registration is called from the module load or attach path. Add a `device_printf` immediately before the registration call to confirm it executes.

29.14.12 Symptom: The Driver Works on Real Hardware but Not in `bhyve`

The simulated hardware in `bhyve` exposes slightly different behaviour from the real device. Often this is an MSI versus INTx difference, or a slightly different PCI capability list.

Fix. Check the capabilities your driver relies on. Use `pciconf -lvc` on both the host and the guest to see what differs. If a capability your driver needs is missing in the guest, the driver should detect this and degrade gracefully, rather than assuming the capability is always present.

29.14.13 Symptom: Performance Varies Wildly Between Architectures

You are accessing unaligned data with a direct cast. On `amd64`, unaligned access is cheap; on `arm64`, it can be several times slower if the hardware supports it at all.

Fix. Replace direct casts with `memcpy` followed by an endian helper, as shown in Section 5. The resulting code is fast on all architectures and correct on all of them.

29.14.14 Symptom: `kldunload` Hangs

Something is still using the module. Usually, a callout is still scheduled, an interrupt is still in flight, or a reference count is positive.

Fix. Add a `callout_drain` call to your detach path. Add `device_printf` traces at each step of detach to see which step is stuck. Look for open file descriptors on character devices the driver creates; `kldunload` will not complete while a device is open. Use `fstat` to identify which process is holding the device.

29.14.15 Symptom: Different Behaviour Between `make PORTDRV_WITH_SIM=yes` and `make PORTDRV_WITH_SIM=yes PORTDRV_DEBUG=yes`

Debug code is changing behaviour it should not. Often this is because a debug `printf` is calling a function that has a side effect, or because the debug path holds a lock longer than the release path.

Fix. Review every `PD_DBG` call. If any of them invokes a function rather than just formatting a value, replace the invocation with a pre-computed string. Debug printing must be an observational no-op; if the log statement has side effects, the release behaviour and the debug behaviour will diverge in ways that are hard to trace.

29.14.16 Symptom: Warning about “Incompatible Pointer Types” After Moving a Function

A function that took a pointer in the original file now takes a slightly different pointer in a new file. Usually the type has drifted between versions of a header, or a typedef has changed subtly.

Fix. Open both files and compare the declarations. If the types are genuinely the same, the declaration in a shared header is needed so both files see the same definition. If the types have drifted, pick the correct one and update the caller or the callee.

29.14.17 Symptom: `bus_dma` Fails with `ENOMEM` on amd64 but Works on arm64

Counter-intuitively, this is usually a `bus_dma_tag_create` configuration issue. The `lowaddr` field was set to a value that does not match the system’s actual memory layout.

Fix. Check the `lowaddr` and `highaddr` parameters. For a 64-bit device with no limits, use `BUS_SPACE_MAXADDR`. For a 32-bit device, use `BUS_SPACE_MAXADDR_32BIT`. Incorrect addresses produce spurious bounce-buffer allocations that can fail on systems with large memory.

29.14.18 Symptom: Userland Program Sees Different Data Than the Kernel Log Shows

The `uiomove(9)` call is moving bytes, but the endianness of the values differs between kernel and userland interpretation.

Fix. Decide what byte order your character-device interface uses. Document it in a comment on the `cdevsw` struct. Use `htole32/le32toh` or similar helpers when values cross the boundary between kernel and userland, just as you would for device boundaries.

29.14.19 Symptom: The Module Loads but `kldstat` Shows It in a Different Position Than Expected

The module’s dependencies are being loaded in an unexpected order. Usually this is a consequence of a missing `MODULE_DEPEND` declaration.

Fix. List every module your module depends on with `MODULE_DEPEND`. The kernel resolves the load order automatically; without the declarations, the order is unspecified.

29.14.20 Symptom: A Debug Build Consumes Much More Memory Than a Release Build

Debug statements are allocating memory on each invocation, or a debug-only data structure is growing without bound.

Fix. Review every `PD_DBG` call to ensure none of them perform allocations. If a debug-only data structure must grow, bound its size explicitly. A debug build that triggers out-of-memory conditions is more misleading than helpful.

29.14.21 Symptom: Tests Pass on the Development Machine but Fail in CI

The CI machine has a different FreeBSD version, a different set of loaded modules, or a different hardware configuration. The difference is exposing a latent bug.

Fix. Investigate the specific difference. If the CI environment is correct and the development machine is masking a bug, accept the bug and fix it. If the CI environment is misconfigured, fix the CI environment. Either way, the divergence between development and CI is a signal worth taking seriously.

29.14.22 Symptom: A Sysctl Can Be Read but Not Written, Even Though CTLFLAG_RW Was Set

The sysctl registration used a pointer to a read-only constant, or the handler ignores writes, or the node's parent is read-only.

Fix. Confirm the backing variable is writable. Confirm that CTLFLAG_RW is actually on the leaf node, not the parent. If a custom handler is installed, ensure it handles the write direction and not only the read direction.

29.14.23 Symptom: The Driver Panics on kldunload After Running for a Long Time

A long-running callout, taskqueue, or workqueue has been freed while still registered, or a resource reference is not released in the right order.

Fix. Call `callout_drain` and equivalent drain functions during detach. Ensure every resource allocated during attach is freed during detach, in reverse order. Walk through the attach and detach paths with a piece of paper and track every allocation; this catches the majority of shutdown panics.

29.14.24 Symptom: Cross-Compiled Module Refuses to Load on the Target

The cross-compiled module's ABI does not match the target kernel's ABI. This is almost always a version mismatch between the build tree and the target.

Fix. Ensure the `TARGET` and `TARGET_ARCH` in the cross-compile match the target exactly. If the target runs FreeBSD 14.3-RELEASE, build against the 14.3 source tree, not the 15-CURRENT tree. Module ABI compatibility across major releases is not guaranteed.

29.14.25 Symptom: A Backend's attach Method Is Called Twice on the Same Softc

Either two threads race to attach, or the backend is being re-attached without a detach in between.

Fix. Add a state flag in the softc that tracks whether the backend has been attached. The core should refuse to re-attach an already-attached softc. For symmetry, the detach should clear the flag. This catches most duplicate-attach bugs at the logic level, rather than waiting for a resource-exhaustion panic.

29.14.26 Symptom: Compiler Warns about an Unused Variable in a Conditional Block

The variable is used only when a specific `#ifdef` is active, and the build being compiled has the flag unset.

Fix. Move the variable declaration inside the `#ifdef` block if it is only used there. If the variable is used in both branches but the compiler cannot see one of them, add `(void)var;` in the unused branch to tell the compiler the variable is intentionally unused.

29.14.27 Symptom: The Build Succeeds but `kldxref` Complains About Missing Metadata

The `MODULE_PNP_INFO` declaration is malformed, or the array it points to is the wrong shape. `kldxref(8)` builds an index that maps hardware identifiers to modules, and a malformed `MODULE_PNP_INFO` breaks that index.

Fix. Check the arguments to `MODULE_PNP_INFO` against the documentation. The format string must match the layout of the identification array, and the count must be correct. A mismatch is caught at boot when `kldxref` runs, but it is easier to catch at build time by running `kldxref -v` on the directory and inspecting the output.

29.14.28 Symptom: A Backend That Worked Yesterday Fails Today After a Kernel Update

A kernel API that the backend depends on has changed in the new release. The core is fine; the backend is broken.

Fix. Check `UPDATING` in the kernel source tree for any notes about the API that changed. Check the release's `SHARED_LIBS` and module ABI notes. Wrap the affected API call in a `__FreeBSD_version` guard so that the driver supports both the old and new versions. Report the breakage to the backend's maintainer if it is not you.

29.14.29 Symptom: The Driver Rejects a Device That Should Work

The probe function's matching table is incomplete, or the device ID is being read in the wrong byte order.

Fix. Print the vendor and device IDs the probe function is seeing. Compare with the device's datasheet. If the values look byte-swapped, the probe is using the wrong accessor or the wrong mask. If the values look correct but the table does not include them, add the new IDs.

29.14.30 Symptom: A USB Backend Works with One Device but Not Another of the Same Type

USB devices have descriptors that can vary slightly between firmware revisions of the same product. The backend is matching too strictly on an optional field.

Fix. Review the USB matching logic. Match on vendor ID and product ID; ignore release numbers and serial numbers unless they are genuinely significant. The goal is to match the entire product family, not a specific build of it.

29.14.31 Symptom: After a File Split, Some `static` Functions Can No Longer Be Inlined

Functions that were `static inline` in one file are now called across files, which prevents inlining and can cause a small performance regression.

Fix. If the function is small and performance-critical, keep it in a header as a `static inline` so every file that includes the header gets its own copy. If the function is larger, move it to the appropriate `.c` file as a plain function. The compiler can still inline across translation units if link-time optimisation is enabled, but for kernel code that is rarely the case.

29.14.32 Symptom: make Recompiles Everything Even When Only One File Changed

The Makefile does not track header dependencies correctly. Changes to a shared header cause all files that include it to recompile, which is correct. But sometimes the Makefile is too aggressive and recompiles unrelated files.

Fix. Check that `bsd.kmod.mk` is generating dependency files (they usually have a `.depend` extension). If they are missing, add `.include <bsd.dep.mk>` or ensure the default include chain runs. For a small driver, full rebuilds are usually acceptable; for a large one, dependency tracking pays for itself.

29.14.33 Generic Guidance

If you are stuck on a portability problem that does not match any of the above, three habits usually help.

Narrow the configuration. If the driver fails only with certain backends enabled, build it with only one backend at a time and find the configuration in which it first breaks.

Narrow the architecture. If the driver fails on `arm64` but not on `amd64`, the bug is almost certainly endianness, alignment, or a type-size mismatch. Those are the only three common causes of architecture-specific behaviour in driver code.

Narrow the function. Add `printfs`, add `KASSERTs`, delete code until the smallest remaining driver still fails. Kernel bugs are hard to reason about, but they become tractable once you can trigger them from a tiny example.

Bisect the change. If the driver worked in an earlier commit and fails now, run `git bisect`. Kernel bugs are often specific regressions, and bisecting finds the first bad commit in $O(\log n)$ steps.

Read the compiler's warnings, even the annoying ones. A “set but not used” warning can point to a field that was renamed and forgotten. An “implicit function declaration” warning is a missed include. A “comparison between signed and unsigned” warning can be the source of the exact wraparound bug you are chasing. Compiler warnings are free advice; use them.

29.15 A Retrospective: The Patterns at a Glance

Before the closing note, here is a compact retrospective of the patterns this chapter introduced. Use it as a quick reference when you return to the chapter or when you are reviewing your own code. Each entry is the idea compressed to a sentence, with a pointer back to the section that introduces it in full.

Accessors over primitives. Wrap every register access in a driver-local function rather than calling `bus_read_*` directly in the code that cares about the device logic. The wrapper is a single point of change, it names the operation, and it lets you swap the implementation without touching callers. See Section 2.

Backend interface. Describe the variable part of the driver as a struct of function pointers. Each bus, hardware variant, or simulation becomes an instance of the struct. The core calls through the struct rather than knowing which backend is present. See Section 3.

File split by responsibility. Put core logic in one file, each backend in its own file, and each large subsystem concern (sysctl, ioctl, DMA helpers) in its own file. A reader should be able to guess which file to open from what they are looking for. See Section 4.

Fixed-width types. Use `uint8_t` through `uint64_t` for values whose size matters. Avoid `int`, `long`, unsigned, and `size_t` when the width is fixed by the device or protocol. See Section 5.

Endian helpers. Every multi-byte value that crosses the hardware boundary passes through `htole32`, `le32toh`, or their siblings. No exceptions. See Section 5.

bus_space(9) and bus_dma(9). Use the architecture-independent APIs for register access and for DMA. Never cast a raw pointer to device memory, and never compute physical addresses directly. See Sections 2 and 5.

Memory barriers. Use `bus_barrier` to enforce ordering between device-visible accesses when the order matters. Use `bus_dmamap_sync` to enforce coherency between CPU caches and DMA buffers. See Section 5.

Conditional compilation with restraint. Use build-time flags for features that should be compiled in or out. Keep `#ifdef` blocks coarse. Hide guards inside macros when they are used in many places. See Section 6.

__FreeBSD_version. Use sparingly to guard code that depends on a specific kernel release. Centralise the guards in a compatibility header if they appear more than a few times. See Section 6.

Cross-BSD wrapping. Isolate OS-specific APIs behind wrapper macros when cross-BSD support is needed. Keep the core free of OS-specific code. See Section 7.

Module versioning. Use `MODULE_VERSION` and `MODULE_DEPEND` to make upgrade and load-order issues visible to the kernel. Bump versions when observable behaviour changes. See Section 8.

Build matrix. Maintain a list of supported build configurations. Run a script that builds every configuration before a release. See Section 8.

Portability README. Document supported platforms, backends, build options, and limitations in a short readme. Update it whenever any of those change. See Section 8.

Telemetry. Expose key counters through a sysctl tree. Bug reports that include sysctl output are easier to triage than reports that do not. See Section 8.

Print this list or keep a copy in your notes. The patterns work because they reinforce one another, and seeing them together is the fastest way to internalise the shape of a portable driver.

29.16 Portability Antipatterns: What to Unlearn

Having seen the patterns that work, it helps to name the patterns that do not. Most driver portability disasters are not spectacular failures of judgement; they are small, comfortable habits that compound. A driver author who copies a working function without understanding it will be tempted, six months later, to copy it again with

a small tweak. A driver that has one `#ifdef` for one architecture will, six months later, have five. Each step feels harmless; together they produce code that nobody wants to touch.

This short catalogue names the antipatterns so that you can recognise them in your own code and in code you review. The goal is not to shame; it is to give you the vocabulary to identify the drift early and redirect it.

29.16.1 The “It Works on My Machine” Driver

A driver that only has one target, one FreeBSD version, and one bus hides portability bugs rather than lacking them. The code may compile and run cleanly for years, but the moment someone else tries to build it on a different architecture or a newer release, every shortcut is exposed at once. The antidote is not to test on every platform from day one; it is to write as if you will one day, so the eventual port is a one-week exercise rather than a three-month one. Fixed-width types, endian helpers, and `bus_read_*` are cheap insurance against the future you cannot yet see.

29.16.2 The Silent `#ifdef`

The `#ifdef` block with no comment explaining why it is there is almost always a mistake. If the block is guarding truly architecture-specific code, say so, and say what the alternative branch does. If it is guarding a workaround for a bug in a specific chip, say which chip, which bug, and when it might be removed. A driver file with undocumented `#ifdefs` is a file where future-you will not know whether the branch is still needed. Document, or delete.

29.16.3 The Casual Cast

A cast from a pointer to an integer type, or from an integer of one size to another, is almost always a bug in waiting. On amd64, a pointer is 64 bits and a `long` is 64 bits, so the cast happens to work. On an i386 system, a pointer is 32 bits and `long` is 32 bits, so the cast happens to work. On 32-bit ARM, a pointer is 32 bits but `uint64_t` is, of course, 64 bits; here the cast changes size and triggers a warning only on a subset of builds. Casts that the compiler accepts silently on one platform and warns about on another are precisely the casts you should avoid. If the logic requires a conversion, use `uintptr_t`, which is explicitly designed to hold a pointer, and document why the cast is needed.

29.16.4 The Optimistic Register

A register read or write that the driver assumes will succeed is an optimistic register. On real hardware, a read from an unmapped address can return `0xFFFFFFFF`, can machine-check the CPU, or can silently produce garbage, depending on the bus and platform. On a simulation backend, the same read returns a known constant. Drivers that never check for the pathological read are drivers that work until one day the hardware is powered off or behind a PCI bus that disconnected due to a hotplug event. Defensive coding at the accessor level (does the return value look sane?) is cheaper than debugging the panic that follows.

29.16.5 The Ad-Hoc Version Check

`if (major_version >= 14)` sprinkled across the driver is an antipattern. Version checks belong in a compatibility header, not scattered through the code. A single `#define PORTDRV_HAS_NEW_DMA_API 1` in one place, guarded by one `__FreeBSD_version` test, keeps the rest of the driver clean. Scattered version checks are also fragile: when the API changes again, you will forget one of the dozen scattered checks, and the driver will fail in a subtle way on one release.

29.16.6 The “Temporary” Hack

A comment that says `// TODO: remove before release` or `// FIXME: arm64` is a promise to yourself. Ninety percent of such promises are never kept. Before you write a temporary hack, ask whether there is a way to solve the problem properly in half an hour. Often there is. When there truly is not, the hack should come with a tracking ticket and a calendar reminder. Without those, “temporary” becomes “permanent” on the timescale of a single release cycle.

29.16.7 The Duplicated Constant

A magic number written once is a design decision. A magic number written twice is a bug waiting for one of the copies to be updated without the other. Constants for register addresses, bit masks, timeouts, and limits should live in one header and be included everywhere they are used. When you catch yourself typing the same number in two places, stop and put it in a `#define`.

29.16.8 The Growing struct softc

A `softc` that accumulates fields across many commits without any re-organisation is a code smell. It is a sign that every feature added to the driver put its state directly into the `softc` without asking whether the state belonged somewhere else. When a `softc` has more than twenty fields, consider grouping related fields into nested structs: `sc->dma.tag`, `sc->dma.map`, `sc->dma.seg` rather than `sc->dma_tag`, `sc->dma_map`, `sc->dma_seg`. The refactor is small, and the resulting structure reads better in logs and in debugger output.

29.16.9 The Uneven Test Coverage

A driver whose tests only cover the happy path is a driver whose error paths will bite someone in production. Every function that can fail should be testable, and should be tested, in at least the obvious failure mode. The simulation backend makes this cheap; use it to inject failures (out of memory, DMA timeout, device not responding) and assert the core handles them gracefully. A driver that has never been tested against a failing backend is a driver whose error paths are wishful thinking.

29.16.10 The Gratuitous Abstraction

It is possible to err in the other direction. A driver with a twelve-method backend interface, three layers of wrapping, and an abstract factory for backend instances is likely over-engineered for the concrete need. Abstractions have a cost: they obscure what the code does, they spread knowledge across files, and they make debugging

harder. The right level of abstraction is the one that lets you solve today's problem cleanly without making tomorrow's problem meaningfully easier. When in doubt, start with less abstraction and add it when a second concrete use case justifies the cost.

29.16.11 The Monolithic Commit

A single commit that introduces accessors, splits files, adds a backend interface, and creates a Makefile matrix is impossible to review, impossible to bisect, and impossible to revert cleanly. Split the work: one commit per step, each commit leaving the driver in a buildable, loadable state. Small commits also communicate design intent: the commit message for “introduce accessors” tells a reader exactly what that commit is trying to achieve, whereas a grand commit titled “refactor for portability” tells them nothing useful.

Recognising these antipatterns in your own code is a sign of maturity. The patterns in the main body of the chapter are what you should do; the antipatterns here are what to watch for. When you find one in a driver you wrote last year, do not be hard on yourself; simply fix it. Everyone writes antipatterns at some point. What separates a seasoned author is the speed at which they notice and correct them.

29.17 Portability in the Real World: Three Short Stories

Principles land better when they are tied to consequences. Here are three short stories based on patterns that recur in real FreeBSD development. No single anecdote below is one specific incident; each is a composite of issues that experienced driver authors have seen more than once. The details are illustrative, not verbatim. The lessons are exactly as stated.

29.17.1 Story 1: The Endian Bug That Slept for Five Years

A driver for a storage controller was written in 2019 on an amd64 workstation, shipped to a handful of production servers, and ran cleanly for five years. In late 2024, a team migrating to arm64 servers for power efficiency loaded the same driver on the new hardware. Reads worked. Writes succeeded. Sporadic data corruption appeared a week later, limited to a small fraction of I/O requests.

The bug was a single line in the driver's descriptor setup: a raw struct assignment that deposited an amd64-native little-endian value into a ring descriptor that the hardware interpreted in its own byte order. On amd64, the hardware byte order happened to match the host byte order, so the raw assignment worked by coincidence. On arm64, the kernel runs little-endian too, so the code did not trip immediately, but the hardware in question had a newer firmware revision that changed the descriptor byte order for certain command types. The one byte order that the driver had been relying on by coincidence disappeared, and only a specific workload (streaming writes crossing a descriptor boundary) hit the corruption.

The fix was a one-line change to use `htole32` for every descriptor field. The diagnosis took three weeks, spanning two teams, because nobody had written the first driver expecting it to encounter a second platform or a hardware revision. The lesson is that endianness bugs do not announce themselves the moment they are introduced; they can sleep for years until a change somewhere else wakes them. Writing `htole32` from the start is cheaper than paying for the sleep.

29.17.2 Story 2: The Conditional Block Nobody Remembered

A network driver that supported both PCIe-attached and embedded FDT-attached variants carried a two-line `#ifdef PCI` block in its attach path. The block enabled an error-handling feature that mattered only on the PCIe variant, because the embedded variant used a different subsystem for the same purpose. The `#ifdef` had no comment.

Three years later, the driver author moved on. The driver acquired a new maintainer. A kernel update changed the semantics of the feature toggled by the `#ifdef`, and the driver started reporting spurious errors on the embedded variant. Nobody knew whether the `#ifdef` was still needed, whether it had ever been needed, or whether it was covering up a bug in either the embedded or the PCIe path. A week of investigation revealed that yes, the `#ifdef` was still correct; it was documenting a real asymmetry between the two paths; but because it had no comment, every new reader had to re-derive that knowledge from scratch.

The fix was to add a three-line comment above the `#ifdef`, citing the subsystem difference and naming the kernel commit that introduced the need for the block. Total cost of the fix: ten minutes. Total cost of the investigation across three years: about forty engineer-hours.

The lesson is that conditional compilation blocks age into mystery very quickly. Every `#ifdef` should have a comment telling a future reader why it is there. The comment pays for itself the first time anyone else touches the file.

29.17.3 Story 3: The Simulation Backend That Saved a Release

A driver for a custom sensor had a simulation backend added at the end of its first development cycle. The addition took two days of work and was considered a nicety rather than a necessity. The real hardware was rare, expensive, and kept in a lab across the building from the main developer.

Late in the release cycle, a regression appeared: under a specific sequence of user operations, the driver would deadlock on unload. Reproducing the bug on the real hardware required booking the lab, which was in use for validation of a separate product. The developer instead used the simulation backend, reproduced the deadlock within an hour, identified the missing `mtx_unlock` that caused it, and shipped the fix the same day.

The lesson is that simulation backends are not just for testing; they are for reproducing bugs without contending for scarce hardware. The two days invested in the simulation backend saved perhaps a week of schedule pressure and arguably saved the release. The pattern is worth the cost.

These three stories illustrate what the chapter has been arguing abstractly. Endianness bugs sleep. Conditional blocks age. Simulation backends pay back quickly. The specific incidents are illustrative, but the patterns are real, and they repeat across drivers and across years. Knowing them in advance is the difference between writing a driver you will maintain and writing a driver that will embarrass you.

29.18 A Short Closing Note on Discipline

This chapter has asked you to be patient with small, structural decisions. The patterns here, accessors, backend interfaces, file splits, endian helpers, version tags, are not thrilling when you first meet them. They are the kind of thing that a new driver author learns because an older one said to. The younger self reads about them, nods, and writes them down as a checklist.

Reading them as a checklist misses the point. The patterns work because they shape the habits with which you write new code. The first driver you write with accessors in place is also the first driver in which you never forget to check for a NULL resource, because the accessor is the natural place to do the check and you wrote it once. The first driver you structure into core and backends is also the first driver in which adding a feature means touching one file. The first driver you version with `MODULE_VERSION` and `MODULE_DEPEND` is also the first driver whose upgrade path is obvious to your users. The benefits are not in the patterns; they are in the habits the patterns create.

Habit takes time. You will write the next driver faster than you wrote this one, and the one after that faster still, not because the patterns have shortcuts but because your fingers stop reaching for the long way. The cost of portability, measured per driver, decreases sharply after the first. That is why this chapter matters for the rest of your career, and not just for this book.

The great FreeBSD driver authors did not become great by memorising the patterns in this chapter. They became great by applying them every time, even on the small, boring drivers that nobody was going to read. That practice scales. Pick it up early.

29.18.1 What Success Looks Like

A signpost, since you have come this far. When the patterns in this chapter start to feel automatic, something changes about the way you write drivers. You stop writing `bus_read_4(res, 0x08)` and reach for `port_drv_read_reg(sc, REG_STATUS)` instinctively. You stop wondering which file a new function belongs in; you know. You stop thinking about whether to `htole32` or not; if the value crosses a hardware boundary, it gets the helper, full stop. You stop arguing in code review about whether a flag should be compile-time or runtime, because you have a working heuristic. These are not trivial gains. They are the difference between writing drivers and writing drivers well.

The shift does not happen on any specific day. It happens gradually, over the course of three or four drivers written in this style. One day you notice that a pattern you used to think about is now just what your fingers do. That is the sign that the habit has taken. Keep going.

29.18.2 A Note on the Path Ahead

Part 7 of this book is titled “Mastery Topics” for a reason. Chapter 29 is the first chapter where the material is about craft rather than technique. Chapters 30 through 38 will continue in this spirit: each chapter addresses a topic that separates a competent driver author from a seasoned one. Virtualisation and containerisation in Chapter 30. Interrupt handling and deferred processing in Chapter 31. Advanced DMA patterns in Chapter 32. And onward.

The patterns in this chapter will reappear throughout those chapters. A virtualisation-aware driver uses the same backend abstraction to add a `virtio` backend. An interrupt-driven driver uses the same accessors to manage interrupt enable and acknowledge registers. An advanced DMA driver uses the same `bus_dmamap_sync` calls in more sophisticated sequences. Everything you learned here is a foundation for what comes next.

Treat Chapter 29 as the hinge between the driver-subsystem chapters of Part 6 and the mastery chapters of Part 7. You have crossed it now. The rest of the book builds on what you learned here.

29.19 Mini-Glossary of Portability Terms

A short glossary follows, aimed at the reader who wants to revisit the chapter's core vocabulary in one place. Use it as a refresher, not as a replacement for the explanations in the main text.

- **Backend.** An implementation of the driver's core interface for a specific bus, hardware variant, or simulation. A driver can have multiple backends in the same module.
- **Backend interface.** A struct of function pointers that the core calls into. Each backend provides an instance of this struct with its own implementations.
- **Core.** The hardware-independent logic of a driver. Calls into the backend interface but knows nothing about specific buses.
- **Accessor.** A driver-local wrapper around a primitive operation such as `bus_read_4`. Gives the driver a single point of change when the primitive or the backend differs.
- **bus_space(9).** The architecture-independent API for memory-mapped and I/O-port device access. Defined in `/usr/src/sys/sys/bus.h` and the per-architecture `/usr/src/sys/<arch>/include/_bus.h` files.
- **bus_dma(9).** The architecture-independent API for direct memory access by devices. Defined in `/usr/src/sys/sys/bus_dma.h`.
- **Endianness.** The byte order in which a multi-byte value is stored in memory. Handled in FreeBSD through helpers declared in `/usr/src/sys/sys/endian.h`.
- **Alignment.** The requirement that a multi-byte value be stored at an address that is a multiple of its size. Relaxed on amd64 and i386; strictly enforced on some ARM cores.
- **Word size.** The native integer width of a CPU. 32-bit and 64-bit FreeBSD platforms exist. Drivers should use fixed-width types whenever the size matters.
- **Fixed-width type.** A C type whose size is guaranteed: `uint8_t`, `uint16_t`, `uint32_t`, `uint64_t`, and their signed counterparts. Declared in `/usr/src/sys/sys/types.h` and its includes.
- **__FreeBSD_version.** An integer macro that identifies the FreeBSD kernel release the driver is being compiled against. Use to guard code that depends on a specific kernel API version.
- **Kernel options.** Named compile-time flags declared in kernel configuration files. Used to enable or disable optional features. Your driver defines `PORTDRV_*` flags in the Makefile and guards code with `#ifdef PORTDRV_*`.
- **Build matrix.** A table of supported build configurations, along with whether each configuration is expected to compile and whether it has been tested. Validated by a script that iterates over the matrix.
- **Backend versioning.** A version field in the backend interface struct that lets the core reject a backend compiled against a mismatched interface.
- **Compatibility wrapper.** A macro or function that abstracts a kernel API difference between FreeBSD releases or between different BSDs. Used sparingly, because each wrapper is a maintenance cost.
- **Simulation backend.** A software-only backend that does not talk to real hardware. Used for testing the core without requiring a physical device.
- **Module dependency.** A declaration, via `MODULE_DEPEND`, that one module requires another at a specific version range. Enforced by the kernel at load time.
- **Subregion.** A named slice of a larger memory-mapped region, carved out with `bus_space_subregion`. Used to give each logical bank of registers its own tag and handle.
- **Memory barrier.** An instruction or compiler directive that enforces ordering between memory operations. Issued via `bus_barrier` or the `atomic_thread_fence_*` family.

- **Bounce buffer.** A temporary buffer used by `bus_dma` when a device cannot reach the physical address of a requested buffer directly. Transparent to the driver; made effective by the cooperation between `bus_dma_tag_create` and `bus_dmamap_sync`.
- **Include graph.** The directed graph of which source or header files include which others. A clean include graph is a sign of a well-structured driver.
- **Compile-time telemetry.** Build-time information (version, build date, enabled backends) embedded into the binary and printed at load time. Useful for debugging and bug reports.
- **API vs. ABI.** The application programming interface is what programmers see; the application binary interface is what linkers see. A change can preserve one and break the other; portability practices must consider both.
- **Stacked backend.** A backend whose implementation wraps another backend, adding logging, tracing, delaying, or other behaviour. Useful for debugging and replay tools.
- **Memory-mapped I/O (MMIO).** A technique in which device registers appear as memory addresses that the CPU can read or write. Accessed through `bus_space` in FreeBSD rather than through raw pointers.
- **Port-mapped I/O (PIO).** An older scheme, common on i386, in which device registers are accessed through a separate I/O address space. Also accessed through `bus_space`, which abstracts the difference between MMIO and PIO.
- **DMA segment.** A contiguous physical address range that a device accesses directly. `bus_dma_segment_t` describes one; a DMA transfer may involve multiple segments.
- **Coherency.** The property that a memory location presents the same value to all observers (CPU, DMA engine, caches) at the same time. On some architectures, achieving coherency requires explicit `bus_dmamap_sync` calls.
- **KASSERT.** A kernel-space assertion macro. Panics the kernel when the condition is false; compiled out in release builds. Used to check invariants during development.
- **DEVMETHOD.** A macro in a `device_method_t` array that binds a Newbus method name to an implementation. Terminated by `DEVMETHOD_END`.
- **DRIVER_MODULE.** The macro that ties together a Newbus driver's name, parent bus, driver definition, and optional event callbacks. Usually appears once per bus attachment.
- **MODULE_PNP_INFO.** A declaration that describes the device IDs a driver claims, so `devmatch(8)` can auto-load the module when matching hardware appears. Orthogonal to `MODULE_VERSION` and `MODULE_DEPEND`.
- **Loader tunable.** A variable set from `/boot/loader.conf` that a kernel module reads via `TUNABLE_INT` or similar. The most common way to parameterise a driver at boot time.
- **sysctl node.** A named variable exposed through the `sysctl(3)` interface. Can be read-only, writable, or a procedural handler. A portable driver exposes counters and options via `sysctl`.
- **device hints.** A legacy but still-useful FreeBSD mechanism for supplying per-instance configuration (IRQs, I/O addresses) from `/boot/device.hints`. Parsed by the Newbus framework.
- **Kernel options (opt_*.h).** Per-configuration header files generated by the build system, used to guard kernel features with `#ifdef`. Distinct from module-level build flags.
- **Module blacklisting.** A mechanism (via `/boot/loader.conf` or `kldxref`) for preventing a module from being auto-loaded. Useful during debugging.
- **bus_space_tag_t and bus_space_handle_t.** Opaque types that together identify a memory region. The tag says which kind of space; the handle points into it. Passed as the first two arguments to `bus_space_read_*` and `bus_space_write_*`.
- **Attach path.** The sequence of Newbus calls (`probe`, `attach`, `detach`) that binds a driver to a device instance. Portable drivers isolate bus-specific logic inside this path.

- **Softc lifetime.** The lifetime of a struct `softc` instance, bounded by `attach` (allocation) and `detach` (free). A portable driver treats the `softc` as the authoritative per-instance state, not a collection of module-global variables.
- **Hot path.** The code path executed on every I/O operation. Performance-critical code. Keep it small and free of unnecessary checks.
- **Cold path.** Code executed rarely, such as during `attach`, `detach`, or error recovery. Correctness trumps performance; explicit error handling belongs here.
- **Hotplug.** The ability of a device to be physically added or removed from a running system. PCI hotplug is the main FreeBSD use case; drivers that are expected to support it must handle `detach` correctly at arbitrary points.
- **Refactor.** A structural change to code that preserves its observable behaviour. Portability refactors typically introduce accessors, split files, and introduce backend interfaces; none of these should change what users see.
- **Invariant.** A property that a piece of code guarantees at a given point in execution. Declaring invariants with `KASSERT` makes them checkable during development and self-documenting thereafter.
- **Build configuration.** A combination of Makefile flags, kernel options, and target platform that defines a specific build. A driver's build matrix is the set of configurations it officially supports.
- **Binary drop.** A delivery of a driver as a precompiled `.ko` file rather than as source. Portable binary drops are harder than portable source drops; platform and version compatibility become runtime concerns.
- **Source drop.** A delivery of a driver as source code, typically a tarball or a git repository. Easier to port than a binary drop, because the user's kernel headers and compiler adapt to their platform.
- **Driver lifecycle.** The set of transitions a driver goes through from load to unload: `register`, `probe`, `attach`, `operate`, `detach`, `unregister`. Portable drivers document where each transition is permitted to fail.
- **Migration path.** The documented steps a user follows when upgrading from an older driver version to a newer one. A portable driver keeps migration paths short and reversible.

Keep this glossary nearby as you read Chapter 30 and the chapters that follow. Each term recurs often enough that a quick reference pays for itself.

29.20 Frequently Asked Questions

New driver authors tend to ask the same questions as they work through their first portability refactor. Here are the most common ones, with short, pointed answers. Each answer is a signpost, not an exhaustive treatment; follow the bread crumbs back to the relevant section of the chapter if you want more detail.

Q: How much of this applies if my driver only needs to run on amd64?

All of it, except the architecture-specific sections. Even if you never plan to support `arm64`, the discipline of using fixed-width types, endian helpers, and `bus_read_*` costs almost nothing and protects you against bugs that would show up on `amd64` too, just in edge cases. The backend interface and the file split help readability and maintenance even when there is only one backend. If your first driver ever becomes a second driver, you will be glad you started the habit.

Q: Should every driver have a simulation backend?

No, but many should. The question to ask is whether the driver can be meaningfully exercised without the real hardware. If yes, a simulation backend lets you run unit tests and catch regressions on CI runners without

provisioning the hardware. If no, a simulation backend is extra code with no payoff. Storage drivers, network drivers, and many sensor drivers benefit; a driver for a very specific piece of custom hardware might not.

Q: Why use a struct of function pointers instead of FreeBSD's kobj (9) framework?

For small drivers, a plain struct is simpler and easier to read. kobj (9) is a capable system that adds compile-time method resolution and interface-file processing, which is why Newbus uses it. For a driver with a handful of backends and a simple method set, the plain struct gets you most of the benefit with a fraction of the machinery. If your driver grows large enough that the ceremony of kobj pays off, switching is a local refactor.

Q: My driver has only one backend today. Should I still define a backend interface?

Probably yes, if the effort is small. A single-entry interface costs almost nothing and lets you add a second backend cheaply later. If the effort is large because the driver is tightly coupled to its current bus, consider refactoring first for separation of concerns, and add the interface when a second backend is actually needed.

Q: How do I decide where to draw the line between core and backend?

A practical test: can you imagine writing the same logic for a simulated backend without changing the code at all? If yes, that logic belongs in the core. If the logic inherently mentions PCI, USB, or any specific bus, it belongs in the backend. In doubtful cases, put the logic in the core and see whether the simulation backend can use it unchanged; if not, move it.

Q: What do I do with a driver that uses a raw volatile pointer to device memory?

Replace every access with `bus_read_*` or `bus_write_*`. This is a one-time refactor and it is the single biggest portability improvement you can make to a driver.

Q: How often should I re-run my build matrix?

On every commit to the main branch, if you can. Weekly if you cannot. The longer a regression lives unnoticed, the more work it takes to bisect. Automated matrix validation is cheap; a bisecting sleuth session is expensive.

Q: Can I use `#ifdef __amd64__` inside a driver source file?

Sparingly. Prefer machine-specific headers for non-trivial architecture differences. If you genuinely need a small amount of platform-specific code, a short `#if` block is acceptable, but if it grows beyond a few lines, consider moving the code to a separate file and including it via an architecture-selective path or a wrapper header.

Q: Why does the reference driver's Makefile fall back to SIM if no backend is selected?

So that a plain make produces a loadable module. A driver that refuses to build without a specific flag set is a friction point for new contributors and for CI. The SIM fallback means anyone who just runs make gets something they can load and explore, even without any hardware.

Q: When should I add `MODULE_VERSION` and `MODULE_DEPEND`?

Always, even for internal drivers. `MODULE_VERSION` is a one-line declaration that tells consumers which release of your driver they have. `MODULE_DEPEND` prevents incompatible combinations from loading. Both are essentially free, and they save hours of debugging when something is mismatched.

Q: How does a cross-BSD driver handle things like `malloc` that have different signatures?

Through a per-OS compatibility header that maps a driver-local wrapper (for example, `portdrv_malloc`) onto the correct OS primitive. The core calls `portdrv_malloc`, and the compatibility header contains a branch per OS. The core is never polluted with OS-specific code; only the wrapper header is.

Q: Is it worth making a production driver cross-BSD compatible if my users are all on FreeBSD?

Generally no. The upkeep cost is real, and compatibility work that is not exercised tends to rot. The patterns in this chapter still benefit the FreeBSD-only driver, but the explicit wrapper layer for other BSDs should only be introduced when there is a concrete plan to support them.

Q: How do I test endianness if my only hardware is amd64?

Use QEMU with a big-endian target such as `qemu-system-ppc64`. Boot a FreeBSD big-endian release in the guest, cross-build your driver for `powerpc64`, and run it there. This is the only reliable way to catch endianness bugs short of deploying on real big-endian hardware. Challenge 3 in this chapter gives a lighter-weight approximation using a build flag.

Q: My driver compiles on FreeBSD 14.3 and fails on 14.2. What is going on?

An API added in 14.3. Use `__FreeBSD_version` to guard the use of the new API and provide a fallback for the older release. If the new API is essential and cannot be worked around, document the minimum supported version clearly in `README.portability.md`.

Q: Why does the chapter keep talking about the UART driver?

Because `/usr/src/sys/dev/uart/` is one of the clearest examples in the FreeBSD tree of a driver with a clean core/backend separation and multiple, well-factored backends. Reading it alongside this chapter is one of the best ways to internalise the patterns, and it is why I reference it so often.

Q: Are there other FreeBSD drivers that illustrate these patterns well?

Yes. Beyond `uart(4)`, the `sdhci(4)` family in `/usr/src/sys/dev/sdhci/` is a good study: core logic in `sdhci.c`, with PCI and FDT backends in `sdhci_pci.c` and `sdhci_fdt.c`. The `ahci(4)` driver in `/usr/src/sys/dev/ahci/` also separates its core from its bus attachments cleanly. The `ixgbe` driver in `/usr/src/sys/dev/ixgbe/` shows layered accessors and a tight separation between hardware-specific helpers and the rest of the driver. Reading any of these as a study-alongside source is valuable; picking the one closest to the kind of driver you are writing is even more so.

Q: My driver already has five hundred lines. Is it too late to refactor for portability?

No. Five hundred lines is small. Even five thousand lines is refactorable, though the refactor will take a few days. The important thing is to do the refactor incrementally: introduce accessors first, then split files, then introduce the backend interface. Each step leaves the driver working, and you can stop at any point if priorities change.

Q: What if my hardware has only one physical variant and is unlikely to ever change?

Then portability across hardware variants is not a concern for you. But portability across architectures, across FreeBSD versions, and between real hardware and a simulated one are still worth the effort. Even a single-variant driver benefits from having a simulation backend for testing and from using the endian helpers so it works on every architecture FreeBSD supports. The patterns here are not only about “what if new hardware comes along”; they are also about making your one driver robust in its current form.

Q: How do I get review feedback on a portability refactor?

If you are working on an in-tree driver, send the change to `freebsd-hackers@freebsd.org` or to the relevant subsystem maintainer. For out-of-tree drivers, ask a colleague or a mentor. Either way, break the refactor into small patches: one patch per step. A reviewer can keep up with six small patches; they cannot keep up with one large one. The smaller you make each change, the better the review you will receive.

Q: Should I rename the driver when I refactor it for portability?

Usually no. The refactor is an internal change; users do not need to care. The module name, the device node name, and the sysctl tree name should all remain stable so that existing configurations continue to work. The internal file structure is a detail the user never sees.

Q: How do I justify the time spent on portability to a manager who wants features?

Talk in terms of concrete future costs. “If we support a second hardware variant later, the current driver will take three weeks to fork; a refactor now takes one week, and any subsequent fork takes two days.” “If a customer reports a bug on arm64, the current driver has to be ported before we can even reproduce; the refactored driver would reproduce in a VM.” Portability pays for itself in the second year, not the first, and communicating that horizon is how the conversation gets easier.

Q: Can two drivers share a common library module?

Yes. FreeBSD supports module-to-module dependencies via `MODULE_DEPEND`. You can build a common library as its own module and have your drivers depend on it. This is how some of the in-tree drivers share helper code. The mechanism is a little fiddly for a small project, but it is the right approach when two drivers genuinely share significant helper code.

Q: What is the minimum test I should run after a refactor before committing?

Build. Load. Run the basic use case once. Unload. Rebuild from clean. Re-load. If all these succeed, the refactor is probably safe. If the driver has a test suite, run it. If there is no test suite, the refactor is a good time to write one, because the simulation backend makes tests easy to run.

Q: How does portability relate to security?

Portable code is usually more secure than non-portable code, because the discipline that supports portability (clear interfaces, narrow responsibilities, careful type usage, strict input validation) also supports security. A driver that uses `uint32_t` consistently is less likely to overflow. A driver with a clean backend interface is less likely to have ill-defined error paths that leak memory. A driver that is tested on multiple architectures is more likely to have encountered edge cases that expose security bugs. This is not a formal relationship, but it is a real one, and the two concerns reinforce each other more than they conflict.

Q: How much of this chapter applies to drivers I download from vendors rather than write myself?

Less directly, but still some. When you review a vendor-provided driver, the patterns in this chapter let you evaluate its quality. A vendor driver that is a single file of five thousand lines with scattered `#ifdef` chains is higher risk than one that is structured into core and backend. When you consume such a driver, you can use the audit questions from Challenge 7 to form an opinion about its maintainability. If the answers are discouraging, factor that into how much you rely on the driver.

Q: What is the single most important idea in this chapter?

That the cost of portability is an investment you make once per driver, and that the return on that investment is proportional to how long the driver lives. The specific patterns (backend interfaces, endian helpers, fixed-width types, file splits) are all instances of the same underlying discipline: **separate the details that can change from the logic that should not change, and express that separation in code rather than in comments**. Learn that discipline and you will apply it everywhere, not just in FreeBSD drivers.

Q: How do I debug a driver that panics only on arm64?

Start with the panic message itself; it often names the offending function and the kind of fault (alignment, unaligned access, null pointer, invalid memory). Rebuild the driver with debug symbols (`CFLAGS+= -g`), load it on the arm64 target under `kgdb` or `ddb`, and reproduce the panic. Unaligned access faults are the most common arm64-only panic; they almost always mean a struct member was accessed at an offset that is not aligned to its type's natural alignment. Fix these by packing or reordering struct fields, or by using `memcpy` for reads and writes that must be unaligned by design.

Q: What is the right balance between runtime flexibility and compile-time flexibility?

A useful rule of thumb: if a choice varies between deployments of the same binary, make it a runtime tunable. If a choice varies between releases of the driver (because a feature is new, or because a platform is not supported), make it a compile-time flag. Tunables let users reconfigure without rebuilding; compile-time flags keep the binary small and sharp. When in doubt, start with compile-time and promote to runtime only when a concrete need arises.

Q: Is it OK to disable a backend at runtime via a sysctl?

Yes, but only for backends that support re-initialisation cleanly. Disabling a backend mid-operation can leak resources or leave the driver in an inconsistent state. The safer pattern is to expose the choice at attach time (via a loader tunable) and to treat the runtime sysctl as read-only except during a well-defined maintenance window. If you do expose runtime disable, test it thoroughly, including under I/O load.

Q: How do I contribute a portability fix upstream to the FreeBSD project?

If the fix is to an existing in-tree driver, the canonical path is to file a bug in the FreeBSD Bugzilla, attach a patch in unified diff format (or, for larger changes, as `git` commits), and either wait for a committer to pick it up or post the patch to freebsd-hackers@freebsd.org for review. Include a clear description of the bug, steps to reproduce, and the platform(s) on which the bug appears. Smaller patches get reviewed faster; if your fix is large, split it into independently reviewable parts.

Q: Does every driver need a `README.portability.md`?

Every driver that ships beyond a single developer's machine benefits from one. The file does not need to be long; even three sections (supported platforms, build configurations, known limitations) are enough to cover the essentials. The file pays for itself the first time a user asks a question that the README answers; you send a link instead of typing the answer again.

Q: What happens if I forget to call `bus_dmamap_sync` after a DMA?

On amd64, usually nothing visible, because the CPU and DMA engine share the same memory and cache hierarchy. On arm64 with a device that is not cache-coherent, you will see stale data: the CPU reads its cached copy rather than the memory the device wrote. The bug is architecture-dependent, intermittent, and hard to reproduce without explicit test cases. This is why `bus_dmamap_sync` is mandatory in portable code even when a specific target does not strictly require it.

Q: Should I use `kobj(9)` or plain function pointers for my backend interface?

For fewer than five or six methods, plain function pointers in a struct are simpler and easier to debug. For larger interfaces, especially those with inheritance or method overriding, `kobj(9)` starts to pay back the ceremony. If you are unsure, start with function pointers; migrating later is a local refactor, and you will have a clear picture of whether `kobj` is worth it by then.

Q: What is the best way to learn how an existing driver works?

Read the code top-down. Start with `DRIVER_MODULE` (the Newbus anchor) and work outward: the attach method, then the methods called from attach, then their callees. Take notes as you go: a one-line description of each function in a plain text file is enough. After an hour or two you will have a functional map of the driver. Depth comes from repeating this exercise across several drivers; no single pass will make you an expert.

Q: How do I verify that my build matrix actually covers what I think it covers?

Write a test that fails if a configuration is missing. The simplest form is a shell loop that iterates over the configurations listed in `README.portability.md` and checks that each one has a corresponding entry in the build matrix script. Less rigorously, review the README and the script side by side once a release and confirm they agree. The point is not to be perfect; it is to make the two sources of truth stay aligned over time.

Q: Can I mix clang-specific and gcc-specific code in a portable driver?

Ideally no. FreeBSD's base system uses `clang` by default, and writing portable C that compiles cleanly under both compilers is rarely difficult. When a specific feature is only available under one compiler (for example, a specific sanitizer or a compiler-specific attribute), guard it with `#ifdef __clang__` or `#ifdef __GNUC__` and provide a fallback. But such cases should be rare; most of the time, plain C11 works everywhere.

Q: What do I do when two backends need to share helper code?

Put the helper in a shared file, say `portdrv_shared.c`, and link both backends against it. Alternatively, put the helper in the core if it genuinely belongs there. Avoid the temptation to copy the helper into each backend; copy-paste is the opposite of portability. If you find yourself wanting to duplicate a function, the function wants to be shared, and the only question is where the shared copy lives.

Q: How do I version a backend interface that needs to evolve?

Add a `version` field to the backend struct. The core checks the field at registration time and rejects backends compiled against an older interface. When the interface evolves in a backward-compatible way, bump the minor version; when it evolves in a breaking way, bump the major version and require all backends to be updated. The mechanism is simple and it prevents the class of bug in which a stale backend silently misbehaves because its struct layout has changed.

Q: What makes a driver “good” beyond the patterns in this chapter?

Good drivers are reliable, fast, maintainable, and kind to their users. Reliability comes from careful error handling and thorough testing. Speed comes from a clean data path that avoids unnecessary work and locks. Maintainability comes from the patterns in this chapter. Kindness comes from clear error messages, useful logging, and documentation that respects the reader's time. A driver that does well on all four dimensions is a driver worth shipping; a driver that does well on only two is a driver that will age poorly. Aim for all four.

Q: How do I know when a driver is finished?

It never is, quite. A driver “in production” is a driver under continuous maintenance, because the hardware world keeps changing around it. A reasonable definition of “ready to ship” is: the driver builds cleanly on every supported configuration, passes the tests you have written for it, survives the reliability soak test, and has a README that reflects its current state. Beyond that, every driver is an ongoing conversation between its author, its users, and the platform. The patterns in this chapter are the shape of that conversation; the driver itself is the record of it.

Q: What should I read next, after Chapter 30?

The chapters that follow in Part 7 build on Chapter 29's foundations in specific directions: virtualisation (Chapter 30), advanced interrupt handling (Chapter 31), advanced DMA patterns (Chapter 32), and so on. Read them in order; each one assumes the patterns of this chapter as table stakes. If you want to go wider rather than deeper, read a driver from an area of FreeBSD you have not touched before (storage if you have been doing network, or vice versa), and look for how the patterns of Chapter 29 show up there. Breadth and depth reinforce each other; alternate between them.

29.21 Where the Chapter's Patterns Appear in the Real Tree

A short tour of the FreeBSD source tree, pointing out where you can see the patterns of this chapter applied. Use this as a reading list when you want to practise recognising the structures in production code.

/usr/src/sys/dev/uart/ for backend abstraction. The core in `uart_core.c` is free of bus-specific code. The backends in `uart_bus_pci.c`, `uart_bus_fdt.c`, and `uart_bus_acpi.c` each implement the same interface through different buses. The interface itself lives in `uart_bus.h` as `struct uart_class`. See also `uart_dev_*.c` files for different hardware variants, each a `struct uart_class` instance.

/usr/src/sys/dev/sdhci/ for layered bus and hardware abstraction. The `sdhci.c` core is tall enough that it has its own internal structure, with backends for PCI (`sdhci_pci.c`) and FDT (`sdhci_fdt.c`) plus SoC-specific helpers for specific platforms. The driver illustrates how a mature abstraction accommodates both bus variations and minor hardware variations within a single bus.

/usr/src/sys/dev/e1000/ for layered register accessors. The Intel Gigabit Ethernet driver stacks its register access in four layers (`bus_space_*` primitives, the `E1000_READ_REG/E1000_WRITE_REG` macros in `e1000_osdep.h`, the chip-family helpers in the per-generation files, and the driver-facing API in `if_em.c`), as discussed earlier. Reading it alongside Section 2 is a good way to understand when multiple layers are justified.

/usr/src/sys/dev/ahci/ for split by both bus and platform. AHCI supports PCI-attached storage controllers across several generations and across x86 and non-x86 platforms. The driver uses a tight backend interface and per-platform initialisation helpers.

/usr/src/sys/dev/virtio/ for the paravirtual pattern. The virtio transport is itself a portable abstraction, and the drivers that use it illustrate how a backend can be purely virtual. Each virtio driver (network, block, console, and so on) talks to the virtio transport rather than a physical bus. This is the pattern that Chapter 30 will return to.

/usr/src/sys/net/if_tuntap.c for the simulation pattern applied to a real driver. The `tuntap(4)` driver is not a backend of something else; it is a full driver that synthesises a network interface purely in software. The pattern is useful even in production code.

/usr/src/sys/sys/bus.h for the `bus_read_*` and `bus_write_*` helpers. The header is instructive to read top to bottom, because it makes clear how much architectural abstraction is layered into what looks like a simple function call.

/usr/src/sys/sys/endian.h for the endian helpers. A short header that is worth reading in its entirety at least once, because understanding what `htole32` actually expands to on each platform is the best way to remember why you should use it.

`/usr/src/sys/sys/bus_dma.h` for the DMA API. Another short header, and the starting point for understanding the `bus_dma` abstraction.

`/usr/src/sys/modules/*/Makefile` for real Makefile patterns. Browse at random; almost every subdirectory has one, and each shows a different shape of portability challenge solved by a concrete Makefile.

Reading these files is one of the best ways to internalise the chapter's ideas. Not every file is simple or small, but each one embodies lessons that are hard to convey in the abstract. Treat the tree as a library of examples, not just as a reference.

29.22 A Self-Study Schedule for the Patterns

If you want to take the chapter's lessons further before moving on to Chapter 30, a modest self-study schedule is one way to do it. The suggestions below are sized to fit into a few evenings rather than a week-long course, and each one leaves you with a small, concrete piece of code to keep.

Week 1: The reference driver end to end. Build `portdrv` in every backend configuration. Load, test, and unload each one. Walk through the source with the chapter in your other hand, and annotate the code with the section numbers that introduce each pattern. You will finish the week with a marked-up copy of a working, portable driver and a clear mental map of where each pattern appears in practice.

Week 2: Real-world reading. Pick one driver from the list in the previous section ("Where the Chapter's Patterns Appear in the Real Tree"). `uart(4)` is a good first choice; `sdhci(4)` is a good second. Read the core file and one backend file. For each pattern this chapter introduced, locate the analogous construct in the real driver and write it down. A few pages of notes from this exercise will do more for your skill than reading another chapter cold.

Week 3: A small driver of your own. Write a tiny, original driver from scratch using the chapter's patterns. It can be a pseudo-device, a simulated sensor, or a wrapper around an existing FreeBSD feature exposed as a character device. The specific subject does not matter; what matters is that you use accessors, separate core and backend, structure the Makefile for optional features, and write a `README.portability.md` file. The result will be small and possibly silly, but you will have written a driver with the chapter's patterns from the first line, not retrofitted them.

Week 4: An audit. Find any FreeBSD driver, in-tree or out-of-tree, that looks interesting to you. Apply Challenge 7 to it: go through the audit questions and grade the driver. Write your findings as a short memo, as if to the driver's original author. Do not send the memo; write it for practice. The exercise of formalising what you notice about a driver will sharpen your eye.

After four weeks, you will have built one driver, read two, written a tiny original, and audited one more. That is not a trivial amount of practice, and it is enough to carry the chapter's patterns into your own long-term work. The schedule is a suggestion, not a prescription; adjust to fit the time you have.

One caveat: do not treat this as a race. The patterns land gradually, and the benefit comes from repeated exposure rather than from any single intense session. A slow, steady schedule, an hour or two per evening, produces more durable understanding than a one-day sprint that covers the same ground.

If you finish the four-week schedule and want to keep going, choose one of the later chapters' topics (interrupts, DMA, or `virtio`) and apply the same four-week pattern to it: read one, study two, build one, audit one. The

method generalises to any topic in FreeBSD kernel development, and once you have done it twice it stops feeling like a schedule at all; it just becomes how you learn.

29.23 A Note on Collaboration and Code Review

Portable drivers are easier to review than non-portable drivers. That is not an accident; it is a consequence of the patterns in this chapter. Accessors make every register access reviewable in isolation. Backend splits make it obvious which parts of the driver are bus-independent and which are not. Fixed-width types and endian helpers let a reviewer verify correctness without running the code. A reviewer who can see the structure can focus on the logic, which is what you actually want from the review.

If you are reviewing a driver written in the style of this chapter, there are a few questions worth having ready at hand. Does every register access go through an accessor? Is the backend interface well defined, with clear method contracts? Are all multi-byte values that cross the hardware boundary passed through the endian helpers? Does the Makefile support the build configurations the README claims? Is the module version bumped when the external behaviour changes? A review that answers these questions is a review that adds value; a review that only checks for formatting is a review that wastes time.

If you are on the receiving end of a review, do not take style comments personally. A reviewer pointing out a missed accessor or a bare `volatile` cast is helping you avoid a bug before it becomes one. Take the feedback, make the change, and thank the reviewer. The fastest path to becoming a better driver author is to be reviewed often by authors who are better than you.

29.23.1 Code Review Checklists

If you find yourself reviewing many drivers, a short checklist saves time. The one below is compatible with the patterns in this chapter; print it and keep it next to your review environment.

- **Every register access goes through an accessor.** Grep for `bus_read_`, `bus_write_`, and `volatile` in files that are not the accessor file. If there are hits, flag them.
- **Every multi-byte value that crosses the hardware boundary uses endian helpers.** Look at every struct that represents a descriptor, packet, or message. Verify that reads use `le*toh/be*toh` and writes use `htole*/htobe*`.
- **Fixed-width types are used consistently.** Grep for `int`, `long`, `short`, and `unsigned` in contexts that touch device registers or DMA descriptors. If the code uses a non-fixed-width type, ask whether the size was actually unknown.
- **The backend interface contract is documented.** A reader of the backend header should understand the contract each method fulfils without reading the core source.
- **Conditional compilation blocks have comments.** `#ifdef` blocks without an explanation of why the block exists are a warning sign. Ask the author to add the justification or remove the block.
- **Module version and dependencies are declared.** `MODULE_VERSION` and, where appropriate, `MODULE_DEPEND` are present. The version matches the driver's documented version.
- **The Makefile supports documented build configurations.** The configurations the README mentions actually build when tried. If the README is out of date, say so.
- **Error paths free what they allocated.** Goto-style cleanup, if used, unwinds correctly. Each allocation is balanced by a free.

- **Locking is consistent.** The same data structure is always protected by the same lock, and the core does not call into the backend while holding a lock unless the backend's documentation allows it.
- **Tests exist and pass.** At minimum, a build-matrix script and a smoke test for each backend. Ideally a CI harness that runs them automatically.

A review that covers these items is a review that makes the driver better. Not every review will find issues in every category, but going through the list quickly confirms which categories are clean and which deserve deeper attention.

29.24 A Short Section on Pragmatism

Not every piece of advice in this chapter applies to every driver equally. The chapter has been pitched at the driver that will ship, be maintained for years, run on more than one platform, and be read by more than one author. A throwaway driver written to confirm a hardware quirk does not need any of this. A personal driver written for a single laptop does not need most of it. The patterns are proportional to the expected lifetime and reach of the driver.

How do you decide how much to apply? A few rules of thumb:

- If the driver will only ever be loaded on one machine and will be rewritten when the hardware is replaced, use fixed-width types and endian helpers, and skip the rest. Even a throwaway driver benefits from those two small disciplines.
- If the driver will be shared with colleagues but not shipped, add accessors and a simple Makefile structure. You will not regret it when a colleague asks to build it on their machine.
- If the driver will be shipped to more than one customer, apply everything in Sections 2 through 5. A backend interface, a clean file split, and careful type usage are all in play.
- If the driver will be upstreamed or maintained for five or more years, apply everything in the chapter. This is the driver where the investment pays off most clearly.

Pragmatism means knowing which of these buckets a given driver belongs in and applying the right amount of effort accordingly. Both under-investing and over-investing hurt; the former leaves you with a brittle driver, the latter burns time on abstractions that never pay back. The chapter has shown you what to do when the driver is worth doing well; the judgement about when it is worth doing well is yours.

29.25 Questions to Ask Yourself Before Calling a Driver Done

Before you consider a portable driver complete, walk through the following questions. They are a final pass, a last readiness review for the patterns this chapter introduced. The list reads quickly; going through it honestly takes more time than you expect, because most drivers find at least one item they can improve.

Would a new reader guess the file layout correctly on the first try? If someone who has never seen your driver is told that a bug exists in the PCI attach path, would they open the right file immediately? If not, the file split may be muddled or the names may be unhelpful.

Would the driver compile unchanged on arm64, riscv64, or powerpc64? You do not need to test on every platform, but the answer should be a confident yes for every platform FreeBSD supports. If you hesitate, the reason for the hesitation is something to fix.

Can a user replace the hardware with a simulation and run every user-facing code path? If the simulation backend cannot reach a given path (say, the error recovery code), the test coverage for that path is implicit. Make the simulation rich enough to reach it.

If you disappeared tomorrow, would the next maintainer know why any given `#ifdef` block exists? Not just from the conditional itself, but from a comment above it. If any `#ifdef` is unexplained, it is a hole in the driver's institutional memory.

Does the driver fail loudly when something is wrong, or fail silently? A driver that silently returns zero when it should return `ENODEV` is harder to debug than one that prints a warning. Quiet failure modes are the ones that surprise people in production.

Can you name every lock in the driver and say what it protects? If you cannot produce a one-sentence description of each lock and the data it guards, the locking design is probably less clear than you think. Fix it before you call the driver done.

Does `kldunload` always succeed? Run the driver, push some traffic through it, then try to unload. If it hangs, the driver has a reference it is not releasing. Find the reference before shipping.

Does the driver survive repeated `kldload`/`kldunload` cycles? Run ten loads and unloads in a loop. If memory usage creeps up, you have a leak. If the tenth unload fails where the first succeeded, you have a stale reference.

Does the driver handle being loaded before its dependencies? `MODULE_DEPEND` declarations are the mechanism, but it is worth manually testing that loading your driver from `/boot/loader.conf` (before full userland is up) works as you expect.

Are the error messages specific enough to be useful in a bug report? If a user sends you `portdrv0: attach failed`, can you identify the cause? If not, add context: which operation failed, with what code, on what bus.

Does the Makefile pass a clean build with `-werror`? If it does not, something in your code is generating warnings. Warnings are the compiler telling you about code smells; do not silence the signal.

Have you removed every `printf` added for debugging? Debug prints left in production code slow the driver down and clutter `dmesg`. Use `if_printf`, `device_printf`, or gated debug macros, and remove everything that is not needed.

Going through this list before every release is a habit worth developing. A driver that passes all twelve questions is a driver that is ready to ship; a driver that fails any of them has an issue that is worth addressing before the release goes out.

29.26 Resources for Further Study

The patterns in this chapter are deep enough that a single reading will not exhaust them. The resources below are the ones most likely to repay the effort of following up.

The FreeBSD source tree. No book about FreeBSD drivers can substitute for time spent reading the tree itself. The specific drivers pointed to in this chapter (`uart`, `sdhci`, `ahci`, `e1000`, `virtio`, `tuntap`) are starting points. When you find one you like, read its full commit history. The evolution of a driver often teaches as much as the current snapshot.

The FreeBSD handbook. The handbook is not primarily about driver development, but its chapters on the kernel, on jails, and on bhyve provide context that informs how drivers get deployed. A portable driver cooperates with these features; reading about them is part of writing for them.

sys/sys/bus.h, sys/sys/bus_dma.h, sys/sys/endian.h, sys/sys/systm.h. These headers are short enough to read top to bottom in a single sitting. Each one teaches a different portability concern: `bus.h` the bus abstractions, `bus_dma.h` the DMA abstractions, `endian.h` the endian helpers, `systm.h` the general kernel utilities. Read them; mark them up; come back to them.

The FreeBSD Architecture Handbook. This is the document to read when you want to understand why things are the way they are. It is less hands-on than this book but complements it by explaining the history and reasoning behind key kernel subsystems.

The style(9) manual page. Not glamorous, but the single most important reference for what your code should look like. Read it once thoroughly; skim it again every six months. Familiarity with the in-tree style makes your drivers easier for the community to read and review.

Community forums: `freebsd-hackers@freebsd.org` and `freebsd-arch@freebsd.org`. These lists are the best places to ask questions about non-trivial driver problems. Search the archives before posting; many questions have been asked before. When you do post, follow the community's conventions: clear subject, self-contained description, specific versions and platforms named.

The FreeBSD commit log (git log in the source tree). When you want to understand how a specific feature came to be, trace it through the log. You will find design discussion embedded in the commit messages, particularly for large changes. Read widely: not just commits to the driver you are studying but also the kernel changes that drive new driver requirements.

Your own changes over time. If you apply the patterns in this chapter across several drivers, keep the drivers in a version control system and read through the history occasionally. Your own evolution as a driver author is as instructive as any external reference; looking back at the choices you made six months ago is one of the best ways to see where you are growing.

These resources will sustain you beyond the boundaries of this book. The book is an introduction and a scaffolding; mastery comes from the continuous work of applying the patterns, reading more code, and refining your own taste in engineering. Pace yourself and stay curious.

29.27 Ten Principles to Carry Forward

A chapter this long deserves a closing compression. The ten principles below are what to remember if nothing else from this chapter sticks. Each one is a distillation of a section; together they are the shape of a portable driver.

1. Separate what changes from what does not. The heart of portability is knowing which parts of your driver are likely to vary and isolating them behind an interface. Buses change. Hardware variants change. Architectures change. The driver's core logic should not.

2. Write through accessors, not through primitives. Every register access goes through a named function in your driver. The name describes the operation, not the underlying primitive. One day you will be glad you did.

- 3. Use fixed-width types at hardware boundaries.** `uint32_t` for a 32-bit register field, `uint64_t` for a 64-bit descriptor word. Never `int` or `long` when the size matters.
- 4. Byte-swap at the boundary, and only at the boundary.** Every multi-byte value that crosses from CPU to hardware or vice versa passes through an endian helper. The rest of the code is blissfully unaware of byte order.
- 5. Express variation as data, not as conditionals.** A table of backends, a struct of function pointers, a registry indexed by device ID. These are easier to read, test, and extend than sprawling `if-else` chains.
- 6. Split files by responsibility, not by size.** The core in one file, each backend in its own file, each large subsystem concern in its own file. File boundaries communicate design intent.
- 7. Keep conditional compilation coarse and commented.** A `#ifdef` block with a clear comment is a feature toggle. A sea of nested `#ifdefs` with no comments is a maintenance crisis.
- 8. Version everything that can change.** `MODULE_VERSION`, backend interface version fields, `README.portability.md`. When the driver's world changes, its version numbers make the change legible.
- 9. Test with simulation, build on a matrix.** A simulation backend exercises your core without hardware. A build matrix catches compile-time portability regressions before they reach users. Both are force multipliers.
- 10. Document the invariants, not the syntax.** Comments explain why a choice was made, not what the code does. Code says what; comments say why. The combination is what makes a driver outlive its author.

These ten principles are the chapter. Everything else is elaboration, example, and exercise. Commit them to memory, apply them consistently, and the patterns will feel natural within a year. That is the payoff.

One more note on the principles. They are not a ranking; they are a set. Leaving any one out weakens the others. A driver with perfect endian handling but no file split is still hard to maintain. A driver with a clean file split but no `MODULE_VERSION` is still hard to upgrade. A driver with flawless abstractions but no tests is still fragile under change. The patterns reinforce each other, and missing one undermines the value of the rest. If you must pick a subset (say, because the driver is small or throwaway), pick based on the lifetime and reach you expect, not on which pattern is cheapest today.

The last encouragement is the simplest: start somewhere. Take one driver, one weekend, one pattern from the list, and apply it. Look at what changed. Notice that the driver got better, even if only slightly. Then do it again, the following weekend, with another pattern. After a month of this, the driver will be in better shape than you can remember it, and your sense for what the patterns feel like in practice will be solid. The path to mastery is not dramatic; it is just the patient accumulation of small improvements over time. You now have the map.

29.28 Wrapping Up

Portability is easier to internalise when you can see it on the page, so let us close the chapter with a small, concrete example of what a cross-release change looks like in the real FreeBSD tree. Open `/usr/src/sys/dev/rtsx/rtsx.c`, find `rtsx_set_tran_settings()`, and look at the short block guarded by `#if __FreeBSD_version >= 1300000`. Inside that guard, the driver handles the `MMC_VCCQ` field, which carries the I/O voltage for an MMC card and was added in the FreeBSD 13 series. On older trees the field does not exist; on 14.x it does; and the guard is the only thing that lets a single source file compile cleanly on both. That is portability expressed as a short conditional rather than as two forks of the same driver, and it is exactly the discipline this chapter has been asking you to adopt.

The lesson of that small block is larger than the block itself. Every change between releases, whether it is a new field in a structure, a renamed function, a deprecated macro, or a reorganised header, can be absorbed by the same pattern you just saw: name the variation, isolate it behind a guard or an accessor, and leave a comment that explains why the block is there. The driver keeps working on old and new trees alike, and your energy goes into the logic rather than into maintaining parallel copies of the same file for every release you care about.

A similar story, at a much larger scale, is on display in the Intel Ethernet driver at `/usr/src/sys/dev/e1000/if_em.c`. There, the attach and detach path now goes through the `iflib` framework: `em_if_attach_pre(if_ctx, ctx)` replaces the bespoke `device_t` attach that this driver once implemented directly, and the `DEVMETHOD` table near the top of the file dispatches `device_probe`, `device_attach`, and `device_detach` through `iflib_device_probe`, `iflib_device_attach`, and `iflib_device_detach`. You are not looking at a small conditional there; you are looking at the result of moving a whole family of NIC drivers onto a shared abstraction so that the per-chip code and the `iflib`-common code can evolve on different schedules. It is the same instinct as the `rtss` example, applied at a bigger scale.

If you take one thing from this chapter, take that instinct. Portability is not a property you add at the end of the project, and it is not a special kind of code you write once and forget about. It is a way of sitting down at a source file and asking: what might change, where will it change, and how do I make sure the change lands in one place rather than twenty? Answer that question consistently, and the drivers you write in the coming years will outlive several hardware generations, several kernel releases, and probably several jobs.

29.29 Looking Ahead: Bridge to Chapter 30

You have just refactored a driver for portability. The next chapter, **Virtualisation and Containerization**, turns from the driver's own internals to the environment it runs in. FreeBSD drivers run not only on bare metal but inside `bhyve` guests, under `jail(8)` with `VNET`, on `virtio`-backed storage and network, and increasingly inside OCI-style container runtimes built on top of jails.

That question is sharper after Chapter 29 than it was before. You have now learned to write drivers that absorb variations in hardware, bus, and architecture as local changes. Chapter 30 will add a new kind of variation: the environment itself is virtualised. The machine your driver sees may not be a real machine; the devices it probes may be paravirtual; the host may have removed whole classes of capability because the guest is not trusted to use them. You will learn how `virtio` guest drivers work, how `bhyve`'s `vmm(4)` and `pci_passthru(4)` fit together, how `VNET` jails isolate network stacks, and how to write drivers that cooperate with those forms of containment without assuming the usual privileges.

You will not be writing a new kind of driver in Chapter 30. You will be learning how the drivers you already know how to write must adapt when the environment around them is virtual, partitioned, or containerised. That is a different kind of step, and it matters the moment you deploy a FreeBSD system in a cloud or in a multi-tenant host.

Before you move on, unload every module you created in this chapter, clean every build directory, and make sure the driver source tree is in a tidy state. Close your lab logbook with a brief note on what worked, what surprised you, and which pattern you expect to reach for most often in your own drivers. Rest your eyes for a minute. Then, when you are ready, turn the page.

29.30 A Final Word: The Long Arc

It is worth stepping back one more time, because chapters about craft are easy to read and hard to apply. The patterns in this book are not a checklist to tick off on a single project; they are a long-running investment in your own capability. The first driver you write using them will feel like a lot of work for modest gain. The fifth driver will feel natural. The tenth driver will be faster and more reliable than any driver you could have written without the patterns, and you will no longer remember that you once found them effortful.

That arc is not unique to FreeBSD driver development. It is the arc of every skilled practice, from carpentry to music to compiler writing. The craft starts as a set of disciplines that feel heavy and deliberate; it becomes, after enough practice, the shape of your attention. When you sit down to write your next driver and find that you have already thought about the backend structure before typing the first line, that is the craft at work.

The chapter ends here, but the practice does not. Keep building. Keep reading. Keep refactoring drivers that are not yet as portable as they could be. The payoff is measurable only over years, which is the exact timescale that FreeBSD drivers tend to live on. You have picked a long game; the patterns in this chapter are the rules that let you play it well.

You have earned the step.

30 Virtualisation and Containerization

30.1 Introduction

You arrive at Chapter 30 with a new habit of mind. Chapter 29 taught you how to shape a driver so that it absorbs variation in hardware, bus, and architecture without collapsing into a maze of conditionals. You have learned to push the parts that change into small, backend-specific files and to let the core remain clean. You have met the idea that a driver is not written for a single machine; it is written for a family of machines that share a programming model. That lesson carries a great deal of weight in this chapter, because the environment around your driver can now change in a way that is more radical than anything Chapter 29 considered. The machine itself may not be real.

This chapter is about what happens when the hardware under your driver is not a physical card plugged into a physical slot, but a software simulation presented to a guest operating system by a hypervisor; or when the driver is asked to attach inside a jail that sees only part of the device tree; or when the network stack it cooperates with is one of several stacks running side by side inside a single kernel. Each of these situations is a departure from the “one kernel, one machine, one device tree” mental model that the earlier chapters built. Each one changes what your driver may assume, what it may do, and what a user of your driver may safely expect from it.

The word “virtualisation” can mean several different things depending on who is speaking. To a system administrator running a cloud fleet, it means virtual machines with full kernels of their own. To a FreeBSD user, it often means `jail(8)` and its descendants, which isolate processes and filesystems without giving each one a kernel. To a driver author, it means both, and more. It means paravirtual devices like `VirtIO` that are explicitly designed to be easy for a guest to drive. It means emulated devices that a hypervisor presents to a guest as if they were physical hardware. It means passthrough devices where a real piece of hardware is handed to a guest more or less directly, with the hypervisor stepping aside as much as it safely can. It means jails whose view of `devfs` is trimmed by a ruleset so that the containerised processes inside cannot see every device the host can see. It means `VNET` jails that own an entire network stack of their own, complete with an `ifnet` that was loaned to them by the host.

If that list already feels like a lot, take a breath. The chapter will introduce each of these pieces one at a time, with enough real FreeBSD grounding that you will be able to close the book and open the source tree and find the relevant files with your own hands. Nothing in this chapter is impossible to learn; it is a set of distinct but related ideas that share a common thread. The thread is this: a driver stops being the single most important piece of software in its particular hardware path. Above it sits a hypervisor, a jail framework, or a container runtime; beside it sit other guests or jails that share the host; below it sits a piece of silicon that the driver no longer owns exclusively. Writing drivers for that world is not harder than writing drivers for bare metal, but it is different in ways that are easy to miss if you have not been shown them.

Two distinct directions run through the chapter. The first direction is about **writing guest drivers**: code that runs inside a virtual machine and talks to devices the hypervisor presents. You will spend the bulk of your time in this direction, because it is where most of the novel programming happens. `VirtIO` is the canonical example,

and we will return to it often. The second direction is about **cooperating with FreeBSD's own virtualisation infrastructure** from the host side: understanding how your driver attaches inside a jail, how it behaves when the host moves an interface into a VNET jail, how it handles a user inside a jail trying to call an `ioctl` that only root on the host should be allowed to call, and how to test it all without ruining a running host. This direction is less about exotic new APIs and more about discipline, privilege boundaries, and a careful mental model of what is visible from where.

The chapter does not try to teach you how to write a hypervisor, how to implement a new VirtIO transport, or how to build a container runtime from scratch. Those are large topics with their own books. What it teaches is how a driver author should think about, prepare for, and work with virtualised and containerised environments, so that the drivers you write make sense everywhere they are loaded. By the end of the chapter, you will recognise a VirtIO guest driver when you see one, you will know how to detect whether your driver is running in a virtual machine, you will be able to explain what `devfs_ruleset(8)` does and why it matters for device exposure, you will be able to reason about the differences between VNET jails and ordinary jails for a network driver, and you will have written a tiny VirtIO guest driver of your own against a FreeBSD `bhyve(8)` backend.

Before we begin, a word about the tone of what follows. Some of the subjects in this chapter, especially hypervisor internals and jail security boundaries, have acquired a reputation for being exotic. A driver author who has never looked under the hood can feel intimidated by their jargon. You should not. The code is FreeBSD code; the APIs are FreeBSD APIs; the mindset is the same mindset you have been building since Chapter 1. We will move slowly, and we will keep coming back to real files you can open. Let us begin.

30.2 Reader Guidance: How to Use This Chapter

This chapter sits in a different place in the learning progression from Chapter 29. Chapter 29 was about how your driver is organised on disk. Chapter 30 is about what the world around your driver looks like at runtime. That difference matters for how you should read and practise. The patterns of Chapter 29 can be absorbed by reading carefully and typing along. The patterns of this chapter land more firmly if you also boot a virtual machine, create a jail, and watch the driver behave inside them. Plan accordingly.

If you choose the **reading-only path**, plan for roughly two to three focused hours. At the end you will understand the conceptual map: what paravirtual, emulated, and passthrough devices are; how VirtIO uses shared rings and feature negotiation; how jails and VNET isolate devices and network stacks; what `rctl(8)` controls from the driver's point of view. You will not yet have the reflexes of a driver author who has debugged a `virtqueue` mismatch at three in the morning, and that is fine. The reading pass is a legitimate first encounter, and the material has enough depth that a second pass with labs later on will extract much more value from it.

If you choose the **reading-plus-labs path**, plan for six to ten hours spread across two or three sessions. You will install `bhyve(8)` on your lab machine, boot a FreeBSD 14.3 guest on top of it with VirtIO devices, write a small VirtIO pseudo-device driver called `vtedu`, and observe it attach, service requests from the host-side device, and detach cleanly. You will also create a simple jail, attach the driver to it under different `devfs` rulesets, and watch what happens when the driver exposes a device inside the jail. The labs are structured so that each one stands on its own, leaves you with a working system, and reinforces a specific concept from the main text.

If you choose the **reading-plus-labs-plus-challenges path**, plan for a long weekend or a handful of evenings. The challenges push the baseline labs into more realistic territory: extending `vtedu` to accept multiple `virtqueues`, writing a small tool that probes the guest's hypervisor through `vm.guest` and adapts behaviour, building a VNET

jail and moving a tap interface into it, and writing a short report on how a driver that exports an `ioctl` surface should decide which `ioctls` should be accessible from inside a jail. Each challenge is invitational rather than mandatory, and each one is sized to be completable without a second weekend.

A note on the lab environment. You will continue to use the throwaway FreeBSD 14.3 machine you established in earlier chapters. That machine will act as the **host** in this chapter. On top of it you will run `bhyve(8)` guests, which are smaller FreeBSD installations managed by your host. You will also create a few jails directly on the host. This nesting sounds complicated the first time it is described, but it is genuinely simple in practice: your host runs FreeBSD, inside the host you start a `bhyve` virtual machine that also runs FreeBSD, and inside either the host or the guest you create jails. Each layer is independent, each layer has its own `dmesg`, and each layer is cheap to recreate from scratch if something goes wrong.

Make a snapshot of the host before you start. The chapter will ask you to change `/etc/devfs.rules`, to load and unload kernel modules, and to create small VMs. None of these are risky if handled carefully, but accidents happen, and the snapshot turns any mistake into a two-minute rollback. If your host is itself a VM in VirtualBox or VMware, the platform's own snapshot tool is the fastest way to do this. If your host is bare metal, a ZFS boot environment with `bectl(8)` is a good substitute.

One more note. This chapter's labs need a few packages that you may not already have installed. You will want `bhyve-firmware` for UEFI guest support, `vm-bhyve` for a more convenient front end to `bhyve` and its accessories, and `jq` for parsing JSON output during some of the more elaborate tests. The commands to install them are in the labs; do not install them now, but be aware that they are coming.

30.2.1 Prerequisites

You should be comfortable with everything from earlier chapters. In particular, this chapter assumes that you already know how to write a loadable kernel module from scratch, how `probe()` and `attach()` fit together in the driver lifecycle, how `softc` is allocated and used, and how `device_t` relates to `devclass`. It assumes fluency with the `bus_read_*` and `bus_write_*` accessors from Chapter 15, basic familiarity with interrupt handlers from Chapter 18, and the portable-driver habits from Chapter 29. If any of that feels uncertain, a brief revisit to the earlier material will save you time here.

You should also be comfortable with ordinary FreeBSD system administration: reading `dmesg`, editing `/etc/rc.conf`, using `sysctl(8)`, and creating and destroying jails with `jail(8)` or its wrapper service `jail`. You do not need prior `bhyve` experience; the labs will walk you through it. You do not need prior container experience either, since FreeBSD's container story is ultimately jails dressed in different operational clothing.

30.2.2 What This Chapter Does Not Cover

A responsible chapter tells you what it leaves out. This chapter does not teach the internals of the `bhyve(8)` hypervisor. It does not teach `libvirt(3)`, `qemu(1)`, or the Linux KVM subsystem. It does not turn you into an OCI container expert. It does not cover the `xen(4)` paravirtualisation code, since Xen has become a narrower niche in the FreeBSD ecosystem and `bhyve` is the FreeBSD-native story worth learning first. It mentions `jail(8)` at exactly the level a driver author needs, not at the depth a jail administrator would want. For the missing topics, the FreeBSD Handbook and the respective manual pages are your friends, and I will point to them when they are relevant.

Several topics that could plausibly appear in a virtualisation chapter have homes elsewhere in this book. Secure coding against hostile input is Chapter 31's subject, not this chapter's; you will meet privilege boundaries and jail visibility here, but the deeper security discipline (Capsicum, MAC framework, sanitiser-driven fuzzing) waits for the next chapter. Advanced DMA under virtualisation (IOMMU setup, mapping pages with `bus_dmamap`) is touched conceptually here and developed more fully in later chapters. Performance tuning under virtualisation (how to measure paravirtual overhead, how to decide between emulated and passthrough for a given workload) is a theme that returns in Chapter 35. We will mention these where they connect, but we will not go deep.

30.2.3 Structure and Pacing

Section 1 establishes the mental model: what virtualisation and containerization mean for a driver author, and how they differ from “hardware, but slower.” Section 2 explains the three styles of guest device (emulated, paravirtualised, passthrough) and what each one implies for the driver. Section 3 takes a careful, beginner-friendly tour of VirtIO: the shared-ring model, feature negotiation, and the `virtqueue(9)` APIs you will use. Section 4 teaches how a driver detects its runtime environment through `vm_guest` and friends, and when that detection is and is not a good idea. Section 5 turns to the host side and looks at `bhyve(8)`, `vmm(4)`, and PCI passthrough. Section 6 covers jails, `devfs`, and VNET: the FreeBSD containerisation story from the driver's perspective. Section 7 addresses resource limits and privilege boundaries. Section 8 talks about testing and refactoring. Section 9 revisits time, memory, and interrupt handling through the lens of virtualisation, the quieter topics where beginner drivers often fail in subtle ways. Section 10 widens the lens to FreeBSD on `arm64` and `riscv64`, whose virtualisation stories have their own shape. The labs and challenges follow, along with a troubleshooting appendix and a closing bridge into Chapter 31.

Read the sections in order. Each one assumes the previous one, and the labs depend on the earlier sections having been read and internalised.

30.2.4 Work Section by Section

A recurring pattern in this book is that each section does one thing. Do not try to read two sections at a time, and do not skip ahead to a “more interesting” section if something in the current one feels difficult. The interesting parts of this chapter rest on the foundational ones, and a reader who has skipped the foundation will spend more time reverse-engineering the labs than the careful reader spends on the whole chapter.

30.2.5 Keep the Reference Driver Close

Several labs in this chapter build on a small pedagogical driver called `vtedu`. You will find it under `examples/part-07/ch30-virtualisation/`, organised the same way as earlier chapters' examples. Each lab directory contains the state of the driver at that step, along with `Makefile`, `README`, and supporting scripts. Clone the directory, type along, and load the module after each change. Refactoring a VirtIO guest driver in your head is harder than refactoring one on disk; the feedback from the build system and from `dmesg` is half the lesson.

30.2.6 Open the FreeBSD Source Tree

Several sections will point to real FreeBSD files. The ones that repay careful reading in this chapter are `/usr/src/sys/dev/virtio/random/virtio_random.c` (the smallest complete VirtIO driver in the tree), `/usr/src/sys/dev/virtio/virtio.h` and `/usr/src/sys/dev/virtio/virtqueue.h` (the public API surfaces), `/usr/src/sys/dev/virtio/virtqueue.c` (the ring machinery), `/usr/src/sys/dev/virtio/p-ci/virtio_pci.c` and `/usr/src/sys/dev/virtio/mmio/virtio_mmio.c` (the two transport backends), `/usr/src/sys/sys/system.h` (for `vm_guest`), `/usr/src/sys/kern/subr_param.c` (for the `vm.guest sysctl`), `/usr/src/sys/net/vnet.h` (for VNET primitives), and `/usr/src/sys/kern/kern_jail.c` (for prison and jail APIs). Open them when the text says to, and read around the exact spot the text points at. The files are not decoration; they are the source of truth.

30.2.7 Keep a Lab Logbook

Continue the lab logbook from earlier chapters. For this chapter, log a short note for each major lab: which commands you ran, which modules loaded, what `dmesg` said, what surprised you. Virtualisation work is easy to forget the details of after a few days, and a paper trail turns every future debugging session into a one-minute lookup rather than a half-hour re-derivation.

30.2.8 Pace Yourself

Several ideas in this chapter will feel new the first time you meet them: shared-ring memory, feature negotiation, VNET's thread-local current `vnet`, the `devfs` ruleset number system. That newness is normal. If you feel your understanding blur during a particular subsection, stop. Re-read the previous paragraph, try a small experiment in the shell, and come back fresh in an hour. Consistent thirty-minute sessions produce better understanding than a single exhausted all-day effort.

30.3 How to Get the Most Out of This Chapter

Chapter 30 rewards curiosity, patience, and a willingness to experiment. The specific patterns it introduces, the ring structures, the feature bits, the prison and `vnet` scopes, are not abstract. Each one corresponds to code you can read, state you can observe with `sysctl` or `vmstat`, and behaviour you can trigger with short commands. The most valuable habit you can build while reading the chapter is to move freely between the text, the source tree, and the running system.

30.3.1 Read With the Source Tree Open

Do not read the VirtIO section without `virtio.h`, `virtqueue.h`, and `virtio_random.c` open in another window. When the text says that a driver calls `virtqueue_enqueue` to hand a buffer to the host, scroll to that function and see it in context. When the text mentions the `VIRTIO_DRIVER_MODULE` macro, open `virtio.h` and see the two `DRIVER_MODULE` lines it expands into. The FreeBSD kernel is far more approachable than its reputation suggests, and the only way to confirm that is to keep opening it.

30.3.2 Type the Labs

Every line of code in the labs is there to teach something. Typing it yourself slows you down enough to notice the structure. Copy-pasting the code often feels productive and usually is not; the finger-memory of typing kernel code is part of how you learn it. If you must copy, copy one function at a time, and read each line as you paste it.

30.3.3 Run What You Read

When the text introduces a command, run it. When the text introduces a `sysctl` name, query it. When the text introduces a kernel module, load it. The running system will surprise you sometimes (the `vm.guest` value may not be what you expect if your lab itself is a VM), and every surprise is an opportunity to learn something the text did not need to explain explicitly. A running FreeBSD system is a patient tutor.

30.3.4 Treat `dmesg` as Part of the Manuscript

A significant fraction of what this chapter teaches is visible only in the kernel's log output. A VirtIO device's negotiated feature set, the attach sequence of a guest driver, the interaction between a module and a jail, all of these surface in `dmesg`. Read it often. Tail it during the labs. Copy relevant lines into your logbook when they teach something non-obvious. Do not treat `dmesg` as noise; treat it as the ground truth of what the kernel actually did.

30.3.5 Break Things Deliberately

At three points in the chapter I will suggest deliberately breaking something to see what happens. These are the most educational moments you can give yourself. Unload a required module before a driver that depends on it and see the dependency graph complain. Remove a `devfs` rule and see the device vanish from inside the jail. Boot a guest with one CPU and then with four and compare the `virtqueue` setup. Deliberate failures teach in a way that success cannot.

30.3.6 Work in Pairs When You Can

If you have a study partner, this is a great chapter to pair on. One of you can run the host and watch `dmesg`, while the other runs the guest and drives the driver. The two perspectives teach different things, and each of you will notice what the other missed. If you are working alone, use two terminal tabs and alternate attention between them.

30.3.7 Trust the Iteration, Not the Memorisation

You will not remember every flag, every enum, every macro in this chapter on the first read. That is fine. What matters is that you remember where to look, what the overall shape of the subject is, and how to tell when your driver is doing the right thing. The specific identifiers will become second nature after you have written and debugged two or three virtualisation-aware drivers of your own; they are not a memorisation exercise.

30.3.8 Take Breaks

Virtualisation-aware debugging has a particular cognitive cost. You are tracking state on several sides at once: the host, the guest, the driver, the device model, the jail. Your mind gets fatigued faster than when you are working on a single-threaded bare-metal driver. Two hours of focused work followed by a real break is almost always more productive than four hours of grinding.

With those habits in place, let us begin.

30.4 Section 1: What Virtualisation and Containerization Mean for Driver Authors

Before we touch any code, we need to agree on what we are talking about. The words “virtualisation” and “containerization” have been worn smooth by marketing language, and they carry different meanings depending on where you encounter them. A vendor’s white paper uses “virtualisation” as a synonym for running multiple operating systems on the same hardware; a cloud provider’s documentation uses it as shorthand for any managed workload; a FreeBSD administrator uses it for anything from `bhyve(8)` to `jail(8)`. For a driver author, those meanings are not interchangeable. The shape of the problem you are solving changes depending on which kind of virtualisation your driver meets. This section anchors the vocabulary for the rest of the chapter.

30.4.1 Two Families, Not One

The first distinction to draw is between **virtual machines** and **containers**. They solve different problems and produce different constraints for driver authors. Conflating them is the single most common confusion in this territory.

A **virtual machine** is a software-emulated computer. A hypervisor, which itself runs on real hardware, creates an execution environment that looks like a complete machine to the software inside it. The machine has a BIOS or UEFI, memory, CPUs, disks, and network cards. The operating system inside the VM boots from scratch just as it would on real hardware, loads a kernel, and attaches drivers. The observation that matters is that the **guest kernel is a full kernel**, independent of the host kernel. A FreeBSD guest running under a FreeBSD host is not sharing kernel code with the host; the two kernels are peers, separated by the hypervisor and by the barrier between guest memory and host memory.

A **container**, on the FreeBSD sense of the word, is a different animal. A container is a namespaced partition of a single kernel. The host kernel is the only kernel in the picture; the containers are separate process groups, separate filesystem views, and often separate network stacks, but all of them run on the same kernel with the same drivers. On FreeBSD, the classical container is a `jail(8)`. Modern container runtimes like `ocijail` and `pot` add scripting and orchestration around that same jail primitive. The observation here is that **there is only one kernel**. A driver in the host is visible to every jail, subject to the rules the host imposes; a jail cannot load a driver of its own, and it does not have a kernel into which to load one.

These two families overlap only in superficial ways. A VM and a jail both look like “another system” from the outside. A VM and a jail both have their own `/`, their own network, and their own users. But the kernel boundary is nowhere near the same, and that matters enormously to drivers.

A VM runs a full guest kernel; the kernel sees virtualised (or passthrough) hardware; the driver you write for that hardware is a **guest driver** that attaches inside the guest. A jail shares the host's kernel; no guest driver is being written, because there is no guest kernel to load it into; instead, the question is how a **host driver** exposes its services to processes running inside the jail. The techniques you use in each case are different.

For the rest of this chapter, when the text says “virtualisation,” it usually means the VM case unless the context makes clear that jails are being discussed. When the text says “containerization,” it usually means the jail case. Read those words with the families in mind, and you will avoid most of the confusion that newcomers have.

30.4.2 Virtual Machines as an Environment for Drivers

A VM presents hardware to the guest. Exactly what that hardware looks like depends on the hypervisor's configuration. There are three broad styles of device that a guest may meet, each of which changes the driver problem.

Emulated devices are the oldest approach. The hypervisor presents to the guest a device that imitates a real, usually well-known, physical device: a ne2000 Ethernet card, for example, or a PIIX IDE controller, or a serial port compatible with the venerable 16550 UART. The hypervisor's device model implements the same register interface the real hardware would expose. The guest loads the driver it would have loaded on real hardware, and the driver runs unchanged. The price is performance: every register access in the guest traps into the hypervisor, which emulates the behaviour in software, which is much slower than real hardware. Emulated devices are perfect for compatibility and for booting unmodified guest kernels; they are poor for serious workloads.

Paravirtual devices solve the performance problem by replacing the compatibility interface with one designed to be cheap for both sides. Instead of imitating physical hardware, the device defines a new interface that is efficient when implemented in software. VirtIO is the canonical example and the one this chapter will spend most of its time on. A VirtIO device does not look like any real hardware; it looks like a VirtIO device, which is a standardised interface that exposes shared memory rings and a few control registers and very little else. The guest must have a driver for VirtIO specifically; that driver is smaller and faster than the equivalent emulated-device driver, because the interface was designed for software on both sides.

Passthrough devices go in the other direction. The hypervisor steps aside and hands the guest a real piece of hardware: a physical NIC, a physical GPU, a physical NVMe SSD. The guest's driver talks to that hardware more or less directly. The hypervisor still mediates (through an IOMMU, for example, to constrain which memory the device can reach) but it no longer emulates or paravirtualises. Passthrough is fast but brittle: the device is no longer shared with other guests, and moving the VM to a different host is no longer trivial.

Each style of device imposes a different design on your driver. An emulated-device driver is typically an old, well-tested driver for the emulated hardware, which just happens to be running on a virtualised version of the same hardware. A paravirtual driver is usually a driver written specifically for the paravirtual interface, with no expectation that the “hardware” exists in real silicon. A passthrough driver is the same driver that would have run on bare metal, with one subtlety: the guest's memory is not the same memory the device DMAs into, and the IOMMU mapping must be correct for the device to work.

The rest of this chapter leans strongly into the second style, because paravirtualisation is where most of the novel driver work in virtualised environments happens, and because it illustrates a programming model (shared rings, feature bits, descriptor-based transactions) that generalises to other parts of FreeBSD.

30.4.3 Containers as an Environment for Drivers

A jail is a different kind of environment, and it asks a different question of a driver. The driver is not running inside the jail; it is running in the single shared kernel. What the jail does is change what the processes in the jail see.

From the host's kernel, nothing changes when a jail is created. The host kernel still has all the drivers it had before; the drivers still attach to the same devices; the same `/dev/` entries still exist in the devfs mounted at the host's root. From inside the jail, a devfs mount is also performed, but that devfs is configured with a ruleset that hides some devices and exposes others. A `/dev/mem` is not normally visible inside a jail, because a process inside a jail should not be able to peek at kernel memory; a `/dev/kvm` equivalent (if FreeBSD had one) would be similarly hidden. A `/dev/null` and `/dev/zero` are visible, because there is no reason to hide them.

So what is a “driver problem” in a container? Two things, mostly. First, when your driver creates device nodes, you must decide whether those nodes should be visible to jailed processes, and if so, under what conditions. If your driver exposes an `ioctl` that allows a process to change the routing table, that `ioctl` should not be accessible to a process inside a jail that does not have the privilege to reconfigure the host's network. Second, when your driver cooperates with VNET (the FreeBSD virtual network stack framework), you must be careful about which global state is per-vnet and which is shared. An `ifnet` moved into a VNET jail should behave correctly inside that jail, which means your driver must have declared the right VNET-scoped variables and must not have cached any cross-vnet state.

These are different concerns from those of VM drivers, and they deserve their own sections. Sections 6 and 7 of this chapter work through them in detail.

30.4.4 Why This Matters for Driver Authors

It is fair to ask: why should a driver author care about any of this? Until recently, most drivers were written for physical hardware on bare metal, and the “virtualisation story” was something that happened upstream. Today, and for the foreseeable future, the majority of FreeBSD installations are virtual machines. A driver that works only on bare metal is a driver that works in a minority of deployments. A driver that works only on the host, and not inside a jail, is a driver that cannot be used in any modern containerised FreeBSD environment. Virtualisation-aware driver design is not optional anymore; it is part of writing drivers at all.

There are three concrete reasons the topic matters.

First, **most of your users are inside a guest**. The FreeBSD VMs running in public clouds, in private clouds, and in local bhyve labs outnumber the FreeBSD installations on real hardware, perhaps by a wide margin. A driver whose design fails in a virtual environment will fail for most of its users.

Second, **host-side drivers expose services to jails**. Even if your driver is about a physical device that lives in the host, the moment a jail wants to use its services, the driver faces the jail question. It may need to expose a device node through the jail's devfs, or decide that certain `ioctls` are jailed-off.

Third, **performance at scale matters more than ever**. In a virtualised environment, the difference between an emulated driver and a paravirtual one is often a factor of ten or more in throughput. Knowing how to write and recognise paravirtual patterns is worth real engineering time. A few extra paragraphs of understanding about `virtqueue(9)` can save you a day of debugging later.

30.4.5 Virtualisation Is Not Just Hardware But Slower

A common misconception is that virtualisation simply makes hardware slower. That view misses the mechanism entirely. In a well-designed virtualised environment, the guest driver does not see “slower hardware”; it sees different hardware with different access patterns. A VirtIO driver does not make one slow register read per descriptor and then complain about the overhead; it batches a dozen descriptors into a shared ring, notifies the host once, and waits for a single completion. The difference between a naive port of a physical-hardware driver to VirtIO and an idiomatic VirtIO driver is not a matter of tuning; it is a matter of architectural intent.

Similarly, containerization is not “processes, but confined.” It is a reorganisation of visibility, privilege, and global state. A driver that exports a sysctl tree has to decide whether that tree should be visible inside a jail, and whether writes from inside the jail should affect only the jail’s view or the host’s. These are not just configuration questions; they are design questions that shape the code.

If you take one thing from this section, let it be this: **the environment your driver runs in is not a transparent wrapper around a machine.** It imposes its own concerns, offers its own APIs, and rewards or punishes driver designs that respect or ignore them.

30.4.6 A Quick Taxonomy

To fix the vocabulary in your mind, here is a compact taxonomy of the environments we will discuss in this chapter. Treat it as a map you can return to when a later section mentions a term.

Environment	Kernel Boundary	What the Driver Sees	Typical FreeBSD Example
Bare metal	Full	Real hardware	Any driver
Emulated VM device	Full, at guest kernel	Imitation of real hardware	xn, em emulated by QEMU
Paravirtual VM device	Full, at guest kernel	Shared-ring interface	virtio_blk, if_vtnet
Passthrough VM device	Full, at guest kernel	Real hardware with IOMMU constraints	em on a passthrough NIC
Jail (no VNET)	Shared with host	Host-side driver; jail sees host’s devfs filtered by ruleset	devfs visibility for /dev/null
VNET jail	Shared with host	Host-side driver; jail owns its network stack; interfaces moved via if_vmove()	vnet.jail=1 in jail.conf

Notice the kernel-boundary column. The boundary is the single most important feature of each row. VMs have a boundary; jails do not. Everything else follows from that.

30.4.7 Wrapping Up

We have drawn the first map of the chapter. Virtual machines and containers are two different families. VMs present hardware (emulated, paravirtual, or passthrough) to a full guest kernel. Containers partition a single host kernel into isolated process environments, changing what they see and what they may do, but not introducing a second kernel. A driver author deals with each family differently: writing guest drivers for VMs, adapting host drivers for jails. The next section takes the first of those two worlds and looks at the three device styles a guest may meet, in enough detail to build intuition before we touch VirtIO specifically.

30.5 Section 2: Guest Drivers, Emulated Devices, and Paravirtualised Devices

A guest kernel running inside a VM must attach drivers to the devices its hypervisor has given it. Those devices fall into the three styles introduced in Section 1: emulated, paravirtual, and passthrough. Each style produces a different kind of driver, a different kind of bug, and a different kind of optimisation opportunity. This section examines them in the order you are most likely to encounter them, and begins to build the vocabulary we will need in Section 3 for VirtIO specifically.

30.5.1 Emulated Devices in Detail

An emulated device is the simplest story to tell. The hypervisor implements, in software, a faithful imitation of a known physical device. The classical FreeBSD examples include the emulated `em(4)` Ethernet NIC (the Intel 8254x family), the emulated `ahci(4)` SATA controller, the emulated 16550-compatible serial port, and the emulated VGA video adapter.

From the guest's point of view, nothing unusual is happening. The PCI device enumerator finds an Intel card; the `em(4)` driver probes it and attaches; the driver issues its usual register writes; packets eventually appear on the wire. Under the hood, each of those register writes is a trap into the hypervisor, which consults its model of the Intel chip, applies the state change, and possibly generates a virtual interrupt back into the guest.

This approach has one huge virtue and one large vice. The virtue is compatibility: the guest kernel needs no special driver at all. A stock FreeBSD install image boots on an emulated `em(4)` card as easily as it boots on a real one. The vice is cost. Every trap into the hypervisor, every software emulation of a register behaviour, every synthesised interrupt, costs CPU cycles. For a busy workload with millions of register accesses per second, emulated devices are measurably slow.

30.5.2 What Emulated Devices Imply for Driver Code

From the driver author's perspective, an emulated device looks like real hardware. The implication is that you do not normally write a "special" driver for emulated hardware; you write one driver that works on the real silicon and lean on emulation for the compatibility case. Most of the emulated-device drivers in `/usr/src/sys/dev/` are therefore the same files that drive the real cards.

There are two small exceptions that matter for our purposes. First, some drivers include a short early-boot probe that distinguishes "this is a real card" from "this is a hypervisor imitating a card." The `em(4)` driver, for example, logs a slightly different message when it detects that the environment is virtualised, because some diagnostic counters are meaningful only on real silicon. Second, a few drivers bypass hardware-specific optimisations

in virtualised environments because those optimisations would be counterproductive: prefetching blocks that the hypervisor's emulation already has in RAM is wasteful, for instance. These are rare and usually framed as conditional performance tweaks rather than architectural changes.

In practice, the first time you care about emulated-versus-real is when you are looking at a trace or a sysctl and wondering why a counter is zero. It is almost never a correctness problem.

30.5.3 Why Emulation Exists at All

It is worth pausing to ask why emulated devices exist, given that they are slower than alternatives. The answer is threefold.

First, emulation provides compatibility with existing guest kernels. A hypervisor that offered only paravirtual devices would need to persuade every guest operating system to install paravirtual drivers. That is a solved problem today, but in the early 2000s (when modern hypervisors were being designed) it was a significant barrier. Emulated devices let guests run unmodified; they gained a performance path (paravirtual) later.

Second, emulation is often good enough for low-frequency workloads. A guest that makes one disk I/O per second does not suffer measurably from emulation. A guest that makes a hundred thousand disk I/Os per second suffers badly. The majority of workloads are closer to the first than the second, and for them, emulation is a fine choice.

Third, emulation is easier to implement correctly than paravirtualisation when the guest side is an existing driver. A hypervisor author who wants to support, say, VMware-format disk images does not have to write a paravirtual disk driver for every guest OS; they write a VMware-compatible emulated disk controller, and the existing VMware guest drivers work.

In FreeBSD's bhyve(8), emulated devices include the LPC bridge (for serial ports and the RTC), PCI-IDE and AHCI controllers (for some storage cases), and the E1000 NIC (through the `e1000` backend). These are used for installers and for compatibility with older guests. For performance-oriented work, VirtIO devices are the common choice.

30.5.4 Passthrough as Seen by the Guest

Passthrough deserves a deeper look from the guest's perspective, because it is the most "hardware-like" of the three styles and introduces subtleties that a novice driver author might not expect.

When a PCI device is passed through, the guest sees an exact copy of the device's PCI configuration: vendor ID, device ID, subsystem IDs, BARs, capabilities, MSI-X table. The guest's PCI enumerator claims the device with the same driver it would have used on bare metal. The driver programs the device through register accesses; those accesses are, for the most part, direct (not trapped and emulated), because the hardware virtualisation extensions (Intel VT-x, AMD-V) support mapping a device's MMIO into a guest's address space.

DMA is where subtlety enters. The guest programs physical addresses into the device's DMA registers, but those addresses are guest-physical, not host-physical. Without help, the device would DMA to host-physical addresses that do not correspond to guest memory at all, which would be a security disaster. The help comes from the IOMMU: Intel VT-d or AMD-Vi sits between the device and the host memory bus, and it remaps device-issued addresses to the correct host memory.

From the guest driver's perspective, all of this is invisible, as long as the driver uses `bus_dma(9)` correctly. The `bus_dma(9)` framework records which physical addresses are valid for a given DMA handle, and the kernel sets up the IOMMU mappings to match. A driver that bypasses `bus_dma(9)` and programs physical addresses directly (perhaps by calling `vtophys` on a kernel pointer) is a driver that will work on bare metal but break under passthrough.

Interrupts under passthrough are handled by MSI or MSI-X exclusively; legacy pin-based interrupts cannot be passed through usefully. The guest driver configures MSI/MSI-X in the usual way, and the hypervisor sets up interrupt remapping so that the device's interrupts are delivered to the guest's virtual interrupt controller rather than to the host's.

30.5.5 Firmware and Platform Dependencies Under Passthrough

One area where passthrough can surprise driver authors is firmware. Many modern devices expect their firmware to be loaded by the host, not by the device itself. A device whose driver assumes firmware has already been loaded (perhaps by a boot-time BIOS routine on the host) may fail to initialise inside a guest, because the guest's BIOS has not done the firmware-loading work.

The solution is usually for the driver to carry firmware and load it explicitly. FreeBSD's `firmware(9)` framework makes this straightforward: the driver registers the firmware image (typically a blob compiled into a loadable module), and at attach time it calls `firmware_get` and uploads the blob to the device. A driver that works on both bare metal and passthrough is a driver that does the firmware load itself, rather than relying on platform code.

Similarly, ACPI tables and other platform tables may be different between the host and a guest. A driver that reads an ACPI table to determine board-specific routing (for example, to identify which GPIO controls a power rail) will find a different table in a guest, because the guest's virtual BIOS generates its own. The driver must either provide defaults for cases where the table is missing or treat the missing table as an unsupported platform.

30.5.6 When to Prefer Which Device Style

The three device styles are not mutually exclusive on a single VM. A `bhyve(8)` guest can have an emulated LPC bridge, a VirtIO block device, a passthrough NIC, and a VirtIO console, all at the same time. The administrator chooses which style to use for each role based on the trade-offs.

For installation and legacy guests, emulated devices are right. They require nothing from the guest and they work out of the box.

For typical FreeBSD guests doing ordinary work, VirtIO devices are right. They are fast, standardised, and well supported in FreeBSD's tree. Most production `bhyve(8)` deployments use VirtIO for disk, network, and console.

For performance-critical or hardware-specific workloads, passthrough is right. A guest that runs a GPU-accelerated workload needs a passthrough GPU; a guest that needs real network-card offload features needs a passthrough NIC.

As a driver author, the most likely device style you will write for is VirtIO, because that is where the new driver work is. Emulated and passthrough drivers are usually existing drivers; VirtIO drivers are designed from scratch

for the paravirtual interface.

30.5.7 Paravirtual Devices in Detail

Paravirtual devices are a deeper change. The hypervisor declines to imitate any physical device and instead defines an interface optimised for software on both sides. The guest must have a driver written for that interface; a stock legacy driver will not work. The benefit is performance: a paravirtual interface can batch, amortise, and simplify the host-guest interaction in ways that a realistic hardware model cannot.

The dominant paravirtual family on FreeBSD is VirtIO. VirtIO is not a FreeBSD invention; it is a cross-platform standard designed for use across Linux, FreeBSD, and other guest operating systems. FreeBSD's VirtIO implementation lives under `/usr/src/sys/dev/virtio/`, with individual drivers for block devices (`virtio_blk`), network devices (`if_vtnet`), serial consoles (`virtio_console`), SCSI (`virtio_scsi`), entropy (`virtio_random`), and memory ballooning (`virtio_balloon`). Other VirtIO device types exist (9p filesystems, input devices, sockets), and they too have FreeBSD drivers in varying states of maturity.

From the outside, a VirtIO device looks like a PCI device (when attached via PCI) or a memory-mapped device (when attached via MMIO, which is common on embedded and ARM systems). The guest kernel enumerates it the same way it would any other device: a PCI bus scan finds a device with vendor ID `0x1af4` and a device ID indicating the type, or the guest's device tree advertises a VirtIO MMIO transport with a known compatible string.

Once probed and attached, the driver talks to the device through a small set of primitives: device feature bits, device status, device configuration space, and a set of **virtqueues**. The virtqueues are the heart of the VirtIO model. Each one is a ring of descriptors in shared memory, writable by the guest and readable by the host; the host has a parallel ring of used descriptors that the guest reads to discover completions. All the actual I/O happens through the rings; the registers the driver touches are almost exclusively used for setup, notification, and feature negotiation.

This design is radically different from an emulated-device driver. A VirtIO driver almost never issues a register write during normal operation. It posts buffers into rings, notifies the host that new work is available, and reads completions from the ring when they arrive. The per-request overhead is a handful of memory accesses, not a register trap. When the system is busy, the driver can post many requests and notify once; the host can batch many completions and signal once. The result is an order-of-magnitude performance improvement over an equivalent emulated driver.

30.5.8 Paravirtual Devices and the Driver Author

For a driver author, paravirtual devices are where a lot of new work happens in FreeBSD's driver ecosystem. VirtIO is well-defined and stable, and writing a new VirtIO-backed device type is a reasonable weekend project once you have read the foundational drivers. More importantly, the patterns of VirtIO (shared rings, feature negotiation, descriptor-based transactions) echo through other FreeBSD subsystems (notably `if_netmap` and portions of the network stack), so time invested in understanding them pays dividends.

This chapter will spend all of Section 3 on VirtIO fundamentals. For now, what matters is the framing: a paravirtual driver is a first-class guest driver that was designed to live inside a VM, with the performance characteristics that design affords.

30.5.9 Passthrough Devices in Detail

Passthrough is the third style, and in some ways the most interesting because it collapses the virtualisation question back into the bare-metal question, with a twist.

In passthrough, the hypervisor declines to abstract the device at all. It hands the guest a real PCI or PCIe device: for example, a specific physical NIC in one of the host's slots, or a specific NVMe SSD, or a specific GPU. The guest's driver talks to that real hardware as if it were the host. The guest even receives the device's interrupts, through a mechanism the hypervisor provides.

There are three reasons passthrough exists. First, performance: a passthrough NIC delivers line-rate traffic to the guest with no software overhead per packet. Second, access to hardware features the hypervisor does not emulate: GPU acceleration, NVMe-specific queuing, hardware crypto engines. Third, licensing or certification: some proprietary drivers only work with real hardware and cannot be used through any emulation layer.

The cost of passthrough is isolation. Once a device is passed through to a guest, the host no longer owns it in any useful sense; it cannot use the NIC itself, and other guests cannot share it. Live migration becomes difficult or impossible, because the target host may not have the same physical device in the same slot. The guest owns the hardware until the guest stops running.

30.5.10 Passthrough and the IOMMU

Passthrough sounds simple in principle, but it requires one major piece of hardware support: an IOMMU. An IOMMU is to DMA what an MMU is to CPU memory access: a hardware-enforced translation table between the view of memory a device has (its "DMA address") and real physical memory. Without an IOMMU, a passthrough device could DMA into any physical memory on the host, including the host's kernel data, with obvious and terrifying consequences. With an IOMMU, the hypervisor can constrain the device to DMA only into the memory regions assigned to the guest, preserving the security boundary.

On amd64 systems, the IOMMU is Intel VT-d (on Intel CPUs) or AMD-Vi (on AMD CPUs). It is usually enabled through a kernel configuration option and some BIOS settings. FreeBSD's `bhyve(8)` uses the IOMMU through the `pci_passthru(4)` mechanism, which we will meet in Section 5.

For the driver author, the IOMMU is invisible most of the time. The `bus_dma(9)` API in the guest behaves the same way it does on bare metal; the guest driver's `bus_dmamem_alloc()` and `bus_dmamap_load()` calls produce DMA addresses that, from the guest's point of view, look the same as they would on bare metal. The IOMMU translation happens one layer below, between the device and the real memory, and the guest driver does not participate in it.

The one place where the IOMMU matters for the driver author is when the IOMMU is misconfigured or missing, and DMA starts to fail in mysterious ways. If you ever see "DMA timeout" messages from a passthrough driver, the IOMMU is often the first suspect. Chapter 32 will go deeper into this.

30.5.11 The Driver Author's Mental Model

If you step back from these three styles, a clear pattern emerges. The guest kernel always loads a driver; the driver always sees a device; the device's behaviour is always defined by some interface. What changes between the styles is which interface and who implements it.

In emulated devices, the interface is the real hardware's register model, and the hypervisor implements it in software. The driver is the real-hardware driver.

In paravirtual devices, the interface is a bespoke software-optimised model, and the hypervisor implements it natively. The driver is paravirtual-specific.

In passthrough devices, the interface is the real hardware's register model, and the hardware itself implements it, with the IOMMU as a gatekeeper. The driver is the real-hardware driver, running in the guest, with DMA addresses translated transparently.

The driver author is therefore working with the same skills in all three cases. The shape of the work differs only in which interface is in play. Once you understand that, the rest of this chapter becomes a study of specific interfaces, specific FreeBSD APIs, and specific deployment contexts.

30.5.12 A Note on Hybrid Models

Real systems often mix these styles. A single guest may have an emulated serial port for early boot logging, a paravirtual NIC for main network traffic, a paravirtual block device for the root filesystem, and a passthrough GPU for acceleration. Each of those devices is governed by its own driver, and the guest's driver toolkit needs to know the patterns for all three. This is not unusual; it is the common case for any non-trivial VM.

As a driver author, the implication is that you usually do not need to build a universal driver for all three styles. You build the driver for the style your device uses, and you coexist with drivers for the other styles. The per-device decisions about which style to use are made by the hypervisor administrator, not by the driver.

30.5.13 Wrapping Up

Three styles of guest device, three kinds of driver work, one underlying mental model: a driver talks to an interface, and the interface is implemented by whichever layer the hypervisor chooses. Emulated is easy but slow; paravirtual is fast and requires custom drivers; passthrough is near-native and requires an IOMMU. The rest of this chapter concentrates on the paravirtual style, with VirtIO as the example, because that is where most of the interesting new driver work in FreeBSD happens. In Section 3 we open the VirtIO toolkit and start examining its parts.

30.6 Section 3: VirtIO Fundamentals and virtqueue(9)

VirtIO is a standard. It defines a way for a guest to talk to a device that exists only in software, without reference to any physical hardware. The standard is maintained by the OASIS VirtIO Technical Committee and is implemented by a number of hypervisors, including bhyve(8), QEMU, and the Linux KVM family. Because the standard is shared, a VirtIO guest driver written for a FreeBSD guest will talk to a VirtIO device presented by any conforming hypervisor.

This section introduces the VirtIO model at the level of detail a driver author needs. It is long, because VirtIO has enough moving parts to justify the space, and short compared to the VirtIO specification itself, which spans hundreds of pages. We will focus on the parts you need to write a FreeBSD guest driver.

30.6.1 The Ingredients of a VirtIO Device

A VirtIO device exposes a small number of elements to its guest driver. Understanding each one is the foundation for everything that follows.

The first element is the **transport**. VirtIO devices can appear over several transports: VirtIO over PCI (the usual case on amd64 desktops, servers, and cloud), VirtIO over MMIO (the usual case on ARM and embedded systems), and VirtIO over channel I/O (used on IBM mainframes). From the guest's view, the transport dictates how the device is enumerated and how registers are read, but once the driver has hold of a `device_t`, the transport recedes into the background. FreeBSD's VirtIO framework provides a transport-agnostic API.

The second element is the **device type**. Every VirtIO device has a single-byte type identifier (`VIRTIO_ID_NETWORK` is 1, `VIRTIO_ID_BLOCK` is 2, `VIRTIO_ID_CONSOLE` is 3, `VIRTIO_ID_ENTROPY` is 4, `VIRTIO_ID_BALLOON` is 5, `VIRTIO_ID_SCSI` is 8, and so on, as listed in `/usr/src/sys/dev/virtio/virtio_ids.h`). The type tells the guest what the device does; the guest dispatches to the right driver based on the type.

The third element is the **device feature bits**. Each device type defines a set of optional features, each represented by a bit in a 64-bit mask. Some features are universal (the ability to use indirect descriptors, for example), and some are device-specific (VirtIO block devices may advertise write-caching, discard support, geometry information, and more). The guest driver reads the device's advertised features, selects which of them the driver knows how to use, and writes back a negotiated feature mask. The device then agrees to the negotiated set and rejects any attempt to use a feature outside it. This negotiation is the mechanism by which VirtIO devices and drivers evolve without breaking each other.

The fourth element is the **device status**. A small byte-level register reports where in the lifecycle the device sits: acknowledged by the driver, driver found for this device type, features negotiated, device set up and ready, and so on. Writing to the status register drives the device through its lifecycle; reading it tells the driver where it is.

The fifth element is the **device configuration space**. Each device type has its own small layout of bytes that carry device-specific configuration: a block device's capacity, a network device's MAC address, a console device's port count. The guest reads the configuration space to learn device-specific details and occasionally writes to it to request a configuration change.

The sixth element, and the most important for this chapter, is the **set of virtqueues**. Each VirtIO device has one or more virtqueues, and the virtqueues are where almost all the actual work happens. Think of each virtqueue as a bounded-size bidirectional conveyor belt between the guest and the host. The guest places requests on the belt; the host consumes them, acts on them, and places completions on a parallel return belt; the guest reads the completions to learn what happened. The conveyor belt is implemented as a ring of descriptors in shared memory.

30.6.2 Virtqueues and the Shared-Ring Model

At the heart of VirtIO is the virtqueue, the single most important abstraction in the whole protocol. A virtqueue is a ring of descriptors, held in memory that both the guest and the host can read and write. Its size is a power of two, chosen at device initialisation; typical values are 128 or 256 entries, though larger values are permitted.

Each descriptor in the ring describes a single scatter-gather buffer in guest memory: its guest physical address, its length, and a couple of flags (is this buffer readable or writable from the device's point of view, does this

descriptor chain to a next descriptor, does it point to an indirect descriptor table). The driver fills descriptors, chains them as needed to represent multi-buffer transactions, and writes to a small index to announce that new descriptors are available. The host's device implementation walks the descriptors, performs the work they describe, and writes to its own index to announce that the work is done.

There are three rings inside a virtqueue, not one. The **descriptor table** holds the actual descriptors. The **available ring** (driven by the guest) lists the indices of descriptor chains the driver has made available. The **used ring** (driven by the host) lists the indices of descriptor chains the device has consumed and whose results are ready. The split is subtle but important: the driver writes to the available ring and reads from the used ring, while the host does the opposite. Each side reads what the other side wrote, without locks, through careful use of memory barriers and atomic index updates.

From the driver author's point of view, you almost never manipulate the rings by hand. FreeBSD's `virtqueue(9)` API abstracts them behind a handful of functions. You call `virtqueue_enqueue()` to push a scatter-gather list onto the available ring. You call `virtqueue_notify()` to let the host know new work is available. You call `virtqueue_dequeue()` to pull the next completion off the used ring. If you are polling rather than taking interrupts, you call `virtqueue_poll()` to wait for the next completion. The API hides the index arithmetic, the memory barriers, and the flag juggling; your code deals with scatter-gather lists and cookies.

The cookie mechanism deserves a line. When you enqueue a scatter-gather list, you supply an opaque pointer, the cookie, which the API remembers. When you dequeue a completion, you receive that cookie back. This lets the driver associate each completion with the request that produced it, without the ring having to carry any driver-specific context. A driver typically passes the pointer to a softc-level request structure as the cookie; dequeue gives back the same pointer, and the driver resumes processing.

30.6.3 Feature Negotiation in Practice

Before the driver uses any of these mechanisms, it must negotiate features. The sequence is simple and looks the same in every VirtIO driver.

First, the driver reads the device's advertised feature bits with `virtio_negotiate_features()`. The argument is a mask of features the driver is prepared to use; the return value is the intersection of the driver's mask and the device's advertised bits. The device has now committed to supporting only that subset, and the driver knows exactly which features are in play.

Second, the driver calls `virtio_finalize_features()` to seal the negotiation. After this call, the device will reject any attempt to enable features outside the negotiated set. The driver's subsequent setup code can inspect the negotiated mask through `virtio_with_feature()`, which returns true if a given feature bit is present.

Third, the driver allocates virtqueues. The exact number and per-queue parameters depend on the device type. A `virtio_random` device allocates one virtqueue; a `virtio_net` device allocates at least two (one for receive, one for transmit), more if multiple queues are negotiated. Allocation uses `virtio_alloc_virtqueues()`, passing an array of `struct vq_alloc_info`, each entry describing one queue's name, callback, and maximum indirect-descriptor size.

Fourth, the driver sets up interrupts with `virtio_setup_intr()`. The interrupt handlers are the callbacks from step three. When the host has posted a completion to a queue, the guest receives a virtual interrupt, the handler runs, and it processes the completions by calling `virtqueue_dequeue()` in a loop.

This four-step sequence is the backbone of every VirtIO driver in `/usr/src/sys/dev/virtio/`. Read `vtrnd_attach()` in `/usr/src/sys/dev/virtio/random/virtio_random.c` and you will see it clearly: feature negotiation, queue allocation, and interrupt setup, in exactly that order. Read `vtblk_attach()` in `/usr/src/sys/dev/virtio/block/virtio_blk.c` and you will see the same sequence, with more moving parts because the device is more complex, but the same skeleton.

30.6.4 A Walkthrough of `virtio_random`

Because `virtio_random` is the smallest complete VirtIO driver in the FreeBSD tree, it is the best one to read first. The whole file is under four hundred lines, and every line is there for a reason. Let us trace through the important parts.

The `softc` is small:

```
struct vtrnd_softc {
    device_t      vtrnd_dev;
    uint64_t      vtrnd_features;
    struct virtqueue *vtrnd_vq;
    eventhandler_tag eh;
    bool          inactive;
    struct sglist  *vtrnd_sg;
    uint32_t       *vtrnd_value;
};
```

The fields are the device handle, the negotiated feature mask (the device has no feature bits so this will always be zero), a pointer to the single virtqueue, an event handler tag for shutdown hooks, a flag that is set to true during teardown, a scatter-gather list used for every enqueue, and a buffer in which the device will store each batch of entropy.

The device methods table is the standard newbus skeleton:

```
static device_method_t vtrnd_methods[] = {
    DEVMETHOD(device_probe,      vtrnd_probe),
    DEVMETHOD(device_attach,     vtrnd_attach),
    DEVMETHOD(device_detach,     vtrnd_detach),
    DEVMETHOD(device_shutdown,   vtrnd_shutdown),
    DEVMETHOD_END
};

static driver_t vtrnd_driver = {
    "vtrnd",
    vtrnd_methods,
    sizeof(struct vtrnd_softc)
};
```

```
VIRTIO_DRIVER_MODULE(virtio_random, vtrnd_driver, vtrnd_modevent, NULL);
MODULE_VERSION(virtio_random, 1);
MODULE_DEPEND(virtio_random, virtio, 1, 1, 1);
MODULE_DEPEND(virtio_random, random_device, 1, 1, 1);
```

VIRTIO_DRIVER_MODULE is a short macro that expands to two DRIVER_MODULE declarations, one for virtio_pci and one for virtio_mmio. This is how the same driver attaches on both transports without any transport-specific code of its own; the framework routes it to whichever transport finds a matching device.

The probe function is one line:

```
static int
vtrnd_probe(device_t dev)
{
    return (VIRTIO_SIMPLE_PROBE(dev, virtio_random));
}
```

VIRTIO_SIMPLE_PROBE consults the PNP match table that was declared above through VIRTIO_SIMPLE_PNPINFO. The match table tells the kernel that this driver wants devices whose VirtIO type is VIRTIO_ID_ENTROPY.

The attach function is more substantial. It allocates the entropy buffer and the scatter-gather list, sets up features, allocates a single virtqueue, installs a shutdown event handler, registers itself with the FreeBSD random(4) framework, and posts its first buffer into the virtqueue:

```
sc = device_get_softc(dev);
sc->vtrnd_dev = dev;
virtio_set_feature_desc(dev, vtrnd_feature_desc);

len = sizeof(*sc->vtrnd_value) * HARVESTSIZE;
sc->vtrnd_value = malloc_aligned(len, len, M_DEVBUF, M_WAITOK);
sc->vtrnd_sg = sglist_build(sc->vtrnd_value, len, M_WAITOK);

error = vtrnd_setup_features(sc);      /* feature negotiation */
error = vtrnd_alloc_virtqueue(sc);     /* allocate queue */

/* [atomic global-instance check] */

sc->eh = EVENTHANDLER_REGISTER(shutdown_post_sync,
    vtrnd_shutdown, dev, SHUTDOWN_PRI_LAST + 1);

sc->inactive = false;
random_source_register(&random_vtrnd);

vtrnd_enqueue(sc);
```

Feature negotiation is trivial because the driver advertises `VTRND_FEATURES = 0`:

```
static int
vtrnd_negotiate_features(struct vtrnd_softc *sc)
{
    device_t dev = sc->vtrnd_dev;
    uint64_t features = VTRND_FEATURES;

    sc->vtrnd_features = virtio_negotiate_features(dev, features);
    return (virtio_finalize_features(dev));
}
```

The feature mask of the device is irrelevant; the driver wants no features and gets no features, and the finalisation succeeds trivially. A more complex driver would build a non-zero mask and check it afterwards.

The virtqueue allocation asks for a single queue:

```
static int
vtrnd_alloc_virtqueue(struct vtrnd_softc *sc)
{
    device_t dev = sc->vtrnd_dev;
    struct vq_alloc_info vq_info;

    VQ_ALLOC_INFO_INIT(&vq_info, 0, NULL, sc, &sc->vtrnd_vq,
        "%s request", device_get_nameunit(dev));

    return (virtio_alloc_virtqueues(dev, 0, 1, &vq_info));
}
```

The first argument to `VQ_ALLOC_INFO_INIT` is the maximum indirect-descriptor-table size, which is zero for this driver because it does not use indirect descriptors. The second argument is the interrupt handler callback, which is `NULL` because this driver uses polling rather than interrupt-driven completion. The third is the argument to that handler. The fourth is the output pointer for the virtqueue handle. The fifth is a format string that produces the queue's name.

The enqueue function is short:

```
static void
vtrnd_enqueue(struct vtrnd_softc *sc)
{
    struct virtqueue *vq = sc->vtrnd_vq;

    KASSERT(virtqueue_empty(vq), ("%s: non-empty queue", __func__));

    error = virtqueue_enqueue(vq, sc, sc->vtrnd_sg, 0, 1);
}
```

```

    KASSERT(error == 0, ("%s: virtqueue_enqueue returned error: %d",
        __func__, error));

    virtqueue_notify(vq);
}

```

This pushes a scatter-gather list describing the entropy buffer onto the ring. The cookie is `sc` itself. The next two arguments are “readable segments” (none, the device writes the buffer) and “writable segments” (one, the entropy buffer). `virtqueue_notify()` kicks the host so it starts filling the buffer.

Because there are no interrupts, the driver uses polling to retrieve completions:

```

static int
vtrnd_harvest(struct vtrnd_softc *sc, void *buf, size_t *sz)
{
    struct virtqueue *vq = sc->vtrnd_vq;
    void *cookie;
    uint32_t rrlen;

    if (sc->inactive)
        return (EADLK);

    cookie = virtqueue_dequeue(vq, &rrlen);
    if (cookie == NULL)
        return (EAGAIN);

    *sz = MIN(rrlen, *sz);
    memcpy(buf, sc->vtrnd_value, *sz);

    vtrnd_enqueue(sc);    /* re-post the buffer */
    return (0);
}

```

The lifecycle here is the full VirtIO cycle. Enqueue posts a buffer; the host fills it with entropy and marks the descriptor “used”; the driver dequeues the used descriptor, extracts the cookie and the length, copies the result out to its caller, and re-posts the buffer for the next round. If the queue is empty (no completion yet), `virtqueue_dequeue()` returns `NULL` and the driver returns `EAGAIN`.

This is the full shape of a VirtIO driver. Everything else, from `virtio_blk` to `if_vtnet`, is elaboration on this base: more queues, more features, more work per completion, more bookkeeping per request. The skeleton is the same.

30.6.5 What the `virtqueue(9)` API Buys You

Step back for a moment and consider how much complexity the API abstracts away. The ring arithmetic, with its wraparound and its careful handling of available versus used indices, is entirely hidden. The memory barriers

that keep the guest and the host in sync, which are subtle enough to be a common source of bugs in handwritten ring code, are placed by the API. The optional features (indirect descriptors, event indexes) are turned on and off based on negotiation without the driver having to know how they work.

The cost of that abstraction is that a driver author who only ever uses the API will not understand the rings themselves in depth. That is usually fine, but on the rare occasion when you debug a ring-layer mismatch (because you posted a descriptor with the wrong writable count, say, and the host is rejecting it) you will want to know what is going on. The VirtIO specification is the reference for the underlying ring layout, and `/usr/src/sys/dev/virtio/virtio_ring.h` is the FreeBSD side of the same layout. They repay reading at least once.

30.6.6 Indirect Descriptors

A small optimisation worth knowing about is the indirect-descriptor feature (`VIRTIO_RING_F_INDIRECT_DESC`). When negotiated, it allows a driver to describe a multi-buffer transaction in an indirect descriptor table rather than a chain of descriptors on the main ring. The ring entry becomes a single descriptor that points to a block of descriptors, so a large scatter-gather list consumes only one slot on the ring rather than many.

Indirect descriptors matter in workloads that do large, scatter-gather-heavy transactions, such as network drivers sending packets with many fragments. For small drivers, they are an optional flourish. The `virtqueue(9)` API handles the mechanism transparently: if you pass a non-zero `vqai_maxindirsz` during queue allocation, the kernel can use indirects; if you pass zero, it cannot.

30.6.7 A Deeper Look at the Ring Layout

For a reader who wants to know what `virtqueue(9)` is hiding, here is a brief tour of the underlying layout. The details matter only when you are debugging a ring-layer issue; you can skip this subsection on first reading.

Each `virtqueue` has three main structures in memory, allocated contiguously (with alignment requirements that differ slightly between legacy and modern VirtIO).

The **descriptor table** is an array of `struct vring_desc`, one entry per descriptor slot:

```
struct vring_desc {
    uint64_t addr;      /* guest physical address of the buffer */
    uint32_t len;       /* length of the buffer */
    uint16_t flags;     /* VRING_DESC_F_NEXT, _WRITE, _INDIRECT */
    uint16_t next;      /* index of the next descriptor if chained */
};
```

The descriptor table has as many entries as the queue size (typically 128 or 256). Unused descriptors are linked into a free list maintained by the driver; used descriptors form chains that describe single transactions.

The **available ring** is what the driver writes and the device reads:

```

struct vring_avail {
    uint16_t flags;
    uint16_t idx;                /* producer index, monotonic */
    uint16_t ring[QUEUE_SIZE];  /* head-of-chain indices */
    uint16_t used_event;        /* for VRING_F_EVENT_IDX */
};

```

When the driver enqueues a new transaction, it picks a chain of descriptors from the free list, fills them in, places the head descriptor's index into `ring[idx % QUEUE_SIZE]`, and then increments `idx`. The increment uses a release-style memory barrier so that the device sees the new ring entry before it sees the new `idx`.

The **used ring** is what the device writes and the driver reads:

```

struct vring_used_elem {
    uint32_t id;                /* index of the head descriptor */
    uint32_t len;               /* number of bytes written */
};

struct vring_used {
    uint16_t flags;
    uint16_t idx;                /* producer index */
    struct vring_used_elem ring[QUEUE_SIZE];
    uint16_t avail_event;        /* for VRING_F_EVENT_IDX */
};

```

When the device finishes a transaction, it writes an entry to `ring[idx % QUEUE_SIZE]` with the head index and the byte count, then increments `idx`. The driver observes the increment and dequeues accordingly.

The subtlety of the format is the synchronisation. Guest and host are not synchronising through locks (they do not share locks); they are synchronising through ordered writes and atomic index updates. The spec is careful to specify the memory barriers on each side, and the `virtqueue(9)` implementation places them correctly. Getting the barriers wrong is a common bug in hand-rolled ring implementations; that is one reason to use the framework.

30.6.8 Event Indexes: A Performance Detail

The `VIRTIO_F_RING_EVENT_IDX` feature allows both sides to suppress notifications when they are not needed. The mechanism is two extra fields, `used_event` in the available ring and `avail_event` in the used ring. Each side writes a value saying “interrupt me only when the other side's producer index passes this value”.

The practical effect is that a driver producing requests at a high rate does not cause the host to be interrupted on every enqueue; instead, the host reads the current `used_event` and only delivers a notification when the producer index catches up. Similarly, a device completing transactions at a high rate does not cause the guest to be interrupted on every dequeue; the guest sets `avail_event` to suppress notifications it does not need.

This optimisation halves the notification overhead in worst-case workloads. It is a feature that most modern VirtIO drivers negotiate, and the `virtqueue(9)` API handles it transparently. As a driver author, you simply negotiate the feature and do not have to think about the details.

30.6.9 Legacy Versus Modern VirtIO

VirtIO has two major versions. Legacy (sometimes called “virtio 0.9”) was the original specification; modern (“virtio 1.0” and up) came later with a cleaner design. FreeBSD supports both.

The practical differences are in configuration-space layout, byte order, and a few feature-bit semantics. Legacy VirtIO puts configuration in native byte order; modern VirtIO is always little-endian. Legacy mandates some fields in a specific position; modern uses capability structures to describe the layout flexibly. Legacy defines a specific set of feature bits below bit 32; modern extends them above bit 32.

For driver authors, the framework hides most of these differences. Negotiating `VIRTIO_F_VERSION_1` puts the driver in modern mode; not negotiating it puts the driver in legacy mode. The `virtio_with_feature` helper checks the negotiated state. As long as your driver follows the `virtqueue(9)` API and uses `virtio_read_device_config` rather than direct configuration-space access, you can ignore the legacy/modern distinction almost entirely.

The one place where the distinction leaks is in how configuration-space fields are accessed. Legacy VirtIO uses `virtio_read_device_config` with a size argument and assumes native byte order; modern VirtIO assumes little-endian and uses helpers that byte-swap if the host is big-endian. The framework handles this, but a driver that does configuration-space access by hand (rather than through the framework) would have to be aware.

30.6.10 Feature Bits Worth Knowing

Each VirtIO device type has its own set of feature bits. A few are worth knowing in the abstract, because they show up in many drivers.

- `VIRTIO_F_VERSION_1` indicates that the device supports the modern, version 1 of the VirtIO specification. Almost all modern drivers negotiate this bit.
- `VIRTIO_F_RING_EVENT_IDX` enables a more efficient form of interrupt suppression. When both sides support it, notifications and interrupts are only sent when they are actually useful, reducing overhead under load.
- `VIRTIO_F_RING_INDIRECT_DESC`, already mentioned, allows indirect descriptors.
- `VIRTIO_F_ANY_LAYOUT` relaxes the rules about how descriptors are ordered in a chain.

Each device type has its own set on top of these. For a block device, `VIRTIO_BLK_F_WCE` indicates that the device has a write cache; `VIRTIO_BLK_F_FLUSH` provides a flush command. For a network device, `VIRTIO_NET_F_CSUM` advertises offloaded checksum calculation. For entropy, there are no device-specific feature bits.

The general rule is: read the feature bits the device advertises, decide which the driver can use, ignore the others. Negotiation is not about “demanding” features; it is about agreeing on an intersection.

30.6.11 A Second Example: Structure of `virtio_net`

It is worth a brief look at a larger VirtIO driver to see how the skeleton scales. The network driver `if_vtnet` lives in `/usr/src/sys/dev/virtio/network/if_vtnet.c`. It is roughly ten times the length of `virtio_random`, but the extra size comes from features and completeness, not from complexity in the core VirtIO interaction. Knowing how the scale-up works makes future reading more productive.

`if_vtnet` begins, like every VirtIO driver, with a module registration and a `device_method_t` table. The methods table is longer because `if_vtnet` hooks into the `ifnet(9)` framework; you will see `DEVMETHOD` entries for `device_probe`, `device_attach`, `device_detach`, `device_suspend`, `device_resume`, and `device_shutdown`, each implemented by the driver. The `VIRTIO_DRIVER_MODULE` macro at the bottom of the file registers the driver for both PCI and MMIO transports, exactly as `virtio_random` does.

The `softc`, `struct vtnet_softc`, is much larger than `vtrnd_softc`, but its role is the same: hold the state that the driver needs to serve the device. Notable additions include a pointer to the kernel's `ifnet` structure (`vtnet_ifp`), an array of receive queues (`vtnet_rxqs`), an array of transmit queues (`vtnet_txqs`), a feature mask, a cached MAC address, and statistics counters. Each queue structure contains its own `virtqueue` pointer, `softc` back-reference, taskqueue context, and a number of bookkeeping fields. A single multi-queue `virtio-net` device can have tens of `virtqueues`; each receive/transmit pair represents one queue pair that can run in parallel with the others.

The probe function uses the same `VIRTIO_SIMPLE_PROBE` pattern as `virtio_random`, but matching on `VIRTIO_ID_NETWORK` (which is 1). The attach function is substantial: it reads feature bits, negotiates them, allocates the queues, reads the device's MAC address from configuration space (`virtio_read_device_config`), initialises the `ifnet`, registers with the network stack, and sets up callouts for link-status polling. Each of these steps is a small function of its own, and the flow follows the same “negotiate, allocate, register, start” rhythm that `virtio_random` illustrates.

The receive path uses `virtqueue_dequeue` in a loop to drain completed packets. For each completed descriptor, the driver reads the packet header (`virtio_net_hdr`) that the device wrote to the first few bytes of the buffer, extracts metadata such as checksum-status flags and GSO segment sizes, and passes the packet up to `if_input`. If the packet is the last one in a batch, the driver re-posts fresh receive buffers to keep the queue primed for the next round.

The transmit path uses `virtqueue_enqueue` with a scatter-gather list covering both the packet header and the packet body. The cookie is the `mbuf(9)` pointer, so the transmit completion callback can free the `mbuf` when the device is done with it. If the queue becomes full, the driver stops accepting outbound packets until some space frees up, which is standard `ifnet` driver discipline.

Feature negotiation in `if_vtnet` is interesting because the feature set is large. Features like `VIRTIO_NET_F_CSUM` (transmit checksum offload), `VIRTIO_NET_F_GUEST_CSUM` (receive checksum offload), `VIRTIO_NET_F_GSO` (generic segmentation offload), and `VIRTIO_NET_F_MRG_RXBUF` (merged receive buffers) each change how the driver programs the `virtqueues` and how it interprets incoming data. The driver's feature-negotiation function picks a set that the driver implements, offers it for negotiation, and then queries the negotiated mask to decide which code paths to enable.

The lesson from `if_vtnet` is that a VirtIO driver scales through feature diversity and queue multiplicity, not through a fundamentally different architecture. If you understand `virtio_random`'s lifecycle, you understand `if_vtnet`'s lifecycle; the extra code is in feature-specific sub-paths and in `ifnet`-specific hooking. When the time comes to read `if_vtnet.c`, focus on `vtnet_attach` first, then walk the feature-negotiation function, then

look at `vtnet_rxq_eof` (receive) and `vtnet_txq_encap` (transmit). Those four functions explain 80% of the driver.

30.6.12 A Third Example for Intuition: `virtio_blk`

`virtio_blk`, in `/usr/src/sys/dev/virtio/block/virtio_blk.c`, is shorter than `if_vtnet` but longer than `virtio_random`. It illustrates a third common pattern: a driver that exposes a block-oriented device rather than a stream-oriented one.

The softc of `vtblk` contains a `virtqueue`, a pool of request structures, statistics, and the geometry information read from the device's configuration space. The probe and attach follow the familiar pattern. The interesting part is how requests are structured.

For every block I/O operation, the driver builds a three-segment descriptor chain: a header descriptor (containing the operation type and sector number), zero or more data descriptors (the actual payload, which is writable from the device's perspective for reads and readable from the device for writes), and a status descriptor (where the device writes a single-byte status code). The header and status are small structures; the data segments are whatever the `bio(9)` request brought in.

This three-segment layout is a common VirtIO idiom. If you see a driver building a chain that starts with a header and ends with a status, you are looking at a request-response device. `virtio_scsi` uses the same layout, as does `virtio_console` (for control messages). Recognising the pattern speeds up reading.

30.6.13 Common Mistakes When Reading VirtIO Code

When reading any VirtIO driver for the first time, a few patterns can confuse a reader who is not expecting them.

The first is the mix of probe patterns. Some drivers use `VIRTIO_SIMPLE_PROBE`; others use their own probe functions that do more complex feature checks. Both are legitimate, and the former is a shorthand for a common case.

The second is the module registration style. `VIRTIO_DRIVER_MODULE` is a macro that expands to two `DRIVER_MODULE` calls, and reading the macro definition (in `/usr/src/sys/dev/virtio/virtio.h`) makes it clear. Without the macro, you might wonder why the driver is not calling `DRIVER_MODULE` explicitly; with it, you see that it is, once per transport.

The third is the distinction between the VirtIO core functions (`virtio_*`) and the `virtqueue` functions (`virtqueue_*`). The core functions operate on the whole device; the `virtqueue` functions operate on a single queue. A driver usually uses both, and the namespace prefix is the hint.

The fourth is the polling-versus-interrupt distinction. A driver that polls (like `virtio_random`) passes `NULL` as the callback in `VQ_ALLOC_INFO_INIT` and calls `virtqueue_poll` to wait for completions. A driver that uses interrupts (like `if_vtnet`) passes a callback and lets the kernel's interrupt infrastructure schedule it. Both are legitimate; the choice depends on the workload's latency sensitivity and on whether the driver can afford to block.

30.6.14 Wrapping Up

This has been a long section, and deliberately so. VirtIO is dense, and its vocabulary is the foundation for most of the interesting work a modern guest-driver author does. You now know that a VirtIO device has a transport, a type, a feature mask, a status, a configuration space, and a set of virtqueues; that the virtqueues are shared rings with separate descriptor, available, and used components; that `virtqueue(9)` abstracts the ring mechanics behind a small API of enqueue, dequeue, notify, and poll; that feature negotiation is the mechanism for forward and backward compatibility; and that the smallest FreeBSD VirtIO driver is `virtio_random`, under four hundred lines of code that illustrate the whole skeleton. You have also seen how larger VirtIO drivers like `if_vtnet` and `virtio_blk` are structured around the same skeleton, scaled up with feature-specific code.

Section 4 takes a different turn. Now that you know what a guest driver is, we consider the question: how does the driver know it is in a guest in the first place?

30.7 Section 4: Hypervisor Detection and Environment-Aware Driver Behaviour

There are legitimate reasons for a driver to know whether it is running inside a virtual machine. A driver that is inclined to use an expensive hardware counter may skip it on a hypervisor where the counter is known to be unreliable. A driver that polls a hardware register in a tight loop may tune its polling interval differently under virtualisation, because each poll becomes a hypervisor exit. A driver that emits a warning about a suspicious interrupt rate may suppress the warning when running in a cloud where background noise is normal. A few FreeBSD drivers in the tree use this kind of adaptation.

There are also illegitimate reasons. A driver that tries to behave differently to “hide” something from a hypervisor is building anti-debugging logic, which has its place in anti-tamper software but has none in a general-purpose driver. A driver that branches on the exact hypervisor brand to gain performance is building fragile code whose behaviour will drift as hypervisors evolve. We will focus on the legitimate uses.

30.7.1 The `vm_guest` Global

The FreeBSD kernel exposes a single global variable, `vm_guest`, which records the hypervisor it detected at boot. The variable is declared in `/usr/src/sys/sys/systm.h`:

```
extern int vm_guest;

enum VM_GUEST {
    VM_GUEST_NO = 0,
    VM_GUEST_VM,
    VM_GUEST_XEN,
    VM_GUEST_HV,
    VM_GUEST_VMWARE,
    VM_GUEST_KVM,
    VM_GUEST_BHYVE,
    VM_GUEST_VBOX,
```

```
VM_GUEST_PARALLELS,  
VM_GUEST_NVMM,  
VM_LAST  
};
```

The values are self-explanatory. `VM_GUEST_NO` means the kernel is running on bare metal; the other values identify specific hypervisors. `VM_GUEST_VM` is a fallback for “a virtual machine of unknown type,” when the kernel could tell it was virtualised but could not pin down which hypervisor.

The corresponding `sysctl` is `kern.vm_guest`, which yields the human-readable form of the same information. The string values mirror the enum: “none”, “generic”, “xen”, “hv”, “vmware”, “kvm”, “bhyve”, “vbox”, “parallels”, “nvmm”. You can query it from the shell:

```
sysctl kern.vm_guest
```

On a bare-metal FreeBSD machine you will see none. On a bhyve(8) guest, you will see bhyve. On a VirtualBox guest, vbox. And so on.

30.7.2 How the Detection Works

The detection happens early in boot, on architectures where hypervisor presence is detectable. On amd64, the kernel examines the CPUID leaf for a hypervisor present bit and then probes specific leaves associated with each hypervisor brand. The code lives in `/usr/src/sys/x86/x86/identcpu.c`, in functions named `identify_hypervisor()` and `identify_hypervisor_cpuid_base()`. On arm64, a similar mechanism exists through firmware interfaces.

The driver author does not need to care about the detection code. What matters is that by the time your driver’s `attach()` runs, `vm_guest` has been set to its final value.

30.7.3 When to Consult `vm_guest`

Consulting `vm_guest` is appropriate in a driver when the driver’s correctness or performance depends on knowing the runtime environment. A few real examples from the tree illustrate the range:

- Some performance counters in `/usr/src/sys/kern/kern_resource.c` adjust their behaviour when `vm_guest == VM_GUEST_NO`, because the kernel assumes a bare-metal cost model is accurate there.
- Some time-related code in the amd64 tree may not use certain timing primitives under specific hypervisors where those primitives are known to be unreliable.
- Some informational messages in driver probe paths are suppressed under virtualisation to avoid confusing users who expect the driver to behave “differently” in a VM.

A driver you write should use `vm_guest` sparingly. A common anti-pattern is to test for `VM_GUEST_VM` as a blanket switch (“if virtualised, do X”), which is usually a sign that the driver has a bug on real hardware that it is papering over. Prefer to handle the underlying cause directly, and use `vm_guest` only when the dependency is genuinely on the environment rather than on a specific hardware quirk.

30.7.4 A Usage Example

Suppose your driver has a `sysctl` that controls how aggressively it polls a hardware register. The tight loop is fine on bare metal, where each poll is cheap, but under virtualisation each poll costs a hypervisor exit, which is expensive. You might want the default polling interval to be larger under virtualisation:

```
#include <sys/systm.h>

static int
my_poll_default(void)
{
    if (vm_guest != VM_GUEST_NO)
        return (100); /* milliseconds */
    else
        return (10);
}
```

This is a legitimate use of `vm_guest`: the driver is choosing a sensible default based on a property of the environment that genuinely affects its performance characteristics. The value remains overridable by a `sysctl` for users who know better than the default.

Contrast that with an illegitimate use:

```
/* DO NOT DO THIS */
if (vm_guest == VM_GUEST_VMWARE) {
    /* skip interrupt coalescing because VMware does it weirdly */
    sc->coalesce = false;
}
```

Here the driver is branching on a specific hypervisor brand to work around a perceived bug. This is fragile for three reasons. The specific behaviour of VMware may change in a later release; the same issue may apply to KVM or Parallels without the code noticing; and the driver now has a maintenance burden tied to a third-party product. A better approach is to address the root cause (the coalescing code is fragile, so either fix it or expose a `sysctl`), not the symptom (VMware happens to trigger it).

30.7.5 The Sysctl Path

For user-space tools and scripts, the `kern.vm_guest` `sysctl` is a better interface than poking at `/dev/mem` or similar. A small shell script can decide whether to run certain tests based on the environment:

```
if [ "$(sysctl -n kern.vm_guest)" = "none" ]; then
    echo "Running on bare metal, enabling hardware tests"
    run_hardware_tests
else
```

```
echo "Running on a hypervisor, skipping hardware tests"
fi
```

This is how the FreeBSD test suite decides which tests to run in which environment. Reusing the same variable from inside a driver keeps the whole system consistent.

30.7.6 Interaction with Subsystems

A few FreeBSD subsystems adapt their behaviour based on `vm_guest` automatically, and a driver author should be aware of the adaptations without having to touch them.

The timecounter selection code in `/usr/src/sys/kern/kern_tc.c` considers `vm_guest` when picking a default timecounter, because some hypervisors' TSC implementations are unreliable across guest migrations. The driver does not need to care; the kernel simply picks a safer timecounter.

The VirtIO transport drivers (`virtio_pci.c` and `virtio_mmio.c`) do not branch on `vm_guest` directly, because they are already guests by their own probe path. They trust that if they have a device at all, they are running in an environment that emulates VirtIO.

Some network driver code handles the case where GRO (generic receive offload) is known to interact badly with certain hypervisor configurations. These adaptations are not driver-by-driver decisions; they are made in the network stack based on observed characteristics.

As an author of a single driver, your rule of thumb is: if you feel the urge to branch on `vm_guest`, ask yourself whether the issue belongs to the kernel's environment handling rather than to your driver. Usually it does.

30.7.7 Detecting Within a VirtIO Driver

A VirtIO driver, by definition, is running inside some kind of environment that speaks VirtIO. The driver does not usually need to know which specific hypervisor is backing the VirtIO device. That is one of VirtIO's virtues: it is environment-agnostic. The same `virtio_net` driver works under bhyve, under QEMU/KVM, under Google Cloud's backend, and under AWS Nitro, because all of them implement the same standard.

There are two exceptions. One is when the driver hits a performance cliff that is hypervisor-specific, in which case `vm_guest` tells you which workaround to apply. The other is when the driver wants to print a diagnostic message that identifies the hypervisor by name. Both are rare.

30.7.8 Detecting From the Host Side

A host-side driver (one that runs in the host, not in a guest) usually does not care about `vm_guest` at all, because the host is not virtualised by definition. The `sysctl` will return `none` on bare metal, and that is the expected case.

The one subtlety is when the host is itself a guest, as in nested virtualisation scenarios. A FreeBSD host inside a VMware ESXi VM, for example, will have `vm_guest = VM_GUEST_VMWARE`. A `bhyve(8)` running inside such a host will present guests that also see virtualisation, though they see the bhyve presentation rather than the VMware one. The chain of environments can go two or three levels deep in research and test setups. Do

not assume a host is bare metal; if your driver has a host-versus-guest split, use the `sysctl` or the variable to distinguish.

30.7.9 Wrapping Up

`vm_guest` is a small, quiet API that tells your driver, and user-space tools, about the environment. It is easy to use and easy to misuse. Use it to adapt sensible defaults, not to work around hypervisor-specific bugs. Use it to inform user-space decisions through the `sysctl`. Do not make your driver's behaviour depend on the exact hypervisor brand; doing so couples your code to a third-party product's version history, and that is a maintenance tax you do not want to pay.

Section 5 looks at the other side of virtualisation for FreeBSD: the host that runs the guests, and the tools and interfaces that a driver author should understand when running or cooperating with `bhyve(8)`.

30.8 Section 5: `bhyve`, PCI Passthrough, and Host-Side Considerations

So far we have focused on what happens inside the guest. The guest is where most of the learning happens, because the guest is where most of the driver code lives. But FreeBSD has another role in the virtualisation story: it is also a hypervisor. `bhyve(8)` runs virtual machines, and understanding how `bhyve(8)` presents devices to its guests is useful both when you are the guest author (so you know what the host is doing) and when you are the host author (so you know how to share a real device with a guest).

This section steps onto the host side. We will not go deep enough to write hypervisor code, because that is a topic of its own. We will go deep enough for you to understand what the host is doing, what the host-side knobs are, and what a driver author needs to know when cooperating with `bhyve(8)`.

30.8.1 `bhyve` From the Driver Author's Perspective

`bhyve(8)` is a type-2 hypervisor that runs on a FreeBSD host and uses hardware virtualisation extensions (Intel VT-x or AMD-V) to execute guest code directly on the CPU. It is implemented as a user-space program (`/usr/sbin/bhyve`) and a kernel module (`vmm.ko`). The kernel module handles the low-level virtualisation primitives: VM entry and exit, page table management for guest memory, virtual APIC emulation, and a handful of performance-critical device backends. The user-space program handles the rest: command-line parsing, emulated device backends that do not need to live in the kernel, VirtIO backends, and the main VCPU loop.

From a driver author's perspective, three things matter about `bhyve(8)`.

First, `bhyve(8)` is a FreeBSD program, so the same kernel that runs your driver might also be running `bhyve(8)` in user space. That means host-side resources (memory, CPU, network interfaces) can be competing with `bhyve(8)` for allocation. If your driver is running on a host that is also a hypervisor, you may want to think about NUMA placement, IRQ affinity, and similar concerns.

Second, `bhyve(8)` uses a FreeBSD kernel interface called `vmm(4)` for its low-level needs. This interface is stable but niche; most driver authors never touch it directly. If you are writing a driver that needs to interact with virtual machines (for example, a driver that provides a paravirtual device to `bhyve(8)` guests from the host side), you would use `vmm(4)` or one of the higher-level libraries that wraps it.

Third, and most importantly for this chapter, `bhyve(8)` can assign a real PCI device directly to a guest. This is called PCI passthrough, and it has important implications for driver authors on both sides of the fence.

30.8.2 `vmm(4)`: The Kernel Side of `bhyve`

`vmm(4)` is a kernel module that exposes an interface for creating and managing virtual machines. It lives at `/usr/src/sys/amd64/vmm/` and related directories. The module is loaded on demand by `bhyvectl(8)` or `bhyve(8)`, and it exports a character device interface through `/dev/vmm/NAME` where `NAME` is the name of the virtual machine.

The `vmm(4)` interface is not something a beginner driver author needs to learn in depth. It is complex, specialised, and mostly of interest to people who are extending or modifying the hypervisor itself. For our purposes, it is enough to know the following. `vmm(4)` manages the virtual CPU state, including registers, page tables, and interrupt controllers. It hands off emulation of devices that are not performance-critical to user space, via a ring buffer interface. For devices that are performance-critical, such as the in-kernel virtual APIC or the virtual IOAPIC, it handles emulation in the kernel itself.

A driver author who is running inside a `bhyve(4)` guest will never interact with `vmm(4)` directly. The guest kernel sees only the virtualised devices; the mechanism by which they are emulated is invisible. The only observable trace is in `sysctl kern.vm_guest`, which will report `bhyve`.

A driver author who is writing host-side code for `bhyve(8)` will see `vmm(4)` only through the user-space libraries. Most tasks are handled by `libvmmapi(3)`, which wraps the raw `ioctl` interface. Direct `vmm(4)` work is rare outside of `bhyve(8)` development itself.

30.8.3 PCI Passthrough: Giving a Guest a Real Device

The most direct way for a guest to interact with a physical device is for the host to give the guest exclusive access to that device. This is called PCI passthrough, and `bhyve(8)` supports it through the `pci_passthru(4)` facility.

The idea is straightforward, but the mechanics are subtle. A real PCI device is normally claimed by a driver on the host. That driver programs the device, handles its interrupts, and owns its memory-mapped registers. When we do passthrough, we want the guest's driver to do all of that instead. The host must step out of the way, and the hardware must be reconfigured so that the guest's memory addresses map to the device's memory correctly and so that the device's DMA operations go to the guest's memory rather than the host's.

The host steps out of the way by detaching the driver that was attached to the device and attaching a placeholder driver (`ppt(4)`) instead. `ppt` is a minimal driver whose only purpose is to claim the device so that no one else does. Its probe function matches any PCI device whose address matches a pattern specified by the user in `/boot/loader.conf`, typically using the `pptdevs` tunable. Once the placeholder driver claims the device, `bhyve(8)` can request a passthrough through the `vmm(4)` interface, and the device becomes accessible inside the guest.

The hardware reconfiguration is handled by the IOMMU. This is the part that makes passthrough both capable and dangerous. Without an IOMMU, DMA from the device would go to physical addresses on the host's memory bus, and a misbehaving guest could program the device to read or write anywhere in host memory. That is obviously unsafe. An IOMMU (Intel VT-d or AMD-Vi on the platforms FreeBSD supports) sits between the

device and the host memory bus, remapping device-issued addresses so that they cannot escape the guest. From the device's perspective, it still does DMA to an address; from the host memory bus's perspective, that address is translated to somewhere inside the guest's memory and nowhere else.

If your host has no IOMMU, `bhyve(8)` will refuse to set up passthrough. This is an intentional safety check. Enabling passthrough without IOMMU protection would be like handing a stranger a signed blank cheque on the host kernel: one bug in the device firmware or one malicious guest, and the host is compromised.

30.8.4 How Passthrough Looks to the Guest Driver

From the guest's perspective, a PCI passthrough device looks exactly like the real hardware. The guest's PCI enumeration finds the device, with its real vendor and device IDs, its real capabilities, and its real BARs. The guest's driver attaches just as it would on bare metal. The read and write operations hit the real hardware (with some address translation in between). Interrupts are delivered to the guest through the hypervisor's virtual interrupt controller. DMA works, though the addresses the guest programs into the device are guest-physical addresses, not host-physical addresses, with the IOMMU taking care of the translation.

This has three practical consequences for a driver author.

First, your driver does not need to know it is running under passthrough. The same driver binary works on bare metal and in a passthrough guest. This is a major design goal of the whole scheme.

Second, if your driver uses DMA, make sure you are using `bus_dma(9)` properly. The bus-DMA framework handles the guest-physical versus host-physical translation transparently if you use it correctly. If you are doing clever things with physical addresses directly (which you should not be), passthrough will break those things.

Third, if your driver relies on platform-specific features (for example, special firmware on the PCI device itself, or a particular BIOS table), those features must be present in the guest too. Passthrough gives the guest the device, but it does not give it the firmware or the BIOS tables. Some passthrough setups fail because the driver assumes the presence of an ACPI table that exists on the host but not inside the guest's virtual BIOS.

The last point matters especially for devices that expect strict ordering or uncached memory access. The bus-DMA and bus-space interfaces, used correctly, handle these cases. Direct pointer manipulation to mapped memory usually does not survive passthrough.

30.8.5 Host-Side Driver Attach Under `bhyve`

When `bhyve(8)` is running on a FreeBSD host, two categories of device exist. Some devices are claimed by host drivers and shared with guests through emulation or `VirtIO`. Others are claimed by `ppt(4)` and passed through entirely.

If you are writing a driver for a device that might be used under passthrough, there are a few things to consider.

The first is whether the device should even allow passthrough. Some devices are fundamental to the host's operation (for example, the SATA controller that the host boots from, or the network interface the host is reachable on). These devices should not be marked as candidates for passthrough, because taking them away from the host would break the host. The mechanism for marking candidates is administrative, through `pptdevs` in `loader.conf`, and the host administrator is responsible. There is no per-driver lockout, but a driver author can document clearly whether passthrough is recommended for the device.

The second is whether the driver releases the device cleanly at detach time. Passthrough requires the original driver to detach, and then `ppt(4)` to attach. If your driver's `DEVICE_DETACH` method is sloppy, passthrough setup will be unstable. The detach code must stop the hardware cleanly, release IRQs, unmap resources, and free any memory that the hardware might touch. Anything that persists after detach is a risk.

The third is whether the driver tolerates being re-attached after a passthrough use. When the guest shuts down and releases the device, the host administrator might want to rebind the device to the original driver for use on the host. The driver should be able to attach to a device that was previously owned by `ppt(4)`, even though the device may have been reset and reconfigured by the guest. This means the driver's `DEVICE_ATTACH` method should not assume anything about the device's initial state; it should program the device from scratch, just as it does on first boot.

None of these are new requirements. They are all things a well-written driver does anyway. Passthrough just makes the habits more important, because the cost of getting them wrong shows up immediately.

30.8.6 IOMMU Groups and the Reality of Partial Isolation

A brief word on IOMMU groups, which come up sometimes in passthrough discussions. An IOMMU cannot always isolate a single device from another device on the same PCI bus. When two devices share a bus or a bridge without ACS (Access Control Services), the IOMMU treats them as a single group, because it cannot guarantee that one cannot see the other's DMA. FreeBSD's `dmr(4)` (Intel) and `amdvi(4)` (AMD) drivers handle this grouping internally, but the administrator sometimes has to pass through a whole group rather than a single device.

For a driver author, the practical implication is that passthrough sometimes grabs more than the device you expected. If your device sits behind a bridge shared with another device, turning on passthrough for your device may pull the other one into the guest too. The solution is usually to place devices on separate bridges in the firmware configuration, but that is an administrator concern, not a driver concern. Knowing it exists helps when diagnosing unexpected behaviour.

30.8.7 Host-Only Considerations: Memory, CPU, and the Hypervisor

A FreeBSD host that runs `bhyve(8)` guests has a few extra responsibilities beyond the usual. Memory for the guest's RAM is allocated from the host's physical memory, so a host running many guests needs correspondingly more memory. Guest VCPUs are backed by host threads, so a host running many guests needs to provision CPU capacity. And the hypervisor itself uses a small amount of memory and CPU for its bookkeeping.

A driver author on the host side does not need to manage these resources directly. They are managed by `bhyve(8)` and the host administrator. But there are two ways in which a host-side driver can interact with them.

The first is when a driver offers a device backend that `bhyve(8)` consumes. An example would be a storage driver that provides the backing store for a guest's virtual disk. If the host-side driver is slow, the guest feels it as slow disk. If the host-side driver consumes too much memory, the host runs out of memory for guests. This is a classic shared-resource problem, and it is usually solved by provisioning rather than by clever code.

The second is when a driver interacts with the hypervisor through `vmm(4)` or similar. Paravirtual device backends sometimes use kernel-side hooks to deliver notifications to guests more efficiently than going through user

space. These are rare and advanced, and outside the scope of this chapter. They are mentioned here so you are not surprised if you see them referenced later.

30.8.8 Cross-Platform Notes: bhyve on arm64

bhyve(8) runs on amd64 and, increasingly, on arm64. The arm64 port uses the ARMv8 virtualisation extensions (EL2) rather than Intel VT-x or AMD-V. The SMMU (System Memory Management Unit) takes the role of the IOMMU. The user-space interface is the same, the guest's VirtIO experience is the same, and from a driver author's perspective, the two architectures are interchangeable. The distinction matters only for the low-level hypervisor code inside vmm(4).

For a book about driver authorship, the lesson is the one we have already learned in Chapter 29: write clean, bus-dma-using, endian-correct code, and you will not notice which architecture you are running on. The hypervisor story is another good reason to follow those habits.

30.8.9 Inspecting bhyve From the Host

A driver author can inspect bhyve(8) state in a few useful ways without getting into vmm(4) internals.

bhyvectl(8) is the command-line tool for querying and controlling virtual machines. `bhyvectl --vm=NAME --get-stats` shows counters maintained by vmm(4) for a running guest, including VM exit counts, emulation counts, and similar diagnostics. This is useful when you suspect that a guest driver is generating unnecessary VM exits (a common performance pitfall).

`pciconf -lvBb` on the host shows the PCI devices and their current driver bindings. A device bound to `ppt(4)` is visible in passthrough mode; a device bound to its native driver is available to the host. This is a quick way to see what is passed through and what is not.

`vmstat -i` on the host shows interrupt counts per device. If a device is passed through to a guest, its interrupts are delivered to the guest's virtual interrupt controller, not to the host. On the host side, you will see the hypervisor's posted-interrupt or interrupt-remapping counts increase instead. This is a subtle but useful diagnostic.

None of this is required reading for driver authorship. It is mentioned here so that when you encounter bhyve(8) on a host while debugging a driver, you know where to look first.

30.8.10 A Typical bhyve Command Line

For readers who want to see what bhyve(8) actually looks like when invoked without a wrapper tool, here is a representative command line. It starts a guest named `guest0` with two VCPUs, two gigabytes of memory, a virtio-blk disk backed by a file, and a virtio-net network interface bridged to the host:

```
bhyve -c 2 -m 2G \  
  -s 0,hostbridge \  
  -s 2,virtio-blk,/vm/guest0/disk0.img \  
  -s 3,virtio-net,tap0 \  
  -s 31,lpc \  
  -l com1,stdio \  
  guest0
```

Each `-s` flag defines a PCI slot. Slot zero is the host bridge; slot two is a virtio-blk device backed by a disk image file; slot three is a virtio-net device backed by a `tap(4)` interface the host has configured; slot thirty-one is the LPC bridge used for legacy devices like the serial console. The `-l com1, stdio` redirects the guest's first serial port to the host's standard I/O, which is convenient for console access.

When this command runs, the host kernel creates a new VM through `vmm(4)`, allocates memory for the guest's RAM, and hands off VCPU execution to the guest's kernel. The virtio-blk backend in `bhyve(8)` (user-space code) services the guest's block requests by reading and writing the disk image file. The virtio-net backend sends and receives packets through the `tap0` interface, which the host's network stack handles as an ordinary interface.

A driver running inside this guest sees a PCI virtio-blk device, a PCI virtio-net device, and the usual assortment of emulated LPC devices. From the driver's perspective, there is no clue that the "hardware" is implemented by a user-space program running a few milliseconds away on the same host. The abstraction is, by design, complete.

30.8.11 Inside the `vmm(4)` Module

`vmm(4)` is the kernel-side infrastructure for `bhyve(8)`. In FreeBSD 14.3, its main source files live in `/usr/src/sys/amd64/vmm/`; an arm64 port is under active development and is expected to ship in a later release, so if you are on FreeBSD 14.3 the amd64 tree is the one to read. The module exports a small control interface through `/dev/vmmctl` and a per-VM interface through `/dev/vmm/NAME`.

The control interface is used by `bhyvectl(8)` and `bhyve(8)` to create, destroy, and enumerate virtual machines. The per-VM interface is used to read and write VCPU state, map guest memory, inject interrupts, and receive VM-exit events from the guest.

When a guest's VCPU executes code that requires emulation (reading from an I/O port, accessing a memory-mapped device register, executing a hypercall), the hardware traps the execution and the control returns to `vmm(4)`. The module either handles the exit in the kernel (for a small set of performance-critical cases, like reading the local APIC) or forwards it to `bhyve(8)` in user space (for most cases, including all VirtIO device emulation).

The kernel/user-space split is a deliberate design choice. Keeping the code in user space makes it easier to develop, debug, and audit. Keeping performance-critical paths in the kernel keeps the overhead low. For FreeBSD, the split has worked well, and `bhyve(8)` has grown from a small academic prototype to a production-quality hypervisor.

For a driver author who is not extending `bhyve(8)` itself, none of this matters in detail. What matters is the observable behaviour: a guest executes code, some operations trap, the hypervisor emulates them, and the guest continues. The driver in the guest sees consistent behaviour regardless of where the emulation happens.

30.8.12 Nested Virtualisation

A brief mention of nested virtualisation, since it comes up. FreeBSD's `bhyve(8)` on amd64 currently does not support running hardware-virtualised guests inside hardware-virtualised guests (no `VIRTUAL_VMX` or `VIRTUAL_SVM` extensions yet). If you try to run `bhyve(8)` inside a `bhyve(8)` guest, the inner hypervisor will fail

to initialise. Intel and AMD both support nested virtualisation in hardware, but the FreeBSD implementation has not yet enabled it.

This matters for labs only in the sense that you must run `bhyve(8)` on bare metal (or on a host that provides nested virtualisation, which some cloud platforms do). If your lab machine is itself a VM, you may find that `bhyve(8)` either fails to load `vmm.ko` or loads it but refuses to start guests.

On arm64, nested virtualisation is a different story; the ARM architecture has cleaner support, and the FreeBSD arm64 port is moving toward enabling it. For up-to-date information, consult the `bhyve(8)` and `vmm(4)` manual pages on the version of FreeBSD you are running.

30.8.13 An Example: Debugging a PCI Passthrough Driver

To make the host-side discussion concrete, consider a scenario that combines several of the ideas above. You have a PCI network card that your host's driver knows how to drive. You want to pass it through to a `bhyve(8)` guest and test that the same driver works unchanged in the guest.

Step 1: Identify the device. `pciconf -lvBb` shows `em0@pci0:2:0:0` with the driver `em` attached. The device is an Intel Gigabit Ethernet controller.

Step 2: Mark it for passthrough. Edit `/boot/loader.conf` and add `pptdevs="2/0/0"`. Reboot.

Step 3: Verify. After reboot, `pciconf -l` shows `ppt0@pci0:2:0:0`, with `ppt` (the placeholder driver) attached instead of `em`. The device is no longer available to the host's network stack.

Step 4: Configure the guest. In the guest's `bhyve` configuration, add `-s 4,passthru,2/0/0`. This tells `bhyve(8)` to pass through the device to the guest at PCI slot 4.

Step 5: Start the guest. Inside the guest, run `pciconf -lvBb`. The device appears, with its real Intel vendor and device IDs, attached to `em`. Check `dmesg`. The guest's `em` driver has attached to the passthrough device exactly as it would on bare metal.

Step 6: Exercise the device. Configure the interface (`ifconfig em0 10.0.0.1/24 up`), send traffic, verify it works.

Step 7: Shut down the guest. Back on the host, decide whether to keep the device in passthrough mode or return it to the host. If you want it back, edit `/boot/loader.conf` to remove `pptdevs`, reboot, and verify that `em` is attached again.

Every step in this workflow is something the administrator does; the driver itself is untouched. That is the point. If the driver is written correctly (with `bus_dma`, clean detach, no hidden platform assumptions), it works in both environments without changes.

30.8.14 Wrapping Up

The host side of virtualisation is where FreeBSD plays a slightly different role. Instead of writing a driver that consumes a hypervisor-provided device, you may find yourself writing (or at least interacting with) the infrastructure that provides devices to a hypervisor. `bhyve(8)`, `vmm(4)`, and `pci_passthru(4)` are the main interfaces to know about. PCI passthrough is the most relevant of these for a driver author, because it exercises the detach-and-reattach lifecycle that a well-written driver already supports.

With guests and hosts both covered, the next major environment in FreeBSD's virtualisation story is the one that does not use a separate kernel at all: jails. Section 6 turns to them, to devfs, and to the VNET framework that extends the jail model into the network stack.

30.9 Section 6: Jails, devfs, VNET, and Device Visibility

Virtualisation and containerization share a goal: they both let one physical machine host several workloads that appear, to their users, to be running on separate machines. The mechanisms they use are dramatically different. A virtual machine runs a complete guest kernel on top of a hypervisor; it has its own memory map, its own device tree, its own everything. A container, in the FreeBSD sense, shares the host's kernel entirely. What it has of its own is a filesystem view, a process table, and (if the administrator sets it up that way) a network stack. FreeBSD's answer to the container question is the jail, and jails have existed in some form since FreeBSD 4.0. For driver authors, jails matter because they change what a process can see and do with respect to devices, without changing the driver code at all.

This section explains how jails interact with devices. It focuses on four topics: the jail model itself, the devfs ruleset system that controls device visibility, the VNET framework that gives jails their own network stacks, and the question every container system eventually has to answer: which processes can reach which drivers.

30.9.1 What a Jail Is, and What It Is Not

A jail is a subdivision of the host kernel's resources. A process running inside a jail sees a subset of the filesystem (rooted at the jail's root directory), a subset of the process table (only processes in the same jail), a subset of the network (depending on whether the jail has its own VNET), and a subset of the devices (depending on the jail's devfs ruleset). The host kernel is a single, shared kernel; there is no separate guest kernel inside the jail. System calls made inside the jail are executed by the same kernel that executes calls from outside the jail, with jail-specific checks inserted at the right places.

Because the kernel is shared, drivers are shared too. There is no separate copy of a driver inside each jail; there is only the one driver that the kernel loaded at boot time. The jail just controls which of the driver's devices are visible to the jail's processes. A jail that has not been configured to see `/dev/null` will see no `/dev/null`; a jail that has been configured to see `/dev/null` will see the same `/dev/null` that the host sees. No new driver instance; no new softc; just a visibility rule.

This simplicity is both jails' great strength and their great limitation. It means jails are extremely cheap: starting a jail is roughly the cost of running a few system calls, whereas starting a VM is the cost of booting a whole kernel. It also means jails cannot isolate kernel-level failures: a driver bug that panics the host kernel panics every jail running on it. A jail is a policy boundary, not a crash boundary. For many workloads that trade-off is excellent; for others, a VM is the right answer.

30.9.2 The Kernel's View of Jails

Inside the kernel, a jail is represented by a struct `prison`, defined in `/usr/src/sys/sys/jail.h`. Each process has a pointer to the prison it belongs to, via `td->td_ucred->cr_prison`. Code that wants to check whether a process is inside a jail can compare this pointer against the global `prison0`, which is the root jail (the host itself). If the pointer is `prison0`, the process is on the host; otherwise, it is in some jail.

Several helper functions exist for the common checks a driver might want to do. `jailed(cred)` returns true if the credential belongs to a jail other than `prison0`. `prison_check(cred1, cred2)` returns zero if two credentials are in the same jail (or one is the parent of the other); it returns an error otherwise. `prison_priv_check(cred, priv)` is how privilege checks are extended for jails: a root user inside a jail does not have all privileges that root has on the host, and `prison_priv_check` implements the reduction.

A driver author will usually not need to call any of these directly. The framework calls them on your behalf. When a process opens a `devfs` node, for example, the `devfs` layer consults the jail's `devfs` ruleset before handing the file descriptor over. When a process tries to use a privilege-gated feature (like `bpf(4)` or `kldload(2)`), the privilege check goes through `prison_priv_check`. A driver only needs to be aware that these checks exist, and to call the framework helpers correctly when it defines its own access rules.

30.9.3 devfs: The Filesystem Through Which Devices Are Exposed

In FreeBSD, devices are exposed through a filesystem called `devfs(5)`. Every entry under `/dev` is a `devfs` node. A driver that calls `make_dev(9)` or `make_dev_s(9)` creates a `devfs` node; the name, permissions, and uid/gid are attributes of that node. The node is visible in every `devfs` instance that the kernel mounts, and FreeBSD mounts one `devfs` instance per filesystem view: one for the host's `/dev`, one for each jail's `/dev` (if the jail has its own `/dev`), and one per `chroot` that mounts its own `devfs`.

This is the first part of the visibility story. Each jail (more precisely, each filesystem view) has its own `devfs` mount, and the kernel can apply different rules to different mounts. The rules are called `devfs` rulesets, and they are the main tool for controlling which devices a jail can see.

30.9.4 devfs Rulesets: Declaring What a Jail Can See

A `devfs` ruleset is a numbered set of rules stored in the kernel. Rules can hide nodes, reveal nodes, change their permissions, or change their ownership. The ruleset is applied to a mounted `devfs` instance; every time a lookup happens in that instance, the kernel walks the ruleset and applies the matching rule to each node.

On a fresh FreeBSD system, four rulesets are predefined in `/etc/defaults/devfs.rules` (which is processed when the kernel starts). The file uses `devfs(8)` syntax, a small declarative language for ruleset construction. Let us look at a representative slice.

```
[devfsrules_hide_all=1]
add hide

[devfsrules_unhide_basic=2]
add path log unhide
add path null unhide
add path zero unhide
add path crypto unhide
add path random unhide
add path urandom unhide

[devfsrules_jail=4]
```

```
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
add include $devfsrules_unhide_login
add path zfs unhide

[devfsrules_jail_vnet=5]
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
add include $devfsrules_unhide_login
add path zfs unhide
add path 'bpf*' unhide
```

Rule 1, `devfsrules_hide_all`, hides everything. On its own it is useless, because a `devfs` mount with nothing visible is not helpful. It is the starting point for other rulesets.

Rule 2, `devfsrules_unhide_basic`, unhides a small set of essential devices: `log`, `null`, `zero`, `crypto`, `random`, `urandom`. These are the devices that essentially every program needs; without them, even basic tools fail.

Rule 4, `devfsrules_jail`, is the ruleset intended for non-VNET jails. It starts by including `devfsrules_hide_all` (so everything is hidden), then layers `devfsrules_unhide_basic` on top (so the essentials are visible), and adds ZFS devices. The result is a jail that sees a small, safe set of devices and nothing else.

Rule 5, `devfsrules_jail_vnet`, is the equivalent for VNET jails. It is the same as rule 4 with the addition that `bpf*` devices are unhidden, because a VNET jail might legitimately need `bpf(4)` (for tools like `tcpdump(8)` or `dhclient(8)`).

When creating a jail, the administrator specifies which ruleset to apply to the jail's `/dev` mount, either through `jail.conf(5)` (`devfs_ruleset = 4`) or on the command line (`jail -c ... devfs_ruleset=4`). The kernel applies the ruleset to the mount, and the jail sees only what the ruleset allows.

30.9.5 Creating a Custom `devfs` Ruleset

For most jails, the default rulesets are enough. When they are not, an administrator can define new ones. A new ruleset must have a unique number (other than the reserved defaults) and can be constructed by inclusion, addition, and override.

A classical example is a jail that needs one specific device that the default rules hide. Suppose we have a jail that runs a service that needs `/dev/tun0`, and we want to expose it without opening the whole `/dev/tun*` family. We would create a ruleset like:

```
[devfsrules_myjail=100]
add include $devfsrules_jail
add path 'tun0' unhide
```

And apply it in `jail.conf(5)`:

```
myjail {  
    path = /jails/myjail;  
    devfs_ruleset = 100;  
    ...  
}
```

The `devfs(8)` tool can load this ruleset into the running kernel with `devfs rule -s 100 add ...`, or the administrator can edit `/etc/devfs.rules` and restart `devfs`. For persistent configuration, the file is the right place.

30.9.6 What devfs Rulesets Do Not Do

It is worth noting what devfs rulesets are not. They are not a capability system. Hiding a device from a jail means the jail cannot open that specific path, but a jail that has the `allow.raw_sockets` privilege can still send arbitrary raw packets, ruleset or no ruleset. Hiding `/dev/kmem` does not prevent a determined attacker with the right privileges from reading kernel memory via other means; it just removes one obvious path.

Rulesets are a visibility policy, layered on top of the standard UNIX permissions model. The UNIX permissions still apply: a file hidden by the ruleset is not openable, but a file visible to the ruleset still respects its own permissions. A jail's root user can open `/dev/null` because the ruleset says so and the permissions say so, not because the ruleset alone grants access.

For strong isolation, combine rulesets with privilege restrictions (`allow.*` parameters in `jail.conf(5)`) and, if the workload warrants it, with a VM. Rulesets alone are one layer of defence, not the only one.

30.9.7 A Driver Author's View of devfs Rulesets

For a driver author, devfs rulesets matter for two reasons.

First, when you create a devfs node with `make_dev(9)`, you pick a default owner, group, and permission. These apply to every devfs view that the node appears in. If your device is something that jails should generally not see (for example, a low-level hardware-management interface), consider whether the name should be obvious (so administrators can easily write a rule that hides it) or whether it should be under a subdirectory (so a single rule can hide the whole subdirectory).

Second, if your driver's device is something that jails commonly need, document that fact in your driver's manual page. The administrator who writes a jail's ruleset is usually not the person who wrote the driver, and they need to know whether to unhide your node. A line like "This device is typically used inside jails; unhide it with `add path mydev unhide` in the jail's ruleset" is very helpful.

Neither of these is a code change. Both are decisions about naming and documentation. Driver authorship is not just about code; it is also about making the code usable by the administrators who will deploy it.

30.9.8 Wrapping Up the Jail and devfs Side

Jails are the lightweight containerization mechanism in FreeBSD. They share the host kernel, and thus share drivers, but they control which devices are visible through the devfs ruleset mechanism. For a driver author,

the relevant design decisions are at the naming and documentation level: pick names that make it easy to write rules, and document which jails should see the device.

The network side of jails is a story of its own, because FreeBSD has two models: single-stack jails that share the host's network, and VNET jails that have their own network stacks. The VNET model is the more interesting one for driver authors, because it has direct consequences for how network drivers are assigned and moved. We turn to that next.

30.9.9 The VNET Framework: One Kernel, Many Network Stacks

The default jail model has one network stack: the host's. Every jail sees the same routing table, the same interfaces, the same sockets. A jail can be restricted to particular IPv4 or IPv6 addresses (via `ip4.addr` and `ip6.addr` in `jail.conf(5)`), but it cannot have a genuinely independent network configuration. That is often enough for simple workloads, but it is not enough for any jail that wants to run its own firewall, use its own default gateway, or be reached by the outside world through a unique set of addresses on its own interfaces.

VNET (short for “virtual network stack”) solves this. It is a kernel feature that replicates the parts of the network stack per jail, so each VNET jail sees its own routing table, its own interface list, its own firewall state, and its own socket namespace. The stack code still belongs to the same kernel, but many of its global variables are now per-VNET instead of truly global. A network driver's per-interface state belongs to whichever VNET it is currently assigned to, and interfaces can be moved from one VNET to another.

For driver authors, VNET is interesting in three respects. It changes how global state in network subsystems is declared. It adds a lifecycle to interfaces: interfaces can be moved, and drivers must support the move cleanly. And it interacts with jail creation and destruction through VNET-specific hooks.

30.9.10 Declaring VNET State: `VNET_DEFINE` and `CURVNET_SET`

VNET's design puts the work on whoever declares global state in a VNET-aware subsystem. Instead of a plain `static int mysubsys_count;`, a VNET-aware declaration looks like:

```
VNET_DEFINE(int, mysubsys_count);  
#define V_mysubsys_count VNET(mysubsys_count)
```

The `VNET_DEFINE` macro expands to a storage declaration that places the variable in a special section of the kernel. At VNET creation time, the kernel allocates a new per-VNET region of memory and initialises it from the section. The `VNET( . . . )` macro, used via a short alias like `V_mysubsys_count`, resolves to the correct copy for the current VNET.

“The current VNET” is thread-local context. When a thread enters code that operates on a VNET, it calls `CURVNET_SET(vnet)` to establish the context, and `CURVNET_RESTORE()` to tear it down. Inside the context, `V_mysubsys_count` resolves to the right instance. Outside the context, accessing `V_mysubsys_count` is a bug; the macro depends on the thread-local current-VNET pointer, and without that pointer set the result is undefined.

Most driver authors do not need to write `VNET_DEFINE` declarations themselves. The network stack and the `ifnet` framework declare their own VNET state. Driver-level state (per-interface softcs, per-hardware private

data) is not usually VNET-scoped, because it is tied to the hardware, not to the network stack. The driver's state lives wherever the driver put it, and the framework takes care of moving the right bits between VNETs when interfaces move.

What driver authors do need to do is wrap any code that touches network-stack objects in a `CURVNET_SET` / `CURVNET_RESTORE` pair if that code is called from outside a network-stack entry point. Most driver code is called from the network stack already, so the VNET context is already set. The exception is callouts and taskqueues: a callback fired from a callout does not inherit a VNET context, and the driver must establish one before touching any `v_` variable.

A typical pattern inside a callout handler:

```
static void
mydev_callout(void *arg)
{
    struct mydev_softc *sc = arg;

    CURVNET_SET(sc->ifp->if_vnet);
    /* code that touches network-stack variables */
    CURVNET_RESTORE();
}
```

The driver stored a reference to the interface's VNET on attach (`sc->ifp->if_vnet` is filled in by the framework when the ifnet is created). On every callout, it establishes the context, does its work, and restores. This is one of the few places where driver authors encounter VNET directly.

30.9.11 `if_vmove`: Moving an Interface Between VNETs

When a VNET jail starts, it typically is given one or more network interfaces to use. There are two common mechanisms. The first is that the administrator creates a virtual interface (an `epair(4)` or `vlan(4)`) and moves one end into the jail. The second is that the administrator moves a physical interface into the jail outright, so that the jail has exclusive access to it while it runs.

The move is implemented by the kernel function `if_vmove()`. It takes an interface and a destination VNET, detaches the interface from the source VNET's network stack (without destroying it), and reattaches it to the destination VNET's network stack. The interface retains its driver, its `softc`, its hardware state, and its configured MAC address. What changes is which VNET's routing table, firewall, and socket namespace it is attached to.

For a driver author, the move imposes a lifecycle requirement. The interface must be able to survive being detached from one VNET and attached to another. The driver's `if_init` function may be called again in the new context. The driver's `if_transmit` function may receive packets from the new VNET's sockets. Any state the driver caches about the "current" network stack (for example, routing-table lookups) must be invalidated or re-established.

For a network driver written to the standard `ifnet(9)` interface, the move usually works without special handling. The ifnet framework does the heavy lifting, and the driver is largely unaware. What the driver must avoid is holding references to VNET-scoped state across entry points. Code like "grab a pointer to the current

routing table at attach and cache it” does not survive an interface move, because the interface may later belong to a different VNET with a different table.

A related primitive, `if_vmove_loan()`, is used for interfaces that should return to the host when the jail shuts down. The jail gets the interface on a loan basis, and on jail destruction the interface is moved back. This is common for `epair(4)` setups where the physical connection (if any) belongs to the host and only the logical presence belongs to the jail.

30.9.12 VNET Lifecycle Hooks

When a VNET is created or destroyed, subsystems that keep VNET state need to initialise it or release it. The `VNET_SYSINIT` and `VNET_SYSUNINIT` macros register functions to be called at those moments. A network protocol might register an `init` function that creates per-VNET hash tables, and an `uninit` function that destroys them.

Driver authors rarely need these hooks. They are relevant to protocols and stack features, not to device drivers. They are mentioned here because you will see them scattered across the network stack code, and knowing that they are VNET lifecycle hooks helps you read the source.

30.9.13 A Concrete VNET Pattern

To make the VNET abstractions concrete, consider a simplified pseudo-driver that keeps a counter of packets received per VNET. The counter must be per-VNET because the same pseudo-driver might be cloned into several VNETs simultaneously, and each clone should have its own count.

The declaration looks like:

```
#include <net/vnet.h>

VNET_DEFINE_STATIC(uint64_t, pseudo_rx_count);
#define V_pseudo_rx_count VNET(pseudo_rx_count)

/* Optional init for the counter */
static void
pseudo_vnet_init(void *unused)
{
    V_pseudo_rx_count = 0;
}
VNET_SYSINIT(pseudo_vnet_init, SI_SUB_PSEUDO, SI_ORDER_ANY,
    pseudo_vnet_init, NULL);
```

The `VNET_DEFINE_STATIC` places the counter in a per-VNET section of the kernel image. When a new VNET is created, the kernel copies the per-VNET section into fresh memory, so each VNET starts with its own zero-initialised copy of the counter. The `V_pseudo_rx_count` shorthand is a macro that expands to `VNET(pseudo_rx_count)`, which in turn dereferences the current VNET’s storage.

When a packet arrives, the receive path increments the counter:

```
static void
pseudo_receive_one(struct mbuf *m)
{
    V_pseudo_rx_count++;
    /* deliver packet to the stack */
    netisr_dispatch(NETISR_IP, m);
}
```

This looks like ordinary code, because the macro hides the per-VNET indirection. The condition for it to be correct is that the thread is already in the right VNET context when `pseudo_receive_one` is called. In a network driver's receive path that condition is automatic: the network stack calls the driver's entry point with the right context already established.

When the counter is accessed from an unusual context, the context must be established explicitly:

```
static void
pseudo_print_counter(struct vnet *vnet)
{
    uint64_t count;

    CURVNET_SET(vnet);
    count = V_pseudo_rx_count;
    CURVNET_RESTORE();
    printf("pseudo: vnet %p has received %lu packets\n", vnet, count);
}
```

Here the function is called from some administrative path that does not know the current VNET, so it sets the context manually, reads the counter, restores the context, and prints the result. This is the pattern you will see repeated in VNET-aware code.

30.9.14 Reading Real VNET Code

If you want to see the pattern in a real driver, `/usr/src/sys/net/if_tuntap.c` is a good starting point. The `tun` and `tap` cloning drivers are VNET-aware: each clone belongs to one VNET, and creating or destroying clones respects the VNET boundaries. The code is well-commented and small enough to read in a couple of evenings.

Two patterns in `if_tuntap.c` are worth noticing. The first is the use of `V_tun_cdevsw` and `V_tap_cdevsw`, per-VNET character device switch structures. Each VNET has its own copy of the switch, so `/dev/tun0` in one VNET can map to a different underlying clone than `/dev/tun0` in another VNET. This is the kind of fine-grained per-VNET duplication that the framework enables.

The second is the use of `if_clone(9)` with VNET. The `if_clone_attach` and `if_clone_detach` functions take VNET into account automatically, so a clone created in a VNET lives in that VNET until it is explicitly moved or destroyed. The cloner does not need to carry VNET state in its `softc`; the framework handles it.

Studying these patterns makes the text in this chapter concrete. Read, take notes, and come back to the text if anything is unclear.

30.9.15 Hierarchical Jails

A brief mention of hierarchical jails, which are a feature some readers will encounter. FreeBSD supports nesting jails: a jail can create child jails, and the child jails are bounded by the parent jail's restrictions. This is useful for services that want to further subdivide their environment.

From a driver author's perspective, hierarchical jails do not introduce new APIs. The `prison_priv_check` helper walks the hierarchy automatically: a privilege is granted only if every level of the hierarchy allows it. A driver that uses the framework correctly works in hierarchical jails without additional code.

The administrative side is more complex (the parent jail must allow child-jail creation, the children inherit a restricted set of privileges), but the driver-side does not need to care. Knowing that the feature exists helps when you see nested jails in a deployment.

30.9.16 Putting It All Together

A FreeBSD system with jails and VNET is a system where a single kernel serves many isolated environments. Each environment sees its own filesystem view, its own process table, its own devices (filtered by devfs ruleset), and possibly its own network stack (under VNET). The driver serving all of them is a single shared binary, but it respects the isolation because it calls the framework APIs correctly.

The framework APIs for this isolation, `priv_check`, `prison_priv_check`, `CURVNET_SET`, `VNET_DEFINE`, and the cloning helpers, are small and self-contained. A driver author who learns them once can write drivers that work correctly in every jail configuration the administrator can dream up. There is no need to special-case specific jail setups; the framework does that work.

30.9.17 Single-Stack Jails and the In-Between

Not every jail needs VNET. A jail that is running a web server that talks through a reverse proxy on the host may do perfectly well with a single-stack jail bound to a specific IPv4 address. The main cost of VNET is complexity in the stack (every protocol must be VNET-aware) and some memory overhead (each VNET has its own hash tables, caches, and counters). For lightweight jails, the single-stack model is often the better choice.

The trade-off for driver authors is worth knowing. A network driver that works correctly in a host-stack jail may still need attention for VNET jails, because the interface can be moved under VNET but not under the single-stack model. Writing the driver with VNET in mind from the start is the right approach; the additional discipline is small, and it future-proofs the driver.

30.9.18 Wrapping Up

Jails share the host's kernel and thus the host's drivers. What they do not share is visibility: devfs rulesets control which device nodes a jail can open, and VNET controls which network interfaces a jail can use. Driver authors benefit from understanding both mechanisms, because the design choices they make (how to name devfs nodes,

how to handle VNET context in callouts, how to support interface moves) affect how their driver behaves in jailed environments.

With the jail picture complete, we can now think about the companion question: once a jail has access to a device, what privileges does it have to use that device? Section 7 takes up resource limits and security boundaries, and looks at the other side of the jail policy story.

30.10 Section 7: Resource Limits, Security Boundaries, and Host-Versus-Jail Access

A driver is not an isolated object. It is a consumer of kernel resources and a provider of services to processes, and both relationships are mediated by the kernel's security and accounting frameworks. When a driver runs on a FreeBSD host that contains jails, the security boundary shifts: some privileges that are unconditional on the host are restricted for jail processes, and some resources that are unmetered on a traditional system are now subject to per-jail limits. A good driver author knows where those boundaries are, because their driver's behaviour on a host is not always its behaviour inside a jail.

This section covers three topics. First, the privilege framework and how `prison_priv_check` reshapes it for jails. Second, `rctl(8)` and how resource limits apply to kernel resources a driver might care about. Third, the practical distinction between attaching a driver from inside a jail (which is usually impossible) and making a driver's services available to a jail (which is the usual case).

30.10.1 The Privilege Framework and `prison_priv_check`

FreeBSD uses a privilege system to make fine-grained decisions about what a process can and cannot do. Traditional UNIX has a single privilege bit (root versus not-root), and that bit determines everything. FreeBSD refines this with the `priv(9)` framework, which defines a long list of named privileges. Each privilege covers a specific kind of operation. Loading a kernel module is `PRIV_KLD_LOAD`. Setting a process's root directory is `PRIV_VFS_CHROOT`. Opening a raw socket is `PRIV_NETINET_RAW`. Configuring an interface's MAC address is `PRIV_NET_SETLLADDR`. Using a BPF device for packet capture is `PRIV_NET_BPF`.

A process that is root (uid 0) has all of these privileges on the host. A process that is a jail's root has some of them, but not all. The restriction is handled by `prison_priv_check(cred, priv)`: it takes the credential and the privilege name, and returns zero if the privilege is granted and an error (usually `EPERM`) if it is denied. The kernel's privilege-checking path is structured so that for a jailed credential, `prison_priv_check` is called first; if it denies the privilege, the caller returns `EPERM` without further ado.

Which privileges a jail is allowed to exercise is determined by two things. The first is a hardcoded list inside `prison_priv_check`: some privileges are simply never granted to jails, regardless of configuration. Examples include `PRIV_KLD_LOAD` (loading kernel modules) and `PRIV_IO` (I/O port access). The second is the `allow.*` parameters in `jail.conf(5)`, which turn on or off specific categories. `allow.raw_sockets` (off by default) controls `PRIV_NETINET_RAW`. `allow.mount` (off by default) controls filesystem mounting privileges. `allow.vmm` (off by default) controls access to `vmm(4)` for running nested hypervisors. The defaults err on the side of denial: if you do not explicitly allow it, the jail does not get it.

For a driver author, the privilege framework matters whenever the driver does something that a process might or might not be allowed to do. A driver that implements a low-level hardware interface might require `PRIV_DRIVER`

(the catch-all for driver-specific privilege checks) or a more specific privilege. A driver that exposes a character device whose `ioctl`s can reconfigure the hardware will call `priv_check(td, PRIV_DRIVER)` (or a more specific name) to decide whether the caller is allowed to do the reconfiguration.

The standard pattern in driver code looks like this:

```
static int
mydev_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
            struct thread *td)
{
    int error;

    switch (cmd) {
    case MYDEV_CMD_RECONFIGURE:
        error = priv_check(td, PRIV_DRIVER);
        if (error != 0)
            return (error);
        /* do the reconfiguration */
        break;
    ...
    }
}
```

`priv_check(td, PRIV_DRIVER)` does the right thing for both host and jail callers. On a host, a root process passes; on a host, a non-root process is denied (unless the driver grants permission by other means). Inside a jail, `prison_priv_check` is consulted, and by default `PRIV_DRIVER` is denied inside jails. If the administrator has configured the jail to allow driver access (a very unusual setting), the privilege is granted and the call proceeds.

The result is that a driver that uses `priv_check` correctly gets jail safety for free. The driver does not need to know whether the caller is in a jail; it just asks whether the caller has the right privilege, and the framework takes care of the rest.

30.10.2 Named Privileges Most Relevant to Drivers

A short reference for some of the privileges a driver author will encounter.

`PRIV_IO` is for direct I/O port access on x86. It is defined in `/usr/src/sys/sys/priv.h` and is denied to jails unconditionally. Drivers that offer raw I/O port access to user space are rare (usually limited to legacy hardware like `/dev/io`), but when they exist, they use this privilege.

`PRIV_DRIVER` is the catch-all for driver-specific privileges. If a driver needs to gate an `ioctl` that only an administrator should call, `PRIV_DRIVER` is the default choice.

`PRIV_KMEM_WRITE` gates write access to `/dev/kmem`. Like `PRIV_IO`, it is denied to jails. Writing to kernel memory is the ultimate privileged operation; no reasonable container policy allows it.

`PRIV_NET_*` is a family of network-related privileges. `PRIV_NET_IFCREATE` is for creating network interfaces; `PRIV_NET_SETLLADDR` is for changing MAC addresses; `PRIV_NET_BPF` is for opening a BPF device. Each has

its own jail policy, and the combinations are how a VNET jail can (for example) run `dhclient(8)` (which needs `PRIV_NET_BPF`) without also being able to arbitrarily reconfigure interfaces.

`PRIV_VFS_MOUNT` gates filesystem mounting. Jails have a very restricted version of this by default: they can mount `nullfs` and `tmpfs` if `allow.mount` is set, but not arbitrary filesystems.

A complete list is in `/usr/src/sys/sys/priv.h`. For driver authorship, you will rarely invent new privilege categories; you will pick the existing one that fits.

30.10.3 `rctl(8)`: Per-Jail and Per-Process Resource Limits

Jails (and, indeed, processes) can be subject to resource limits beyond the traditional UNIX `ulimit(1)` model. FreeBSD's `rctl(8)` (the runtime resource control framework) lets an administrator set limits on a wide variety of resources, and enforce them with specified actions when the limits are hit.

The limits cover things like memory use, CPU time, number of processes, number of open files, I/O bandwidth, and so on. They can be applied per user, per process, per login class, or per jail. The typical use in a jail setup is to cap a jail's total memory and CPU so that a misbehaving application inside the jail cannot affect other jails on the same host.

For a driver author, `rctl(8)` matters for a subtle reason. Drivers allocate resources on behalf of processes. When a driver calls `malloc(9)` to allocate a buffer, the memory goes somewhere. When a driver creates a file descriptor by opening a file internally, the descriptor goes somewhere. When a driver spawns a kernel thread, the thread runs as part of somebody's accounting. If the "somebody" is a process inside a jail, the accounting might hit the jail's `rctl` limits.

Usually this is exactly what you want. If a jail is supposed to be limited to 100 MB of memory, and an allocation on behalf of a jail process should count against that limit, and `rctl` hits the limit, the allocation should fail with `ENOMEM`. Your driver then propagates the failure back to user space, and the well-behaved application inside the jail handles it.

Occasionally the accounting is less obvious. A driver that maintains a pool of buffers shared across all callers will, by default, charge the pool to the kernel rather than to any single process. That is fine, but it means the pool is unmetered: a very active jail can consume a larger share of the pool than it "should" under the resource limits. For most drivers this is acceptable, but for drivers whose resources are expensive (large DMA buffers, for instance) it may be worth considering whether the resource should be tracked per-process through `racct(9)`, the underlying accounting layer that `rctl` sits on top of.

The `racct(9)` framework exposes `racct_add(9)` and `racct_sub(9)` functions for drivers that want to participate in accounting. Most drivers never call these directly. Adding `racct` support is a deliberate design choice, usually made when a driver's resource consumption is large enough to matter in aggregate. For everyday character-device drivers or network drivers, the default accounting done by the kernel (per-socket buffer memory, per-process file descriptor counts, and so on) is sufficient.

30.10.4 Enforcement Actions and What They Mean for Drivers

When a resource limit is hit, `rctl(8)` can do one of several things: deny the operation, send a signal to the offending process, log the event, or throttle (for rate-based resources). The enforcement is handled by the

kernel's accounting layer, not by drivers. What drivers see is the result: an allocation fails, a signal delivers, a rate-limited operation takes longer.

For a driver, the practical implication is that every allocation and every resource acquisition must be written to handle failure. This is not specific to jails or `rctl`; it is good defensive coding anyway. A `malloc(9)` with `M_WAITOK` can wait for memory indefinitely, but in a jail with a memory limit, it may still fail (if `M_WAITOK` is not set) or it may block a long time waiting for memory that will never be freed (because no other process in the jail has any to free).

The rule of thumb: if your driver is doing allocations on behalf of a user process, consider whether `M_NOWAIT` is more appropriate than `M_WAITOK`, and whether the caller can tolerate a delayed or failed allocation. Jails (and the resource limits around them) make the consideration more than theoretical.

30.10.5 Host-Side Drivers versus Jail-Side Processes

A recurring question for driver authors is: can my driver be loaded or attached from inside a jail? The short answer is almost always no. Loading kernel modules (`kldload(2)`) requires `PRIV_KLD_LOAD`, which is never granted to jails. A jail that needs access to a driver's services must have that driver already loaded and attached on the host, and then the jail can use the driver through the usual user-space interfaces.

This is a consequence of the single-kernel model. A jail does not have its own kernel, so it cannot load drivers of its own. What it has is access (subject to the devfs ruleset) to the drivers that the host has loaded. In practice this means:

- Driver loading and unloading happen on the host. The host administrator is responsible for `kldload` and `kldunload`.
- Device attachment to devices happens on the host. The driver's `DEVICE_ATTACH` runs in host context, not in jail context.
- Device access from user space happens inside the jail, through `/dev` (if the ruleset allows) and through the driver's `open/read/write/ioctl` methods.

The separation is usually clean. The driver does not need to know whether its caller is in a jail; the kernel handles the context. Where it sometimes matters is in `ioctl` handlers that want to distinguish host and jail callers, or in drivers that allocate resources per-open whose release policy differs.

A specific caveat: when a driver creates state on `open`, that state survives until `close`. If the jail that held the open file descriptor goes away before the descriptor is closed (because the jail was destroyed while processes still had the device open), the kernel will close the descriptor on the jail's behalf. The driver's `close` method will run in a safe context. But the driver should not assume that the jail still exists during `close`; it may not, and if the driver tries to reach into the jail's state, it will encounter a freed `struct prison`. The clean rule is that `close` should only touch driver state, not jail state.

30.10.6 How Drivers Cooperate with Jails in Practice

Putting the pieces together, a typical FreeBSD setup with a driver and a jail looks like this.

1. The administrator loads the driver on the host, either at boot through `/boot/loader.conf` or at runtime through `kldload(8)`.

2. The driver's probe and attach functions run on the host, create whatever devfs nodes are appropriate, and register their `cdev_methods`.
3. The administrator creates a jail, possibly with a specific devfs ruleset and possibly with VNET.
4. The jail's processes open the driver's devices (if they are visible through the ruleset) and make `ioctl` or `read/write` calls.
5. The driver's methods execute on behalf of the jail process, with the jail's credential attached to the thread, and the driver's `priv_check` calls correctly return `EPERM` for privileges the jail does not hold.
6. When the jail is destroyed, open file descriptors are closed, the driver's `close` methods run cleanly, and the driver's state returns to its normal host-only view.

Nothing in this flow requires the driver to know about jails explicitly. The driver is a passive participant that calls the right framework functions, and the framework handles the rest. This is the cleanest possible design, and it is what you should aim for.

30.10.7 The Container Frameworks: `ocijail` and `pot`

FreeBSD's jail infrastructure is a kernel mechanism; the user-space tooling around it has multiple forms. The base system provides `jail(8)`, `jail.conf(5)`, `jls(8)`, and related tools. These are enough to manage jails by hand or with shell scripts.

Higher-level container frameworks have emerged on top. `ocijail` aims to provide an OCI (Open Container Initiative) runtime that uses jails as the isolation mechanism, letting FreeBSD participate in container ecosystems that use OCI-compliant images. `pot` (available from ports) is a more FreeBSD-native container manager that bundles a jail with a filesystem layer, a network configuration, and a lifecycle. Both are external to the base system and are installed through the ports collection or packages.

For a driver author, these frameworks do not change the fundamentals. They still use jails underneath; they still rely on devfs rulesets and VNET for isolation; they still respect the same privilege framework. What they change is how administrators describe and deploy the containers, not how the drivers interact with them. A driver that works with a hand-crafted `jail.conf(5)` will work with `ocijail` and `pot` as well.

The most a driver author usually needs to know is that these frameworks exist and are becoming common. If your driver's documentation mentions jails, mention that the recommendations apply equally to container frameworks built on top. That single sentence saves administrators a lot of guesswork.

30.10.8 Wrapping Up

Jails are a policy boundary around a shared kernel. The policy extends into three dimensions: which devices are visible (devfs rulesets), which privileges are granted (`prison_priv_check` and `allow.*` parameters), and which resources can be consumed (`rctl(8)`). Driver authors encounter each of these in small, local ways: `priv_check` for privileged operations, sensible naming of devfs nodes, graceful handling of allocation failures. There is no large new API to learn; there are small new habits to pick up.

With the security and resource picture covered, the final conceptual topic is how to actually test and develop drivers in virtualised and containerised environments. Section 8 pulls the chapter's ideas together into a development workflow.

30.11 Section 8: Testing and Refactoring Drivers for Virtualised and Containerised Environments

A driver that runs on bare metal is a driver that works on one configuration. A driver that runs across virtualisation and containerisation has been exercised under varied conditions: different bus presentations, different interrupt delivery mechanisms, different memory-mapping behaviours, different privilege contexts. The driver that makes it through all of those without changes is the driver that will survive the next new environment too. This section describes the development and testing workflow that gets you there.

The workflow has three layers. The development layer uses a VM as a disposable kernel host, so that panics and hangs cost you nothing. The integration layer uses VirtIO devices, passthrough, and jails to exercise the driver in realistic environments. The regression layer uses automation to run the whole suite repeatedly as the driver evolves.

30.11.1 Using a VM as Your Development Host

When you are writing a kernel module, the cost of a panic is your session. On a bare-metal development machine, a panic interrupts your work, possibly forces a filesystem check, and may require a reboot with manual recovery steps. On a VM, a panic is a detail: the VM stops, you restart it, and the host is untouched.

For this reason, experienced driver authors do almost all of their new-driver development inside a bhyve(8) or QEMU-based VM, not on bare metal. The workflow looks like this:

1. A FreeBSD 14.3 VM is installed in bhyve(8) with a standard disk image.
2. The source tree is either on the VM's own disk or mounted via NFS from a host-side build machine.
3. The driver is built inside the VM (`make clean && make`) or on the host and copied in.
4. `kldload(8)` loads the module. If the module panics the kernel, the VM crashes, and the VM is restarted.
5. Once the module loads cleanly, it is exercised against whatever test fixture you have: a VirtIO device, a loopback mode, or a passthrough target.

The key point is that iteration is fast. A broken module that would make a bare-metal machine unbootable is a minor inconvenience in a VM. You can try things that you would never try on a machine you rely on.

For VirtIO driver development specifically, the VM is not just convenient; it is the only sensible platform. VirtIO devices only exist inside VMs (or under qemu emulation), so the VM is where the devices are. Starting a VM with a virtio-rnd device, or a virtio-net device, or a virtio-console device, gives you a target to develop against. The hypervisor provides everything a real device would provide, including interrupts, DMA, and register access, so the driver you write inside the VM is the same driver that will run anywhere else.

30.11.2 Using VirtIO as a Test Substrate

VirtIO has a second role beyond being the target for VirtIO drivers: it is a test substrate. Because VirtIO devices are easy to define, easy to emulate, and well-documented, they are useful for building controlled test scenarios even for drivers that are not VirtIO drivers.

For example, suppose you are writing a driver for a physical PCI device, and you want to test how your driver handles a specific error condition. On the real hardware, reproducing the error may require a specific physical

fault, which is hard to arrange. On a VirtIO-based proxy, you can implement a device that always returns the error, and test your driver's error path without touching the physical hardware. The caveat is that your driver must be loosely coupled to the specific hardware (the techniques from Chapter 29 matter here); the more the driver is split along the accessor/backend lines described there, the easier it is to test the upper layers against a synthetic backend.

The mechanism for synthesizing VirtIO devices in user space is bhyve's own pluggable emulated devices. Writing a new bhyve device emulator is beyond the scope of this chapter, but the relevant code lives in `/usr/src/usr.sbin/bhyve/` and is approachable if you have basic C skills. For simpler cases, using a pre-existing virtio-blk, virtio-net, or virtio-console device configured with specific parameters is often enough.

30.11.3 Using Jails for Integration Testing

When your driver is working and you want to verify it under container-style isolation, jails are the obvious next step. The setup is simple: create a jail with an appropriate devfs ruleset that exposes your device, and run your user-space test harness inside the jail.

A typical test shape:

```
myjail {
    path = /jails/myjail;
    host.hostname = myjail;
    devfs_ruleset = 100;    # custom ruleset that unhides /dev/mydev
    ip4 = inherit;
    allow.mount = 0;
    exec.start = "/bin/sh /etc/rc";
    exec.stop = "/bin/sh /etc/rc.shutdown";
    persist;
}
```

Inside the jail, you run your test harness. It opens `/dev/mydev`, exercises the `ioctl`s or the `read/write` methods, and records results. On the host, you run the same harness and compare. If the jail-side test passes and the host-side test passes, your driver tolerates the jail environment.

If one passes and the other does not, you have a diagnostic opportunity. Possible reasons for a divergence include: a privilege check that denies the jail call (look for `priv_check` in your driver), a device node permission the ruleset does not account for, a resource limit the host happens to avoid, or a jail-specific code path in your driver that exists by mistake. Each of these is fixable once identified.

30.11.4 Using VNET Jails for Network Driver Testing

For network drivers, the test is similar but uses VNET. Create a jail with `vnet = 1` in `jail.conf(5)`, move one end of an `epair(4)` into the jail, and run traffic between the jail and the host. If your driver is a physical network driver, you can also move the physical interface into the jail for a full-isolation test.

The VNET test exercises the `if_vmove()` lifecycle: the interface is detached from the host's VNET, reattached to the jail's VNET, and eventually returned. A driver that survives this without losing state is a driver that tolerates VNET. A driver that panics, hangs, or stops delivering packets after a move has work to do.

The common failure modes in VNET testing are:

- The driver holds a pointer to the host's ifnet or VNET across the move, and uses it from a callout after the move has happened.
- The driver's `if_init` assumes it is called in the original VNET and fails when called in the new one.
- The driver cleans up incorrectly at `if_detach`, because it does not distinguish “detach to move” from “detach to destroy”.

Each of these is diagnosable with `dtrace(1)` or kernel `printfs` at the right place. The first time you see a VNET-related crash, find the point in the driver where the move happens and work backward from there.

30.11.5 Passthrough Testing

PCI passthrough is the exercise that validates your driver's detach path. Create a `bhyve(8)` guest with your device passed through, install FreeBSD inside, and load your driver there. If the driver attaches cleanly in the guest, your device setup and DMA code handle IOMMU remapping correctly. If the driver loads, the test is simple: run the driver's normal workload inside the guest.

The detach test is the harder one. Shut down the guest, rebind the device to its native driver on the host (by unloading `ppt(4)` from that device, if necessary, and letting the host's driver re-attach), and exercise the driver on the host. If the driver attaches cleanly after the guest has used the device and put it through whatever state changes, the driver's `DEVICE_ATTACH` is properly defensive. If it fails, look for assumptions about the device's initial state that should not be assumptions.

The full round-trip (host, guest, host) is the gold standard for passthrough compatibility. A driver that passes it can be handed to any administrator with confidence.

30.11.6 Hypervisor Detection in Tests

If your driver uses `vm_guest` to adjust defaults, test the adjustment. Run the driver on bare metal (if available), inside `bhyve(8)`, inside QEMU/KVM, and observe whether the defaults it picks make sense. The `kern.vm_guest sysctl` is your quick check:

```
sysctl kern.vm_guest
```

If your driver logs its environment at attach time (“attaching on bhyve host, defaulting to X”), the log makes the detection visible, which helps with debugging. Do not over-log: once at attach is usually enough.

30.11.7 Automating the Test Suite

Once the individual tests are known, the next step is to run them repeatedly as the driver evolves. FreeBSD's `kyua(1)` test runner, combined with the `atf(7)` test framework, is the standard mechanism. A test suite that

includes a “bare-metal test”, a “VirtIO guest test”, a “VNET jail test”, and a “passthrough test” covers most of what you want to verify.

The details of writing tests in `atf(7)` are outside this chapter; they are treated more fully in Chapter 32 (Debugging Drivers) and Chapter 33 (Testing and Validation). The point for now is that the test suite should exercise the driver across the environments it is expected to run in. A single test on bare metal proves very little about virtualisation; a suite of tests across environments proves something about portability.

30.11.8 Refactoring Tips Revisited

In Chapter 29 we introduced a discipline for portability: accessor layers, backend abstractions, endian helpers, no hidden hardware assumptions. Virtualisation and containerisation put that discipline to the test. A driver written with clean abstractions will survive the variety of environments described in this chapter; a driver with hidden assumptions will hit them as soon as the environment changes.

The refactoring tips most relevant to this chapter are:

- Put all register access through accessors, so the access path can be simulated or redirected in tests.
- Handle the full lifecycle: attach, detach, suspend, resume. Passthrough exercises attach and detach repeatedly; VNET exercises detach in a way the driver might not see on bare metal.
- Use `bus_dma(9)` and `bus_space(9)` correctly, never physical addresses directly. The guest-versus-host address translation under passthrough depends on correct use of these APIs.
- Use `priv_check` for privilege gating, not hardcoded uid 0 checks. Jail restrictions work correctly only if the framework is called.
- Use `CURVNET_SET` around any callout or taskqueue code that touches network-stack state. This is the one VNET-specific discipline that catches most driver authors off guard.

None of these are new concepts. They are all standard FreeBSD driver practice. What this chapter adds is the context in which each one matters: which environments exercise which disciplines. Knowing that lets you prioritise when deciding what to refactor first.

30.11.9 A Development Order That Works

Putting the pieces together, here is a development order that has proven effective.

1. Start in a `bhyve(8)` VM. Write the driver’s basic skeleton (module hooks, probe and attach, simple I/O path). Exercise it with `kldload` and a minimal test.
2. Add the accessor layer and the backend abstraction from Chapter 29. Test that the simulation backend runs, even if the real hardware is not yet plugged in.
3. If VirtIO is the target, develop against `virtio_pci.c` in the VM. You have a real device to talk to, and you can iterate quickly.
4. If real hardware is the target, begin PCI passthrough testing when the driver reaches a stable point. The round-trip (host, guest, host) becomes part of the regular test cycle.
5. Add jail-based tests when the driver exposes user-space interfaces. Start with a single-stack jail; move to VNET if the driver is a network driver.
6. Add automation with `kyua(1)` and `atf(7)` as the test count grows.

7. When a bug is found, reproduce it in the smallest environment that shows the bug, fix it, and add a regression test at that level.

This order keeps the iteration fast at the beginning (where it matters most) and adds environmental complexity only as the driver stabilises. Trying to test everything at once is a common beginner mistake; it is how projects stall. The incremental path is slower per step but much faster in aggregate.

30.11.10 An End-to-End Example: From Bare Metal to Passthrough

To illustrate the workflow, here is a complete example walkthrough for a hypothetical driver called `mydev`. The driver is a PCI-based character device; it has a small register interface, uses MSI-X interrupts, and performs DMA. The development order below is condensed into a single narrative so you can see how the steps connect.

Day 1: skeleton in a VM. You install a FreeBSD 14.3 guest in `bhyve(8)`, set up NFS so the source tree on your host is visible in the guest, and write the module skeleton. It is a `KMOD=mydev`, `SRCS=mydev.c` Makefile and a `mydev.c` with `DECLARE_MODULE`, a stub probe, a stub attach, and a stub detach. It loads and unloads cleanly. `dmesg` shows “`mydev: hello`” on load.

Day 2: accessor layer. You add the Chapter 29 accessor pattern: all register access goes through `mydev_reg_read32` and `mydev_reg_write32`, with the real backend calling `bus_read_4` and `bus_write_4`. You also add a simulation backend that stores register values in a small in-memory array. The simulation backend is selected by a module parameter. The accessor layer means the same driver can run against a real device or against the simulated backend without changes to the upper code.

Day 3: upper-layer code. You add the driver’s core logic: initialisation, the character-device interface (`open`, `close`, `read`, `write`), the `ioctl` surface, and the DMA setup. The simulation backend does not model DMA, but the upper layer is structured to treat DMA through `bus_dma(9)` handles, so the code is written correctly from the start. You exercise the code through the simulation backend in a simple test program: open the device, issue `ioctl`s, verify the responses.

Day 4: real hardware, passthrough setup. You have the target hardware in a workstation. You add `pptdevs` to `/boot/loader.conf`, reboot, and confirm that `ppt(4)` has claimed the device. You add `passthru` to the `bhyve(8)` guest configuration and boot the guest. Inside the guest, you load your driver. The driver attaches to the passed-through device. You have now demonstrated that the real hardware path works.

Day 5: interrupts and DMA testing. The driver receives interrupts; the MSI-X setup code works. You test DMA: a short DMA read works, a long DMA read works, a simultaneous read and write works. You find one bug: the driver programs a physical address computed incorrectly, but only for DMA regions crossing a page boundary. You fix it. Total time spent debugging: two hours, all in a VM that would have required a hard reboot of the workstation on bare metal.

Day 6: jail test. You exit the guest, return to the host, and configure a jail that sees `/dev/mydev0`. Your test program runs inside the jail and exercises the driver exactly as it did on the host. One `ioctl` fails with `EPERM`; you look at the driver and find that you forgot to add a `priv_check` for an operation that should require privilege. You add the check, and now the jail behaves correctly (the `ioctl` is denied for non-privileged callers; the host’s root can still run it).

Day 7: VNET test (if the driver has a network interface). You create a VNET jail and move a cloned interface into it. The interface works. You notice that one of your callouts does not set `CURVNET_SET` before accessing

a per-VNET counter; you fix it. The callout now works in both the host VNET and the jail VNET without interference.

Day 8: full round-trip. You destroy the jail, shut down the guest, unload `ppt(4)` from the device (or reboot without `pptdevs`), and wait for the host's driver to re-attach. The attach works cleanly. You exercise the device on the host. It works. The round trip host-guest-host is complete.

This eight-day cycle is a stylised version of real development; your mileage will vary. The important point is that each day's work builds on the previous one, and the test environments become more exacting as the driver stabilises. By day eight, you have exercised the driver under every environment it will see in production, and you have fixed the bugs that each environment exposes. What remains is soak testing and user-facing polish, which are topics for Chapters 33 and 34.

30.11.11 Measuring Virtualisation Overhead

A quick note on performance. Drivers running under virtualisation sometimes show measurable overhead compared to bare metal. The sources of overhead include VM exits on I/O, interrupt delivery through the hypervisor, and DMA address translation through the IOMMU.

For most drivers most of the time, the overhead is not significant. Modern hardware accelerates almost every part of the virtualisation path (posted interrupts, EPT page tables, SR-IOV), and the fraction of CPU time spent in hypervisor code is typically in the low single digits. For performance-sensitive drivers, though, measuring and understanding the overhead is essential.

The tools for measurement are the same ones you use in other performance work. `pmcstat(8)` samples hardware counters, including counters for VM exits and for translation-lookaside-buffer misses that the IOMMU may cause. `dtrace(1)` can trace specific kernel paths, and with the `fbt` provider you can measure how often each path is entered and how long it takes. `vmstat -i` shows interrupt rates.

For VirtIO drivers, the most common source of overhead is excessive notifications. Every `virtqueue_notify` potentially causes a VM exit, and a driver that notifies on every packet rather than coalescing can generate hundreds of thousands of exits per second. The `VIRTIO_F_RING_EVENT_IDX` feature, if negotiated, lets the guest and host cooperate to reduce notification frequency. Check that your driver negotiates this feature if it runs in a high-packet-rate path.

For passthrough drivers, the most common source of overhead is IOMMU translation misses. Each DMA buffer must be walked through the IOMMU's page tables, and a driver that maps and unmaps buffers many times per second spends a lot of CPU on that. The fix is usually to keep DMA mappings alive for longer (using `bus_dma(9)`'s mapping-retention features) rather than map-and-unmap every transaction.

Performance tuning is a whole chapter of its own (Chapter 34). For now, the takeaway is that virtualisation has measurable costs, those costs are usually small, and the standard FreeBSD tooling applies without modification.

30.11.12 Wrapping Up

A driver that runs correctly under virtualisation and containerisation is not the result of special virtualisation code. It is the result of standard FreeBSD driver discipline, exercised in environments that expose hidden assumptions. The test and development workflow in this section is the practical side of that discipline: a VM for fast iteration,

VirtIO for a controlled test substrate, jails for privilege and visibility checks, VNET for network-stack testing, passthrough for hardware round-trips, and automation to keep the whole thing honest.

With the conceptual and practical material in place, the rest of the chapter turns to hands-on labs that let you try these techniques yourself. Before we get there, two more sections complete the picture. Section 9 covers the quieter but equally important topics of time, memory, and interrupt handling under virtualisation, the areas where beginner drivers often fail in subtle ways that only manifest in a VM. Section 10 widens the lens to architectures beyond amd64, because FreeBSD on arm64 and riscv64 is increasingly common and the virtualisation story there has its own shape. After those two sections, we move into the labs.

30.12 Section 9: Timekeeping, Memory, and Interrupt Handling Under Virtualisation

So far the chapter has concentrated on devices, the visible artefacts that a driver binds to and talks to. But a driver also depends on three ambient services that the kernel provides transparently: time, memory, and interrupts. Under virtualisation, all three change in subtle ways that rarely break a driver outright but often make it behave strangely. A driver that ignores these differences will usually pass functional tests and then fail in production when a user notices that timeouts are wrong, throughput is lower than expected, or interrupts are being lost. This section gathers what every driver author should know.

30.12.1 Why Time Is Different Inside a VM

On bare metal, the kernel has direct access to several hardware time sources. The TSC (time-stamp counter) reads a per-CPU cycle counter; the HPET (high-precision event timer) provides a system-wide counter; the ACPI PM timer provides a lower-frequency fallback. The kernel chooses one as the current timecounter(9) source, wraps it in a small API, and uses it to derive `getbintime`, `getnanotime`, and friends.

Inside a VM, those same sources exist, but they are emulated or passed through, and each has its own quirks. The TSC, which is normally the best source, can become unreliable when the VM migrates between physical hosts, when the host's TSCs are unsynchronised, or when the hypervisor rate-limits the guest in ways that cause TSC skew. The HPET is emulated and costs a VM exit on every read, which is cheap for occasional use but expensive if a driver reads it in a tight loop. The ACPI PM timer is generally reliable but slow.

To address this, major hypervisors expose *paravirtual* clock interfaces. Linux popularised the term `kvm-clock` for the KVM paravirtual clock; Xen has `xen-clock`; VMware has `vmware-clock`; Microsoft's Hyper-V has `hyperv_tsc`. Each of these is a small protocol by which the hypervisor publishes time information in a shared memory page that the guest can read without a VM exit. FreeBSD supports several of them. You can see which the kernel has chosen as follows.

```
% sysctl kern.timecounter.choice
kern.timecounter.choice: ACPI-fast(900) i8254(0) TSC-low(1000) dummy(-1000000)

% sysctl kern.timecounter.hardware
kern.timecounter.hardware: TSC-low
```

On a guest under bhyve, the kernel may select TSC-low or one of the paravirtual options depending on the CPU flags the hypervisor advertises. The important point is that the choice is automatic and the `timecounter(9)` API is the same regardless.

30.12.2 What This Means for Drivers

For a driver that only uses the high-level time APIs (`getbintime`, `ticks`, `callout`), nothing needs to change. The `timecounter(9)` abstraction shields you from the underlying details. The driver asks “what time is it” or “how many ticks have elapsed” and the kernel answers correctly, whether on bare metal or in a VM.

Problems arise when a driver bypasses the abstraction and reads time sources directly. A driver that does `rdtsc()` inline and uses the result for timing will be wrong under virtualisation whenever the host’s TSC changes (for example, during a live migration). A driver that spins on a device register with a timeout measured in CPU cycles will consume excessive CPU inside a VM where one “CPU cycle” is not a predictable unit.

The cure is simple: use the kernel’s time primitives. `DELAY(9)` for short, bounded waits. `pause(9)` for yields that can sleep. `callout(9)` for deferred work. `getbintime(9)` or `getsbinuptime(9)` for clock readings. Each of these is correct under virtualisation because the kernel has already adapted to the environment.

A concrete pattern that breaks in VMs and is surprisingly common is the “reset and wait” sequence.

```
/* Broken pattern: busy-wait without yielding. */
bus_write_4(sc->res, RESET_REG, RESET_ASSERT);
for (i = 0; i < 1000000; i++) {
    if ((bus_read_4(sc->res, STATUS_REG) & RESET_DONE) != 0)
        break;
}
```

On bare metal, this loop might complete in a few microseconds because the device clears the status bit quickly. In a VM, the bus read and write each cost a VM exit, and the loop body runs much slower because every iteration makes a round trip through the hypervisor. The 1,000,000 iteration bound, which is instant on bare metal, can become a multi-second hang inside a VM. Worse, during a VM pause (a live migration), the guest does not execute at all, and the timeout loses its meaning.

The corrected pattern uses `DELAY(9)` and a bounded real-time wait.

```
/* Correct pattern: bounded wait with DELAY and a wallclock timeout. */
bus_write_4(sc->res, RESET_REG, RESET_ASSERT);
for (i = 0; i < RESET_TIMEOUT_MS; i++) {
    if ((bus_read_4(sc->res, STATUS_REG) & RESET_DONE) != 0)
        break;
    DELAY(1000);    /* one millisecond */
}
if (i == RESET_TIMEOUT_MS)
    return (ETIMEDOUT);
```

DELAY(9) is calibrated against the kernel's time source, so it sleeps for the intended number of microseconds regardless of how fast or slow the CPU is executing at that moment. The loop's bound is now expressed in milliseconds, which is meaningful in both bare-metal and virtualised environments.

30.12.3 Callouts and Timers Across Migration

A more subtle concern is what happens to a driver's callouts when the VM pauses. If a callout was scheduled to fire in 100 ms and the VM is paused for 5 seconds (during a live migration, for example), does the callout fire 5.1 seconds after it was scheduled, or 100 ms after the VM resumes?

The answer is that it depends on the clock source the callout(9) subsystem uses. callout uses sbt (signed binary time), which under normal circumstances is derived from the selected timecounter. For hypervisors that pause the guest's virtual TSC during migration, the callout behaves as if no time had passed during the pause; the 100 ms wait is 100 ms of guest-observed time, which may be 5.1 seconds of wallclock time. For hypervisors that do not pause the virtual TSC, the callout fires at the scheduled wallclock time, which may be "immediately" after the VM resumes.

For most drivers, either behaviour is acceptable. The callout eventually fires and the code it triggers runs. But a driver that measures real-world time (for example, a driver that talks to a hardware device whose state depends on wallclock time) may need to re-sync after a resume. FreeBSD's suspend-and-resume infrastructure provides DEVMETHOD(device_resume, ...), and a driver can detect a resume and take corrective action.

```
static int
mydrv_resume(device_t dev)
{
    struct mydrv_softc *sc = device_get_softc(dev);

    /*
     * After a resume (from ACPI suspend or VM pause), the device
     * may have lost state and the driver's view of time may no
     * longer align with the device's. Reinitialise what needs
     * reinitialising.
     */
    mydrv_reset(sc);
    mydrv_reprogram_timers(sc);

    return (0);
}
```

bhyve(8) supports guest suspend through its own suspend interface (on hypervisors that implement it); the kernel delivers a normal device_resume method call on wake-up. A driver that writes device_resume correctly works in both cases.

30.12.4 Memory Pressure, Ballooning, and Pinned Buffers

Drivers that own DMA buffers or pinned memory have a relationship with the memory subsystem that changes under virtualisation. On bare metal, the physical memory the kernel sees is the memory actually installed in the machine. Inside a VM, the guest's "physical" memory is virtual from the host's point of view: it is backed by host RAM plus possibly swap, and its extent can change during the guest's lifetime.

The `virtio-balloon` device is the mechanism hypervisors use to reclaim memory from a guest that is not using it. When the host needs memory, it asks the guest to "inflate" its balloon, which allocates pages from the guest kernel's free pool and declares them unusable. Those pages can then be unmapped from the guest and reused by the host. Conversely, when the host has memory to spare, it can "deflate" the balloon and return pages to the guest.

FreeBSD has a `virtio_balloon` driver (in `/usr/src/sys/dev/virtio/balloon/virtio_balloon.c`) that participates in this protocol. For most drivers, this is invisible: the balloon takes from the general free pool, so only drivers that pin significant amounts of memory can be affected. If your driver allocates a 256 MB DMA buffer and pins it (for a frame buffer, for example), the balloon cannot reclaim that memory. This is the correct behaviour for a pinned buffer, but it does mean that a VM running your driver cannot shrink its memory footprint as much as a VM with only non-pinning drivers.

A pragmatic guideline: avoid allocating more pinned memory than you absolutely need. For buffers that can be allocated on demand, allocate them on demand. For buffers that must be resident, size them to a reasonable working-set bound rather than a pessimistic maximum. The balloon driver will return the rest to the host when it needs to.

30.12.5 Memory Hotplug

Some hypervisors (including bhyve with appropriate support) can hot-add memory to a running guest. FreeBSD handles this through ACPI events and the generic hotplug machinery. Drivers that cache memory information at attach time must be prepared for that cache to become stale when hotplug occurs; the robust pattern is to re-read the information when needed rather than caching it indefinitely.

Hot-removal of memory is rarer and more delicate. For driver authors, it is usually enough to note that if a driver owns pinned memory, the hypervisor cannot remove it; if the driver owns unpinned memory, the kernel's memory management handles relocation. Drivers that violate this (by expecting that physical addresses they have read from the kernel remain valid forever) will break under memory hot-removal. The fix is to go through `bus_dma(9)` for every physical address that gets programmed into hardware, not to cache physical addresses outside of a DMA map.

30.12.6 DMA and the IOMMU Path

We covered IOMMU in Section 5 from the host's perspective. Here, from the driver's perspective, there are two practical consequences.

First, every address programmed into hardware must come from a `bus_dma(9)` load operation. Under bare metal without an IOMMU, a driver that programs a physical address obtained from `vmem_alloc` or a similar interface usually works, because physical-equals-bus in that environment. Under passthrough with an IOMMU, the bus address the device needs is not the physical address; it is the IOMMU-mapped address, which `bus_dma_load`

computes. A driver that programs physical addresses directly will transfer data to or from the wrong memory, sometimes corrupting unrelated data.

Second, `bus_dma` mappings have lifetimes. A typical pattern is to allocate a DMA tag at attach, allocate a DMA map per buffer, load the buffer, program the device, wait for completion, and then unload the buffer. The load and unload each cost a small amount of CPU, and under the IOMMU they also cost an IOMMU invalidation. For drivers that cycle through many small buffers per second, the invalidation cost can become significant.

The fix, when it applies, is to keep DMA mappings alive for longer. `bus_dma` supports pre-allocated maps that can be reused; a driver that needs to DMA into the same physical region repeatedly can load it once and reuse the bus address until the region is no longer needed. This is a standard optimisation and is entirely orthogonal to virtualisation, but it matters more under passthrough because the IOMMU work is bigger than the host-to-bus work on bare metal.

30.12.7 Interrupt Delivery in Virtualised Environments

Interrupts have always been the sharp edge of driver design, and under virtualisation they become sharper. The two interrupt styles a driver encounters are *INTx* (pin-based) and *MSI/MSI-X* (message-signalled).

INTx is the old-style interrupt pin. In a real machine, the pin connects through the PCI bus and an interrupt controller (APIC, IOAPIC) to the CPU. In a VM, each *INTx* delivery requires the hypervisor to intercept the device's pin assertion, map it to an internal interrupt, and inject it into the guest. The intercept and injection both cost VM exits. For low-rate interrupts (the classic “something happened” signal) this is fine. For high-rate interrupts, it can be a bottleneck.

MSI (Message-Signalled Interrupts) and its successor MSI-X avoid the pin entirely. The device writes a small message to a well-known memory-mapped address, and the interrupt controller delivers the corresponding interrupt vector. Under virtualisation, MSI-X works much better than *INTx* because the hypervisor can map the message write directly to a guest interrupt without needing to intercept every edge transition on a virtual pin. Modern hardware supports *posted interrupts*, which let the hypervisor deliver MSI-X interrupts to a running vCPU without any VM exit at all.

The driver-side implication is clear: prefer MSI-X. FreeBSD's `pci_alloc_msix` API lets a driver request MSI-X interrupts. Most modern drivers already use it. If you are writing a new driver or updating an old one, use MSI-X unless you have a specific reason not to.

```
static int
mydrv_setup_msix(struct mydrv_softc *sc)
{
    int count = 1;
    int error;

    error = pci_alloc_msix(sc->dev, &count);
    if (error != 0)
        return (error);

    sc->irq_rid = 1;
    sc->irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ,
```

```
        &sc->irq_rid, RF_SHAREABLE | RF_ACTIVE));
if (sc->irq_res == NULL) {
    pci_release_msi(sc->dev);
    return (ENXIO);
}

error = bus_setup_intr(sc->dev, sc->irq_res,
    INTR_TYPE_NET | INTR_MPSAFE, NULL, mydrv_intr, sc,
    &sc->irq_handle);
if (error != 0) {
    bus_release_resource(sc->dev, SYS_RES_IRQ,
        sc->irq_rid, sc->irq_res);
    pci_release_msi(sc->dev);
    return (error);
}

return (0);
}
```

This is the standard MSI-X setup sequence. The `pci_alloc_msix` call negotiates with the kernel's PCI layer to allocate one MSI-X vector. The resource and interrupt handler are set up as usual. The cleanup path releases the MSI-X vector along with the other resources.

For drivers with multiple queues or multiple event sources, MSI-X supports up to 2048 vectors per device, and a driver can allocate one per queue to avoid lock contention. The `pci_alloc_msix` API supports requesting multiple vectors; `count` is an in-out parameter. Under virtualisation, each vector maps to a separate guest interrupt, and posted interrupts deliver them with no VM exit on modern hardware.

30.12.8 Interrupt Coalescing and Notification Suppression

Even with MSI-X, an interrupt-per-transaction model can be too expensive under virtualisation. A high-rate device that fires an interrupt for every received packet can generate hundreds of thousands of interrupts per second, and although each is cheap individually, the aggregate cost is noticeable.

Hardware interrupt coalescing addresses this on real devices: the device can be configured to deliver one interrupt for a batch of events rather than one per event. Under VirtIO, the equivalent mechanism is *notification suppression*, exposed through the `VIRTIO_F_RING_EVENT_IDX` feature.

With event indexes, the guest tells the device “do not interrupt me until you have processed up to descriptor N”, and the device honours this by checking the guest's `used_event` field before raising an interrupt. A guest that is already polling the ring does not need an interrupt at all; a guest that wants to be interrupted only after a batch can set the event index to the batch size.

FreeBSD's `virtqueue(9)` framework supports event indexes when negotiated. A driver that knows it may process multiple buffers per interrupt can enable event indexes to reduce interrupt rate. The classic pattern is:

```
static void
mydrv_intr(void *arg)
{
    struct mydrv_softc *sc = arg;
    void *cookie;
    uint32_t len;

    virtqueue_disable_intr(sc->vq);
    for (;;) {
        while ((cookie = virtqueue_dequeue(sc->vq, &len)) != NULL) {
            /* process the completed buffer */
        }
        if (virtqueue_enable_intr(sc->vq) == 0)
            break;
        /* a new buffer arrived between dequeue and enable; loop again */
    }
}
```
