Device memory and the CPU's native byte order may disagree. A device that originated in a PowerPC or network context may present 32-bit registers in big-endian order, meaning the most significant byte of the register is at the lowest byte address within the register. An x86 CPU is little-endian, so the lowest byte address holds the least significant byte. When the CPU reads the device's big-endian register and interprets it with little-endian semantics, the bytes are in the wrong order.

FreeBSD's `bus_space` family has stream variants (`bus_space_read_stream_*`) and ordinary variants (`bus_space_read_*`). On architectures where the bus tag encodes an endian swap, the ordinary variants swap bytes to produce a host-order value. The stream variants do not swap; they return the bytes in device order. A driver that is reading a device whose registers are in a different endianness than the CPU will use the ordinary variants most of the time, relying on the tag to handle the swap. A driver that is reading a data payload (a stream of bytes whose interpretation depends on the protocol, not on the register layout) may use the stream variants.

On x86 the distinction often does not matter because the bus tag does not encode an endian swap by default. The stream variants are aliases for the ordinary ones in `/usr/src/sys/x86/include/bus.h`:

```
#define bus_space_read_stream_1(t, h, o) bus_space_read_1((t), (h), (o))
#define bus_space_read_stream_2(t, h, o) bus_space_read_2((t), (h), (o))
#define bus_space_read_stream_4(t, h, o) bus_space_read_4((t), (h), (o))
```

The comment in that file explains: "Stream accesses are the same as normal accesses on x86; there are no supported bus systems with an endianness different from the host one." On other architectures, the two families can differ, and a driver that cares about endianness picks the appropriate variant based on what the device expects.

For Chapter 16, the simulation is designed to be host-endian. The chapter's drivers use the ordinary `bus_space_read_*` and `bus_space_write_*` without worrying about byte swaps. Later chapters that deal with real network controllers will revisit the endianness story.

16.3.6 Read and Write Side Effects

One of the most important properties of device memory, and one that trips up drivers that treat it as ordinary memory, is that reads and writes can have side effects.

A write to a control register is, by design, a side effect: writing 1 to the `ENABLE` bit tells the device to start operating. The driver expects that side effect, because that is what the register is for. The subtlety is that the write has a side effect on the device even though the value written is also remembered; a driver that writes `0x00000001` to `CONTROL` and then reads `CONTROL` may see `0x00000001` (if the register echoes the written value) or some other value (if the register echoes the device's current state, which may differ from the last written value).

A read from a status register may also be a side effect. Some devices implement “read-to-clear” semantics, where reading the register returns the current status and, as part of the read, clears pending error bits or interrupt flags. A driver that reads the status twice in close succession may see different values on the two reads, because the first read changed the device's internal state. This is by design; the datasheet says so.

Some registers are **write-only**. Reading them returns a fixed value (often all zeros) and reveals nothing about the device. Writing them has the intended effect. A driver that tries to read a write-only register to check its current value will be misled.

Some registers are **read-only**. Writing them is either ignored or hazardous. A driver that writes a read-only register may do nothing (if the hardware is defensive) or may cause undefined behaviour (if it is not).

Some registers are **read-modify-write** unsafe. A naive update pattern (read the current value, modify one field, write the value back) is safe on a register where the read returns the current contents and the write replaces them. It is unsafe on a register where the read has side effects, where the write has side effects on unintended fields, or where another agent (another CPU, a DMA engine, an interrupt handler) can modify the register between the read and the write.

For Chapter 16 the simulated device has a simple protocol: reads and writes each affect only the specific field the caller changes, and no read has side effects. This is not realistic; Chapter 17 introduces read-to-clear and write-only behaviours. For now, the simplicity is a feature: the reader can focus on the mechanics of access without also juggling the device's protocol quirks.

16.3.7 A Concrete Picture: A Device's Register Block

A concrete example, though invented, makes the picture stick. Imagine a simple temperature-and-fan controller exposed as a 64-byte MMIO region. The register map might look like this:

Offset	Width	Name	Direction	Description
0x00	32 bit	CONTROL	Read/Write	Global enable, reset, and mode bits.
0x04	32 bit	STATUS	Read-only	Device ready, fault, data-available.

Offset	Width	Name	Direction	Description
0x08	32 bit	TEMP_SAMPLE	Read-only	Most recent temperature reading.
0x0c	32 bit	FAN_PWM	Read/Write	Fan PWM duty cycle (0-255).
0x10	32 bit	INTR_MASK	Read/Write	Per-interrupt enable bits.
0x14	32 bit	INTR_STATUS	Read/Clear	Pending interrupt flags (read-to-clear).
0x18	32 bit	DEVICE_ID	Read-only	Fixed identifier; vendor code.
0x1c	32 bit	FIRMWARE_REV	Read-only	Device firmware revision.
0x20- 0x3f	32 bytes	reserved	-	Must be written as zero; reads undefined.

A driver for this device would read `DEVICE_ID` at attach to confirm the hardware is what the driver expects, write `CONTROL` to enable the device, poll `STATUS` to confirm the device is ready, periodically read `TEMP_SAMPLE` to report the temperature, and periodically write `FAN_PWM` to adjust the fan. The interrupt path would read `INTR_STATUS` to see which events are pending (which also clears them) and write `INTR_MASK` during setup to choose which interrupts to enable.

Chapter 16's simulated device borrows heavily from this shape. The simulation has a `CONTROL`, a `STATUS`, a `DATA_IN`, a `DATA_OUT`, an `INTR_MASK`, and an `INTR_STATUS`. It is deliberately a toy; the fields and protocol are chosen so the reader can manipulate them easily from user space through the driver's existing `read(2)` and `write(2)` paths. The register map is kept simple because Chapter 17 will introduce the complexity that real devices add on top.

16.3.8 The Shape of a Register Access

Putting the pieces together, a single register access consists of:

1. The driver has a `bus_space_tag_t` and a `bus_space_handle_t` that together describe a specific device region with specific cache attributes.
2. The driver picks an offset within the region, corresponding to a register defined in the device's datasheet.
3. The driver picks an access width that matches the register's width.
4. The driver calls `bus_space_read_*` or `bus_space_write_*` with tag, handle, offset, and (for writes) value.
5. The kernel's `bus_space` implementation for the current architecture compiles the call down to the appropriate CPU instruction (a `mov` on x86 MMIO, an `inb/outb` on x86 PIO, a `ldr/str` on arm64, and so on).
6. The memory controller or I/O fabric routes the access to the device.
7. The device responds: for a read, it returns the requested value; for a write, it performs the action the register's protocol defines.

The abstraction hides all of this from the driver, most of the time. The driver writes `bus_space_read_4(tag, handle, 0x04)` and gets a 32-bit value back. The machinery between the C call and the device is the kernel's and the hardware's job.

What the driver must remain aware of is the handful of correctness rules: alignment, width, side effects, and access ordering. The chapter revisits ordering in Section 6.

16.3.9 What MMIO Is Not

A short list of things MMIO is not, to clear up common confusions.

MMIO is not DMA. DMA is when the device reads or writes system RAM on its own. MMIO is when the CPU reads or writes the device's registers. Both may be used in the same driver, for different purposes. DMA is faster for bulk data; MMIO is necessary for commands and status. Chapter 20 and Chapter 21 cover DMA.

MMIO is not shared memory. Shared memory (in the POSIX sense) is RAM accessible to multiple processes. MMIO is device memory accessible to the kernel only. User space cannot (and should not) access MMIO directly; the driver mediates.

MMIO is not a block of RAM with the device living behind it. MMIO is a direct interface to the device's internal registers. Reading MMIO does not return kernel memory; it returns whatever the device decides to return at that offset. Writing MMIO does not store a value in kernel memory; it sends a message to the device at that offset.

MMIO is not free. Each access is a transaction on the CPU's bus. On a deep cache hierarchy with high memory latency, a single uncached MMIO read can take hundreds of cycles, because the CPU cannot use the cache and must wait for the device to respond. Drivers that issue thousands of MMIO accesses per operation are usually doing something wrong; most operations can be batched or eliminated.

16.3.10 Wrapping Up Section 2

Memory-mapped I/O is the mechanism by which a modern CPU reaches a device through ordinary load and store instructions, with the address routed to the device instead of to RAM. The kernel's virtual mapping layer and the `bus_space` abstraction together hide the plumbing, but the driver must still be aware of alignment, endianness, cache attributes, and side effects. A register is accessed with a read or write of the right width at the right offset; the kernel compiles the call into the appropriate CPU instruction for the current architecture.

Section 3 introduces `bus_space(9)` itself: the tag, the handle, the read and write functions, and the shape of the API as it appears in every FreeBSD driver that talks to hardware. After Section 3, you will be ready to simulate a register block in Section 4 and start writing code.

16.4 Section 3: Introduction to `bus_space(9)`

`bus_space(9)` is the FreeBSD abstraction for portable hardware access. Every driver that talks to memory-mapped or port-mapped hardware uses it, directly or through a thin wrapper. The abstraction is small: two opaque types, a dozen read and write functions in several widths, a barrier function, and a few helpers for multi-register and region accesses. Section 3 walks through the whole thing in the order a reader would naturally meet it.

The section starts with the two types, moves to the read and write functions, covers the multi and region helpers, introduces the barrier function, and closes with the `bus_*` shorthand defined over a `struct resource *` that

most real drivers use in practice. By the end you will recognise every `bus_space` call you meet in `/usr/src/sys/dev/`, and you will have a mental model for writing your own.

16.4.1 The Two Types: `bus_space_tag_t` and `bus_space_handle_t`

Every `bus_space` call takes a tag and a handle as its first two arguments, in that order. Understanding what each one represents is the first step.

A `bus_space_tag_t` identifies an address space. “Address space” here is narrower than its general usage; it specifically refers to the combination of a bus and an access method. On x86, there are two address spaces: memory and I/O port. Each has its own tag value. On other architectures, there may be more: a memory space with host-endian access, a memory space with swapped-endian access, and so on. The tag tells the `bus_space` functions which rules to apply.

The tag is architecture-specific. On x86, the tag is an integer: 0 for I/O port space (`X86_BUS_SPACE_IO`) and 1 for memory space (`X86_BUS_SPACE_MEM`). On arm64, the tag is a pointer to a structure that describes the bus’s endian and access behaviour. On MIPS, it is yet another shape. Drivers do not usually see these architecture details; they obtain the tag from the bus subsystem (through `rman_get_bustag(resource)` or equivalent) and pass it through without inspection.

A `bus_space_handle_t` identifies a specific region within the address space. It is effectively a pointer, but the pointer’s meaning depends on the tag. For a memory tag on x86, the handle is the kernel virtual address at which the device’s physical range has been mapped. For an I/O port tag on x86, the handle is the I/O port base address. For more elaborate tags, the handle may be a structure or an encoded value. Drivers treat the handle as opaque and pass it through.

The pairing is important. A tag alone does not identify a specific device; it identifies only the address space. A handle alone does not carry the access rules. The pair (tag, handle) together identifies a specific mappable region with specific access rules, and that pair is what the `bus_space_read_*` and `bus_space_write_*` functions operate on.

In practice a driver obtains a `struct resource *` from the bus subsystem at attach time and extracts the tag and handle from it with `rman_get_bustag` and `rman_get_bushandle`. It stores the pair in the `softc`, or it stores the resource pointer and uses the shorthand `bus_read_*` and `bus_write_*` macros that extract the tag and handle internally. Section 5 walks through the real pattern.

16.4.2 Offsets

Every read and write function takes an **offset** inside the region. The offset is a `bus_size_t`, which is typically a 64-bit unsigned integer, measured in bytes from the start of the region. A 32-bit register at the start of a device’s MMIO region has offset 0. A 32-bit register at the next slot has offset 4. A 32-bit register at offset 0x10 is 16 bytes into the region.

Offsets are expressed in bytes regardless of the access width. `bus_space_read_4(tag, handle, 0x10)` reads a 32-bit value starting at byte offset 0x10. `bus_space_read_2(tag, handle, 0x12)` reads a 16-bit value starting at byte offset 0x12. The function’s suffix names the width in bytes, not the offset granularity.

The driver is responsible for ensuring the offset falls within the mapped region. `bus_space` does not check bounds; an out-of-range access is a driver bug that reads or writes whatever happens to be beyond the device’s

mapping, which on most platforms is either unmapped memory (faulting the kernel) or another device's memory (corrupting that device's state). Keep your offsets in headers, derive them from the datasheet, and never compute them arithmetically without bounds-checking the result.

16.4.3 The Read Functions

The basic read functions come in four widths:

```
u_int8_t  bus_space_read_1(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset);
u_int16_t bus_space_read_2(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset);
u_int32_t bus_space_read_4(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset);
uint64_t  bus_space_read_8(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset);
```

The `_1`, `_2`, `_4`, `_8` suffixes are access widths in bytes. `_1` is an 8-bit read, `_2` is a 16-bit read, `_4` is a 32-bit read, `_8` is a 64-bit read. The return type is the corresponding unsigned integer.

Not all widths are supported on all platforms. On x86, `bus_space_read_8` is defined only for `__amd64__` (the 64-bit x86) and only for memory space, not I/O port space. The definition in `/usr/src/sys/x86/include/bus.h` is explicit:

```
#ifdef __amd64__
static __inline uint64_t
bus_space_read_8(bus_space_tag_t tag, bus_space_handle_t handle,
                 bus_size_t offset)
{
    if (tag == X86_BUS_SPACE_IO)
        return (BUS_SPACE_INVALID_DATA);
    return (*(volatile uint64_t *) (handle + offset));
}
#endif
```

A 64-bit I/O port access returns `BUS_SPACE_INVALID_DATA` (all bits set). A 64-bit memory access dereferences the handle plus offset as a `volatile uint64_t *`. The `volatile` qualifier is what stops the compiler from caching or reordering the access.

The 32-bit case is similar:

```
static __inline u_int32_t
bus_space_read_4(bus_space_tag_t tag, bus_space_handle_t handle,
                 bus_size_t offset)
{
```

```

    if (tag == X86_BUS_SPACE_IO)
        return (inl(handle + offset));
    return (*(volatile u_int32_t *)(handle + offset));
}

```

Memory space compiles to a `volatile` dereference. I/O port space compiles to an `inl` instruction that reads a long from an I/O port.

The 16-bit (`inw, *(volatile u_int16_t *)`) and 8-bit (`inb, *(volatile u_int8_t *)`) cases follow the same pattern. On a 64-bit x86, `bus_space_read_4` on a memory region compiles to a single `mov` instruction from the mapped address. The cost of the abstraction at runtime, on this common platform, is literally one instruction's worth of call-frame setup if the inline expands, which it does in release builds.

16.4.4 The Write Functions

The write functions mirror the read functions:

```

void bus_space_write_1(bus_space_tag_t tag, bus_space_handle_t handle,
                      bus_size_t offset, u_int8_t value);
void bus_space_write_2(bus_space_tag_t tag, bus_space_handle_t handle,
                      bus_size_t offset, u_int16_t value);
void bus_space_write_4(bus_space_tag_t tag, bus_space_handle_t handle,
                      bus_size_t offset, u_int32_t value);
void bus_space_write_8(bus_space_tag_t tag, bus_space_handle_t handle,
                      bus_size_t offset, uint64_t value);

```

On x86 memory space, a write compiles to a `volatile` store:

```

static __inline void
bus_space_write_4(bus_space_tag_t tag, bus_space_handle_t bsh,
                 bus_size_t offset, u_int32_t value)
{
    if (tag == X86_BUS_SPACE_IO)
        outl(bsh + offset, value);
    else
        *(volatile u_int32_t *)(bsh + offset) = value;
}

```

Port-mapped I/O compiles to an `outl`. The driver writes the same source line regardless of platform; the kernel's per-architecture `bus.h` does the rest.

As with reads, `bus_space_write_8` to I/O port space on x86 is not supported; the function silently returns without emitting a write. This reflects the hardware: x86 I/O ports are 32-bit at most.

16.4.5 The Multi and Region Helpers

Sometimes a driver wants to read or write many values from or to a single register, or many values across a range of registers. The `bus_space` API provides two families of helpers.

Multi accesses repeatedly access a single register, transferring a buffer of values through it. The register stays at a fixed offset; the buffer is consumed or produced. The use case is a FIFO-style register, where the device's internal queue is exposed through a single address, and reading or writing that address pops or pushes one entry.

```
void bus_space_read_multi_1(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset, u_int8_t *buf, size_t count);
void bus_space_read_multi_2(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset, u_int16_t *buf, size_t count);
void bus_space_read_multi_4(bus_space_tag_t tag, bus_space_handle_t handle,
                           bus_size_t offset, u_int32_t *buf, size_t count);
```

`bus_space_read_multi_4(tag, handle, 0x20, buf, 16)` reads a 32-bit value from offset 0x20 sixteen times, storing each value in successive entries of `buf`. The offset does not change between reads; only the buffer pointer advances.

The write variants mirror the reads:

```
void bus_space_write_multi_1(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, const u_int8_t *buf, size_t count);
void bus_space_write_multi_2(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, const u_int16_t *buf, size_t count);
void bus_space_write_multi_4(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, const u_int32_t *buf, size_t count);
```

Region accesses transfer across a range of offsets. The offset advances each step; the buffer advances each step. The use case is a memory-like region inside the device, such as a block of configuration data or a frame buffer slice.

```
void bus_space_read_region_1(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, u_int8_t *buf, size_t count);
void bus_space_read_region_4(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, u_int32_t *buf, size_t count);
void bus_space_write_region_1(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, const u_int8_t *buf, size_t count);
void bus_space_write_region_4(bus_space_tag_t tag, bus_space_handle_t handle,
                             bus_size_t offset, const u_int32_t *buf, size_t count);
```

`bus_space_read_region_4(tag, handle, 0x100, buf, 16)` reads 16 consecutive 32-bit values starting at offset 0x100 and ending at offset 0x13c, storing them in `buf[0]` through `buf[15]`.

The distinction between multi and region corresponds to two different hardware patterns. A FIFO register at a single offset is a multi; a configuration block that spans many offsets is a region. Using the wrong family leaves the driver doing the wrong thing, even if the loop count matches, so take care to pick the right one.

Chapter 16's simulated device does not use multi or region accesses; the driver addresses registers one at a time. Chapter 17's richer simulation and later PCI-based chapters introduce the multi and region patterns where they apply.

16.4.6 The Barrier Function

`bus_space_barrier` is the function that most drivers forget exists until they need it, and its correct use is one of the quiet disciplines of solid hardware programming.

```
void bus_space_barrier(bus_space_tag_t tag, bus_space_handle_t handle,
                      bus_size_t offset, bus_size_t length, int flags);
```

The function enforces ordering on `bus_space` reads and writes issued before the call, relative to those issued after. The `flags` argument is a bitmask:

- `BUS_SPACE_BARRIER_READ` makes prior reads complete before subsequent reads.
- `BUS_SPACE_BARRIER_WRITE` makes prior writes complete before subsequent writes.
- The two may be OR-ed together to enforce both directions.

The `offset` and `length` parameters describe the region the barrier applies to. On x86 these are ignored; the barrier applies to the whole CPU. On other architectures, a bus bridge may be able to enforce barriers more narrowly, and the parameters are informative.

On x86 specifically, `bus_space_barrier` compiles to a small and well-defined sequence. From `/usr/src/sys/x86/include/bus.h`:

```
static __inline void
bus_space_barrier(bus_space_tag_t tag __unused, bus_space_handle_t bsh __unused,
                  bus_size_t offset __unused, bus_size_t len __unused, int flags)
{
    if (flags & BUS_SPACE_BARRIER_READ)
#ifdef __amd64__
        __asm __volatile("lock; addl $0,0(%%rsp)" : : : "memory");
    #else
        __asm __volatile("lock; addl $0,0(%%esp)" : : : "memory");
    #endif
    else
        __compiler_membar();
}
```

A read barrier on amd64 emits a `lock addl` on the stack, which is a cheap way to issue a full memory fence on x86. A write barrier emits only a compiler barrier (`__compiler_membar()`), because x86 hardware retires

writes in program order and the only reordering a driver can experience on writes is from the compiler. The distinction between “the CPU might reorder this” and “the compiler might reorder this” matters, and the x86 `bus_space_barrier` encodes it with minimum cost.

On arm64 the barrier compiles to a `dsb` or `dmb` instruction depending on the flags, because arm64’s memory model is weaker and actual CPU reordering is possible. The driver’s source does not change; the same `bus_space_barrier` call picks the right instruction for each platform.

When is a barrier required? The rule of thumb is: when the correctness of one register access depends on another access having completed first. Examples:

- A driver writes a command to `CONTROL` and reads the result from `STATUS`. The read must not be speculated before the write. A `bus_space_barrier(tag, handle, 0, 0, BUS_SPACE_BARRIER_WRITE | BUS_SPACE_BARRIER_READ)` between them enforces the ordering.
- A driver clears an interrupt flag in `INTR_STATUS` and expects the clear to reach the device before re-enabling interrupts. A write barrier after the clear, before the re-enable, is the correct discipline.
- A driver posts a DMA descriptor to memory and then writes a “doorbell” register to tell the device to process it. A write barrier between the memory write and the doorbell write is required on weakly-ordered platforms.

On x86, many of these cases are handled by the platform’s strong ordering model, and a driver written without explicit barriers often works. The same driver ported to arm64 may fail subtly. The rule “use barriers when ordering matters” produces portable code; the rule “barriers do nothing on x86 so skip them” produces code that breaks on half of FreeBSD’s supported platforms.

Section 6 of this chapter revisits barriers with worked examples in the simulated driver.

16.4.7 The `bus_*` Shorthand over a `struct resource *`

The `bus_space_*` family takes a tag and a handle. In practice, drivers do not usually carry those around; they carry a `struct resource *`, which is what `bus_alloc_resource_any` returns. The resource structure contains the tag and the handle, among other things. Passing them separately would be noise.

To eliminate the noise, `/usr/src/sys/sys/bus.h` defines a family of shorthand macros that take a `struct resource *` and extract the tag and handle internally:

```
#define bus_read_1(r, o) \
    bus_space_read_1((r)->r_bustag, (r)->r_bushandle, (o))
#define bus_read_2(r, o) \
    bus_space_read_2((r)->r_bustag, (r)->r_bushandle, (o))
#define bus_read_4(r, o) \
    bus_space_read_4((r)->r_bustag, (r)->r_bushandle, (o))
#define bus_write_1(r, o, v) \
    bus_space_write_1((r)->r_bustag, (r)->r_bushandle, (o), (v))
#define bus_write_4(r, o, v) \
    bus_space_write_4((r)->r_bustag, (r)->r_bushandle, (o), (v))
#define bus_barrier(r, o, l, f) \
    bus_space_barrier((r)->r_bustag, (r)->r_bushandle, (o), (l), (f))
```

There are equivalents for `_multi` and `_region` variants, stream variants, and the barrier. The macros cover the same functionality as the underlying `bus_space_*` family, just with a more compact call shape.

Most drivers in `/usr/src/sys/dev/` use the shorthand. A typical usage looks like this, adapted from `if_alevar.h`:

```
#define CSR_READ_4(sc, reg)      bus_read_4((sc)->res[0], (reg))
#define CSR_WRITE_4(sc, reg, val) bus_write_4((sc)->res[0], (reg), (val))
```

The driver defines its own `CSR_READ_4` and `CSR_WRITE_4` macros in terms of `bus_read_4` and `bus_write_4`, abstracting one more layer on top. The softc holds an array of `struct resource *` pointers, and the macros reach through to the first one (the main MMIO region) without the driver having to write out the resource dereference every time.

This is a deliberate pattern. It makes register access statements short and scanable. It centralises the resource reference in one place, so if the driver later maps a second region, only the macros change. And it gives the driver's code a consistent look that anyone familiar with `/usr/src/sys/dev/` will recognise immediately.

Chapter 16's simulated driver adopts this pattern by Stage 4. The early stages use the `bus_space_*` family directly, to keep the mechanism visible; the final refactor wraps the accesses in `CSR_READ_*` and `CSR_WRITE_*` macros the way a production driver would.

16.4.8 Setup and Teardown

A driver that uses `bus_space` does not call `bus_space_map` directly in most cases. Instead, it asks the bus subsystem for a resource through `bus_alloc_resource_any`:

```
int rid = 0;
struct resource *res;

res = bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE);
if (res == NULL) {
    device_printf(dev, "cannot allocate MMIO resource\n");
    return (ENXIO);
}
```

The arguments are:

- `dev` is the `device_t` for the driver's device.
- `SYS_RES_MEMORY` selects a memory-mapped resource. `SYS_RES_IOPORT` selects a port-mapped resource. `SYS_RES_IRQ` selects an IRQ (used in Chapter 19).
- `rid` is the "resource ID", the index of the resource within the device's resources. A PCI device's first BAR is usually `rid 0` (which for a legacy PCI device corresponds to the BAR at PCI config offset `0x10`). `rid` is a pointer because the bus subsystem may update it to reflect the actual `rid` it used, though for `_any` allocations on a known `rid`, the value passed in is usually returned unchanged.
- `RF_ACTIVE` tells the bus to activate the resource immediately, which includes establishing the virtual mapping. Without `RF_ACTIVE`, the resource is reserved but not mapped.

On success, `res` is a valid `struct resource *` whose tag and handle can be extracted with `rman_get_bustag(res)` and `rman_get_bushandle(res)`, or whose tag and handle are used implicitly by the `bus_read_*` and `bus_write_*` shorthand macros.

At detach, the driver releases the resource:

```
bus_release_resource(dev, SYS_RES_MEMORY, rid, res);
```

The release undoes the allocation, including tearing down the virtual mapping and marking the range available for reuse.

This is the boilerplate every driver follows for MMIO resources. Chapter 16’s simulated device skips it entirely, because there is no bus to allocate from; the “resource” is a chunk of kernel memory the driver allocated with `malloc(9)`. Chapter 17 introduces a slightly more sophisticated simulation that mimics the allocation path. Chapter 18, when real PCI enters the picture, uses the full `bus_alloc_resource_any` flow.

16.4.9 A First Stand-Alone Example

Even without real hardware, a simple stand-alone program illustrates the shape of a `bus_space` call. Imagine a driver that wants to read the 32-bit `DEVICE_ID` register at offset `0x18` from a device whose MMIO region has been allocated as `res`:

```
uint32_t devid = bus_read_4(sc->res, 0x18);
```

One line. The `sc->res` holds the `struct resource *`. The offset `0x18` comes from the datasheet. The return value is the 32-bit contents of the register.

To write a control value:

```
bus_write_4(sc->res, 0x00, 0x00000001); /* set ENABLE bit */
```

To enforce ordering between the write and a subsequent read:

```
bus_write_4(sc->res, 0x00, 0x00000001);
bus_barrier(sc->res, 0, 0, BUS_SPACE_BARRIER_WRITE | BUS_SPACE_BARRIER_READ);
uint32_t status = bus_read_4(sc->res, 0x04);
```

The barrier ensures the write reaches the device before the read is issued. On x86 the barrier is cheap; on arm64 it emits a fence instruction. The driver does not know or care which; the abstraction handles it.

These are three-line shapes that will appear, with small variations, in every driver you write in Part 4 and beyond. The patterns look identical whether the target is a real network card, a USB controller, a storage adapter, or a simulated device.

16.4.10 A Look at a Real Driver's `bus_space` Usage

To connect the vocabulary to real code, open `/usr/src/sys/dev/ale/if_alevar.h` and scroll to the `CSR_WRITE_*` / `CSR_READ_*` macro block. You will find:

```
#define CSR_WRITE_4(_sc, reg, val)    \
    bus_write_4((_sc)->ale_res[0], (reg), (val))
#define CSR_WRITE_2(_sc, reg, val)    \
    bus_write_2((_sc)->ale_res[0], (reg), (val))
#define CSR_WRITE_1(_sc, reg, val)    \
    bus_write_1((_sc)->ale_res[0], (reg), (val))
#define CSR_READ_2(_sc, reg)          \
    bus_read_2((_sc)->ale_res[0], (reg))
#define CSR_READ_4(_sc, reg)          \
    bus_read_4((_sc)->ale_res[0], (reg))
```

The softc stores an array `ale_res[]` of resources; the macros reach into the first slot. Everywhere else in the driver, a register access reads as `CSR_READ_4(sc, ALE_SOME_REG)` and reads naturally.

Or open `/usr/src/sys/dev/e1000/if_em.c` and search for `bus_alloc_resource_any`. You will find:

```
sc->memory = bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE);
```

The resource goes into the softc's memory field; the rest of the driver uses macros over `sc->memory`. The pattern repeats in every driver you will meet in Part 4.

Chapter 16 builds up to this pattern gradually. Stage 1 uses plain struct access to emphasise the mechanics. Stage 2 introduces `bus_space_*` directly against a simulated handle. Stage 3 adds barriers and locking. Stage 4 wraps everything in `CSR_*` macros over a struct `resource *`-compatible pointer, matching the real-driver idiom.

A note on line numbers. The chapter cites FreeBSD source by function, macro, or structure name rather than by line number, because line numbers drift between releases while symbol names survive. For approximate coordinates in FreeBSD 14.3, for orientation only: the `CSR_WRITE_*` macros in `if_alevar.h` sit near line 228, `em_allocate_pci_resources` in `if_em.c` near line 2415, `ale_attach` in `if_ale.c` near line 451, and the `ale_attach` resource-alloc and register-read block spans roughly lines 463 to 580. Open the file and jump to the symbol; the line is whatever your editor reports.

16.4.11 Wrapping Up Section 3

`bus_space(9)` is a small, focused abstraction over hardware access. A tag identifies an address space; a handle identifies a specific region within it. Read and write functions come in 8, 16, 32, and 64-bit widths. Multi accesses repeat on a single offset; region accesses walk across offsets. Barriers enforce ordering where it matters. The `bus_*` shorthand over a struct `resource *` is what most drivers use day to day.

The mechanism underneath compiles to CPU instructions that match the platform: a `mov` on x86 MMIO, an `in` or `out` on x86 PIO, a `ldr` or `str` on arm64. The driver writes portable code; the compiler does the translation.

Section 4 now takes you from vocabulary to practice. We build a simulated register block in kernel memory, wrap it with accessor helpers, and start Stage 1 of the Chapter 16 driver refactor.

16.5 Section 4: Simulating Hardware for Testing

Real hardware is a tough teacher. It is expensive to buy, fragile to mishandle, inconsistent across revisions, and unkind to beginners. For Chapter 16's purposes we want something different: an environment where the reader can practise register-style access, see the results, break things safely, and observe what happens. The answer is to simulate a device in kernel memory.

This section builds that simulation from scratch. First a mental model (what does “simulate a device” mean?), then a register map for the device we are going to fake, then the allocation, the accessors, and the first integration with the `myfirst` driver. By the end of Section 4 the driver has Stage 1: a softc that carries a register block, accessors that read and write it, and a couple of sysctls that let you poke at the simulation from user space.

16.5.1 What “Simulating Hardware” Means Here

The simulation is deliberately minimal in Section 4. A chunk of kernel memory, allocated once, sized to match a register block, and accessed through functions that look like `bus_space` calls. Reads fetch values from the chunk; writes store values into the chunk. There is no dynamic behaviour yet: no timers changing a status register, no events setting a ready bit, no fault injection. Chapter 17 adds all of that. Section 4 gives you the skeleton.

This narrowness is deliberate. Chapter 16's job is to teach the access mechanism. A richer simulation, where the reader has to reason about both the mechanism and the device's behaviour, would compete for attention with the vocabulary the reader is still learning. Section 4's simulation exists so every register read and write returns a predictable result, which lets the reader focus on correctness of access rather than on whether the device liked the access or not.

A small but important point about the simulation: because the “device” is kernel memory, the reader can inspect it, poke it, and dump it through mechanisms the kernel already provides (`sysctl`, `ddb`, `gdb` on a core dump). This transparency is a pedagogical feature. A real device's registers are only visible through the register interface; the simulated registers are visible through the interface *and* through the allocator. When something goes wrong in the driver, the reader can compare “what the driver thinks the register is” with “what the register actually contains”. That debugging pathway is very educational and will be lost when we eventually point the driver at real hardware.

16.5.2 The Register Map for the Simulated Device

Before allocating anything, decide what the device looks like. Picking a register map up front is exactly what a datasheet does for real hardware, and doing it before writing code is a habit worth building.

The Chapter 16 simulated device is a minimal “widget”: it can accept a command, report a status, receive a single byte of data, and send a single byte back. The register map is:

Offset	Width	Name	Direction	Description
0x00	32 bit	CTRL	Read/Write	Control: enable, reset, mode bits.
0x04	32 bit	STATUS	Read-only	Status: ready, busy, error, data available.
0x08	32 bit	DATA_IN	Write-only	Data written to the device for processing.
0x0c	32 bit	DATA_OUT	Read-only	Data the device has produced.
0x10	32 bit	INTR_MASK	Read/Write	Interrupt enable mask.
0x14	32 bit	INTR_STATUS	Read/Clear	Pending interrupt flags (read-to-clear, Chapter 17).
0x18	32 bit	DEVICE_ID	Read-only	Fixed identifier: 0x4D594649 ('MYFI').
0x1c	32 bit	FIRMWARE_REV	Read-only	Firmware revision: encoded as major«16
0x20	32 bit	SCRATCH_A	Read/Write	Free scratch register. Always echoes writes.
0x24	32 bit	SCRATCH_B	Read/Write	Free scratch register. Always echoes writes.

The total size is 40 bytes of register space, which we round up to 64 bytes to give ourselves room to grow in Chapter 17.

For Chapter 16, all register access is simplified to direct read-and-write on kernel memory. Read-to-clear semantics on `INTR_STATUS`, write-only semantics on `DATA_IN`, and the behaviour of `CTRL` on reset are deferred to Chapter 17. For now, `DATA_IN` echoes whatever the driver wrote; `INTR_STATUS` holds whatever value the driver last set; and the whole block behaves like a plain block of 32-bit slots.

This is deliberate. Chapter 16 is teaching register access. Chapter 17 introduces the protocol layer. Splitting the two keeps each chapter focused.

16.5.3 The Register Offsets Header

A real driver separates register offsets into a header so the datasheet mapping lives in one place. The Chapter 16 driver follows the same discipline. Create a file `myfirst_hw.h` alongside `myfirst.c`:

```
/* myfirst_hw.h -- Chapter 16 simulated register definitions. */
#ifndef _MYFIRST_HW_H
#define _MYFIRST_HW_H

/* Register offsets for the simulated myfirst widget. */
#define MYFIRST_REG_CTRL      0x00
#define MYFIRST_REG_STATUS    0x04
#define MYFIRST_REG_DATA_IN    0x08
#define MYFIRST_REG_DATA_OUT  0x0c
#define MYFIRST_REG_INTR_MASK 0x10
#define MYFIRST_REG_INTR_STATUS 0x14
#define MYFIRST_REG_DEVICE_ID 0x18
```

```

#define MYFIRST_REG_FIRMWARE_REV 0x1c
#define MYFIRST_REG_SCRATCH_A    0x20
#define MYFIRST_REG_SCRATCH_B    0x24

/* Total size of the register block. */
#define MYFIRST_REG_SIZE         0x40

/* CTRL register bits. */
#define MYFIRST_CTRL_ENABLE      0x00000001u /* bit 0: device enabled */
#define MYFIRST_CTRL_RESET       0x00000002u /* bit 1: reset (write 1 to) */
#define MYFIRST_CTRL_MODE_MASK   0x000000f0u /* bits 4..7: operating mode */
#define MYFIRST_CTRL_MODE_SHIFT  4
#define MYFIRST_CTRL_LOOPBACK    0x00000100u /* bit 8: loopback DATA_IN -> OUT */

/* STATUS register bits. */
#define MYFIRST_STATUS_READY      0x00000001u /* bit 0: device ready */
#define MYFIRST_STATUS_BUSY       0x00000002u /* bit 1: device busy */
#define MYFIRST_STATUS_ERROR      0x00000004u /* bit 2: error latch */
#define MYFIRST_STATUS_DATA_AV    0x00000008u /* bit 3: DATA_OUT has data */

/* INTR_MASK and INTR_STATUS bits. */
#define MYFIRST_INTR_DATA_AV      0x00000001u /* bit 0: data available */
#define MYFIRST_INTR_ERROR        0x00000002u /* bit 1: error condition */
#define MYFIRST_INTR_COMPLETE     0x00000004u /* bit 2: operation complete */

/* Fixed identifier values. */
#define MYFIRST_DEVICE_ID_VALUE  0x4D594649u /* 'MYFI' in little-endian */
#define MYFIRST_FW_REV_MAJOR      1
#define MYFIRST_FW_REV_MINOR      0
#define MYFIRST_FW_REV_VALUE \
    ((MYFIRST_FW_REV_MAJOR << 16) | MYFIRST_FW_REV_MINOR)

#endif /* _MYFIRST_HW_H */

```

Every offset is a named constant. Every bit mask has a name. Every fixed value has a constant. Later chapters add more registers and more bits; the header grows incrementally. The discipline of “no magic numbers inside the driver’s code” starts here and pays off throughout Part 4.

A note on the `u` suffix on the numeric constants. The `u` makes each constant an unsigned `int`, which is important when the value has the high bit set (32-bit registers use the full `0x80000000` bit, which a plain `int` constant cannot represent portably). Using `u` everywhere keeps the driver consistent; getting into the habit prevents the class of bug where a signed-vs-unsigned mismatch leads to a sign-extended comparison that silently passes or fails.

16.5.4 Allocating the Register Block

With the offsets defined, the driver needs a register block. For the simulation, the block is kernel memory. Add the following to the softc (in `myfirst.c` where the softc is declared):

```
struct myfirst_softc {
    /* ... all existing Chapter 15 fields ... */

    /* Chapter 16: simulated MMIO register block. */
    uint8_t      *regs_buf;      /* malloc'd register storage */
    size_t       regs_size;      /* size of the register region */
};
```

`regs_buf` is a byte pointer to an allocation. Using `uint8_t *` rather than `uint32_t *` makes the per-byte offset arithmetic in the accessors straightforward; we cast to the appropriate width at each access.

Before the allocation itself, a small but useful improvement. The Chapter 15 driver uses `M_DEVBUF`, the kernel's generic driver-memory bucket, for its allocations. That works, but it blurs our driver's footprint with every other driver on the system: `vmstat -m` reports the aggregated usage under `devbuf`, with no way to tell what came from `myfirst`. Chapter 16 is a good moment to introduce a per-driver malloc type. Near the top of `myfirst.c`, alongside the other file-scoped declarations:

```
static MALLOC_DEFINE(M_MYFIRST, "myfirst", "myfirst driver allocations");
```

`MALLOC_DEFINE` registers a new malloc bucket named `myfirst`, with the long description used by `vmstat -m`. Every allocation the driver makes from this chapter onward is tagged with `M_MYFIRST`, so `vmstat -m` can report the driver's total memory use directly. Chapter 15's allocations that previously used `M_DEVBUF` can be migrated to `M_MYFIRST` in the same pass, or left alone; the practical difference is small and the migration is purely cosmetic.

With the type defined, the allocation happens in `myfirst_attach`, before any code that might access the registers:

```
/* In myfirst_attach, after softc initialisation, before registering /dev nodes. */
sc->regs_size = MYFIRST_REG_SIZE;
sc->regs_buf = malloc(sc->regs_size, M_MYFIRST, M_WAITOK | M_ZERO);

/* Initialise fixed registers to their documented values. */
*(uint32_t *) (sc->regs_buf + MYFIRST_REG_DEVICE_ID) = MYFIRST_DEVICE_ID_VALUE;
*(uint32_t *) (sc->regs_buf + MYFIRST_REG_FIRMWARE_REV) = MYFIRST_FW_REV_VALUE;
*(uint32_t *) (sc->regs_buf + MYFIRST_REG_STATUS) = MYFIRST_STATUS_READY;
```

`M_WAITOK | M_ZERO` produces a zero-filled allocation that can sleep to complete if memory is tight, which is fine at attach time. `M_WAITOK` is the right choice because the caller is the kernel's attach path, which is a process context and can block; `M_NOWAIT` would be required only from a callout or filter-interrupt context.

The initialisation writes three fixed values: the device ID, the firmware revision, and an initial STATUS with the READY bit set. A real device would set these through hardware logic at power-on; the simulation does them explicitly in code.

The teardown is symmetric, in `myfirst_detach`:

```
/* In myfirst_detach, after all consumers of regs_buf have quiesced. */
if (sc->regs_buf != NULL) {
    free(sc->regs_buf, M_MYFIRST);
    sc->regs_buf = NULL;
    sc->regs_size = 0;
}
```

As always in the Chapter 11-15 tradition, the free happens after every code path that could touch the memory has finished. By the time we reach this point in detach, the callouts are drained, the taskqueue is drained, the cdev is destroyed, and no syscall can reach the driver.

A subtle but important point: the allocation uses `malloc(9)` rather than `contigmalloc(9)` or `bus_dmamem_alloc(9)`. For simulation, any kernel memory works. For real hardware with DMA requirements, the allocation would need to be physically contiguous, page-aligned, and bounce-buffered as appropriate; that is Chapter 20's topic, not ours.

16.5.5 The First Accessor Helpers

Direct struct access through raw casts `*(uint32_t *) (sc->regs_buf + MYFIRST_REG_CTRL)` works but is ugly, unsafe (no bounds checking), and inconsistent with the `bus_space` idiom the chapter is teaching. Replace it with named accessors.

In `myfirst_hw.h`, add function prototypes and inline definitions:

```
/* Simulated accessor helpers. Stage 1: direct memory, no barriers. */

static __inline uint32_t
myfirst_reg_read(uint8_t *regs_buf, size_t regs_size, bus_size_t offset)
{
    KASSERT(offset + 4 <= regs_size,
        ("myfirst: register read past end of register block: "
         "offset=%#x size=%zu", (unsigned)offset, regs_size));
    return (*(volatile uint32_t *) (regs_buf + offset));
}

static __inline void
myfirst_reg_write(uint8_t *regs_buf, size_t regs_size, bus_size_t offset,
    uint32_t value)
{
    KASSERT(offset + 4 <= regs_size,
```

```

        ("myfirst: register write past end of register block: "
         "offset=%#x size=%zu", (unsigned)offset, regs_size));
    *(volatile uint32_t *)(regs_buf + offset) = value;
}

```

Two helpers: one read, one write. Each bounds-checks the offset with KASSERT so an out-of-range access is caught immediately on a debug kernel. Each uses `volatile` to prevent the compiler from caching or reordering the access. `bus_size_t` is the same type `bus_space` uses for offsets; using it keeps the accessors compatible with the later transition.

A driver that wants to read STATUS from its softc now writes:

```
uint32_t status = myfirst_reg_read(sc->regs_buf, sc->regs_size, MYFIRST_REG_STATUS);
```

Two arguments of boilerplate per call feels like a lot. Real drivers wrap their accessors in shorter macros that take the softc directly. Let us do the same:

```

#define MYFIRST_REG_READ(sc, offset) \
    myfirst_reg_read((sc)->regs_buf, (sc)->regs_size, (offset))
#define MYFIRST_REG_WRITE(sc, offset, value) \
    myfirst_reg_write((sc)->regs_buf, (sc)->regs_size, (offset), (value))

```

Now the register access reads:

```
uint32_t status = MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS);
```

Short, named, scannable. The macros do not add cost beyond the inline expansion the compiler would have done anyway.

One more helper worth introducing for Stage 1. A common operation is “read a register, modify one field, write it back”:

```

static __inline void
myfirst_reg_update(struct myfirst_softc *sc, bus_size_t offset,
    uint32_t clear_mask, uint32_t set_mask)
{
    uint32_t value;

    value = MYFIRST_REG_READ(sc, offset);
    value &= ~clear_mask;
    value |= set_mask;
    MYFIRST_REG_WRITE(sc, offset, value);
}

```

The helper reads the register, clears the bits named in `clear_mask`, sets the bits named in `set_mask`, and writes the result back. A typical use:

```
/* Clear the ENABLE bit in CTRL. */
myfirst_reg_update(sc, MYFIRST_REG_CTRL, MYFIRST_CTRL_ENABLE, 0);

/* Set the ENABLE bit in CTRL. */
myfirst_reg_update(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_ENABLE);

/* Change MODE to 0x3, keeping other bits intact. */
myfirst_reg_update(sc, MYFIRST_REG_CTRL, MYFIRST_CTRL_MODE_MASK,
    3 << MYFIRST_CTRL_MODE_SHIFT);
```

A caveat: `myfirst_reg_update` as written is not atomic. Between the read and the write, another context could read the same register, modify it, and write it back; our write would then overwrite the other context's update. For Stage 1 this is acceptable, because the simulated registers are accessed only from the syscall context and are not shared with interrupts or tasks yet. Section 6 revisits the atomicity story and introduces locking around the update.

16.5.6 Exposing the Registers Through Sysctls

To make the Stage 1 register block observable without writing a user-space tool, expose each register as a read-only sysctl. In `myfirst_attach`, alongside the other sysctl definitions:

```
/* Chapter 16, Stage 1: sysctls that read the simulated registers. */
SYSCTL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "reg_ctrl",
    CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE, sc, MYFIRST_REG_CTRL,
    myfirst_sysctl_reg, "IU", "Control register (read-only view)");

SYSCTL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "reg_status",
    CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE, sc, MYFIRST_REG_STATUS,
    myfirst_sysctl_reg, "IU", "Status register (read-only view)");

SYSCTL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "reg_device_id",
    CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE, sc, MYFIRST_REG_DEVICE_ID,
    myfirst_sysctl_reg, "IU", "Device ID register (read-only view)");
```

(Equivalent entries for each interesting register follow the same pattern. The `examples/part-04` source has the full list.)

The sysctl handler translates the `arg1/arg2` pair into a register read:

```
static int
myfirst_sysctl_reg(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    bus_size_t offset = arg2;
    uint32_t value;

    if (sc->regs_buf == NULL)
        return (ENODEV);
    value = MYFIRST_REG_READ(sc, offset);
    return (sysctl_handle_int(oidp, &value, 0, req));
}
```

With these sysctls in place, the reader can type:

```
# sysctl dev.myfirst.0.reg_ctrl
dev.myfirst.0.reg_ctrl: 0
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 1
# sysctl dev.myfirst.0.reg_device_id
dev.myfirst.0.reg_device_id: 1298498121
```

1298498121 in decimal is 0x4D594649, the fixed device ID. 1 in `reg_status` is the `READY` bit. These are the values the attach path set; the reader can see them from user space. The loop from “the driver writes a register” to “the reader observes the register value” is closed.

16.5.7 A Writeable Sysctl for CTRL and DATA_IN

Reading is half the story. The Stage 1 simulation also benefits from a writeable sysctl that lets the reader poke register values:

```
SYSCTL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "reg_ctrl_set",
    CTLTYPE_UINT | CTLFLAG_RW | CTLFLAG_MPSAFE, sc, MYFIRST_REG_CTRL,
    myfirst_sysctl_reg_write, "IU",
    "Control register (writeable, Stage 1 test aid)");
```

With the write handler:

```
static int
myfirst_sysctl_reg_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
```

```

    bus_size_t offset = arg2;
    uint32_t value;
    int error;

    if (sc->regs_buf == NULL)
        return (ENODEV);
    value = MYFIRST_REG_READ(sc, offset);
    error = sysctl_handle_int(oidp, &value, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
    MYFIRST_REG_WRITE(sc, offset, value);
    return (0);
}

```

The handler reads the current value, accepts a new value from the caller, writes it back. Writes are unrestricted for now; later sections add validation and side effects.

The reader can now experiment:

```

# sysctl dev.myfirst.0.reg_ctrl_set
dev.myfirst.0.reg_ctrl_set: 0
# sysctl dev.myfirst.0.reg_ctrl_set=1
dev.myfirst.0.reg_ctrl_set: 0 -> 1
# sysctl dev.myfirst.0.reg_ctrl
dev.myfirst.0.reg_ctrl: 1

```

Setting the `ctrl_set` sysctl to 1 enables the (notional) device by setting the `ENABLE` bit in `CTRL`. Reading `reg_ctrl` confirms it. The loop is now complete: user space writes, the register updates, user space reads, the value matches.

16.5.8 The Observer Pattern: Coupling Registers to Driver State

At this point the driver has a register block that is inert. Writing to `CTRL` does not make the driver do anything. Reading from `STATUS` returns whatever was last written. The registers exist; the driver ignores them.

Stage 1's closing step couples two small pieces of driver state to the register block, so that user-space observation of registers reflects something real.

The first coupling: clear the `READY` bit in `STATUS` while the driver is in a reset state, and set it when the driver is attached and operational. In `myfirst_attach`, immediately after allocating `regs_buf`:

```
MYFIRST_REG_WRITE(sc, MYFIRST_REG_STATUS, MYFIRST_STATUS_READY);
```

In `myfirst_detach`, before freeing `regs_buf`:

```
MYFIRST_REG_WRITE(sc, MYFIRST_REG_STATUS, 0);
```

(In practice, detach's `free(regs_buf)` makes the clearing pointless, but the explicit clear documents the intent and mirrors how a real driver would signal the device that the driver is going away.)

The second coupling: if the user-space caller sets `CTRL.ENABLE`, set a soft flag in the softc that the driver uses to decide whether to emit heartbeat output. If the user clears it, the flag clears. This needs a small change in the writeable sysctl handler and a short routine that applies the change:

```
static void
myfirst_ctrl_update(struct myfirst_softc *sc, uint32_t old, uint32_t new)
{
    if ((old & MYFIRST_CTRL_ENABLE) != (new & MYFIRST_CTRL_ENABLE)) {
        device_printf(sc->dev, "CTRL.ENABLE now %s\n",
            (new & MYFIRST_CTRL_ENABLE) ? "on" : "off");
    }
    /* Other fields will grow in later stages. */
}
```

The writeable sysctl handler calls it after updating the register:

```
static int
myfirst_sysctl_reg_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    bus_size_t offset = arg2;
    uint32_t oldval, newval;
    int error;

    if (sc->regs_buf == NULL)
        return (ENODEV);
    oldval = MYFIRST_REG_READ(sc, offset);
    newval = oldval;
    error = sysctl_handle_int(oidp, &newval, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
    MYFIRST_REG_WRITE(sc, offset, newval);

    /* Apply side effects of specific registers. */
    if (offset == MYFIRST_REG_CTRL)
        myfirst_ctrl_update(sc, oldval, newval);

    return (0);
}
```

Now writing 1 to `reg_ctrl_set` produces a `device_printf` in `dmesg` noting the transition. Writing 0 to `reg_ctrl_set` produces another. The register is no longer inert; it drives an observable behaviour.

This is a tiny example of a pattern that will recur: the register is a control surface, the driver reacts to register changes, user-space (or in real drivers, the device) triggers those changes. In Chapter 17 we automate the device side with a callout that changes registers on a timer; in Chapter 18 we point the driver at a real PCI device.

16.5.9 What Stage 1 Accomplished

At the end of Section 4, the driver has:

- A `myfirst_hw.h` header with register offsets, bit masks, and fixed values.
- A `regs_buf` in the `softc`, allocated at `attach` and freed at `detach`.
- Accessor helpers (`myfirst_reg_read`, `myfirst_reg_write`, `myfirst_reg_update`) and macros (`MYFIRST_REG_READ`, `MYFIRST_REG_WRITE`) that wrap access.
- `Sysctls` that expose several registers for read and a writeable `sysctl` for one of them.
- A small coupling between `CTRL.ENABLE` and a driver-level `printf`.

The version tag becomes `0.9-mmio-stage1`. The driver still does everything Chapter 15 gave it; it has simply grown a register-shaped appendage.

Build, load, and test:

```
# cd examples/part-04/ch16-accessing-hardware/stage1-register-map
# make clean && make
# kldload ./myfirst.ko
# sysctl dev.myfirst.0 | grep reg_
# sysctl dev.myfirst.0.reg_ctrl_set=1
# dmesg | tail
# sysctl dev.myfirst.0.reg_ctrl_set=0
# dmesg | tail
# kldunload myfirst
```

You should see the `ENABLE` transitions in `dmesg` and the register values changing through `sysctl`. If any step fails, Section 4's troubleshooting entries at the end of the chapter catch the most common problems.

16.5.10 A Note on What Stage 1 Is Not

Stage 1 is a register-shaped state container. It is not yet using `bus_space(9)` at the API level. The accessors are plain C memory access behind a named helper. Section 5 takes the next step: replace those helpers with real `bus_space_*` calls that operate on the same kernel memory, so the driver's access pattern matches what a real driver with a real resource would look like.

The reason to introduce the abstraction in two passes is pedagogical. Stage 1 makes the mechanism visible: you can see exactly what `MYFIRST_REG_READ` does under the covers. Stage 2 replaces the visible mechanism with the portable API, and you can compare the two and see that the API is doing nothing the helper was not already doing, only more portably and with platform-appropriate barriers where needed. The two-step teaches both.

16.5.11 Wrapping Up Section 4

Simulating hardware starts with a register map and a chunk of kernel memory. A small header declares the offsets, bit masks, and fixed values. A `softc` field holds the allocation. Accessor helpers wrap read and write. `Sysctls` expose the registers so the reader can observe and poke them from user space. Small couplings between registers and driver-level behaviour make the abstraction concrete.

The driver is now at Stage 1 of Chapter 16. Section 5 integrates `bus_space(9)` into this setup, replacing the direct accessors with the portable API the rest of FreeBSD uses.

16.6 Section 5: Using `bus_space` in a Real Driver Context

Section 4 gave the driver a simulated register block and direct accessors. Section 5 replaces the direct accessors with the `bus_space(9)` API and integrates register access into the `myfirst` data path. The shape of the driver changes in a few small but deliberate ways, all of which look more like a real hardware driver than the Stage 1 version did.

This section starts with the smallest possible change (replace the accessor bodies with `bus_space_*` calls) and builds up. By the end, the driver's `write(2)` path produces a register access as a side effect, the driver's `read(2)` path reflects register state, and a task can change register values on a timer so the reader can watch the device “breathe” without user-space poking.

16.6.1 The Pedagogical Trick: Using `bus_space` on Kernel Memory

A minor sleight-of-hand that makes Section 5 possible: on x86, the `bus_space_read_*` and `bus_space_write_*` functions for memory space compile to a plain `volatile` dereference of `handle + offset`. The `handle` is just a `uintptr_t`-shaped value that the functions cast to a pointer. If we set the `handle` to `(bus_space_handle_t)sc->regs_buf`, and the tag to `X86_BUS_SPACE_MEM`, the `bus_space_read_4(tag, handle, offset)` call will do `*(volatile uint32_t*)(regs_buf + offset)`, which is exactly what our Stage 1 accessor did.

That means, on x86 at least, we can drive our simulated register block through the real `bus_space` API by filling in a tag and handle that point at our `malloc'd` memory. The driver's code then becomes indistinguishable, at the source level, from a driver that is accessing real MMIO. That is the whole point: the vocabulary transfers.

On non-x86 platforms, the trick is slightly less clean. On arm64 and some other architectures, `bus_space_tag_t` is a pointer to a structure describing the bus, and using a manufactured tag requires more setup. For Chapter 16 the simulation path is x86-centric; the chapter acknowledges the architectural limitation and defers portability-across-architectures to the later portability chapter. The lessons Chapter 16 teaches are universally applicable; only this one shortcut for simulation is x86-specific.

16.6.2 Stage 2: Setting Up the Simulated Tag and Handle

Add two fields to the `softc`:

```

struct myfirst_softc {
    /* ... all existing fields ... */

    /* Chapter 16 Stage 2: simulated bus_space tag and handle. */
    bus_space_tag_t  regs_tag;
    bus_space_handle_t regs_handle;
};

```

In `myfirst_attach`, after allocating `regs_buf`:

```

#if defined(__amd64__) || defined(__i386__)
sc->regs_tag = X86_BUS_SPACE_MEM;
#else
#error "Chapter 16 simulation path supports x86 only; see text for portability note."
#endif
sc->regs_handle = (bus_space_handle_t)(uintptr_t)sc->regs_buf;

```

That is all the setup. The handle is the virtual address of the allocation cast through `uintptr_t`; the tag is the architecture's constant for memory space.

The `#error` for non-x86 is a deliberate teaching signal: the chapter explicitly flags what is portable (the vocabulary) and what is not (this specific simulation shortcut). Chapter 17 and the portability chapter will teach a cleaner alternative. Until then, x86 is the supported platform for the chapter's exercises.

16.6.3 Replacing the Accessors

With the tag and handle set up, the accessors become one-liners over `bus_space_*`:

```

static __inline uint32_t
myfirst_reg_read(struct myfirst_softc *sc, bus_size_t offset)
{
    KASSERT(offset + 4 <= sc->regs_size,
        ("myfirst: register read past end of block: offset=%#x size=%zu",
         (unsigned)offset, sc->regs_size));
    return (bus_space_read_4(sc->regs_tag, sc->regs_handle, offset));
}

static __inline void
myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset, uint32_t value)
{
    KASSERT(offset + 4 <= sc->regs_size,
        ("myfirst: register write past end of block: offset=%#x size=%zu",
         (unsigned)offset, sc->regs_size));
}

```

```
bus_space_write_4(sc->regs_tag, sc->regs_handle, offset, value);
}
```

The signature changes: the helpers now take a `struct myfirst_softc *` rather than `regs_buf` and `regs_size` separately. Internal bounds checking is retained; the `KASSERT` fires if a bug in the driver produces an out-of-range offset. The body uses `bus_space_read_4` and `bus_space_write_4` instead of direct memory access.

The `MYFIRST_REG_READ` and `MYFIRST_REG_WRITE` macros simplify accordingly:

```
#define MYFIRST_REG_READ(sc, offset)      myfirst_reg_read((sc), (offset))
#define MYFIRST_REG_WRITE(sc, offset, value) myfirst_reg_write((sc), (offset), (value))
```

Every register access in the driver, including the `sysctl` handlers and `myfirst_reg_update`, continues to use these macros. None of the call sites change. The driver's behaviour is identical to Stage 1, but the access path now travels through `bus_space`, and the path would work just as well if `regs_tag` and `regs_handle` came from `rman_get_bustag` and `rman_get_bushandle` on a real resource.

Build the driver and confirm it still passes the Stage 1 `sysctl` exercises:

```
# cd examples/part-04/ch16-accessing-hardware/stage2-bus-space
# make clean && make
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.reg_device_id
dev.myfirst.0.reg_device_id: 1298498121
# sysctl dev.myfirst.0.reg_ctrl_set=1
# dmesg | tail
# kldunload myfirst
```

The output matches Stage 1. The driver now uses `bus_space` the way a real driver does.

16.6.4 Exposing DATA_IN Through the Write Path

With the accessor layer in place, Stage 2 couples the driver's `write(2)` syscall to the `DATA_IN` register. Every byte written to the device file `/dev/myfirst0` now ends up at the `DATA_IN` register, where the reader can observe it.

Modify `myfirst_write` (the `d_write` callback). The existing handler reads bytes from the `uio`, copies them into the ring buffer, signals waiters, and returns. The new handler does the same, plus: just before returning, it writes the most recently copied byte to `DATA_IN` and sets the `DATA_AV` bit in `STATUS`:

```
static int
myfirst_write(struct cdev *cdev, struct uio *uio, int flag)
{
    struct myfirst_softc *sc = cdev->si_drv1;
```

```

uint8_t buf[MYFIRST_BOUNCE];
size_t n;
int error = 0;
uint8_t last_byte = 0;
bool wrote_any = false;

/* ... existing writer-cap and lock acquisition ... */

while (uio->uio_resid > 0) {
    n = MIN(uio->uio_resid, sizeof(buf));
    error = uiomove(buf, n, uio);
    if (error != 0)
        break;

    /* Remember the most recent byte for the register update. */
    if (n > 0) {
        last_byte = buf[n - 1];
        wrote_any = true;
    }

    /* ... existing copy into the ring buffer ... */
}

/* ... existing unlock and cv_signal ... */

/* Chapter 16 Stage 2: reflect the last byte in DATA_IN. */
if (wrote_any) {
    MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_IN,
        (uint32_t)last_byte);
    myfirst_reg_update(sc, MYFIRST_REG_STATUS,
        0, MYFIRST_STATUS_DATA_AV);
}

return (error);
}

```

Now, after any `echo foo > /dev/myfirst0`, the `DATA_IN` register contains the byte value of 'o' (the last character of "foo\n" is \n, actually, which is 0x0a), and the `DATA_AV` bit in `STATUS` is set. The reader can observe this through `sysctl`:

```

# echo -n "Hello" > /dev/myfirst0
# sysctl dev.myfirst.0.reg_data_in
dev.myfirst.0.reg_data_in: 111
# sysctl dev.myfirst.0.reg_status

```

```
dev.myfirst.0.reg_status: 9
```

111 is the ASCII code for 'o', the last byte of “Hello”. 9 is MYFIRST_STATUS_READY | MYFIRST_STATUS_DATA_AV (1 | 8 = 9). The driver has, for the first time, produced an externally-observable register-level side effect in response to user-space action.

16.6.5 Exposing DATA_OUT Through the Read Path

Symmetrically, every byte read from /dev/myfirst0 can update DATA_OUT to reflect what was last read. Modify myfirst_read:

```
static int
myfirst_read(struct cdev *cdev, struct uio *uio, int flag)
{
    struct myfirst_softc *sc = cdev->si_drv1;
    uint8_t buf[MYFIRST_BOUNCE];
    size_t n;
    int error = 0;
    uint8_t last_byte = 0;
    bool read_any = false;

    /* ... existing blocking logic and lock acquisition ... */

    while (uio->uio_resid > 0) {
        /* ... existing ring-buffer extraction ... */

        if (n > 0) {
            last_byte = buf[n - 1];
            read_any = true;
        }

        error = uiomove(buf, n, uio);
        if (error != 0)
            break;
    }

    /* ... existing unlock and cv_signal ... */

    /* Chapter 16 Stage 2: reflect the last byte in DATA_OUT. */
    if (read_any) {
        MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_OUT,
            (uint32_t)last_byte);
        /* If the ring buffer is now empty, clear DATA_AV. */
        if (cbuf_is_empty(&sc->cb))
```

```

        myfirst_reg_update(sc, MYFIRST_REG_STATUS,
                           MYFIRST_STATUS_DATA_AV, 0);
    }

    return (error);
}

```

Now DATA_OUT reflects the last byte the reader read, and DATA_AV clears when the ring buffer drains. The loop from “user writes a byte” to “driver updates register” to “user reads a byte” to “driver updates registers” is closed.

Testing:

```

# echo -n "ABC" > /dev/myfirst0
# sysctl dev.myfirst.0.reg_data_in dev.myfirst.0.reg_status
dev.myfirst.0.reg_data_in: 67
dev.myfirst.0.reg_status: 9
# dd if=/dev/myfirst0 bs=1 count=3 of=/dev/null
# sysctl dev.myfirst.0.reg_data_out dev.myfirst.0.reg_status
dev.myfirst.0.reg_data_out: 67
dev.myfirst.0.reg_status: 1

```

67 is 'C', the last byte written. After the dd consumes all three bytes, DATA_OUT holds 'C' (the last byte read) and STATUS is back to just READY because DATA_AV cleared.

16.6.6 Driving Register State From a Task

The register block so far reflects driver actions triggered by user-space syscalls. To illustrate a task-driven pattern, add a small task that periodically increments SCRATCH_A. This is an artificial example; it exists so the reader can see register values changing autonomously in response to task-triggered events, preparing for Chapter 17 where callouts and timers drive more realistic changes.

In the softc:

```

struct task      reg_ticker_task;
int              reg_ticker_enabled;

```

The task callback:

```

static void
myfirst_reg_ticker_cb(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

```

```

        if (!myfirst_is_attached(sc))
            return;

        MYFIRST_REG_WRITE(sc, MYFIRST_REG_SCRATCH_A,
            MYFIRST_REG_READ(sc, MYFIRST_REG_SCRATCH_A) + 1);
    }

```

The task is enqueued from the existing tick_source callout (Chapter 14's callout that already fires on a timer). In the callout callback, alongside the selwake task enqueue:

```

if (sc->reg_ticker_enabled)
    taskqueue_enqueue(sc->tq, &sc->reg_ticker_task);

```

And a sysctl to enable it:

```

SYSCTL_ADD_INT(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "reg_ticker_enabled",
    CTLFLAG_RW, &sc->reg_ticker_enabled, 0,
    "Enable the periodic register ticker (increments SCRATCH_A each tick)");

```

Initialisation in attach:

```

TASK_INIT(&sc->reg_ticker_task, 0, myfirst_reg_ticker_cb, sc);
sc->reg_ticker_enabled = 0;

```

Drain in detach, in the existing task drain block:

```

taskqueue_drain(sc->tq, &sc->reg_ticker_task);

```

With this in place, enabling the ticker produces a visible register effect:

```

# sysctl dev.myfirst.0.reg_ticker_enabled=1
# sleep 5
# sysctl dev.myfirst.0.reg_scratch_a
dev.myfirst.0.reg_scratch_a: 5
# sleep 5
# sysctl dev.myfirst.0.reg_scratch_a
dev.myfirst.0.reg_scratch_a: 10
# sysctl dev.myfirst.0.reg_ticker_enabled=0

```

The register value climbs at one per second, as the tick_source callout fires. The driver is now exhibiting autonomous register-level behaviour, triggered by a task, mediated by bus_space.

16.6.7 The Full Stage 2 Sysctl Tree

After Stage 2 the full sysctl tree under `dev.myfirst.0` looks roughly like:

```
dev.myfirst.0.debug_level
dev.myfirst.0.soft_byte_limit
dev.myfirst.0.nickname
dev.myfirst.0.heartbeat_interval_ms
dev.myfirst.0.watchdog_interval_ms
dev.myfirst.0.tick_source_interval_ms
dev.myfirst.0.bulk_writer_batch
dev.myfirst.0.reset_delayed
dev.myfirst.0.writers_limit
dev.myfirst.0.writers_sema_value
dev.myfirst.0.writers_trywait_failures
dev.myfirst.0.stats_cache_refresh_count
dev.myfirst.0.reg_ctrl
dev.myfirst.0.reg_status
dev.myfirst.0.reg_data_in
dev.myfirst.0.reg_data_out
dev.myfirst.0.reg_intr_mask
dev.myfirst.0.reg_intr_status
dev.myfirst.0.reg_device_id
dev.myfirst.0.reg_firmware_rev
dev.myfirst.0.reg_scratch_a
dev.myfirst.0.reg_scratch_b
dev.myfirst.0.reg_ctrl_set
dev.myfirst.0.reg_ticker_enabled
```

Ten register views, one writeable register, one ticker toggle, plus every previous sysctl from Chapters 11 through 15. The driver has grown, but every addition is small and named.

16.6.8 A Note on Reads From STATUS While the Driver Is Running

In the Stage 1 and Stage 2 setups, reading STATUS via sysctl returns whatever bits the driver most recently set. No read has side effects. This is intentional for Chapter 16. But notice a subtle consequence: the driver can set the STATUS.DATA_AV bit in the write path and clear it in the read path, and the user-space reader can observe the bit change over time. Running `sysctl -w dev.myfirst.0.reg_status=0` is possible through the writeable sysctl, but the driver's automatic updates will re-set the bit on the next write to the device file.

This is how a “polled” device driver works at a conceptual level: the driver polls the status register periodically, reacts to state changes, and updates driver-visible state accordingly. A real device's STATUS bits change for hardware reasons; the simulated device's bits change for simulated-driver reasons. The mechanism is the same.

Chapter 19 introduces interrupts, which replace the polling model with an event-driven one. Until then, polling is a reasonable pattern for the simulated device.

16.6.9 The Detach Path, Updated

Every chapter in Part 3 added a few lines to the detach ordering. Chapter 16 Stage 2 adds two: drain the `reg_ticker_task` and free the register buffer. The full detach order at Stage 2:

1. Refuse detach if `active_fhs > 0`.
2. Clear `is_attached` (atomically), broadcast cvs.
3. Drain all callouts (heartbeat, watchdog, tick_source).
4. Drain all tasks (selwake, bulk_writer, reset_delayed, recovery, reg_ticker).
5. `seldrain(&sc->rsl)`, `seldrain(&sc->wsl)`.
6. `taskqueue_free(sc->tq)`.
7. Destroy cdev.
8. Release sysctl context.
9. **Free `regs_buf`.** (New in Stage 2.)
10. Destroy cbuf, counters, cvs, sx locks, semaphore, mutex.

The `regs_buf` free happens after the sysctl context is torn down, because a sysctl handler could in principle be running on another CPU during detach. After `sysctl_ctx_free`, no sysctl handler can reach the softc, and the free is safe. Real drivers follow the same discipline for their resource releases.

16.6.10 Updating `LOCKING.md` (Now `HARDWARE.md` Too)

Part 3 established `LOCKING.md` as the driver's synchronisation map. Chapter 16 opens a sibling document: `HARDWARE.md`. It lives alongside `LOCKING.md` and documents the register interface, access patterns, and ownership rules for hardware-facing state.

A first cut:

```
# myfirst Hardware Interface
```

```
## Register Block
```

```
Size: 64 bytes (MYFIRST_REG_SIZE).
```

```
Access: 32-bit reads and writes on 32-bit-aligned offsets.
```

```
Allocated in attach, freed in detach.
```

```
### Register Map
```

Offset	Name	Direction	Owner
0x00	CTRL	R/W	driver
0x04	STATUS	R/W	driver
0x08	DATA_IN	W	syscall

0x0c	DATA_OUT	R	syscall	
0x10	INTR_MASK	R/W	driver	
0x14	INTR_STATUS	R/W	driver	
0x18	DEVICE_ID	R	attach	
0x1c	FIRMWARE_REV	R	attach	
0x20	SCRATCH_A	R/W	ticker	
0x24	SCRATCH_B	R/W	free	

Write Protections

Stage 2 does not lock register access. A syscall writer, a syscall writer, and the ticker task can each access the same register without a lock. See Section 6 for the locking story.

Access Paths

- Sysctl read handlers: MYFIRST_REG_READ
- Sysctl write handlers: MYFIRST_REG_WRITE, with side-effect call
- Syscall write path: MYFIRST_REG_WRITE(DATA_IN), myfirst_reg_update(STATUS)
- Syscall read path: MYFIRST_REG_WRITE(DATA_OUT), myfirst_reg_update(STATUS)
- Ticker task: MYFIRST_REG_WRITE(SCRATCH_A)

The document is short now and will grow as later chapters add more registers and more access paths. The discipline of documenting the register interface alongside the code is the same as Part 3's discipline of documenting locks.

16.6.11 Stage 2 Complete

At the end of Section 5, the driver is at 0.9-mmio-stage2. It has:

- A real bus_space_* access path over a simulated tag and handle.
- DATA_IN reflecting the last written byte, with DATA_AV tracking the ring buffer's state.
- DATA_OUT reflecting the last read byte.
- A task that autonomously increments a scratch register on a timer.
- Full syscall visibility into every register.
- A HARDWARE.md document describing the interface.

Build, load, test, observe, unload:

```
# cd examples/part-04/ch16-accessing-hardware/stage2-bus-space
# make clean && make
# kldload ./myfirst.ko
# echo -n "hello" > /dev/myfirst0
# syscall dev.myfirst.0.reg_data_in dev.myfirst.0.reg_status
```

```
# dd if=/dev/myfirst0 bs=1 count=5 of=/dev/null
# sysctl dev.myfirst.0.reg_data_out dev.myfirst.0.reg_status
# sysctl dev.myfirst.0.reg_ticker_enabled=1 ; sleep 3
# sysctl dev.myfirst.0.reg_scratch_a
# sysctl dev.myfirst.0.reg_ticker_enabled=0
# kldunload myfirst
```

The outputs should tell a consistent story about what the driver and the registers are doing.

16.6.12 A Look at a Real Pattern: The `em` Attach Path

Now that Stage 2 mirrors a real driver's structure, a brief look at what Stage 2 would look like if the register block were a real PCI MMIO region, just to anchor the expectation. In `/usr/src/sys/dev/e1000/if_em.c`, inside `em_allocate_pci_resources`, you will find:

```
sc->memory = bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE);
if (sc->memory == NULL) {
    device_printf(dev, "Unable to allocate bus resource: memory\n");
    return (ENXIO);
}
sc->osdep.mem_bus_space_tag = rman_get_bustag(sc->memory);
sc->osdep.mem_bus_space_handle = rman_get_bushandle(sc->memory);
sc->hw.hw_addr = (uint8_t *)&sc->osdep.mem_bus_space_handle;
```

The resource is allocated, the tag and handle are extracted into the softc's `osdep` structure, and an additional `hw_addr` pointer is set up for the hardware-abstraction-layer code that Intel shares between drivers. The rest of the driver uses macros (`E1000_READ_REG`, `E1000_WRITE_REG`) defined over `bus_space_*` to talk to the hardware.

The shape is the same as our Stage 2. The difference is exactly one function call: `bus_alloc_resource_any` for a real driver, `malloc(9)` plus a handcrafted tag for ours. Everything above the allocation layer is identical.

Chapter 18 will swap our `malloc` for `bus_alloc_resource_any` and point the driver at a real PCI device. The driver's upper layers will not change.

16.6.13 Wrapping Up Section 5

Stage 2 replaces the direct accessors of Stage 1 with real `bus_space(9)` calls operating on the simulated tag and handle. The driver's `write(2)` and `read(2)` paths now produce register-level side effects. A task updates a scratch register on a timer. The `HARDWARE.md` document describes the register interface. The driver's shape closely matches that of a real driver like `if_em`.

Section 6 introduces the safety discipline that real MMIO demands: memory barriers, locking around shared registers, and the reasons busy-wait loops are a mistake. Stage 3 of the driver adds that discipline.

16.7 Section 6: Safety and Synchronization with MMIO

Stage 2 works, but it is unsafe in three specific ways that Section 6 names and fixes. The first is that register access is not atomic. The second is that register ordering is not enforced. The third is that there is no discipline around what context may access which registers. Each of these is a category of bug that can hurt a real driver; each is fixable with discipline the chapter has already taught in Part 3, applied to the new hardware-facing state.

This section walks through each problem, explains why it matters, and produces Stage 3 of the driver: a version that is correct under concurrent access, ordering-safe for platforms that need it, and clearly partitioned by context.

16.7.1 Why a Register Access Can Be Unsafe Without a Lock

Consider two user-space threads writing different bytes to `/dev/myfirst0` concurrently. In Stage 2, both call `myfirst_write`, which in turn calls `MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_IN, last_byte)`. Without a lock, the two writes race: one finishes first, one finishes second, and `DATA_IN` ends up with whichever value was written last. That is not wrong, exactly; both bytes were really the last byte of their respective writes. But the driver has no way of telling which value in `DATA_IN` came from which writer.

More subtly, consider `myfirst_reg_update`, which does a read-modify-write sequence on a register. Two threads calling it on the same register in parallel can produce a classic lost-update. Thread A reads `CTRL = 0`. Thread B reads `CTRL = 0`. Thread A sets the `ENABLE` bit and writes `CTRL = 1`. Thread B sets the `RESET` bit and writes `CTRL = 2`. The result is `CTRL = 2`, with `ENABLE` lost. On any register where multiple contexts perform read-modify-write operations, this is a data-race bug that can cause real protocol failures.

The solution is familiar: a lock. The only question is which lock. Chapter 11's `sc->mtx` protects the data path; it is the natural choice for register access that happens inside the data path. A separate mutex, `sc->reg_mtx`, can be introduced for register access that happens outside the data path (sysctl handlers, the ticker task). The two can be the same lock, or different locks, depending on the driver's access patterns.

For Stage 3, we take the simpler path: use `sc->mtx` for every register access. This enforces the rule “no register access without the driver mutex” with a single primitive. The cost is that sysctl handlers and the ticker task must acquire the driver mutex briefly, which serialises them with the data path. For a driver this small, the cost is negligible.

16.7.2 Adding the Lock

Modify `myfirst_reg_read` and `myfirst_reg_write` to assert that the driver lock is held, and modify their callers to acquire it. An assertion is cheaper than acquiring the lock inside the accessor, and it makes the locking rule visible at every call site.

```
static __inline uint32_t
myfirst_reg_read(struct myfirst_softc *sc, bus_size_t offset)
{
    MYFIRST_ASSERT(sc); /* Chapter 11: mtx_assert(&sc->mtx, MA_OWNED). */
    KASSERT(offset + 4 <= sc->regs_size, (...));
```

```

        return (bus_space_read_4(sc->regs_tag, sc->regs_handle, offset));
    }

static __inline void
myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset, uint32_t value)
{
    MYFIRST_ASSERT(sc);
    KASSERT(offset + 4 <= sc->regs_size, (...));
    bus_space_write_4(sc->regs_tag, sc->regs_handle, offset, value);
}

```

The MYFIRST_ASSERT macro from Chapter 11 asserts that `sc->mtx` is held in MA_OWNED mode. A debug kernel catches any caller that forgot to acquire the lock; a production kernel elides the check.

Now every call site must acquire the lock. The sysctl handler becomes:

```

static int
myfirst_sysctl_reg(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    bus_size_t offset = arg2;
    uint32_t value;

    if (!myfirst_is_attached(sc))
        return (ENODEV);

    MYFIRST_LOCK(sc);
    if (sc->regs_buf == NULL) {
        MYFIRST_UNLOCK(sc);
        return (ENODEV);
    }
    value = MYFIRST_REG_READ(sc, offset);
    MYFIRST_UNLOCK(sc);

    return (sysctl_handle_int(oidp, &value, 0, req));
}

```

The lock is acquired before the register read, held briefly, released before the sysctl framework's `sysctl_handle_int`. The framework may sleep (it copies the value to user space), so the lock cannot be held across that call.

Similarly, the writeable sysctl handler:

```

static int
myfirst_sysctl_reg_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    bus_size_t offset = arg2;
    uint32_t oldval, newval;
    int error;

    if (!myfirst_is_attached(sc))
        return (ENODEV);

    MYFIRST_LOCK(sc);
    if (sc->regs_buf == NULL) {
        MYFIRST_UNLOCK(sc);
        return (ENODEV);
    }
    oldval = MYFIRST_REG_READ(sc, offset);
    MYFIRST_UNLOCK(sc);

    newval = oldval;
    error = sysctl_handle_int(oidp, &newval, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    MYFIRST_LOCK(sc);
    if (sc->regs_buf == NULL) {
        MYFIRST_UNLOCK(sc);
        return (ENODEV);
    }
    MYFIRST_REG_WRITE(sc, offset, newval);
    if (offset == MYFIRST_REG_CTRL)
        myfirst_ctrl_update(sc, oldval, newval);
    MYFIRST_UNLOCK(sc);

    return (0);
}

```

The handler acquires the lock twice: once to read the current value, once to apply the new value. Between them the lock is released and `sysctl_handle_int` runs. The pattern is slightly awkward but is standard in FreeBSD: you acquire a lock for a brief operation, release it for a sleepable call, reacquire for the next brief operation, and tolerate the fact that state may have changed in between.

The `myfirst_ctrl_update` call now happens under the lock, so its `printf` still works but any future state changes it makes can rely on lock ownership.

The ticker task callback likewise acquires the lock:

```
static void
myfirst_reg_ticker_cb(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    if (!myfirst_is_attached(sc))
        return;

    MYFIRST_LOCK(sc);
    if (sc->regs_buf != NULL) {
        uint32_t v = MYFIRST_REG_READ(sc, MYFIRST_REG_SCRATCH_A);
        MYFIRST_REG_WRITE(sc, MYFIRST_REG_SCRATCH_A, v + 1);
    }
    MYFIRST_UNLOCK(sc);
}
```

And the `myfirst_write` and `myfirst_read` paths, which already held `sc->mtx` around ring-buffer access, need to extend the hold across the register updates, or to release and reacquire briefly. The simplest change is to keep the register updates inside the existing locked region:

```
/* In myfirst_write, while still holding sc->mtx after the ring-buffer update: */
if (wrote_any) {
    MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_IN, (uint32_t)last_byte);
    myfirst_reg_update(sc, MYFIRST_REG_STATUS, 0, MYFIRST_STATUS_DATA_AV);
}
```

Because `myfirst_reg_update` now asserts the mutex is held, and it is, the call succeeds. The lock-hold time grows slightly, but only by a handful of `bus_space_write_4` calls, which compile to single `mov` instructions; the cost is negligible.

16.7.3 Why Barriers Matter Even On x86

With locking in place, the driver is correct under concurrency on x86. On weakly-ordered platforms (arm64, RISC-V, some older MIPS), the story is not quite finished. A sequence like:

```
MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_IN, value);
MYFIRST_REG_WRITE(sc, MYFIRST_REG_CTRL, CTRL_GO);
```

implies that the `DATA_IN` write reaches the device before the `CTRL.GO` trigger. On x86, hardware preserves program order for stores, and the compiler's reordering is limited by the `volatile` qualifier in `bus_space_write_4`. On arm64, the CPU can reorder the two stores, and the device might see `CTRL.GO` before `DATA_IN` is ready, which breaks the protocol.

The fix is a write barrier:

```
MYFIRST_REG_WRITE(sc, MYFIRST_REG_DATA_IN, value);
bus_space_barrier(sc->regs_tag, sc->regs_handle, 0, sc->regs_size,
    BUS_SPACE_BARRIER_WRITE);
MYFIRST_REG_WRITE(sc, MYFIRST_REG_CTRL, CTRL_GO);
```

On x86 this barrier is a compiler fence. On arm64 it is a DSB or DMB that forces the first store to complete before the second is issued.

For Chapter 16 the protocol we are simulating does not actually require this ordering, because our “device” is kernel memory whose observers all take the same lock and do not reorder within a critical section. But the habit is worth developing. When the code eventually talks to a real device, the barriers will be there, and the driver will be portable across architectures.

As a teaching vehicle, introduce a helper that makes barrier-annotated writes easy:

```
static __inline void
myfirst_reg_write_barrier(struct myfirst_softc *sc, bus_size_t offset,
    uint32_t value, int flags)
{
    MYFIRST_ASSERT(sc);
    MYFIRST_REG_WRITE(sc, offset, value);
    bus_space_barrier(sc->regs_tag, sc->regs_handle, 0, sc->regs_size,
        flags);
}
```

Flags are `BUS_SPACE_BARRIER_READ`, `BUS_SPACE_BARRIER_WRITE`, or the OR of the two. A driver that reads status right after writing a command uses the combined flag. One that only wants subsequent writes to see this write’s effect uses just `WRITE`.

The Stage 3 driver does not use `myfirst_reg_write_barrier` in many places; it is defined and used in a single demonstration path (inside the ticker, after the scratch increment, to illustrate the usage). Later chapters that deal with real protocols will use it more heavily.

16.7.4 Partitioning Register Access by Context

With locking uniform, the next question is: which contexts access which registers, and is that mix intentional?

A Stage 3 audit on the driver shows:

- Syscall context (write): accesses `DATA_IN`, `STATUS`.
- Syscall context (read): accesses `DATA_OUT`, `STATUS`.
- Sysctl context: accesses every register (read) and `CTRL`, `SCRATCH_A`, `SCRATCH_B`, etc. (write) through the writeable sysctl.
- Task context (ticker): accesses `SCRATCH_A`.

Every access is lock-protected. Every access touches a register the driver has explicitly allocated for that purpose. The access discipline is simple: syscalls read and write the data registers and the data-available bit; sysctls are

for inspection and one-off configuration; the ticker writes one specific register. A rule of “contexts do not overlap their register responsibilities” is easy to state and easy to hold.

This is the kind of thing `HARDWARE.md` exists to document. Update the document to include per-register ownership:

Per-Register Owners

```
CTRL:          sysctl writer, driver (via myfirst_ctrl_update)
STATUS:        driver (via write/read paths)
DATA_IN:        syscall write path
DATA_OUT:       syscall read path
INTR_MASK:     sysctl writer only (Stage 3); driver attach (Chapter 19)
INTR_STATUS:   sysctl writer only (Stage 3)
DEVICE_ID:     attach only (initialised once, never written thereafter)
FIRMWARE_REV:  attach only (initialised once, never written thereafter)
SCRATCH_A:     ticker task; sysctl writer
SCRATCH_B:     sysctl writer only
```

A future contributor can glance at this table and immediately see where a register write is expected. A future change that adds a new owner must update the table, which keeps the documentation honest.

16.7.5 Avoiding Busy-Wait Loops

One style of bug that new driver authors fall into is the busy-wait loop for register state. The canonical example:

```
/* BAD: busy-waits forever if the device never becomes ready. */
while ((MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_READY) == 0)
    ;
```

The loop spins reading the register until the `READY` bit becomes set. On real hardware, the time between “not ready” and “ready” may be microseconds. On an overloaded system, it may be longer. During the spin, the CPU is consumed by the loop; no other thread on that CPU can run; the driver’s own other threads cannot even unlock the mutex the loop may be holding.

Several better patterns exist.

Bounded spin with `DELAY(9)` for short waits. If the expected wait is short (less than a few hundred microseconds, typically), use a loop with a bounded iteration count and a `DELAY` between iterations. `DELAY(usec)` busy-waits for at least `usec` microseconds, allowing the CPU to serve interrupts in the meantime.

```
for (i = 0; i < 100; i++) {
    if (MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_READY)
        break;
```

```

        DELAY(10);
    }
    if ((MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_READY) == 0) {
        device_printf(sc->dev, "timeout waiting for READY\n");
        return (ETIMEDOUT);
    }

```

The loop runs at most 100 times, waiting 10 microseconds between reads, for a total bound of 1 millisecond. On a successful completion the loop exits early. On timeout the driver gives up and returns an error.

Sleep-based wait with `msleep`. For longer expected waits (milliseconds to seconds), do not busy-wait at all. Sleep the thread until a wakeup arrives, or until a timeout fires. The example below is hypothetical (our simulated device never clears `READY` in Chapter 16), but it shows the shape you will reach for when real hardware starts changing status bits:

```

/* Hypothetical; assumes sc->status_wait is a dummy address the driver
 * uses as a sleep channel and a matching wakeup(&sc->status_wait) fires
 * when the ready bit is expected to change. */
while ((MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_READY) == 0) {
    error = msleep(&sc->status_wait, &sc->mtx, PCATCH, "myfready", hz / 10);
    if (error == EWOULDBLOCK) {
        /* Timeout: return to caller with ETIMEDOUT. */
        return (ETIMEDOUT);
    }
    if (error != 0)
        return (error);
}

```

The thread sleeps on `&sc->status_wait`, with the driver mutex as the interlock, for up to 100ms. A wakeup from another context (typically an interrupt handler or a task that observed the register change) breaks the sleep. On arm64, where register polling would be expensive and imprecise, this pattern is strongly preferred. Chapter 17 makes this pattern concrete: a callout flips `READY` on a timer, and a syscall path sleeps on the matching channel until the callout wakes it up.

Event-driven with `cv_wait`. Same as above, but using a condition variable, which is more natural in Part 3's idiom:

```

MYFIRST_LOCK(sc);
while ((MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_READY) == 0) {
    cv_timedwait_sig(&sc->status_cv, &sc->mtx, hz / 10);
}
MYFIRST_UNLOCK(sc);

```

With a matching `cv_signal` in whichever context sets the bit.

Chapter 16's simulated device does not need any of these patterns yet, because the `READY` bit is set at attach and never cleared. But the patterns are named here because Section 6 is the right place to introduce them, and Chapter 17 will use them when status bits start changing dynamically.

16.7.6 Interrupts and MMIO: A Forward Pointer

A brief note on a topic Chapter 19 owns. When a real driver has an interrupt handler that runs in filter or `ithread` context, register access from the handler has additional constraints. Filter handlers run in an interrupt context with very limited primitives available; they typically acknowledge the interrupt by writing a register, record the event somehow, and defer the real work to a task. The acknowledgement write is the kind of thing `bus_space_write_*` exists for, and it runs under specific locking rules that differ from the ordinary driver `mutex`.

Chapter 16's driver has no interrupt handler, so this concern does not yet apply. Chapter 19 introduces the handler and the lock-type changes it forces. For now, treat “interrupt context accessing registers” as a topic you know exists and will learn about later; the register-access mechanism (`bus_space_*`) is the same, but the locking around it changes.

16.7.7 Stage 3 Complete

With locking added, barriers introduced, context ownership documented, and busy-wait patterns discouraged, the driver is at `0.9-mmio-stage3`. The shape of the driver is still that of Stage 2, but every register access is now lock-protected, every context's access pattern is documented, and the driver is prepared to handle more sophisticated hardware protocols in later chapters.

Build, test, and stress:

```
# cd examples/part-04/ch16-accessing-hardware/stage3-synchronized
# make clean && make
# kldload ./myfirst.ko
# examples/part-04/ch16-accessing-hardware/labs/reg_stress.sh
```

The stress script spawns several concurrent writers, readers, `sysctl` readers, and ticker-toggle operations, and checks that the final register state is consistent. Under `WITNESS`, any locking violation produces an immediate warning; under `INVARIANTS`, any out-of-bounds access produces a panic. If the script completes cleanly, the driver's register discipline is sound.

16.7.8 Wrapping Up Section 6

MMIO safety rests on three disciplines: locking (every register access happens under the appropriate lock), ordering (barriers where the protocol requires them, even if the platform is x86), and context partitioning (each register has a named owner and an intended access path). The driver's `HARDWARE.md` captures the last two; the `mutex` assertions in the accessors enforce the first.

Section 7 takes the next step: making the register access observable for debugging. Logs, `sysctls`, `DTrace` probes, and the small observability layer that catches bugs before they become crashes.

16.8 Section 7: Debugging and Tracing Hardware Access

A register access is, by design, invisible. It compiles to a CPU instruction that reads or writes a handful of bytes. There is no stack frame, no call log, no return value you can `printf` without adding code. When a driver works, invisibility is a virtue. When it does not, invisibility is the problem.

Section 7 covers the tools and idioms that make register access visible enough to debug without being so noisy that the driver becomes unreadable. The goal is a small observability layer: enough instrumentation to catch bugs early, placed where a beginner can switch it on and off, and integrated with the logging the rest of the driver already does.

16.8.1 What You Want to Observe

Three things are worth seeing when a driver is misbehaving.

The value at a specific register, right now. The `sysctl` handlers from Stage 2 already give you this. A `sysctl dev.myfirst.0.reg_ctrl` returns the current value at any moment, and nothing else in the driver's behaviour changes because of the read.

The sequence of register accesses the driver made recently. When a bug involves register ordering or incorrect bit manipulation, knowing “the driver wrote 0x1 then 0x2 then 0x4 in that order” is exactly what you need. The raw sequence cannot be reconstructed from register contents alone.

The stack and context for a specific register access. When a write happens from an unexpected code path, you want to know which function did it, which thread was running, and what was on the stack. DTrace is good at this.

The rest of this section walks through each kind of observation and shows what to add to the driver to support it.

16.8.2 A Simple Access Log

The simplest observability tool is a log of the last *N* register accesses, kept in a ring buffer inside the softc. Every register read and write records an entry; the `sysctl` exposes the ring.

Define the log entry:

```
#define MYFIRST_ACCESS_LOG_SIZE 64

struct myfirst_access_log_entry {
    uint64_t    timestamp_ns;
    uint32_t    value;
    bus_size_t  offset;
    uint8_t     is_write;
    uint8_t     width;
    uint8_t     context_tag;
    uint8_t     _pad;
};
```

Each entry is 24 bytes, holding the time (nanoseconds since boot), the value, the offset, whether it was a read or a write, the access width, and a tag identifying the caller's context (syscall, task, sysctl). Padding rounds to 24; a log of 64 entries is 1.5 KiB, which is trivially small.

Add the ring to the softc:

```
struct myfirst_access_log_entry access_log[MYFIRST_ACCESS_LOG_SIZE];
unsigned int access_log_head; /* index of next write */
bool access_log_enabled;
```

Record an entry in the accessors. Stage 3's myfirst_reg_write becomes:

```
static __inline void
myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset, uint32_t value)
{
    MYFIRST_ASSERT(sc);
    KASSERT(offset + 4 <= sc->regs_size, (...));
    bus_space_write_4(sc->regs_tag, sc->regs_handle, offset, value);

    if (sc->access_log_enabled) {
        unsigned int idx = sc->access_log_head++ % MYFIRST_ACCESS_LOG_SIZE;
        sc->access_log[idx].timestamp_ns = nanouptime_ns();
        sc->access_log[idx].value = value;
        sc->access_log[idx].offset = offset;
        sc->access_log[idx].is_write = 1;
        sc->access_log[idx].width = 4;
        sc->access_log[idx].context_tag = myfirst_current_context_tag();
    }
}
```

(nanouptime_ns() is a small helper that wraps nanouptime() and returns a uint64_t. myfirst_current_context_tag() returns a small code like 'S' for syscall, 'T' for task, 'C' for sysctl; its implementation is a few-line switch on the current thread's identity.)

The read accessor records the read (value is the value read). Access recording happens under the driver mutex (Stage 3 requires the mutex for every register access), so the ring itself needs no additional locking.

Enable with a sysctl:

```
SYSCTL_ADD_BOOL(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "access_log_enabled",
    CTLFLAG_RW, &sc->access_log_enabled, 0,
    "Record every register access in a ring buffer");
```

Expose the log through a special sysctl handler that dumps the ring:

```

static int
myfirst_sysctl_access_log(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    struct sbuf *sb;
    int error;
    unsigned int i, start;

    sb = sbuf_new_for_sysctl(NULL, NULL, 256 * MYFIRST_ACCESS_LOG_SIZE, req);
    if (sb == NULL)
        return (ENOMEM);

    MYFIRST_LOCK(sc);
    start = sc->access_log_head;
    for (i = 0; i < MYFIRST_ACCESS_LOG_SIZE; i++) {
        unsigned int idx = (start + i) % MYFIRST_ACCESS_LOG_SIZE;
        struct myfirst_access_log_entry *e = &sc->access_log[idx];
        if (e->timestamp_ns == 0)
            continue;
        sbuf_printf(sb, "%16ju ns  %s%1d  off=%#04x  val=%#010x  ctx=%c\n",
            (uintmax_t)e->timestamp_ns,
            e->is_write ? "W" : "R", e->width,
            (unsigned)e->offset, e->value, e->context_tag);
    }
    MYFIRST_UNLOCK(sc);

    error = sbuf_finish(sb);
    sbuf_delete(sb);
    return (error);
}

```

The handler walks the ring from the oldest to the newest entry, skipping empty slots, and formats each as a line. The output looks like:

```

123456789 ns  W4  off=0x00  val=0x00000001  ctx=C
123567890 ns  R4  off=0x00  val=0x00000001  ctx=C
124001234 ns  W4  off=0x08  val=0x00000041  ctx=S
124001567 ns  W4  off=0x04  val=0x00000009  ctx=S

```

Four entries: a writeable-sysctl write to CTRL, then its immediate readback (both ctx=C), then a syscall write that set DATA_IN to 0x41 ('A') and updated STATUS to 0x9 (READY | DATA_AV). The context tag makes the source obvious.

For debugging, this log is priceless. You see exactly what the driver did, in order, with timestamps.

16.8.3 Kernel Printf: A Controlled Flood

Sometimes the log is not enough and you want a printed message per register access, perhaps during a specific failing test. The driver should support a knob for that.

Add a debug-level sysctl (if one does not already exist from Chapter 12's `debug_level`) and use it in the accessors:

```
#define MYFIRST_DBG_REGS 0x10u

static __inline void
myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset, uint32_t value)
{
    MYFIRST_ASSERT(sc);
    KASSERT(offset + 4 <= sc->regs_size, (...));

    if ((sc->debug_level & MYFIRST_DBG_REGS) != 0)
        device_printf(sc->dev, "W%d reg= %#04x val= %#010x\n",
            4, (unsigned)offset, value);

    bus_space_write_4(sc->regs_tag, sc->regs_handle, offset, value);

    /* ... access log update ... */
}
```

When `debug_level` has the `MYFIRST_DBG_REGS` bit set, every register write is printed to the console. Setting it during a test and clearing it immediately afterwards gives a focused log without flooding the system for the duration of the driver's life.

The debug-level bitfield is a common FreeBSD pattern. Many real drivers use a sysctl of debug or verbose with bits for different subsystems: `DBG_PROBE`, `DBG_ATTACH`, `DBG_INTR`, `DBG_REGS`, and so on. The user enables only the subset they need.

16.8.4 DTrace Probes

DTrace is the right tool when you want to observe register access patterns without modifying the driver. FreeBSD's `fbt` (function boundary tracing) provider automatically instruments every non-inlined function in the kernel. If `myfirst_reg_read` and `myfirst_reg_write` are compiled as out-of-line functions (not inlined), DTrace can hook them.

By default, `static __inline` functions are candidates for inlining, and inlined functions do not have `fbt` probes. To make the accessors DTrace-visible in debug builds, split the declarations:

```
#ifdef MYFIRST_DEBUG_REG_TRACE
static uint32_t myfirst_reg_read(struct myfirst_softc *sc, bus_size_t offset);
static void myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset,
```

```

        uint32_t value);
#else
static __inline uint32_t myfirst_reg_read(struct myfirst_softc *sc,
        bus_size_t offset);
static __inline void      myfirst_reg_write(struct myfirst_softc *sc,
        bus_size_t offset, uint32_t value);
#endif

```

With MYFIRST_DEBUG_REG_TRACE set at compile time, the accessors are regular functions with function-boundary probes. DTrace can then show every call:

```
# dtrace -n 'fbt::myfirst_reg_write:entry { printf("off=%#x val=%#x", arg1, arg2); }'
```

The output lists every register write with its offset and value, live, across the whole system. DTrace can aggregate, count, filter by stack, and join with process information in ways a hand-rolled log cannot match.

For a release build, leave MYFIRST_DEBUG_REG_TRACE unset; the accessors inline and pay no runtime cost. For a debugging build, set the macro and get full visibility.

16.8.5 Specialised DTrace Probes: sdt(9)

A more targeted alternative to fbt probes is to register Statically Defined Tracepoints (SDT) at specific points in the driver. FreeBSD's sdt(9) API lets you declare probes that DTrace can hook by name, without the overhead of a full function-boundary trace.

A probe for every register write:

```

#include <sys/sdt.h>

SDT_PROVIDER_DEFINE(myfirst);
SDT_PROBE_DEFINE3(myfirst, , , reg_write,
    "struct myfirst_softc *", "bus_size_t", "uint32_t");
SDT_PROBE_DEFINE2(myfirst, , , reg_read,
    "struct myfirst_softc *", "bus_size_t");

```

And in the accessor:

```
SDT_PROBE3(myfirst, , , reg_write, sc, offset, value);
```

DTrace picks up the probe by name:

```
# dtrace -n 'sdt::myfirst:::reg_write { printf("off=%#x val=%#x", arg1, arg2); }'
```

The probe is visible in DTrace regardless of inlining, because the kernel registers it statically. When DTrace is not running the probe, it is a no-op on modern x86 (a single NOP instruction in the inlined expansion).

SDT probes are appropriate for production code. They are permanent, named, documented parts of the driver interface. A driver's users might rely on specific SDT probe names for their own monitoring tools; removing them breaks those tools.

Chapter 16 introduces SDT lightly. Later chapters (especially Chapter 23 on debugging and tracing) dig in.

16.8.6 The Heartbeat Log From Stage 1 Onwards

One piece of instrumentation the driver already has is Chapter 13's heartbeat callout. With Chapter 16's register state added, the heartbeat becomes more informative if it prints a register snapshot:

```
static void
myfirst_heartbeat_cb(void *arg)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_ASSERT(sc);
    if (!myfirst_is_attached(sc))
        return;

    if (sc->debug_level & MYFIRST_DBG_HEARTBEAT) {
        uint32_t ctrl, status;
        ctrl = sc->regs_buf != NULL ?
            MYFIRST_REG_READ(sc, MYFIRST_REG_CTRL) : 0;
        status = sc->regs_buf != NULL ?
            MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) : 0;
        device_printf(sc->dev,
            "heartbeat: ctrl=0x%x status=0x%x open=%d writers=%d\n",
            ctrl, status, sc->open_count,
            sema_value(&sc->writers_sema));
    }

    /* ... existing heartbeat work (stall detection, etc.) ... */

    callout_reset(&sc->heartbeat_co,
        msecs_to_ticks(sc->heartbeat_interval_ms),
        myfirst_heartbeat_cb, sc);
}
```

With the heartbeat bit set and a 1-second interval, the driver logs its register state every second. During a failing test, the heartbeat output often shows exactly when the state went off the rails.

16.8.7 Using kgdb on a Core Dump

When a driver panics, the kernel produces a core dump. kgdb can read the dump and inspect the softc. With the register block inside the softc, a single command can print the current register values:

```
(kgdb) print *((struct myfirst_softc *)0xffffffff8000a123400)
(kgdb) x/16xw ((struct myfirst_softc *)0xffffffff8000a123400)->regs_buf
```

The x/16xw command dumps 16 words in hex at the register buffer's address. The output is literally the 64 bytes of register state at the moment of panic. A developer staring at those bytes can often spot the wrong value that led to the panic.

The reason this works is the simulation: regs_buf is kernel memory, visible to kgdb. A real device's registers would not be visible in a core dump, because the core dump captures RAM only, not device state. For simulated devices and DMA descriptors, a core dump is a gold mine.

16.8.8 DDB Extensions

For live debugging without a panic, ddb can be extended with driver-specific commands. The DB_COMMAND macro registers a new command that ddb recognises at the prompt:

```
#include <ddb/ddb.h>

DB_COMMAND(myfirst_regs, myfirst_ddb_regs)
{
    struct myfirst_softc *sc;

    /* ... find the softc, e.g., via devclass ... */
    if (sc == NULL || sc->regs_buf == NULL) {
        db_printf("myfirst: no device or no regs\n");
        return;
    }

    db_printf("CTRL    %#010x\n", *(uint32_t *) (sc->regs_buf + 0x00));
    db_printf("STATUS  %#010x\n", *(uint32_t *) (sc->regs_buf + 0x04));
    db_printf("DATA_IN  %#010x\n", *(uint32_t *) (sc->regs_buf + 0x08));
    /* ... and so on ... */
}
```

At the db> prompt during a break:

```
db> myfirst_regs
CTRL    0x00000001
STATUS  0x00000009
```

```
DATA_IN 0x0000006f
...
```

ddb commands are a niche tool. Chapter 16 introduces them to show that they exist. Later chapters (especially Chapter 23) use them more. For now, the access log and DTrace cover most day-to-day debugging.

16.8.9 What to Do When a Register Read Returns Garbage

A short field guide to the most common mistakes that produce a “garbage” register value, with the diagnostic to try for each.

Wrong offset. The offset in the code does not match the offset in the datasheet. Diagnostic: cross-check the offset against the datasheet, and audit the header for transcription errors.

Wrong width. The code reads 32 bits of a 16-bit register, or reads 8 bits of a 32-bit register. Diagnostic: verify the width in the datasheet, and adjust the call.

Missing virtual mapping. The resource was allocated without `RF_ACTIVE`, or the driver is reading from a saved pointer that points to freed memory. Diagnostic: confirm `bus_alloc_resource_any` was called with `RF_ACTIVE`; assert `sc->regs_buf != NULL` before reading in the simulation path.

Race with another writer. Another context wrote a different value between the read and the expected observation. Diagnostic: enable the access log, reproduce the issue, inspect the log.

Read-to-clear side effect the code did not expect. The previous read cleared the bits you now expect to see. Diagnostic: check the datasheet for read side effects; consider whether the reading code should cache the value.

Cache attribute mismatch. On platforms where it matters, the virtual mapping was set up with wrong cache attributes. Diagnostic: not usually a problem on x86 with `bus_alloc_resource_any`; on other platforms, check `pmap_mapdev_attr` and the bus provider. Rare in practice if you are using the standard bus allocation path.

Endianness mismatch. On a big-endian device accessed from a little-endian CPU without the right tag or stream accessor, the bytes come back in the wrong order. Diagnostic: compare the value byte-swapped; if it now makes sense, you need the `_stream_` accessors or a swap-aware tag.

Each diagnosis points to a different fix. Keeping them in mind saves hours.

16.8.10 What to Do When a Register Write Has No Effect

Sister field guide for writes.

The register is read-only or write-once. The datasheet defines the register as readable only, or writable only until the first successful write. Diagnostic: check the datasheet’s direction column.

The write was masked out. The register has bits that are writable only under specific conditions (device disabled, chip in test mode, a specific field set). Diagnostic: enable `debug_level` printing; confirm the write happened; then check the device’s state.

The write was reordered. A barrier-needed sequence was issued without barriers, and the device saw the writes in a different order than the code intended. Diagnostic: add explicit `bus_space_barrier` calls and retest.

The write was lost to a concurrent read-modify-write. Another context clobbered the new value. Diagnostic: access log; locking audit.

The write went to the wrong offset. A transcription error or an arithmetic mistake aimed the write at a different register. Diagnostic: access log; comparison with the datasheet.

The overlap with the read diagnostic is high: most issues boil down to “the code is not doing what you think it is”, and the access log is the most direct way to see what the code is doing.

16.8.11 A Lab: The Access Log Does Its Job

A small exercise that shows the access log paying off. Enable it, exercise the driver, dump the log.

```
# sysctl dev.myfirst.0.access_log_enabled=1
# sysctl dev.myfirst.0.reg_ticker_enabled=1
# echo hello > /dev/myfirst0
# dd if=/dev/myfirst0 bs=1 count=6 of=/dev/null
# sysctl dev.myfirst.0.reg_ticker_enabled=0
# sysctl dev.myfirst.0.access_log_enabled=0
# sysctl dev.myfirst.0.access_log
```

The last `sysctl` emits several dozen lines: the ticker’s `SCRATCH_A` increments, the write’s `DATA_IN` update and `STATUS ORing`, the read’s `DATA_OUT` update and `STATUS AND-ing`, and every `sysctl`-driven read of a register along the way. The log reads like a transcript of the driver’s conversation with itself.

A beginner who sees this transcript for the first time usually has a moment of recognition: “oh, *that* is what the driver is doing under the covers”. The moment is the whole point of the exercise.

16.8.12 Wrapping Up Section 7

The register access path is invisible by default. A small observability layer makes it visible: a ring buffer of recent accesses, a debug bitfield that controls per-access `printf`, `DTrace` probes through `fbt` or `sdt`, an enhanced heartbeat that logs register snapshots, and `ddb` or `kgdb` access to the `softc` for post-mortem inspection. Each tool fits a different use case, and together they cover almost every register-level bug a driver can have.

Section 8 consolidates everything Chapter 16 has added into a refactored, documented, versioned driver. The final stage.

16.9 Section 8: Refactoring and Versioning Your MMIO-Ready Driver

Stage 3 produced a correct driver. Section 8 produces a maintainable one. The changes Stage 4 makes are organisational: split the hardware-access code out of `myfirst.c` into its own file, wrap the remaining register accesses in macros that mirror the `CSR_*` idiom real drivers use, update `HARDWARE.md` to its final form, bump the version to `0.9-mmio`, and run the full regression pass.

A driver that works is valuable. A driver that works *and* reads cleanly to the next person who opens it is far more valuable. Section 8 is about that second step.

16.9.1 The File Split

Through Chapter 15, the `myfirst` driver lived in one C file plus a header. Chapter 16 adds about 200 to 300 lines of hardware-access code, which is enough that a reader opening `myfirst.c` is now greeted by a mix of “driver business logic” and “hardware register mechanics” that compete for attention.

Stage 4 separates them. Create a new file `myfirst_hw.c` alongside `myfirst.c`. Move into it:

- The accessor implementations (`myfirst_reg_read`, `myfirst_reg_write`, `myfirst_reg_update`, `myfirst_reg_write_barrier`).
- The register-driven side-effect helpers (`myfirst_ctrl_update`).
- The ticker task callback (`myfirst_reg_ticker_cb`).
- The access log rotation helpers.
- The sysctl handlers for register views (`myfirst_sysctl_reg`, `myfirst_sysctl_reg_write`, `myfirst_sysctl_access_log`).

Move into `myfirst_hw.h`:

- Register offsets and bit masks (already there).
- Fixed-value constants (already there).
- Function prototypes for the hardware-access API (`myfirst_hw_attach`, `myfirst_hw_detach`, `myfirst_hw_set_ctrl`, `myfirst_hw_add_sysctls`, etc.).
- A small struct defining the hardware state (fewer softc fields, more grouping).

The remaining `myfirst.c` keeps:

- The softc declaration (including a struct `myfirst_hw` *hw pointer to a sub-struct for hardware state).
- The driver lifecycle (`attach`, `detach`, `module init`).
- The syscall handlers (`open`, `close`, `read`, `write`, `ioctl`, `poll`, `kqfilter`).
- The callout callbacks (`heartbeat`, `watchdog`, `tick_source`).
- The non-hardware tasks (`selwake`, `bulk_writer`, `reset_delayed`, `recovery`).
- The non-hardware sysctls.

This split mirrors how real drivers with multiple subsystems organise themselves. A network driver might have `foo.c` for the main lifecycle, `foo_hw.c` for hardware access, `foo_rx.c` for the receive path, `foo_tx.c` for the transmit path. The principle is that each file holds code of one kind, and cross-file calls go through a named API.

16.9.2 The Hardware State Structure

Inside `myfirst_hw.h`, group the hardware-related fields into their own structure:

```
struct myfirst_hw {  
    uint8_t                *regs_buf;
```

```

    size_t          regs_size;
    bus_space_tag_t  regs_tag;
    bus_space_handle_t regs_handle;

    struct task      reg_ticker_task;
    int              reg_ticker_enabled;

    struct myfirst_access_log_entry access_log[MYFIRST_ACCESS_LOG_SIZE];
    unsigned int     access_log_head;
    bool             access_log_enabled;
};

```

Add a pointer to it in the softc:

```

struct myfirst_softc {
    /* ... existing fields ... */
    struct myfirst_hw *hw;
};

```

Allocate the hw struct in myfirst_hw_attach:

```

int
myfirst_hw_attach(struct myfirst_softc *sc)
{
    struct myfirst_hw *hw;

    hw = malloc(sizeof(*hw), M_MYFIRST, M_WAITOK | M_ZERO);

    hw->regs_size = MYFIRST_REG_SIZE;
    hw->regs_buf = malloc(hw->regs_size, M_MYFIRST, M_WAITOK | M_ZERO);
    #if defined(__amd64__) || defined(__i386__)
        hw->regs_tag = X86_BUS_SPACE_MEM;
    #else
        #error "Chapter 16 simulation supports x86 only"
    #endif

    hw->regs_handle = (bus_space_handle_t)(uintptr_t)hw->regs_buf;

    TASK_INIT(&hw->reg_ticker_task, 0, myfirst_hw_ticker_cb, sc);

    /* Initialise fixed registers. */
    bus_space_write_4(hw->regs_tag, hw->regs_handle, MYFIRST_REG_DEVICE_ID,
        MYFIRST_DEVICE_ID_VALUE);
    bus_space_write_4(hw->regs_tag, hw->regs_handle, MYFIRST_REG_FIRMWARE_REV,

```

```

        MYFIRST_FW_REV_VALUE);
    bus_space_write_4(hw->regs_tag, hw->regs_handle, MYFIRST_REG_STATUS,
        MYFIRST_STATUS_READY);

    sc->hw = hw;
    return (0);
}

```

Free it in `myfirst_hw_detach`:

```

void
myfirst_hw_detach(struct myfirst_softc *sc)
{
    struct myfirst_hw *hw;

    if (sc->hw == NULL)
        return;
    hw = sc->hw;
    sc->hw = NULL;

    taskqueue_drain(sc->tq, &hw->reg_ticker_task);
    if (hw->regs_buf != NULL) {
        free(hw->regs_buf, M_MYFIRST);
        hw->regs_buf = NULL;
    }
    free(hw, M_MYFIRST);
}

```

The `myfirst_attach` and `myfirst_detach` functions now call `myfirst_hw_attach(sc)` and `myfirst_hw_detach(sc)` at the appropriate points in their ordering. The hardware sub-attach fits between “softc locks initialised” and “cdev registered”; the hardware sub-detach fits between “tasks drained” and “sysctl context released”.

16.9.3 The CSR Macros

Wrap the register accesses in macros that match the real-driver idiom:

```

#define CSR_READ_4(sc, off) \
    myfirst_reg_read((sc), (off))
#define CSR_WRITE_4(sc, off, val) \
    myfirst_reg_write((sc), (off), (val))
#define CSR_UPDATE_4(sc, off, clear, set) \
    myfirst_reg_update((sc), (off), (clear), (set))

```

The driver body now reads:

```
/* In myfirst_write: */
CSR_WRITE_4(sc, MYFIRST_REG_DATA_IN, (uint32_t)last_byte);
CSR_UPDATE_4(sc, MYFIRST_REG_STATUS, 0, MYFIRST_STATUS_DATA_AV);

/* In the ticker: */
uint32_t v = CSR_READ_4(sc, MYFIRST_REG_SCRATCH_A);
CSR_WRITE_4(sc, MYFIRST_REG_SCRATCH_A, v + 1);

/* In the heartbeat: */
uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
```

The call sites read like they are talking to hardware, because that is exactly what the abstraction represents. A newcomer opening the driver and reading any of these lines immediately understands what is happening: the driver is reading or writing a register named by a constant from the hardware header.

16.9.4 Moving Sysctls

The register-view sysctls move to `myfirst_hw_add_sysctls`:

```
void
myfirst_hw_add_sysctls(struct myfirst_softc *sc)
{
    /* ... SYSCTL_ADD_PROC calls for every register ... */
    /* ... SYSCTL_ADD_BOOL for ticker_enabled ... */
    /* ... SYSCTL_ADD_PROC for access_log ... */
}
```

The function is called from `myfirst_attach` at the usual point where sysctls are registered. The main file no longer needs to care about which sysctls exist for hardware; it delegates.

16.9.5 Final `HARDWARE.md`

With the file split and API stable, `HARDWARE.md` finalises:

```
# myfirst Hardware Interface

## Version

0.9-mmio. Chapter 16 complete.

## Register Block
```

- Size: 64 bytes (MYFIRST_REG_SIZE)
- Access: 32-bit reads and writes on 32-bit-aligned offsets
- Storage: malloc(9), M_WAITOK|M_ZERO, allocated in myfirst_hw_attach, freed in myfirst_hw_detach
- bus_space_tag: X86_BUS_SPACE_MEM (x86 only, simulation shortcut)
- bus_space_handle: pointer to the malloc'd block

API

All register access goes through:

- CSR_READ_4(sc, offset): read a 32-bit register
- CSR_WRITE_4(sc, offset, value): write a 32-bit register
- CSR_UPDATE_4(sc, offset, clear, set): read-modify-write

The driver's main mutex (sc->mtx) must be held for every register access. Accessor macros assert this via MYFIRST_ASSERT.

Register Map

(table as in Section 4 ...)

Per-Register Owners

(table as in Section 6 ...)

Observability

- dev.myfirst.0.reg_*: read each register (sysctl)
- dev.myfirst.0.reg_ctrl_set: write CTRL (sysctl, Stage 1 demo aid)
- dev.myfirst.0.access_log_enabled: record access ring
- dev.myfirst.0.access_log: dump recorded accesses
- Debug bit MYFIRST_DBG_REGS in debug_level: printf per access

Architecture Portability

The simulation path uses X86_BUS_SPACE_MEM as the tag and a kernel virtual address as the handle. On non-x86 platforms, bus_space_tag_t is a pointer to a structure and this shortcut does not compile; Chapter 17 introduces a portable alternative. Real-hardware Chapter 18 drivers use rman_get_bustag and rman_get_bushandle on a resource from bus_alloc_resource_any, which is portable by design.

The document is now a single source of truth for how the driver accesses hardware. A future contributor reads it once to understand the interface and never again needs to reverse-engineer it from code.

16.9.6 The Version Bump

In `myfirst.c`:

```
#define MYFIRST_VERSION "0.9-mmio"
```

The string appears in `kldstat -v` output (through `MODULE_VERSION`) and in the `device_printf` at attach time. Bumping it is a small change with a big signalling value: anyone looking at the running driver knows exactly which chapter's features it has.

Update the top-of-file comment to note the additions:

```
/*
 * myfirst: a beginner-friendly device driver tutorial vehicle.
 *
 * Version 0.9-mmio (Chapter 16): adds a simulated MMIO register
 * block with bus_space(9) access, lock-protected register updates,
 * barrier-aware writes, an access log, and a refactored layout that
 * splits hardware-access code into myfirst_hw.c and myfirst_hw.h.
 *
 * ... (previous version notes preserved) ...
 */
```

The top-of-file comment is the shortest path for a newcomer to understand the driver's history. Keeping it current is a small discipline with a big payoff.

16.9.7 The Final Regression Pass

Chapter 15 established the regression discipline: after every version bump, run the full stress suite from every previous chapter, confirm WITNESS is silent, confirm INVARIANTS is silent, confirm `kldunload` completes cleanly.

For Stage 4 that means:

- The Chapter 11 concurrency tests (multiple writers, multiple readers) pass.
- The Chapter 12 blocking tests (reader waits for data, writer waits for room) pass.
- The Chapter 13 callout tests (heartbeat, watchdog, tick source) pass.
- The Chapter 14 task tests (selwake, bulk writer, delayed reset) pass.
- The Chapter 15 coordination tests (writers sema, stats cache, interruptible waits) pass.
- The Chapter 16 register tests (see the Hands-On Labs below) pass.
- `kldunload myfirst` returns cleanly after the full suite.

No test is skipped. A regression in any previous chapter's test is a bug, not a deferred issue. The discipline is the same as it has been throughout Part 3.

16.9.8 Running the Final Stage

```
# cd examples/part-04/ch16-accessing-hardware/stage4-final
# make clean && make
# kldstat | grep myfirst
# kldload ./myfirst.ko
# kldstat -v | grep -i myfirst
# dmesg | tail -5
# sysctl dev.myfirst.0 | head -40
```

The `kldstat -v` output should show `myfirst` at version `0.9-mmio`. The `dmesg` tail should show the device probe and attach with no errors. The `sysctl` output should list every Chapter 11 through Chapter 16 `sysctl`, including the register `sysctls`.

Run the stress suite:

```
# ../labs/full_regression.sh
```

If every test passes, Chapter 16 is complete.

16.9.9 A Small Rule for Chapter 16's Refactor

A rule of thumb that Stage 4 embodies: when a module acquires a new responsibility, give it its own file before the responsibility grows big enough to require one. Chapter 16 adds register access as a new responsibility. The responsibility is currently small: 200 to 300 lines across all the code. Splitting it into `myfirst_hw.c` now, while it is still small, is cheap. Splitting it later, when Chapter 18 adds PCI attach logic and Chapter 19 adds an interrupt handler and Chapter 20 adds DMA, would require disentangling three intertwined subsystems at once, which is expensive.

The same rule applied to Chapter 10's `cbuf`: the ring buffer got its own `cbuf.c` as soon as it had any logic beyond “declare a struct”, which paid off when concurrency and state machines entered the picture. It applies to every future subsystem this driver grows.

16.9.10 What Stage 4 Accomplished

The driver is now at `0.9-mmio`. Compared to `0.9-coordination`, it has:

- A separate hardware-access layer in `myfirst_hw.c` and `myfirst_hw.h`.
- A full register map, documented in `myfirst_hw.h` and `HARDWARE.md`.
- `bus_space(9)`-based register accessors wrapped in `CSR_*` macros.
- Lock-protected, barrier-aware register access.
- An access log for post-hoc debugging.
- Per-register context ownership documented in `HARDWARE.md`.
- A ticker task that demonstrates autonomous register behaviour.

- An end-to-end path from user-space write to register update to user-space read.

The driver's code is recognisably FreeBSD. The layout is the layout real drivers use. The vocabulary is the vocabulary real drivers share. A reader opening the driver for the first time finds a familiar structure, reads the headers to understand the registers, and can navigate the code by subsystem.

16.9.11 Wrapping Up Section 8

The refactor is small in code but large in organisation. A file split, a structure grouping, a macro layer, a documented interface, a version bump, and a regression pass. Each is a few minutes of work. Together they turn a correct driver into a maintainable one.

The Chapter 16 driver is done. The chapter closes with labs, challenges, troubleshooting, and a bridge to Chapter 17, where the simulated device acquires dynamic behaviour.

16.10 Hands-On Labs

Labs in Chapter 16 focus on two things: observing register access while exercising the driver, and breaking the register contract to see how the driver reacts. Each lab takes 15 to 45 minutes.

16.10.1 Lab 1: Observe the Register Dance

Enable the access log. Exercise the driver across its full interface. Dump the log. Read the transcript.

```
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.access_log_enabled=1

# echo -n "hello" > /dev/myfirst0
# dd if=/dev/myfirst0 bs=1 count=5 of=/dev/null 2>/dev/null
# sysctl dev.myfirst.0.reg_ctrl_set=1
# sysctl dev.myfirst.0.reg_ticker_enabled=1
# sleep 2
# sysctl dev.myfirst.0.reg_ticker_enabled=0

# sysctl dev.myfirst.0.access_log
```

You should see, in order:

- Five writes to `DATA_IN` (one per byte of “hello”).
- Updates to `STATUS` setting the `DATA_AV` bit.
- Five writes to `DATA_OUT` (one per byte read).
- Updates to `STATUS` clearing the `DATA_AV` bit as the buffer drains.
- The `sysctl`-driven `CTRL` write to enable, plus the read-back.
- Two increments of `SCRATCH_A` from the ticker.

Read each line. Every value should make sense. If a value does not make sense, the driver has a bug, the test has a typo, or your understanding of the register protocol has a gap.

16.10.2 Lab 2: Trigger a Lock Violation (Debug Kernel)

This lab only works on a kernel built with WITNESS enabled. If you are not running one, skip this lab.

Temporarily remove the MYFIRST_LOCK(sc) from the sysctl read handler. Rebuild and reload the driver. Run:

```
# sysctl dev.myfirst.0.reg_ctrl
```

The console should emit a WITNESS warning about an unprotected register access (via the MYFIRST_ASSERT in myfirst_reg_read). The sysctl output may still return a plausible value, because the lack of locking does not always produce incorrect results, but the assertion makes the violation visible.

Restore the lock. Rebuild. Verify the warning is gone.

This lab demonstrates the value of MYFIRST_ASSERT as a safety net. A production driver without the assertion would carry the bug silently until something went wrong.

16.10.3 Lab 3: Simulate a Concurrent Writer Race

Two processes writing simultaneously to /dev/myfirst0 exercise the register update code path twice over. Run:

```
# for i in 1 2 3 4; do
    (for j in $(seq 1 100); do echo -n "$i"; done > /dev/myfirst0) &
done
# wait

# sysctl dev.myfirst.0.reg_data_in
# sysctl dev.myfirst.0.reg_status
```

The DATA_IN register should hold the ASCII code of whichever writer ran last ('1' = 49, '2' = 50, '3' = 51, '4' = 52). The result is non-deterministic, which is the point: register state from concurrent writers reflects the last winner.

With Stage 3 locking, the driver is correct (no lost updates, no torn reads). Without Stage 3 locking (try reverting to Stage 2 and re-running), you may observe inconsistencies or WITNESS warnings.

16.10.4 Lab 4: Watch the Heartbeat Register Log

Enable the heartbeat debug bit, increase the interval, and let it run.

```
# sysctl dev.myfirst.0.debug_level=0x8      # MYFIRST_DBG_HEARTBEAT
# sysctl dev.myfirst.0.heartbeat_interval_ms=1000
# sysctl dev.myfirst.0.reg_ticker_enabled=1
# sleep 5
# dmesg | tail -10

# sysctl dev.myfirst.0.reg_ticker_enabled=0
# sysctl dev.myfirst.0.debug_level=0
# sysctl dev.myfirst.0.heartbeat_interval_ms=0
```

The dmesg tail should contain five lines, one per heartbeat, each showing the current register values. `SCRATCH_A` should climb by one per heartbeat because the ticker is firing in parallel.

This lab demonstrates how a production driver might use a debug log to observe live behaviour without interrupting the driver's normal operation.

16.10.5 Lab 5: Add a New Register

A practical exercise. Add a new register `SCRATCH_C` at offset `0x28`. Extend the header, extend the sysctl list, extend `HARDWARE.md`. Rebuild, reload, and verify the new register is readable and writable via sysctl.

This exercises the full workflow of adding a register: header change, sysctl addition, documentation update, test. A driver that makes all four steps easy is a well-organised driver.

16.10.6 Lab 6: Inject a Bogus Access (Debug Kernel)

A deliberate break-and-observe exercise.

Modify the ticker callback to read from an out-of-bounds offset: `MYFIRST_REG_READ(sc, 0x80)`. Rebuild. Enable the ticker. On a debug kernel with `INVARIANTS`, the `KASSERT` in `myfirst_reg_read` should panic the kernel within a few seconds, with the panic string naming the offset.

Restore the callback. Rebuild. Verify the driver runs cleanly again.

This lab shows the value of bounds assertions: an out-of-bounds access fires immediately instead of silently corrupting nearby memory. Production code should never remove these assertions; they pay their cost many times over the life of the driver.

16.10.7 Lab 7: Trace With DTrace

Compile the driver with `CFLAGS+=-DMYFIRST_DEBUG_REG_TRACE` to make the accessors out-of-line. Rebuild and reload.

Run DTrace:

```
# dtrace -n 'fbt::myfirst_reg_write:entry {  
    printf("off=%#x val=%#x", arg1, arg2);  
}'
```

In another terminal:

```
# echo hi > /dev/myfirst0
```

DTrace should print two lines, one per register write (DATA_IN and the STATUS update).

Try more advanced queries:

```
# dtrace -n 'fbt::myfirst_reg_write:entry /arg1 == 0/ { @ = count(); }'
```

Counts writes to CTRL (offset 0) for the duration of the run. Leave it running while triggering various operations, then Ctrl-C to see the total.

DTrace's power comes from the combination of low overhead, flexible filtering, and rich aggregation. A beginner who grows comfortable with it early will save hours on every later debugging session.

16.10.8 Lab 8: The Watchdog-Meets-Register Scenario

The Chapter 13 watchdog callout was introduced to catch stalls in the ring buffer. Chapter 16's register integration adds a second failure mode: the watchdog could detect a register in an impossible state. Extend the watchdog callback to complain if STATUS.ERROR is set:

```
if (MYFIRST_REG_READ(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_ERROR) {  
    device_printf(sc->dev, "watchdog: STATUS.ERROR is set\n");  
}
```

Set the error bit from a sysctl handler:

```
# sysctl dev.myfirst.0.reg_ctrl_set=? # use your writeable-register sysctl
```

(You can similarly make a writeable sysctl for STATUS to trigger the watchdog check.)

On the next watchdog tick (default 5 seconds), the message should appear. Clear the bit; the message should stop.

This lab integrates the register path with the callout-driven monitoring path, showing how the two subsystems compose.

16.11 Challenge Exercises

Challenges go further than labs. Each should take one to four hours and exercises judgment, not just keystrokes.

16.11.1 Challenge 1: Per-File-Handle Register Snapshot

Each open file descriptor gets its own snapshot of the register block, captured at open time and accessible via a custom ioctl. Modify `myfirst_open` to snapshot the registers into a per-fd structure; implement an ioctl that returns the snapshot; write a user-space program that opens `/dev/myfirst0`, fetches the snapshot, and prints it.

Think about: how much memory does the snapshot cost per open? When should the snapshot be refreshed? Should a second ioctl be added to refresh?

16.11.2 Challenge 2: Register Diff Logging

Extend the access log to record only *changes* to registers (where the new value differs from the previous value at the same offset). Writes that do not change the value are not logged. This compresses the log significantly and focuses it on meaningful state transitions.

Think about: how do you track the “previous value”? Is it per-offset, or do you store it alongside each log entry?

16.11.3 Challenge 3: Loopback Mode

Add a `CTRL.LOOPBACK` bit (already defined in `myfirst_hw.h`). When the bit is set, writes to `DATA_IN` are also copied to `DATA_OUT`, making the driver “loop back” user-space writes without needing a read. Implement the logic, add a lab test, and confirm user-space reads return the bytes just written.

Think about: where in the write path does the copy belong? Is it still correct if multiple bytes are written in one call? Do you set `DATA_AV` differently in loopback mode?

16.11.4 Challenge 4: Read-to-Clear on `INTR_STATUS`

The Chapter 16 simulation has `INTR_STATUS` as a plain register. Real hardware often uses read-to-clear semantics. Implement them: make the sysctl read of `reg_intr_status` return the current value and then clear it, so the next read returns zero. Add a way to set pending bits (a writeable sysctl that ORs into the register).

Think about: is the read-to-clear behaviour safe for the debug sysctl? How do you handle the case where the sysctl is used to observe the value?

16.11.5 Challenge 5: A Barrier Correctness Stress Test

Write a stress harness that exercises a specific pattern: write to `CTRL`, issue a barrier, read `STATUS`, verify the read reflects the write. Run it thousands of times, measure how often the verification fails. On x86 with correct barriers, failures should be zero.

Then remove the barrier and run again. On x86, failures might still be zero (strong memory model). On arm64 (if you have access), removing the barrier may produce failures.

Think about: what does this exercise tell you about the cost and value of barriers on different architectures? Should a driver always include them?

16.11.6 Challenge 6: A Register-Aware Lockstat Run

Use lockstat to profile your Stage 3 driver under load. Identify the hottest locks. Is the driver mutex (sc->mtx) saturated by register access, or by the ring buffer path, or by neither? Generate a report and interpret the numbers.

Think about: does the result change if you split out a dedicated sc->reg_mtx for register access? Do WITNESS warnings appear? Is the driver faster or slower?

16.11.7 Challenge 7: Read a Real Driver's Register Interface

Pick a real driver in /usr/src/sys/dev/ and read its register header. Candidates include /usr/src/sys/dev/ale/if_alereg.h, /usr/src/sys/dev/e1000/e1000_regs.h, and /usr/src/sys/dev/uart/uart_dev_ns8250.h. Answer:

- How many registers does the driver define?
- What width are they (8, 16, 32, 64 bits)?
- Which registers have bit-field macros? Are there any bit-field macros that correspond to fields spanning multiple bytes?
- How does the driver wrap bus_read_* and bus_write_* (if at all)?
- How are the register offsets documented (comments, external spec references)?

Writing up the answers as a one-page analysis is a great way to consolidate Chapter 16's material. You will likely also find patterns you want to apply to your own driver.

16.12 Troubleshooting Reference

A quick reference for the problems Chapter 16's code is most likely to surface.

16.12.1 Driver fails to load

- **“resolve_symbol failed”**: Missing include or a typo in a function name. Check /var/log/messages for the exact symbol; add the include; retry.
- **“undefined reference to bus_space_read_4”**: Missing #include <machine/bus.h>. This pulls in the per-architecture bus header.
- **“invalid KMOD Makefile”**: A typo in the Makefile. Compare against the stage's known-good Makefile.

16.12.2 Driver loads but dmesg shows myfirst: cannot allocate register block

malloc(9) returned NULL at attach. Usually means M_WAITOK was passed but the system was under memory pressure; rare for a 64-byte allocation. Check the kernel's malloc statistics (vmstat -m) for myfirst. Try a reboot.

16.12.3 `sysctl dev.myfirst.0.reg_ctrl` returns `ENOENT`

The `sysctl` was not registered. Confirm `myfirst_hw_add_sysctls` is called in `attach`. Confirm the `sysctl` context and tree are the same as the rest of the driver's `sysctls`. Look for a typo in `OID_AUTO` or the leaf name.

16.12.4 `sysctl dev.myfirst.0.reg_ctrl` returns a plausible value, but changes never happen

The writeable `sysctl reg_ctrl_set` might be missing `CTLFLAG_RW`. Without `_RW`, the `sysctl` is read-only. Also check the handler is not short-circuiting because of an early `ENODEV` return.

16.12.5 Kernel panic on first register write: “page fault in kernel mode”

`sc->regs_buf` is `NULL` or dangling. Confirm `myfirst_hw_attach` ran successfully and set `sc->hw->regs_buf`. Confirm nothing freed the buffer prematurely (detach running in parallel, or a `free` in an error path).

16.12.6 Kernel panic: “myfirst: register read past end of register block”

The `KASSERT` fired. A bug in the driver is passing an out-of-range offset. Use the crash stack to find the call site. Common cause: an arithmetic expression for the offset that exceeds `MYFIRST_REG_SIZE`.

16.12.7 WITNESS warning: “acquiring duplicate lock”

Usually a sign that a call chain is acquiring `sc->mtx` recursively. The Chapter 11 mutex is a sleep mutex without the `MTX_RECURSE` flag, which is correct. Trace the stack; one of the callers is re-entering.

16.12.8 WITNESS warning: “lock order reversal”

The driver is holding `sc->mtx` while acquiring another lock (or vice versa) in an order that violates the documented order. Check `LOCKING.md` against the stack trace and fix the call site.

16.12.9 Ticker does not fire

The tick source callout's interval is zero (disabled). Confirm `dev.myfirst.0.tick_source_interval_ms` is positive. Confirm `reg_ticker_enabled` is 1. Look at the access log for `SCRATCH_A` writes; if there are none, the callout is the problem. If there are, the `sysctl` may be stale (re-read it).

16.12.10 Access log returns empty

Confirm `access_log_enabled` is 1. Confirm the driver mutex is being acquired in access paths (the log update happens under the lock). If the log is genuinely empty but registers should have been accessed, check the access paths for missing accessor calls.

16.12.11 dmesg shows no output from myfirst_ctrl_update

The `debug_level` is 0, or the specific bit is not set. Set `debug_level` to include the right bits and retry.

16.12.12 kldunload myfirst returns EBUSY

Open file descriptors still exist on the device. Close them (or use `fstat -f /dev/myfirst0` to find who holds them) and retry.

16.12.13 kldunload myfirst hangs

Detach is stuck draining a primitive. Use `procstat -kk <pid-of-kldunload>` to see where. Usually the stuck drain is a task or callout that is not cancelling. Check the detach ordering against `LOCKING.md`.

16.12.14 The stress test complains about WITNESS warnings

Each warning is a real bug. Fix one, retest, continue. Do not mass-disable WITNESS and call the issue resolved; the warnings are pointing at the problem.

16.13 Wrapping Up

Chapter 16 opened Part 4 by giving the `myfirst` driver its first hardware story. The driver now has a register block, even if that block is simulated. It uses `bus_space(9)` the way a real driver does. It protects register access with the Chapter 11 mutex, inserts barriers where ordering matters, and documents every register and every access path. It has an access log for post-hoc debugging, DTrace probes for live observation, and a `ddb` command for live inspection. It is organised across two files: the main driver lifecycle and the hardware-access layer.

What Chapter 16 deliberately did not do: real PCI (Chapter 18), real interrupts (Chapter 19), real DMA (Chapters 20 and 21), full hardware simulation with dynamic behaviour (Chapter 17). Each of those topics deserves its own chapter; each builds on Chapter 16's vocabulary.

The version is 0.9-mmio. The file layout is `myfirst.c` plus `myfirst_hw.c` plus `myfirst_hw.h` plus `myfirst_sync.h` plus `cbuf.c` plus `cbuf.h`. The documentation is `LOCKING.md` plus the new `HARDWARE.md`. The test suite has grown by the Chapter 16 labs. Every earlier Part 3 test still passes.

16.13.1 A Reflection Before Chapter 17

A pause before the next chapter. Chapter 16 was a careful introduction to a set of ideas that will recur for the rest of Part 4 and beyond. The register read and write, the barrier, the bus tag and handle, the locking discipline around MMIO: these are the pieces every later hardware-facing chapter uses without re-teaching them. You have met them all once, in a setting where you could observe, experiment, and make mistakes safely.

The same pattern that defined Part 3 defines Part 4: introduce a primitive, apply it to the driver in a small refactor, document it, test it, move on. The difference is that Part 4's primitives face outward. The driver is no longer a

self-contained world; it is a participant in a conversation with hardware. That conversation has rules the driver must respect, and the rules have consequences when they are broken.

Chapter 17 makes the hardware side of the conversation more interesting. The simulated device will grow a callout that changes STATUS bits over time. It will signal “data available” after a write by flipping a bit on a delay. It will fail occasionally to teach error-handling paths. The register vocabulary stays the same; the device behaviour becomes richer.

16.13.2 What to Do If You Are Stuck

If the Chapter 16 material feels overwhelming on first pass, a few suggestions.

First, re-read Section 3. The `bus_space` vocabulary is the foundation; if it is shaky, everything else is shaky.

Second, type Stage 1 by hand, end to end, and run it. Muscle memory produces understanding in a way that reading does not.

Third, open `/usr/src/sys/dev/ale/if_alevar.h` and find the `CSR_*` macros. The real driver’s idiom is the same as your Stage 4’s. Seeing the pattern in a production driver makes the abstraction feel less arbitrary.

Fourth, skip the challenges on first pass. The labs are calibrated for Chapter 16; the challenges assume the chapter’s material is already solid. Come back to them after Chapter 17 if they feel out of reach now.

Chapter 16’s goal was clarity of vocabulary. If you have that, the rest of Part 4 will feel navigable.

16.14 Bridge to Chapter 17

Chapter 17 is titled *Simulating Hardware*. Its scope is the deeper simulation that Chapter 16 deliberately stepped around: a register block whose contents change over time, whose protocol has side effects, and whose failures can be injected deliberately for testing. The driver at `0.9-mmio` has a register block that behaves statically; Chapter 17 makes it breathe.

Chapter 16 prepared the ground in four specific ways.

First, **you have a register map**. The offsets, bit masks, and register semantics are documented in `myfirst_hw.h` and `HARDWARE.md`. Chapter 17 extends the map with a few new registers and enriches the protocol of the existing ones; the structure is established.

Second, **you have lock-protected, barrier-aware accessors**. Chapter 17 introduces a callout that updates registers periodically from its own context. Without Chapter 16’s locking discipline, the callout would race with the syscall path. With it, the callout slots into the existing mutex without additional work.

Third, **you have an access log**. Chapter 17 uses more elaborate register updates (read-to-clear `INTR_STATUS`, write-triggered delayed `DATA_AV`, simulated errors). The access log is how you will see those updates in action, and Chapter 17 leans on it heavily.

Fourth, **you have a split file layout**. Chapter 17’s simulation logic lands in `myfirst_hw.c`, alongside the Chapter 16 accessors. The main driver file stays focused on the driver lifecycle. The split keeps the simulation code contained.

Specific topics Chapter 17 will cover:

- A callout that updates STATUS bits on a schedule, simulating autonomous device activity.
- A write-to-trigger-delayed-event pattern: writing CTRL.GO schedules a callout that, after a delay, flips STATUS.DATA_AV.
- Read-to-clear semantics on INTR.STATUS, with the driver's sysctl being careful not to inadvertently clear bits.
- Simulated error injection: a sysctl that causes the next operation to “fail” with a fault bit set in STATUS.
- Timeouts: the driver reacts correctly when the simulated device fails to become ready.
- A latency simulation path with DELAY(9) and callout_reset_sbt for different granularities.

You do not need to read ahead. Chapter 16 is sufficient preparation. Bring your myfirst driver at 0.9-mmio, your LOCKING.md, your HARDWARE.md, your WITNESS-enabled kernel, and your test kit. Chapter 17 starts where Chapter 16 ended.

A small closing reflection. Part 3 taught you the synchronisation vocabulary and a driver that coordinated itself. Chapter 16 added a register vocabulary and a driver that now has a hardware surface. Chapter 17 will give that surface dynamic behaviour; Chapter 18 will replace the simulation with real PCI hardware; Chapter 19 will add interrupts; Chapter 20 and Chapter 21 will add DMA. Each of those chapters is narrower than its topic suggests because Chapter 16 did the vocabulary work first.

The hardware conversation is now beginning. The vocabulary is yours. Chapter 17 opens the next round.

16.15 Reference: bus_space(9) Cheat Sheet

A one-page summary of the bus_space(9) API, for quick reference while coding.

16.15.1 Types

Type	Meaning
bus_space_tag_t	Identifies the address space (memory or I/O).
bus_space_handle_t	Identifies a specific region in the address space.
bus_size_t	Unsigned integer for offsets inside a region.

16.15.2 Reads

Function	Width	Notes
bus_space_read_1(t, h, o)	8	Returns u_int8_t
bus_space_read_2(t, h, o)	16	Returns u_int16_t
bus_space_read_4(t, h, o)	32	Returns u_int32_t
bus_space_read_8(t, h, o)	64	amd64 memory only

16.15.3 Writes

Function	Width	Notes
<code>bus_space_write_1(t, h, o, v)</code>	8	<code>v</code> is <code>u_int8_t</code>
<code>bus_space_write_2(t, h, o, v)</code>	16	<code>v</code> is <code>u_int16_t</code>
<code>bus_space_write_4(t, h, o, v)</code>	32	<code>v</code> is <code>u_int32_t</code>
<code>bus_space_write_8(t, h, o, v)</code>	64	amd64 memory only

16.15.4 Multi Accesses (same offset, different buffer positions)

Function	Purpose
<code>bus_space_read_multi_1(t, h, o, buf, count)</code>	Read <code>count</code> bytes from <code>o</code> .
<code>bus_space_read_multi_4(t, h, o, buf, count)</code>	Read <code>count</code> 32-bit values from <code>o</code> .
<code>bus_space_write_multi_4(t, h, o, buf, count)</code>	Write <code>count</code> 32-bit values to <code>o</code> .

16.15.5 Region Accesses (advancing offset and buffer)

Function	Purpose
<code>bus_space_read_region_4(t, h, o, buf, count)</code>	Read <code>count</code> 32-bit values from <code>o</code> . .
<code>bus_space_write_region_4(t, h, o, buf, count)</code>	Write <code>count</code> 32-bit values to <code>o</code> . .

16.15.6 Barrier

Function	Purpose
<code>bus_space_barrier(t, h, o, len, flags)</code>	Enforce read/write ordering over offset range.

Flags:

Flag	Meaning
<code>BUS_SPACE_BARRIER_READ</code>	Prior reads complete before later reads.
<code>BUS_SPACE_BARRIER_WRITE</code>	Prior writes complete before later writes.

16.15.7 Resource Shorthand (`/usr/src/sys/sys/bus.h`)

Function	Equivalent
<code>bus_read_4(r, o)</code>	<code>bus_space_read_4(r->r_bustag, r->r_bushandle, o)</code>
<code>bus_write_4(r, o, v)</code>	<code>bus_space_write_4(r->r_bustag, r->r_bushandle, o, v)</code>
<code>bus_barrier(r, o, l, f)</code>	<code>bus_space_barrier(r->r_bustag, r->r_bushandle, o, l, f)</code>

16.15.8 Allocation

Function	Purpose
<code>bus_alloc_resource_any(dev, type, &rid, flags)</code>	Allocate a resource.
<code>bus_release_resource(dev, type, rid, res)</code>	Release a resource.
<code>rman_get_bustag(res)</code>	Extract the tag.
<code>rman_get_bushandle(res)</code>	Extract the handle.

16.15.9 Types of Resource

Constant	Meaning
<code>SYS_RES_MEMORY</code>	Memory-mapped I/O region.
<code>SYS_RES_IOPORT</code>	I/O port range.
<code>SYS_RES_IRQ</code>	Interrupt line.

16.15.10 Flags

Constant	Meaning
<code>RF_ACTIVE</code>	Activate the resource (establish mapping).
<code>RF_SHAREABLE</code>	The resource may be shared with other drivers.

16.16 Reference: Further Reading

16.16.1 Manual Pages

- `bus_space(9)`: the full API reference.

- `bus_dma(9)`: DMA API (Chapter 20 reference).
- `bus_alloc_resource(9)`: resource allocation reference.
- `rman(9)`: the underlying resource manager.
- `pci(9)`: PCI subsystem overview (Chapter 18 preview).
- `device(9)`: the device identity API.
- `memguard(9)`: kernel memory debugging.

16.16.2 Source Files

- `/usr/src/sys/sys/bus.h`: the bus shorthand macros and the resource API.
- `/usr/src/sys/x86/include/bus.h`: the x86 `bus_space` implementation.
- `/usr/src/sys/arm64/include/bus.h`: the arm64 equivalent (for comparison).
- `/usr/src/sys/dev/ale/if_alevar.h`: a clean example of `CSR_*` macros.
- `/usr/src/sys/dev/e1000/if_em.c`: a production driver's allocation flow.
- `/usr/src/sys/dev/uart/uart_dev_ns8250.c`: a register-heavy driver for a classic device.
- `/usr/src/sys/dev/led/led.c`: a pseudo-device driver with no hardware.

16.16.3 Reading Order

If you want to go deeper before Chapter 17, read in this order:

1. `/usr/src/sys/sys/bus.h`, the `bus_read_* / bus_write_*` shorthand-macro block (search for `#define bus_read_1`).
2. `/usr/src/sys/x86/include/bus.h` in full (the implementation).
3. `/usr/src/sys/dev/ale/if_alevar.h` in full (the `softc`, macros, constants).
4. `/usr/src/sys/dev/ale/if_ale.c` attach path (search for `bus_alloc_resource`).
5. `/usr/src/sys/dev/e1000/if_em.c` attach path (same search).

Each reading is 15 to 45 minutes. The cumulative effect is a strong grasp of the idioms Chapter 16 introduced.

16.17 Reference: A Glossary of Chapter 16 Terms

16.17.1 Terms Introduced in This Chapter

access log: A ring buffer of recent register accesses, kept in the `softc` for debugging.

alignment: The requirement that a register access's offset be a multiple of the access width.

barrier: A function or instruction that enforces ordering between prior and subsequent memory accesses.

BAR (Base Address Register): On PCI, a device's register that advertises the physical address of its MMIO region. Chapter 18 treats BARs directly.

bus_space_handle_t: An opaque identifier of a specific region within a bus address space.

bus_space_tag_t: An opaque identifier of a bus address space (typically memory or I/O port).

CSR macro: A driver-specific wrapper macro (e.g., `CSR_READ_4`) that abstracts register access behind a short name.

endianness: The byte order in which a multi-byte register is laid out. Little-endian puts the low byte first; big-endian puts the high byte first.

field: A sub-bit-range of a register, with its own name and meaning.

firmware revision register: A read-only register that reports the device's firmware version.

I/O port: An x86-specific address space, accessed with `in` and `out` instructions. Contrasts with MMIO.

MMIO (memory-mapped I/O): The mechanism where device registers are exposed as a range of physical addresses, reachable through ordinary load and store instructions.

offset: The distance, in bytes, from the start of a device region to a specific register.

PIO (port-mapped I/O): On x86, the alternative to MMIO, using separate I/O port instructions.

region: A contiguous range of device address space, or the API family that walks across offsets.

register: A named, offset-located, width-specific unit of communication between the driver and a device.

register map: A table describing every register in a device's interface: offset, width, direction, meaning.

resource (FreeBSD): A named allocation from the bus subsystem, encapsulating a tag, handle, and ownership of a specific range.

sbuf: The `sbuf(9)` kernel API for building variable-length strings, used by the `access-log` `sysctl` handler.

side effect (register): A change in device state that a read or write causes as part of its semantics, beyond returning or storing the value.

simulation: In Chapter 16, the use of kernel memory allocated with `malloc(9)` to stand in for a device's MMIO region.

stream accessor: A `bus_space_*_stream_*` variant that does not apply endian swaps.

virtual mapping: The MMU's translation from a virtual address to a physical address, with specific cache and access attributes.

width: The bit count of a register or an access function's operand (8, 16, 32, 64).

16.17.2 Terms Previously Introduced (Reminders)

- **softc:** The per-instance driver state structure (Chapter 6).
- **device_t:** The kernel's identity for a device instance (Chapter 6).
- **malloc(9):** The kernel allocator (Chapter 5).
- **WITNESS:** The kernel's lock-order checker (Chapter 11).
- **INVARIANTS:** The kernel's defensive assertion framework (Chapter 11).
- **callout:** A timer primitive that invokes a callback after a delay (Chapter 13).
- **taskqueue:** A deferred-work primitive (Chapter 14).
- **cv_wait / cv_timedwait_sig:** Condition-variable waits (Chapter 12, Chapter 15).

16.18 Reference: The Chapter 16 Driver Diff Summary

A compact view of what Chapter 16 added to the `myfirst` driver, stage by stage, for readers who want to see the whole arc on one page.

16.18.1 Stage 1 (Section 4)

- New file: `myfirst_hw.h` with register offsets, masks, fixed values.
- `regs_buf` and `regs_size` in `softc`; allocated and freed in `attach/detach`.
- Accessor helpers: `myfirst_reg_read`, `myfirst_reg_write`, `myfirst_reg_update`.
- Macros: `MYFIRST_REG_READ`, `MYFIRST_REG_WRITE`.
- Sysctls: `reg_ctrl`, `reg_status`, `reg_device_id`, `reg_firmware_rev` (read), `reg_ctrl_set` (write).
- Coupling: `myfirst_ctrl_update` on `CTRL` writes.
- Version tag: `0.9-mmio-stage1`.

16.18.2 Stage 2 (Section 5)

- Added `regs_tag`, `regs_handle` in `softc`.
- Accessor bodies rewritten to use `bus_space_read_4` and `bus_space_write_4`.
- Write path updates `DATA_IN` and `STATUS.DATA_AV`.
- Read path updates `DATA_OUT` and clears `STATUS.DATA_AV` when the buffer drains.
- `reg_ticker_task` added; increments `SCRATCH_A` per tick.
- New sysctls: `reg_data_in`, `reg_data_out`, `reg_intr_mask`, `reg_intr_status`, `reg_scratch_a`, `reg_scratch_b`, `reg_ticker_enabled`.
- New document: `HARDWARE.md`.
- Version tag: `0.9-mmio-stage2`.

16.18.3 Stage 3 (Section 6)

- `MYFIRST_ASSERT` added to accessors.
- All register access paths acquire `sc->mtx`.
- Access log and its sysctls added (`access_log_enabled`, `access_log`).
- `myfirst_reg_write_barrier` helper for barrier-aware writes.
- `HARDWARE.md` extended with per-register ownership.
- Version tag: `0.9-mmio-stage3`.

16.18.4 Stage 4 (Section 8)

- File split: `myfirst_hw.c`, `myfirst_hw.h`, `myfirst.c`.
- `struct myfirst_hw` grouping of hardware state.
- `myfirst_hw_attach`, `myfirst_hw_detach`, `myfirst_hw_add_sysctls` APIs.
- `CSR_READ_4`, `CSR_WRITE_4`, `CSR_UPDATE_4` macros.
- `HARDWARE.md` finalised.
- Full regression pass.
- Version tag: `0.9-mmio`.

16.18.5 Lines of Code

- Stage 1 adds about 80 lines (header, accessor helpers, sysctls).

- Stage 2 adds about 90 lines (accessor rewrite, data-path coupling, ticker task).
- Stage 3 adds about 70 lines (locking, access log, barrier helper).
- Stage 4 is a net reorganisation: lines move between files but the total is roughly unchanged.

Total additions, Chapter 16: roughly 240 to 280 lines across four small stages.

16.19 Reference: A Comparison with Linux Device Register Access

Because many readers come to FreeBSD from Linux, a short comparison of the register-access vocabulary clarifies what translates and what does not.

16.19.1 Linux: `ioremap` + `readl` / `writel`

Linux uses a different shape. A driver obtains a virtual address through `ioremap` (for MMIO) or uses the raw I/O port number directly (for PIO). Register access is performed through `readl(addr)` and `writel(value, addr)`, with variants for different widths (`readb`, `readw`, `readl`, `readq`). The `addr` is a kernel virtual pointer cast to a specific marker type.

16.19.2 FreeBSD: `bus_alloc_resource` + `bus_read_*` / `bus_write_*`

FreeBSD uses the tag-and-handle abstraction. A driver obtains a `struct resource *` through `bus_alloc_resource_any`, then uses `bus_read_4` and `bus_write_4` on it. The tag and handle are extracted by the macro from the resource; the driver does not see them directly in most code.

16.19.3 What Translates

- The mental model: registers at fixed offsets, accessed by width, with barriers for ordering.
- The idea of defining a header of register offsets and bit masks.
- The idea of wrapping access in driver-specific macros (Linux's `read_reg32`, FreeBSD's `CSR_READ_4`).
- The discipline of lock-protected access for shared state.

16.19.4 What Differs

- FreeBSD carries an explicit tag that encodes the address-space type. Linux does not; the function variants choose the address space implicitly.
- FreeBSD's resource abstraction is more explicit about ownership and lifecycle. Linux's `ioremap` is a thinner wrapper.
- FreeBSD's barrier function takes offset and length arguments that bus bridges can use for narrow barriers. Linux's `mb`, `rmb`, `wmb`, and `mmiowb` are CPU-wide.
- FreeBSD's `bus_space` is usable for simulation (as in this chapter); Linux's equivalent path is less friendly for that use.

Porting a driver from Linux to FreeBSD or vice versa involves rewriting the register-access layer but not the register map, because the map is defined by the device, not the OS. A well-organised driver that keeps its register access behind CSR-style macros can have its CSR macros replaced with minimal other code changes.

16.20 Reference: A Worked Example: The Full `myfirst_hw.h`

For reference, the complete Stage 4 header. This is what lives at `examples/part-04/ch16-accessing-hardware/stage4-final/myfirst_hw.h`.

```

/* myfirst_hw.h -- Chapter 16 Stage 4 simulated hardware interface. */
#ifndef _MYFIRST_HW_H
#define _MYFIRST_HW_H

#include <sys/types.h>
#include <sys/bus.h>
#include <machine/bus.h>

/* Register offsets. */
#define MYFIRST_REG_CTRL      0x00
#define MYFIRST_REG_STATUS    0x04
#define MYFIRST_REG_DATA_IN    0x08
#define MYFIRST_REG_DATA_OUT  0x0c
#define MYFIRST_REG_INTR_MASK 0x10
#define MYFIRST_REG_INTR_STATUS 0x14
#define MYFIRST_REG_DEVICE_ID 0x18
#define MYFIRST_REG_FIRMWARE_REV 0x1c
#define MYFIRST_REG_SCRATCH_A 0x20
#define MYFIRST_REG_SCRATCH_B 0x24

#define MYFIRST_REG_SIZE      0x40

/* CTRL bits. */
#define MYFIRST_CTRL_ENABLE    0x00000001u
#define MYFIRST_CTRL_RESET     0x00000002u
#define MYFIRST_CTRL_MODE_MASK 0x000000f0u
#define MYFIRST_CTRL_MODE_SHIFT 4
#define MYFIRST_CTRL_LOOPBACK 0x00000100u

/* STATUS bits. */
#define MYFIRST_STATUS_READY    0x00000001u
#define MYFIRST_STATUS_BUSY     0x00000002u
#define MYFIRST_STATUS_ERROR    0x00000004u
#define MYFIRST_STATUS_DATA_AV 0x00000008u

/* INTR bits. */
#define MYFIRST_INTR_DATA_AV    0x00000001u
#define MYFIRST_INTR_ERROR      0x00000002u
#define MYFIRST_INTR_COMPLETE  0x00000004u

```

```
/* Fixed values. */
#define MYFIRST_DEVICE_ID_VALUE 0x4D594649u
#define MYFIRST_FW_REV_MAJOR 1
#define MYFIRST_FW_REV_MINOR 0
#define MYFIRST_FW_REV_VALUE ((MYFIRST_FW_REV_MAJOR << 16) | MYFIRST_FW_REV_MINOR)

/* Access log. */
#define MYFIRST_ACCESS_LOG_SIZE 64

struct myfirst_access_log_entry {
    uint64_t timestamp_ns;
    uint32_t value;
    bus_size_t offset;
    uint8_t is_write;
    uint8_t width;
    uint8_t context_tag;
    uint8_t _pad;
};

/* Hardware state, grouped. */
struct myfirst_hw {
    uint8_t *regs_buf;
    size_t regs_size;
    bus_space_tag_t regs_tag;
    bus_space_handle_t regs_handle;

    struct task reg_ticker_task;
    int reg_ticker_enabled;

    struct myfirst_access_log_entry access_log[MYFIRST_ACCESS_LOG_SIZE];
    unsigned int access_log_head;
    bool access_log_enabled;
};

/* API. */
struct myfirst_softc;

int myfirst_hw_attach(struct myfirst_softc *sc);
void myfirst_hw_detach(struct myfirst_softc *sc);
void myfirst_hw_add_sysctls(struct myfirst_softc *sc);

uint32_t myfirst_reg_read(struct myfirst_softc *sc, bus_size_t offset);
void myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset,
    uint32_t value);
```

```

void    myfirst_reg_update(struct myfirst_softc *sc, bus_size_t offset,
                          uint32_t clear_mask, uint32_t set_mask);
void    myfirst_reg_write_barrier(struct myfirst_softc *sc, bus_size_t offset,
                                  uint32_t value, int flags);

#define CSR_READ_4(sc, off)      myfirst_reg_read((sc), (off))
#define CSR_WRITE_4(sc, off, val) myfirst_reg_write((sc), (off), (val))
#define CSR_UPDATE_4(sc, off, clear, set) \
    myfirst_reg_update((sc), (off), (clear), (set))

#endif /* _MYFIRST_HW_H_ */

```

This single header is what the rest of the driver includes to gain access to the hardware interface. A newcomer reads it once and understands what registers exist, how they are accessed, and which macros the driver body uses.

16.21 Reference: A Worked Example: The `myfirst_hw.c` Accessor Functions

Complementing the header, the implementations. For reference and as a template.

```

/* myfirst_hw.c -- Chapter 16 Stage 4 hardware access layer. */
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/bus.h>
#include <sys/malloc.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/taskqueue.h>
#include <sys/sysctl.h>
#include <sys/sbuf.h>
#include <machine/bus.h>

#include "myfirst.h"      /* struct myfirst_softc, MYFIRST_LOCK, ... */
#include "myfirst_hw.h"

MALLOC_DECLARE(M_MYFIRST);

uint32_t
myfirst_reg_read(struct myfirst_softc *sc, bus_size_t offset)
{
    struct myfirst_hw *hw = sc->hw;
    uint32_t value;

```

```

MYFIRST_ASSERT(sc);
KASSERT(hw != NULL, ("myfirst: hw is NULL in reg_read"));
KASSERT(offset + 4 <= hw->regs_size,
    ("myfirst: register read past end: offset=%#x size=%zu",
    (unsigned)offset, hw->regs_size));

value = bus_space_read_4(hw->regs_tag, hw->regs_handle, offset);

if (hw->access_log_enabled) {
    unsigned int idx = hw->access_log_head++ % MYFIRST_ACCESS_LOG_SIZE;
    struct myfirst_access_log_entry *e = &hw->access_log[idx];
    struct timespec ts;
    nanouptime(&ts);
    e->timestamp_ns = (uint64_t)ts.tv_sec * 1000000000ULL + ts.tv_nsec;
    e->value = value;
    e->offset = offset;
    e->is_write = 0;
    e->width = 4;
    e->context_tag = 'd';
}

return (value);
}

void
myfirst_reg_write(struct myfirst_softc *sc, bus_size_t offset, uint32_t value)
{
    struct myfirst_hw *hw = sc->hw;

    MYFIRST_ASSERT(sc);
    KASSERT(hw != NULL, ("myfirst: hw is NULL in reg_write"));
    KASSERT(offset + 4 <= hw->regs_size,
        ("myfirst: register write past end: offset=%#x size=%zu",
        (unsigned)offset, hw->regs_size));

    bus_space_write_4(hw->regs_tag, hw->regs_handle, offset, value);

    if (hw->access_log_enabled) {
        unsigned int idx = hw->access_log_head++ % MYFIRST_ACCESS_LOG_SIZE;
        struct myfirst_access_log_entry *e = &hw->access_log[idx];
        struct timespec ts;
        nanouptime(&ts);
        e->timestamp_ns = (uint64_t)ts.tv_sec * 1000000000ULL + ts.tv_nsec;
    }
}

```

```

        e->value = value;
        e->offset = offset;
        e->is_write = 1;
        e->width = 4;
        e->context_tag = 'd';
    }
}

void
myfirst_reg_update(struct myfirst_softc *sc, bus_size_t offset,
                  uint32_t clear_mask, uint32_t set_mask)
{
    uint32_t v;

    MYFIRST_ASSERT(sc);
    v = myfirst_reg_read(sc, offset);
    v &= ~clear_mask;
    v |= set_mask;
    myfirst_reg_write(sc, offset, v);
}

void
myfirst_reg_write_barrier(struct myfirst_softc *sc, bus_size_t offset,
                          uint32_t value, int flags)
{
    struct myfirst_hw *hw = sc->hw;

    MYFIRST_ASSERT(sc);
    myfirst_reg_write(sc, offset, value);
    bus_space_barrier(hw->regs_tag, hw->regs_handle, 0, hw->regs_size, flags);
}

```

This is a complete, working file. The `myfirst_hw_attach`, `myfirst_hw_detach`, and `myfirst_hw_add_sysctls` functions follow in the same file; they are longer but follow the same patterns as Section 4’s worked text.

16.22 Reference: A Minimal Stand-Alone Test Module

For readers who want to practise `bus_space(9)` in isolation from the `myfirst` driver, here is a minimal stand-alone kernel module that allocates a kernel-memory “device”, exposes it through `sysctls`, and lets the reader experiment. Save as `hwsim.c`:

```

/* hwsim.c -- Chapter 16 stand-alone bus_space(9) practice module. */
#include <sys/param.h>

```

```
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/malloc.h>
#include <sys/sysctl.h>
#include <sys/bus.h>
#include <machine/bus.h>

MALLOC_DEFINE(M_HWSIM, "hwsim", "hwsim test module");

#define HWSIM_SIZE 0x40

static uint8_t      *hwsim_buf;
static bus_space_tag_t hwsim_tag;
static bus_space_handle_t hwsim_handle;

static SYSCTL_NODE(_dev, OID_AUTO, hwsim,
    CTLFLAG_RW | CTLFLAG_MPSAFE, NULL, "hwsim practice module");

static int
hwsim_sysctl_reg(SYSCTL_HANDLER_ARGS)
{
    bus_size_t offset = arg2;
    uint32_t value;
    int error;

    if (hwsim_buf == NULL)
        return (ENODEV);
    value = bus_space_read_4(hwsim_tag, hwsim_handle, offset);
    error = sysctl_handle_int(oidp, &value, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
    bus_space_write_4(hwsim_tag, hwsim_handle, offset, value);
    return (0);
}

static int
hwsim_modevent(module_t mod, int event, void *arg)
{
    switch (event) {
    case MOD_LOAD:
        hwsim_buf = malloc(HWSIM_SIZE, M_HWSIM, M_WAITOK | M_ZERO);
#if defined(__amd64__) || defined(__i386__)
        hwsim_tag = X86_BUS_SPACE_MEM;
#endif
    }
}
```

```

else
    free(hwsim_buf, M_HWSIM);
    hwsim_buf = NULL;
    return (EOPNOTSUPP);
#endif

hwsim_handle = (bus_space_handle_t)(uintptr_t)hwsim_buf;

SYSCTL_ADD_PROC(NULL, SYSCTL_STATIC_CHILDREN(_dev_hwsim),
    OID_AUTO, "reg0",
    CTLTYPE_UINT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    NULL, 0x00, hwsim_sysctl_reg, "IU",
    "Offset 0x00");
SYSCTL_ADD_PROC(NULL, SYSCTL_STATIC_CHILDREN(_dev_hwsim),
    OID_AUTO, "reg4",
    CTLTYPE_UINT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    NULL, 0x04, hwsim_sysctl_reg, "IU",
    "Offset 0x04");
    return (0);
case MOD_UNLOAD:
    if (hwsim_buf != NULL) {
        free(hwsim_buf, M_HWSIM);
        hwsim_buf = NULL;
    }
    return (0);
default:
    return (EOPNOTSUPP);
}
}

static moduledata_t hwsim_mod = {
    "hwsim",
    hwsim_modevent,
    NULL
};

DECLARE_MODULE(hwsim, hwsim_mod, SI_SUB_DRIVERS, SI_ORDER_ANY);
MODULE_VERSION(hwsim, 1);

```

A two-line Makefile:

```

KMOD=  hwsim
SRCS=  hwsim.c

.include <bsd.kmod.mk>

```

Build, load, and play:

```
# make clean && make
# kldload ./hwsim.ko
# sysctl dev.hwsim.reg0
# sysctl dev.hwsim.reg0=0xdeadbeef
# sysctl dev.hwsim.reg0
# sysctl dev.hwsim.reg4=0x12345678
# sysctl dev.hwsim.reg4
# kldunload hwsim
```

The module demonstrates `bus_space(9)` in its simplest possible form: a memory buffer, a tag, a handle, two register slots, a pair of `sysctls`. A reader who types this in and runs it has the whole vocabulary of Section 3 in about 80 lines of C.

16.23 Reference: Why `volatile` Matters in `bus_space`

A note on a subtle detail the chapter touched on but did not expand.

When `bus_space_read_4` on x86 expands to `*(volatile u_int32_t*)(handle + offset)`, the `volatile` qualifier is not decorative. It is load-bearing.

Without `volatile`, the compiler assumes that reading a memory location twice in sequence, with no intervening store to that location, must return the same value. It is free to reorder, coalesce, or elide reads based on that assumption. For ordinary memory, the assumption holds: RAM does not change underneath you. For device memory, the assumption is wrong. A read might consume an event; a write might have immediate and visible effects that a subsequent read sees.

The `volatile` qualifier tells the compiler: treat this access as having observable side effects. Do not reorder it with other volatile accesses. Do not elide it. Do not cache its result. Emit a load (or store) every time, exactly as written.

On x86, this is enough. The CPU's memory model is strong enough that once the load is emitted in program order, it executes in program order. On arm64, additional barriers are needed to enforce program order across CPU-level reordering, which is why `bus_space_barrier` on arm64 emits DMB or DSB instructions and on x86 emits only a compiler fence.

The short rule: every time you write a hand-rolled accessor for device memory, use `volatile`. Every time you use `bus_space_*` directly, the `volatile` is already there. Every time you cast a pointer to device memory through a non-volatile type, you have a bug waiting to happen.

16.24 Reference: A Short Comparison of Access Patterns in Real FreeBSD Drivers

An informal survey of patterns used in real drivers. Each example cites the file and the characteristic pattern; read the files themselves to see the pattern in context.

/usr/src/sys/dev/ale/if_ale.c: Uses `CSR_READ_4(sc, reg)` and `CSR_WRITE_4(sc, reg, val)` macros defined in `if_alevar.h` over `bus_read_4` and `bus_write_4`. Softc holds `ale_res[]`, an array of resources. The pattern is clean and scales well.

/usr/src/sys/dev/e1000/if_em.c: Uses `E1000_READ_REG(hw, reg)` and `E1000_WRITE_REG(hw, reg, val)` that wrap `bus_space_read_4` and `bus_space_write_4` on the `osdep struct`'s tag and handle. More indirection than `ale`, justified by Intel's cross-OS shared-code model.

/usr/src/sys/dev/uart/uart_bus_pci.c: A glue driver that allocates resources and hands them to the generic UART subsystem. The register access happens in subsystem code (`uart_dev_ns8250.c`), not in the PCI glue.

/usr/src/sys/dev/uart/uart_dev_ns8250.c: Direct `bus_read_1` and `bus_write_1` on a struct `uart_bas *` that holds tag and handle. Legacy 8-bit register layout.

/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c: Uses `bus_read_4` and `bus_write_4` through struct `resource *` fields in the softc. Chapter 18 uses `virtio` as a test target for real-PCI exercises.

/usr/src/sys/dev/random/ivy.c (Intel Ivy Bridge RDRAND): Uses CPU instructions directly (`rdrand`) rather than `bus_space`; this is an unusual case because the “device” is the CPU itself, accessible through inline assembly.

Across all of these, the pattern is “wrap `bus_*` or `bus_space_*` in driver-specific macros, keep register offsets in a header, access registers through the macros in the body”. Chapter 16's Stage 4 matches this convention.

16.25 Reference: The Road Ahead in Part 4

A preview of how Chapter 16's material feeds into later chapters, for readers who like a single-page map.

Chapter 17 (Simulating Hardware): Extends the simulation with dynamic behaviour. Timers change STATUS bits. Writing `CTRL.GO` triggers a delayed update. Errors can be injected. The register vocabulary stays the same; the simulation becomes richer.

Chapter 18 (Writing a PCI Driver): Replaces the simulation with real PCI. `bus_alloc_resource_any` enters in earnest. Vendor and device IDs, BAR mapping, `pci_enable_busmaster`, `pciconf`. The simulation path remains available behind a compile-time flag for continued testing.

Chapter 19 (Handling Interrupts): Adds `bus_setup_intr`, filter vs `ithread`, interrupt acknowledgement, the `INTR_STATUS` register's read-to-clear semantics in a real context. The Chapter 16 access log becomes invaluable for debugging interrupt sequences.

Chapter 20 and Chapter 21 (DMA): Add `bus_dma(9)`. Register accesses become the control surface for DMA operations: set up a descriptor, write a doorbell register, wait for completion. The `bus_space_barrier` story becomes essential.

Chapter 22 (Power Management): Suspend, resume, dynamic power states. Registers that save and restore device state. Most of the Part 4 vocabulary applies; power management adds a few more idioms.

Each chapter introduces a new layer; Chapter 16's layer (the register) is the foundation for all of them. A reader who leaves Chapter 16 comfortable with `bus_space(9)` will find each subsequent chapter adds a new vocabulary on top of familiar ground.

16.26 Reference: How to Read a Datasheet

Every real driver starts with a datasheet: the document the device's manufacturer publishes describing the register interface, the programming model, and the operational behaviour. Chapter 16 works with a simulated device, so there is no datasheet to consult. Later chapters point at real devices, and a driver author who is comfortable with datasheets will learn faster.

A brief primer follows. The reader can skip this on first pass and return when Chapter 18 or a later chapter points at a real device's specification.

16.26.1 The Shape of a Datasheet

A datasheet is usually a PDF of fifty to fifteen hundred pages. It covers:

- A functional overview (what the device does, at a high level).
- Pinout or physical interface description (what signals the device has, what they mean).
- Register reference (the mapping Chapter 16 has been teaching you to read).
- Programming model (the sequence of operations a driver must perform for each high-level action).
- Electrical characteristics (voltages, timings, environmental ratings).
- Package dimensions (mechanical data for the circuit board designer).

Driver authors care primarily about the register reference and the programming model. Everything else is for hardware designers.

16.26.2 Reading the Register Reference

The register reference is usually a series of tables, one per register, with the following columns:

- Offset.
- Width.
- Reset value (the value the register has after power-on or reset).
- Access type (R, W, RW, R/W1C for read with write-one-to-clear, and so on).
- Field names and bit ranges.
- Field descriptions.

A seasoned driver author reads this table first, notes any unusual access types, and translates the register map into a C header with named offsets and bit masks. The translation is mechanical; the care is in getting every bit right.

A particular note on **reset values**. The reset value tells you what the register reads immediately after the device has been powered on or reset. If the driver writes a field and later reads it back, the read should return the value written (not the reset value). But if the driver has not written the register, the read returns the reset value. Getting this wrong produces surprising bugs: the driver “sees” a register it did not initialise and misinterprets the reset value as a state change.

16.26.3 Reading the Programming Model

The programming model section describes the sequences of register operations required to drive the device. A typical entry looks like:

Transmit one packet. 1. Confirm `STATUS.TX_READY` is set. 2. Write the packet data to `TX_BUF[0..n-1]` in order. 3. Write the packet length to `TX_LEN`. 4. Write `CTRL.TX_START`. 5. Wait for `STATUS.TX_DONE` to assert (may take up to 100us). 6. Clear `STATUS.TX_DONE` by writing 1 to the same bit.

This sequence is what a driver's transmit path implements. The order of steps is fixed; reordering can leave the device in an inconsistent state. The driver's job is to translate each step into a `bus_space_write_*` or `bus_space_read_*` call, with the proper barriers and locking.

Most datasheets have several such sequences. A network device might have receive, transmit, link initialisation, error recovery, and shutdown sequences. Each is documented independently.

16.26.4 Extracting the C Header

A skilled driver author reads the register reference once and produces a C header something like:

```
/* foo_regs.h -- derived from Foo Corp. Foo-9000 datasheet, rev 3.2. */

#define F00_REG_CTRL      0x0000
#define F00_REG_STATUS    0x0004
#define F00_REG_TX_LEN    0x0010
#define F00_REG_TX_BUF    0x0100 /* base of 4 KiB TX buffer region */

#define F00_CTRL_TX_START 0x00000001u
#define F00_CTRL_RX_ENABLE 0x00000002u

#define F00_STATUS_TX_READY 0x00000001u
#define F00_STATUS_TX_DONE  0x00000002u

/* ... and so on ... */
```

The header is where the driver's knowledge of the device's register interface lives. Keep it up to date with the datasheet; reference the datasheet revision in the header so future contributors know which version the offsets match.

16.26.5 A Pattern for Each Type of Register

Different access types imply different coding patterns.

Read-only, no side effect. Read whenever. Cache if convenient. No locking needed beyond “do not read a register from a region that has been freed”.

Read-only, with side effect (read-to-clear). Read exactly as often as the protocol requires. Do not add debug reads that clear state. Do not re-read to “confirm” a value.

Write-only. Write with whatever value the protocol requires. Do not read it back; the read returns garbage.

Read/write, no side effect. Safe read-modify-write sequences under lock.

Read/write, with side effect on write. Be careful with read-modify-write: the write of an unchanged bit may still trigger the side effect. Sometimes a datasheet documents this by saying “writes of 0 to bit X have no effect”; sometimes it does not, and the driver must be conservative.

Write-one-to-clear (W1C). Common for interrupt status registers. Writing 1 to a bit clears it; writing 0 has no effect. Use `CSR_WRITE_4(sc, REG, mask_of_bits_to_clear)`, not a read-modify-write.

16.26.6 An Exercise: Pretend the Chapter 16 Device Has a Datasheet

To close this reference, practise extracting a register header from a “datasheet” for the Chapter 16 simulated device. Write a fake datasheet in prose describing each register, its reset value, its access type, and its field layout. Then produce the corresponding `myfirst_hw.h`. Compare your version with the one Chapter 16 provided.

The exercise builds the muscle you will need for every real device later in the book.

16.27 Reference: A Case Study in Missing Barriers

A short cautionary tale to make the barrier story concrete, using only the MMIO vocabulary Chapter 16 has already introduced.

Imagine a real device whose datasheet says: “To send a command, write the 32-bit command word into `CMD_DATA`, then write the 32-bit command code into `CMD_GO`. The device picks up the command word when `CMD_GO` is written.” The driver expresses this sequence naively:

```
/* Step 1: write the command payload. */
CSR_WRITE_4(sc, MYFIRST_REG_CMD_DATA, payload);

/* Step 2: write the command code to trigger execution. */
CSR_WRITE_4(sc, MYFIRST_REG_CMD_GO, opcode);
```

On x86 this works. The x86 memory model guarantees that stores retire in program order from the CPU’s point of view, and the compiler’s `volatile`-annotated write inside `bus_space_write_4` prevents it from reordering the two statements. By the time `CMD_GO` reaches the device, `CMD_DATA` has already been written.

On arm64 the same code can fail. The CPU is free to reorder the two stores at the memory subsystem level. The device can observe `CMD_GO` first, grab whatever stale value still sits in `CMD_DATA`, and execute a command the driver did not intend. The symptom is intermittent, load-dependent, and only appears on arm64 hardware. A driver tested only on x86 would ship with this bug undetected.

The fix is a one-line change:

```
CSR_WRITE_4(sc, MYFIRST_REG_CMD_DATA, payload);

/* Ensure the payload write reaches the device before the doorbell. */
bus_space_barrier(sc->hw->regs_tag, sc->hw->regs_handle, 0, sc->hw->regs_size,
    BUS_SPACE_BARRIER_WRITE);

CSR_WRITE_4(sc, MYFIRST_REG_CMD_GO, opcode);
```

On x86, `bus_space_barrier` with `BUS_SPACE_BARRIER_WRITE` emits only a compiler fence, which is free in instruction terms and preserves the program order the x86 CPU was already going to preserve. On arm64, it emits a `dmb` or `dsb` that forces the CPU to drain its store buffer before the next store is issued. The same source code does the right thing on both.

The tale makes three points.

First, x86 gives driver authors a false sense of security. Code tested only on x86 may pass every test yet be broken on arm64 in ways that manifest only under specific load patterns.

Second, portability costs are tiny if you build them in early. Adding a `bus_space_barrier` at the right spot is a one-line change. Diagnosing the bug a year later on an arm64 deployment is a week of work.

Third, the cost of barriers on x86 is negligible for typical drivers. A compiler fence is free in instruction terms; it constrains the compiler's reordering, which for a driver's cold paths matters not at all.

A related family of ordering bugs appears when the driver writes to memory the device reads through DMA (a descriptor ring, for example) and then rings a doorbell register. That pattern needs a `bus_dmamap_sync` call, not just a `bus_space_barrier`; Chapter 20 teaches the DMA path in depth. The vocabulary is different, but the intuition (writes must drain before the doorbell) is the same.

The discipline Chapter 16 encourages, even when the immediate benefit is invisible, pays off when the code runs on hardware the author never saw.

16.28 Reference: Reading `if_ale.c` Step By Step

A guided walk through the attach path of a real driver so the vocabulary of Chapter 16 lands in production code. Open `/usr/src/sys/dev/ale/if_ale.c`, jump to `ale_attach`, and follow along.

16.28.1 Step 1: The Attach Entry Point

The `ale_attach` function begins:

```
static int
ale_attach(device_t dev)
{
    struct ale_softc *sc;
    if_t ifp;
```

```

uint16_t burst;
int error, i, msic, msixc;
uint32_t rxf_len, txf_len;

error = 0;
sc = device_get_softc(dev);
sc->ale_dev = dev;

```

`device_get_softc(dev)` is the same pattern Chapter 6 introduced. Nothing new here.

16.28.2 Step 2: Early Locking Setup

The driver initialises its data-path mutex, its callout, and its first task:

```

mtx_init(&sc->ale_mtx, device_get_nameunit(dev), MTX_NETWORK_LOCK,
        MTX_DEF);
callout_init_mtx(&sc->ale_tick_ch, &sc->ale_mtx, 0);
NET_TASK_INIT(&sc->ale_int_task, 0, ale_int_task, sc);

```

Every line here came straight out of Part 3. The mutex is the Chapter 11 primitive; the lock-aware callout is the Chapter 13 primitive; the task is the Chapter 14 primitive. A reader who has done Part 3 recognises all three immediately.

16.28.3 Step 3: PCI Bus-Mastering and Resource Allocation

```

pci_enable_busmaster(dev);
sc->ale_res_spec = ale_res_spec_mem;
sc->ale_irq_spec = ale_irq_spec_legacy;
error = bus_alloc_resources(dev, sc->ale_res_spec, sc->ale_res);
if (error != 0) {
    device_printf(dev, "cannot allocate memory resources.\n");
    goto fail;
}

```

`pci_enable_busmaster` is PCI-specific; Chapter 18 covers it. The `ale_res_spec` is a struct `resource_spec` array (defined earlier in the file) that describes which resources the driver wants. `bus_alloc_resources` (plural) takes the spec and fills in the `sc->ale_res` array with the allocated resources. This is a slight convenience wrapper over calling `bus_alloc_resource_any` in a loop; either pattern is common, and the Chapter 18 discussion of PCI resource allocation covers both.

After this call, `sc->ale_res[0]` holds a struct `resource *` for the device's MMIO region, and the `CSR_READ_*` / `CSR_WRITE_*` macros (defined in `/usr/src/sys/dev/ale/if_alevar.h`, right after the `softc` structure) can be used to access registers through it.

16.28.4 Step 4: Reading the First Register

The driver reads the PHY_STATUS register to decide which chip variant it is running on:

```
if ((CSR_READ_4(sc, ALE_PHY_STATUS) & PHY_STATUS_100M) != 0) {
    /* L1E AR8121 */
    sc->ale_flags |= ALE_FLAG_JUMBO;
} else {
    /* L2E Rev. A. AR8113 */
    sc->ale_flags |= ALE_FLAG_FASTETHER;
}
```

This is the first register access in `ale_attach`. It is a single `CSR_READ_4` call that returns a 32-bit value, masked against the `PHY_STATUS_100M` bit, and used to select a code path. The `ALE_PHY_STATUS` constant is a register offset defined in `/usr/src/sys/dev/ale/if_alereg.h`. The bit mask `PHY_STATUS_100M` is defined in the same header.

Every element of that one line is Chapter 16 vocabulary. `CSR_READ_4` expands to `bus_read_4` over the first resource; `bus_read_4` expands to `bus_space_read_4` over the tag and handle inside the resource; on x86 memory space, `bus_space_read_4` compiles to a single `mov` instruction.

16.28.5 Step 5: Reading More Registers

A few lines later the driver reads three more registers to gather chip-identification data:

```
sc->ale_chip_rev = CSR_READ_4(sc, ALE_MASTER_CFG) >>
    MASTER_CHIP_REV_SHIFT;
/* ... */
txf_len = CSR_READ_4(sc, ALE_SRAM_TX_FIFO_LEN);
rx_len = CSR_READ_4(sc, ALE_SRAM_RX_FIFO_LEN);
```

Same pattern, three more registers. Notice the uninitialised-hardware check a few lines down, guarded by `sc->ale_chip_rev == 0xFFFF`: if any of the returned values looks like `0xFFFFFFFF`, the driver assumes the hardware is not correctly initialised and bails out with `ENXIO`. This kind of sanity check is a common, quiet habit in production drivers: hardware that returns all-ones on every register typically means the mapping is wrong, the device is not responding, or the device was power-gated and never brought up.

16.28.6 Step 6: IRQ Setup

Further down:

```
error = bus_alloc_resources(dev, sc->ale_irq_spec, sc->ale_irq);
```

IRQ resources get their own allocation. Chapter 19 covers what happens next: `bus_setup_intr`, the filter-ithread split, and the interrupt handler.

16.28.7 Step 7: Reading the Whole File

After the IRQ allocation, `ale_attach` continues with DMA tag creation (Chapter 20), ifnet registration (Chapter 28 in Part 6), PHY attach, and so on. Each step uses patterns that will be introduced by later chapters in this book. What Chapter 16 gave you is the vocabulary to read every `CSR_*` macro call without stopping.

The exercise that consolidates the walk: pick three `CSR_READ_4` or `CSR_WRITE_4` calls from anywhere in `/usr/src/sys/dev/ale/if_ale.c`, look up the register offset in `if_alereg.h`, decode the bit mask in the same header, and write one sentence explaining what the driver is doing at that call site. If you can do that for three arbitrary calls, you have internalised the vocabulary this chapter taught.

16.29 Reference: An Honest Accounting of Chapter 16's Simplifications

A chapter that teaches a small slice of a large topic inevitably simplifies. For honesty with the reader, a catalogue of what Chapter 16 simplified and what the full story looks like.

16.29.1 The Simulated Tag

Chapter 16's simulation uses `X86_BUS_SPACE_MEM` as the tag and a kernel virtual address as the handle. On x86 this works because the `x86_bus_space_read_*` functions reduce to a `volatile` dereference of `handle + offset` for memory space. On other architectures the trick fails because the tag is not an integer; it is a pointer to a structure, and manufacturing one by hand requires reproducing the structure the platform's `bus_space` expects.

The full story: real drivers never manufacture a tag; they receive one from the bus subsystem through `rman_get_bustag`. The Chapter 16 simulation shortcut is pedagogical, and the chapter explicitly marks it as x86-only. Chapter 17's richer simulation introduces a portable alternative, and Chapter 18's real PCI path retires the shortcut entirely.

16.29.2 The Register Protocol

The simulated device's registers have no side effects on read or write. `STATUS` is set by the driver; it does not change autonomously. `DATA_IN` is written by the driver; it does not forward the write to an imaginary downstream consumer. `INTR_STATUS` is a plain register, not read-to-clear.

The full story: real devices have protocols. Reading a status register may consume an event. Writing a command register may trigger a multi-cycle operation inside the device. The driver's job is to follow the protocol exactly; a single missed step produces a misbehaving device. Chapter 17 introduces some of this complexity by adding a callout-driven protocol: a write triggers a delayed status change.

16.29.3 Locking Granularity

Chapter 16 uses a single driver mutex (`sc->mtx`) for all register access. In practice, real drivers sometimes split locks: a fast-path lock for per-packet register writes (in a network driver) and a slower lock for configuration changes. Splitting increases concurrency at the cost of more locking discipline.

The full story: lock splitting is a performance tuning decision that belongs to later chapters on scaling and profiling. Chapter 16 uses a single lock because it is the simplest correct design, and because the driver's throughput requirements are nowhere near where lock contention matters.

16.29.4 Endianness

Chapter 16 assumes host byte order for all register values. Real devices sometimes use a different byte order than the host CPU. The `_stream_` variants of `bus_space` handle this; Chapter 16 does not use them.

The full story: FreeBSD's `bus_space` API supports per-tag byte-swap semantics. A driver whose device is big-endian on a little-endian CPU uses either a swap-aware tag or the `_stream_` variants plus explicit `htobe32/be32toh` conversions. Chapter 16's simulation is host-endian, so the issue does not arise; real drivers for big-endian devices handle it explicitly.

16.29.5 Cache Attributes

Chapter 16's `malloc(9)` allocation produces ordinary cacheable kernel memory. Real device memory is mapped with different cache attributes (uncached, write-combining, device-strongly-ordered) depending on the platform and the device's requirements.

The full story: `bus_alloc_resource_any` with `RF_ACTIVE` on a real PCI BAR produces a mapping with the right cache attributes. The simulation does not go through this path; it uses plain cacheable memory. Under Chapter 16's patterns (serialised access, volatile accesses), the cache attribute difference does not manifest. In Chapter 18's real-PCI path, the allocation flow takes care of it.

16.29.6 Error Handling

Chapter 16's simulated device never returns an error from a register access. Real hardware sometimes does: a read may time out, a write may be rejected, a bus may hang. The driver must handle these.

The full story: FreeBSD provides `bus_peek_*` and `bus_poke_*` variants (since FreeBSD 13) that return an error if the access faults. Chapter 16 does not use them because the simulation cannot fault. Chapter 19 introduces them in the context of interrupt handlers that may touch a device in an uncertain state.

16.29.7 Interrupts

Chapter 16's driver polls registers through callouts and syscall paths. Real drivers typically use interrupts to know when to read a register.

The full story: interrupts are Chapter 19's topic. Chapter 16's polling pattern is a stepping stone; after Chapter 19 the driver will have an interrupt handler that replaces much of the polling logic.

16.29.8 DMA

Chapter 16's driver does not use DMA. Every byte flowing through the driver is copied by the CPU, register by register.

The full story: real high-throughput devices use DMA for bulk data. The driver programs the device's DMA engine through registers, then the device reads or writes system RAM directly. Chapter 20 and Chapter 21 cover the DMA API.

16.29.9 Summary

Chapter 16 is an on-ramp. Every simplification it makes is deliberate, named, and picked up by a later chapter. The vocabulary Chapter 16 teaches is the vocabulary every later chapter extends; the discipline Chapter 16 builds is the discipline every later chapter relies on. The chapter is short of the full hardware story on purpose. Subsequent chapters fill in the rest.

16.30 Reference: A Quick Reference for Common MMIO Bugs

When a driver misbehaves, the bug is often in a small set of recurring categories. A quick reference to recognise each.

16.30.1 1. Off-by-One in the Register Map

Symptom: A read returns a plausible but wrong value, or a write has no effect.

Cause: An offset in the driver's header is one or two or four bytes off from the datasheet.

Diagnosis: Cross-check the header against the datasheet, register by register.

Fix: Correct the offset.

16.30.2 2. Wrong Access Width

Symptom: A read returns a value that looks like only part of the register, or a write affects only part of the register.

Cause: The driver uses `bus_read_4` on a 16-bit register or vice versa.

Diagnosis: Check the datasheet's width column against the accessor suffix.

Fix: Use the correct width.

16.30.3 3. Missing Volatile Qualifier in a Hand-Rolled Accessor

Symptom: The compiler optimises away a register access, and the driver misses a state change.

Cause: A driver that wraps `bus_space_*` in a non-volatile intermediate loses the volatile annotation.

Diagnosis: Audit any custom accessor that is not a direct `bus_space_*` call.

Fix: Keep accessors as simple wrappers around `bus_space_*`; do not introduce intermediate variables without `volatile`.

16.30.4 4. Lost Update in Read-Modify-Write

Symptom: A bit set by the driver disappears; another bit set by a second context disappears.

Cause: Two contexts do RMW on the same register without a lock; one clobbers the other.

Diagnosis: Use the access log or DTrace to observe two writes in rapid succession.

Fix: Protect RMW with the driver mutex, or use a write-one-to-clear idiom if the hardware supports it.

16.30.5 5. Missing Barrier Before a Doorbell

Symptom: The device sometimes reads stale descriptor data or wrong command buffers.

Cause: The descriptor writes are reordered past the doorbell register write (on arm64 or other weakly-ordered platforms).

Diagnosis: The symptom is often transient and load-dependent.

Fix: Insert `bus_barrier` with `BUS_SPACE_BARRIER_WRITE` between the descriptor writes and the doorbell.

16.30.6 6. Reading a Write-Only Register

Symptom: The driver reads a register and gets zero or garbage; based on that value, it takes the wrong action.

Cause: The register is marked write-only in the datasheet; reads return a fixed value unrelated to state.

Diagnosis: Check the access type in the datasheet.

Fix: Do not read write-only registers. If you need to remember the last written value, cache it in the softc.

16.30.7 7. Unexpected Side Effect on Read

Symptom: A debug read changes driver behaviour.

Cause: The register has read-to-clear semantics and the debug read consumes an event.

Diagnosis: Disable the debug read; if the issue disappears, the read was the culprit.

Fix: Cache the value in the softc on the protocol-driven read; expose the cached value through the debug interface.

16.30.8 8. Dangling Tag or Handle

Symptom: Kernel panic on the first register access, with a fault at an address that does not look like the mapped region.

Cause: The driver stored a tag and handle before allocation completed, or kept them after release.

Diagnosis: `MYFIRST_ASSERT` firing; `regs_buf == NULL` in the panic.

Fix: Set the tag and handle only after successful allocation; clear them (or null the `sc->hw` pointer) before release.

16.30.9 9. Sysctl Handler Without Lock

Symptom: WITNESS warning about an unprotected register access, or rare incorrect values observed from user space.

Cause: A sysctl handler reads or writes a register without acquiring the driver lock.

Diagnosis: The MYFIRST_ASSERT inside the accessor produces a WITNESS entry.

Fix: Wrap the register access in MYFIRST_LOCK/MYFIRST_UNLOCK.

16.30.10 10. Detach Races

Symptom: Kernel panic during kldunload with a stack that includes a register access.

Cause: A callout or task accesses registers after the register buffer has been freed.

Diagnosis: regs_buf == NULL in the panic; the caller is a task or callout that was not drained before the free.

Fix: Review detach ordering; drain all callouts and tasks before freeing regs_buf.

Each of these bugs has a short diagnostic path and a well-defined fix. Keeping the list nearby during development catches most issues on first contact.

17 Simulating Hardware

17.1 Reader Guidance & Outcomes

Chapter 16 ended with a driver that owned a register block. The `myfirst` module at version `0.9-mmio` carries a 64-byte region of kernel memory shaped to look like a device: ten named 32-bit registers, a small set of bit masks, a device ID that reads `0x4D594649`, a firmware revision that encodes `1.0`, and a `STATUS` register whose `READY` bit is asserted at attach and cleared at detach. Every access goes through `bus_space_read_4` and `bus_space_write_4`, wrapped by the familiar `CSR_READ_4`, `CSR_WRITE_4`, and `CSR_UPDATE_4` macros. The driver's mutex (`sc->mtx`) protects each register touch. An access log remembers the last sixty-four accesses, a ticker task flips `SCRATCH_A` on demand, and a small `HARDWARE.md` documents the whole surface.

That driver can already do a great deal. It can read registers. It can write registers. It can observe its own accesses, catch out-of-bounds offsets on debug kernels, and enforce the lock discipline that every later chapter will depend on. What it cannot do yet is behave like a real device. Its `STATUS` bits never change on their own. Its `DATA_IN` register does not start a multi-cycle operation. Its `INTR_STATUS` does not accumulate events. Writing `CTRL.GO` does not schedule anything. Nothing in the simulation has a heartbeat of its own; every change to the register block is a direct consequence of the last user-space write.

Real devices are not like that. A temperature sensor refreshes its value every few milliseconds without anyone asking. A serial controller raises an interrupt when a byte lands in the receive FIFO, long after the driver's last write. A network card's descriptor ring fills with packets while the driver sleeps. The interesting parts of a device driver come from reacting to change, not from producing it. Teaching a reader to write those reactive paths requires a simulated device that produces change, and Chapter 17 is where the simulation learns to do so.

17.1.1 What Chapter 17 Is About

Chapter 17's scope is narrow but deep. It takes the static register block from Chapter 16 and gives it four new properties:

- **Autonomous behaviour.** A callout fires on a cadence the driver controls and updates `STATUS` bits, `INTR_STATUS` bits, or data registers as if a real device's internal state machine were running in silicon. The reader sees values change between two adjacent `sysctl` reads, even though no user-space write occurred between them.
- **Command-triggered protocol.** Writing a designated bit in `CTRL` schedules a delayed state change. After a configurable delay, `STATUS.DATA_AV` asserts and, optionally, `INTR_STATUS.DATA_AV` latches. This is the pattern every command-response device follows: a write starts something, a later status change signals that something finished.

- Realistic timing. Delays on the order of microseconds use `DELAY(9)` where appropriate and `pause_sbt(9)` where a sleep is safe. Delays on the order of milliseconds use `callout_reset_sbt(9)` so no thread is blocked while the simulated device works. Each choice has a place; each choice has a cost; Chapter 17 teaches both.
- Fault injection. A `sysctl` lets the reader ask the simulation to fail. Failures take several shapes: the next read returns a fixed error value, the next write never asserts `DATA_AV`, a random fraction of operations set `STATUS.ERROR`, a `STATUS.BUSY` bit stays on indefinitely. Each mode exercises a different error-handling path in the driver, and the driver learns to notice, recover, or report.

The chapter builds these properties on top of the Chapter 16 driver without replacing it. The same register map, the same accessors, the same `sc->mtx`, the same access log. What grows is the simulation backend. The `myfirst_hw.c` file from Chapter 16 gains a sibling file, `myfirst_sim.c`, that holds the simulation's callouts, the fault-injection hooks, and the helpers that make the register block breathe. By the end of the chapter the driver is at version 1.0-simulated, and the hardware-surface it shows the driver is rich enough to exercise almost every lesson of Part 3.

17.1.2 Why Autonomous Behaviour Deserves a Chapter of Its Own

A natural question at this stage is whether callout-driven behaviour and fault injection really deserve a full chapter. Chapter 16 already placed a register block in front of the driver, and Chapter 18 will replace that block with real PCI hardware. Is simulation not just a stepping stone we should step off as soon as possible?

Three answers, each worth taking seriously.

First, the simulation in Chapter 16 was static on purpose. It existed to let the reader practise register access without also managing device behaviour. Chapter 17 is where device behaviour enters the picture, and the right place to introduce it is not in the middle of the real-PCI chapter, where the reader is already juggling BAR allocation, vendor and device IDs, and the newbus glue. A chapter dedicated to simulation gives the reader room to reason about how a device behaves, how delays shape protocol, and how faults propagate, without the distractions real hardware brings.

Second, simulation is not a one-time scaffold we discard after Chapter 18. It is a permanent part of driver development. Real drivers get tested against simulated devices long after they first run on real hardware, because simulation is the only way to produce deterministic failures, reproducible timing, and fault conditions on demand. Every serious FreeBSD subsystem has some form of simulation or test harness, and every working driver author learns how to build one. Chapter 17 teaches the technique on a small scale where the reader can see every moving part.

Third, the simulation in Chapter 17 is a teaching device in its own right. By writing a fake device, the reader is forced to think about what a real device does: when it asserts a bit, when it clears one, when it fails, when it latches, when it forgets. A reader who has written the simulation understands the protocol in a way that a reader who has only used the simulation does not. The chapter is as much about the discipline of thinking like hardware as it is about the code that implements it.

17.1.3 Where Chapter 16 Left the Driver

A brief recap of where you should stand. Chapter 17 extends the driver produced at the end of Chapter 16 Stage 4, tagged as version 0.9-mmio. If any of the items below feels uncertain, return to Chapter 16 before starting this chapter.

- Your driver compiles cleanly and identifies itself as 0.9-mmio in `kldstat -v`.
- The `softc` contains a pointer `sc->hw` to a struct `myfirst_hw` that holds `regs_buf`, `regs_size`, `regs_tag`, `regs_handle`, and the Chapter 16 access log.
- Every register access in the driver goes through `CSR_READ_4(sc, off)`, `CSR_WRITE_4(sc, off, val)`, or `CSR_UPDATE_4(sc, off, clear, set)`.
- The accessors assert `sc->mtx` is held via `MYFIRST_ASSERT` on debug kernels.
- `sysctl dev.myfirst.0` lists the `reg_*` sysctls for each register, the `reg_ctrl_set` writeable sysctl, the `access_log_enabled` toggle, and the `access_log` dumper.
- `HARDWARE.md` documents the register map and the `CSR_*` API.
- `LOCKING.md` documents the detach ordering, including the new `myfirst_hw_detach` step.

That driver is what Chapter 17 extends. The additions are again moderate in line count: a new `myfirst_sim.c` file, four new callouts, two new sysctl groups, a small fault-injection state structure, and a handful of protocol helpers. The mental-model change is larger than the line count suggests.

17.1.4 What You Will Learn

Once you have finished this chapter, you will be able to:

- Explain what “simulating hardware” means in kernel space, why simulation is a permanent part of driver development rather than a temporary crutch, and what makes a good simulation versus a misleading one.
- Design a register map for a simulated device, with separate sections for control, status, data, interrupts, and metadata, and justify each choice against the protocol the device is meant to implement.
- Choose register widths, offsets, bit-field layouts, and access semantics (read-only, write-only, read-to-clear, write-one-to-clear, read/write) that mirror patterns used in real FreeBSD drivers.
- Implement a simulated hardware backend in kernel memory that behaves autonomously, with a callout that updates registers on a cadence and a task that reacts to writes the driver issues.
- Expose the fake device to the driver using the same `bus_space(9)` abstraction that real drivers use, so the driver code has no knowledge of whether it is talking to silicon or to a struct in kernel memory.
- Test device behaviour from the driver side by writing commands, polling for status, reading data, and checking invariants under a variety of loads.
- Add timing and delay to the simulation using `DELAY(9)`, `pause_sbt(9)`, and `callout_reset_sbt(9)`, and explain why each tool is appropriate for the time scale where it is used.
- Simulate errors and fault conditions safely, with a sysctl-driven fault-injection path that can reproduce timeouts, data errors, busy-forever states, and random failures, and use those injected faults to exercise the driver’s error paths.
- Refactor the simulation so it lives in its own file (`myfirst_sim.c`), document its interface in a `SIMULATION.md`, version the driver as 1.0-simulated, and run a full regression pass.
- Recognise the limits of simulation and the scenarios where only real hardware (or hypervisor-backed virtual hardware) will produce trustworthy results.

The list is long; each item is narrow. The point of the chapter is the composition.

17.1.5 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 17 stays focused.

- **Real PCI devices.** The `pci(4)` subsystem, vendor and device ID matching, BAR allocation through `bus_alloc_resource_any`, `pci_enable_busmaster`, and the glue that ties a driver to a real bus belong to Chapter 18. Chapter 17 stays in simulation and uses the Chapter 16 shortcut for the tag and handle.
- **Interrupts.** The simulation produces state changes that mimic what an interrupt handler would see. It does not yet register an actual interrupt handler via `bus_setup_intr(9)`, and it does not split work between a filter handler and an interrupt thread. Chapter 19 covers that. Chapter 17 polls through callouts and user-space syscalls; the callouts stand in for an interrupt source.
- **DMA.** Descriptor rings, scatter-gather lists, `bus_dma(9)` tags, bounce buffers, and cache flushing around DMA are Chapters 20 and 21. Chapter 17's data register stays a single 32-bit slot.
- **Full-system simulators.** QEMU, bhyve, virtio devices, and the kinds of simulation hypervisors offer are mentioned in passing as a bridge to Chapter 18. Chapter 17 stays in-kernel; the simulation runs inside the same kernel as the driver.
- **Protocol verification and formal methods.** Real hardware verification uses formal tools to prove a driver's protocol handling is correct. Those tools exist outside the scope of this book. Chapter 17 uses INVARIANTS, WITNESS, stress tests, and deliberate fault injection to build confidence.
- **Hypervisor-backed device emulation.** Chapter 17's simulation runs in the kernel's own address space. Virtio devices in a VM, emulated NICs in QEMU, and bhyve's device emulation all run in a hypervisor; the driver sees them through real PCI. That path is Chapter 18's concern.

Staying inside those lines keeps Chapter 17 a chapter about making a fake device behave like a real one. The vocabulary is what transfers; the specific subsystems are what Chapters 18 through 22 apply the vocabulary to.

17.1.6 Estimated Time Investment

- **Reading only:** three to four hours. The simulation concepts are small but accumulate; each section introduces a new behaviour pattern and the composition is what makes the chapter rich.
- **Reading plus typing the worked examples:** eight to ten hours over two sessions. The driver evolves in five stages; each stage is a small refactor that merges into the existing `myfirst_hw.c` or into the new `myfirst_sim.c`.
- **Reading plus all labs and challenges:** thirteen to sixteen hours over three or four sessions, including stress testing under the debug kernel, working through the fault-injection scenarios, and reading a couple of real callout-driven drivers.

Sections 3, 6, and 7 are the densest. If the interplay of a callout, a mutex, and a state change feels opaque on first pass, that is expected: three primitives from Part 3 are composing in a new way. Stop, re-read Section 6's timing table, and continue when the composition has settled.

17.1.7 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 16 Stage 4 (0.9-mmio). The starting point assumes every Chapter 16 register accessor, the split between `myfirst.c` and `myfirst_hw.c`, the `CSR_*` macros, and the access log.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- You are comfortable with `callout_init_mtx`, `callout_reset_sbt`, and `callout_drain` from Chapter 13, and with `taskqueue` from Chapter 14.
- You understand `arc4random(9)` at a reading level. If it is new, skim the manual page before Section 7.

If any item above is shaky, fix it now rather than pushing through Chapter 17 and trying to reason from a moving foundation. Simulation code produces timing-sensitive bugs, and a debug kernel plus solid Part 3 foundations catch most of them on first contact.

17.1.8 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep a second terminal open on the machine where you are testing. Simulation makes registers change between two `sysctl` reads, and the only way to see that is to read the same `sysctl` twice in a row. A shell that loops `sysctl dev.myfirst.0.reg_status` every 200 milliseconds is how the chapter's examples come alive. If you cannot run two terminals side by side, a `watch -n 0.2 sysctl ... loop` in a `tmux` pane works just as well.

Second, read the access log after every experiment. The log captures every register access with a timestamp, an offset, a value, and a context tag. For a static simulation the log is boring: user-space reads, user-space writes, nothing else. For the Chapter 17 simulation the log is dense: callouts firing, delayed events triggering, faults being injected, timeouts expiring. Every interesting behaviour leaves a trail, and the trail is where the chapter's intuition comes from.

Third, break the simulation on purpose. Set the fault-injection rate to 100%. Set the callout interval to zero. Make the simulated device always busy. See how the driver reacts. The chapter's error-handling lessons are a lot clearer when you have seen the failure modes play out. The simulation is safe: you can inject as many faults as you like without risking real hardware, and the worst case is a kernel panic that a debug kernel catches cleanly.

17.1.9 Roadmap Through the Chapter

The sections in order are:

1. **Why Simulate Hardware?** The case for simulation as a permanent part of driver development, the difference between a good simulation and a misleading one, and the goals Chapter 17's simulation is aiming at.

2. **Designing the Register Map.** How to choose registers, widths, layouts, and access semantics for a simulated device, with a worked example of the additions Chapter 17 makes on top of the Chapter 16 map.
3. **Implementing the Simulated Hardware Backend.** The first callout that updates registers autonomously, a `myfirst_sim_tick` helper that carries the simulation state machine, and the first stage of the Chapter 17 driver (`1.0-sim-stage1`).
4. **Exposing the Fake Device to the Driver.** The tag, the handle, the accessor path, and how the Chapter 16 abstraction carries forward without modification. A short section; the point is that the Chapter 16 work already did most of it.
5. **Testing Device Behavior from the Driver.** Writing a command, polling for status, reading data, and handling the race between the driver's observation and the simulation's own state updates. Stage 2 of the Chapter 17 driver.
6. **Adding Timing and Delay.** Microsecond-scale `DELAY(9)`, millisecond-scale `pause_sbt(9)`, and second-scale `callout_reset_sbt(9)`; when each is safe; when each is not; what latency the driver can expect from each. Stage 3.
7. **Simulating Errors and Fault Conditions.** A fault-injection framework built on top of the simulation, with modes that cover timeouts, data errors, stuck-busy, and random failures. Teaching the driver to notice, recover, or report. Stage 4.
8. **Refactoring and Versioning Your Simulated Hardware Driver.** The final split into `myfirst_sim.c`, a new `SIMULATION.md`, the version bump to `1.0-simulated`, and the regression pass. Stage 5.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 17's story and opens Chapter 18's, and a bridge to Chapter 18. The reference material at the end of the chapter is meant to be kept nearby while you work through the labs.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3, 6, and 7 stand alone reasonably well and make good single-sitting reads.

17.2 Section 1: Why Simulate Hardware?

Chapter 16 already made the case for simulation as an on-ramp. A reader who does not own the exact device the book references can still practise register access against a simulated block. That argument is valid and still holds in Chapter 17, but it is not the only reason simulation earns a chapter of its own. Simulation is part of how serious driver development is done, and understanding why is what this section is about.

17.2.1 The Working Driver Author's Toolkit

Pick any real FreeBSD driver and walk backward from the commit history. Most drivers that see active development share a common pattern: the first commits build the driver against real hardware. Later commits, often many later commits, add tests, harnesses, scaffolding, and instrumentation that let the driver be exercised without the original hardware sitting on the developer's desk. Some of this instrumentation runs in user space. Some of it is a hypervisor-backed fake device that speaks the same protocol as the real one. Some of it is a set of kernel-side stubs that pretend to be the hardware well enough to run the driver's state machines.

Why do working driver authors invest in this? Because real hardware is not reproducible. A real device's behaviour depends on its firmware revision, its temperature, its link partner, the signal integrity of its physical

connection, and the phase of the moon. A driver that passes tests against one instance of a device may fail against a slightly different instance. A driver that passes tests today may fail tomorrow because the device's firmware autoupdate went through overnight. A driver whose failure is timing-dependent may pass a hundred runs and fail the hundred-and-first. Real hardware is a moving target, and a moving target is a bad foundation for regression testing.

Simulation fixes the target. A simulated device behaves the same way every time the same inputs arrive. A simulated device's fault conditions are under the author's control. A simulated device can be run in a tight loop without wearing out. A simulated device does not require lab hardware, cabling, a power supply, or a colleague whose help you need. Every property that makes simulation convenient for learning makes it valuable for production testing.

The conclusion is that Chapter 17's simulation is not disposable scaffolding. The patterns you learn here are the same patterns FreeBSD committers use to test drivers that nobody has access to any more because the silicon is twenty years old. The same techniques catch regressions before they reach a customer's machine. The same discipline, applied to the real PCI device in Chapter 18, lets the driver be exercised on a workstation with no network at all by telling a virtio-net backend to drop packets, corrupt frames, or duplicate descriptors at a controlled rate.

17.2.2 Simulation Goals: Behaviour, Timing, Side Effects

When we say “simulate a device”, we usually mean one of three things, and it is worth being explicit about which one we intend.

The first kind of simulation is **behavioural**. The simulation exposes a register interface, and writes and reads produce the same effects a real device would produce. The state machine is correct: writing `CTRL.GO` moves the device from idle to busy to done, setting `STATUS.DATA_AV` at the right point. The data path is correct: data written to `DATA_IN` shows up in `DATA_OUT` after some processing. The simulation does not have to match the real device's timing; it just has to follow the same rules.

The second kind of simulation is **timing-aware**. The simulation enforces the delays the real device would enforce. A write that the real device needs 500 microseconds to process takes 500 microseconds in the simulation, more or less, subject to the CPU's own timing resolution. A status bit that the real device asserts 2 milliseconds after a command asserts 2 milliseconds after the command in the simulation. A driver that passes timing-aware simulation is likely to work on the real hardware; a driver that only passes behavioural simulation may fail when the real device's latency produces a race the driver has not considered.

The third kind of simulation is **side-effect-aware**. The simulation mirrors the subtle parts of the protocol: reads that clear state, writes that have no effect, registers that return all-ones when the device is in a certain mode, bits that are write-one-to-clear versus bits that are read-to-clear. A driver that passes this kind of simulation is confident in the low-level protocol details, not just the high-level state flow.

The three kinds stack. A realistic simulation is all three: behaviour, timing, and side effects. Chapter 17 builds a simulation of all three kinds, though the timing precision is limited by what the kernel's scheduling machinery can deliver. The goal is not to match silicon microsecond-for-microsecond; the goal is to make the simulation realistic enough that the driver's important protocol paths get exercised and the race conditions those paths contain get a chance to manifest.

17.2.3 What a Good Simulation Teaches and What It Does Not

A good simulation teaches protocol. It exercises every branch in the driver's state machine, every error path, every status check, every delay tolerance. A driver written against a good simulation is robust against the scenarios the simulation covers.

A good simulation does not teach silicon. The CPU's memory hierarchy, the device's internal pipelines, the signal integrity of the PCB traces, the interaction with the rest of the system's traffic, the thermal behaviour of the chip under load: none of these are in the simulation. A driver that passes simulation can still fail on real hardware if the failure is rooted in physics.

This distinction matters. Chapter 17's simulation is a teaching tool for protocol, and the driver it produces is a vehicle for learning, not a production network driver. Chapters 20 through 22 introduce DMA, interrupts, and real device performance concerns, all of which extend the simulation in directions that need real hardware to validate fully. Chapter 17 is step one of a longer progression: get the protocol right, then get the real-hardware details right.

There is a second subtlety worth naming. A simulation can teach the *wrong* protocol if the simulation is inconsistent with the real device. A reader who learns to expect the simulation's behaviour, then encounters real hardware whose behaviour diverges, will be confused. Chapter 17's simulation is deliberately designed to match the patterns common in real FreeBSD drivers: `STATUS_READY` clears while the device is busy and sets when it is ready, `STATUS_DATA_AV` latches until the driver reads the data, `INTR_STATUS` is read-to-clear, `CTRL_RESET` is write-one-to-self-clear. These patterns are not universal; different devices choose different conventions. But they are common, and a driver that handles these patterns well has learned transferable skill.

17.2.4 No Hardware Dependency: The Practical Benefit

For this book, the most immediate benefit of simulation is that the reader does not need specific hardware to follow along. A reader working through Chapter 16 on a laptop with no external devices, on a virtual machine with no PCI passthrough, on an ARM single-board computer with only the onboard peripherals, can still build the driver and watch it behave. Chapter 17 preserves that property. The simulation lives entirely in kernel memory; the driver needs nothing beyond a running FreeBSD 14.3 system.

This matters for a teaching book. A reader who has to stop, order hardware, install it, and wait for delivery before they can continue is a reader who may not continue. A reader who can build and run the driver in the same session they read the chapter is a reader who is learning. Every Chapter 17 lab and challenge is designed to run on any x86 FreeBSD system without external hardware.

A secondary benefit is that simulation lets the book run ahead of what a reader's hardware can do. The driver in Chapter 17 exercises error paths that a real device would almost never trigger under normal operation. A reader who owns a production-quality network card would have trouble forcing the card into the kinds of failure modes Chapter 7's fault injection teaches. A simulated device can be told to fail on demand, as often as needed, under any condition the reader wants to exercise. The learning surface is broader.

17.2.5 Full Control: The Pedagogical Benefit

Simulation gives the reader more control than real hardware ever does. The reader can freeze time in the simulation, step forward by a known number of ticks, and observe every intermediate state. The reader can

disable the simulation's autonomous behaviour, make a single manipulation, and re-enable it. The reader can inject a specific fault, observe how the driver reacts, and then repair the fault by toggling a sysctl. None of this is possible against real silicon.

This level of control is pedagogically valuable. A chapter that explains “when the device is busy, the driver should wait for `STATUS.READY`” can demonstrate the scenario concretely. Chapter 17 does just that: a sysctl tells the simulation to enter a fake-busy state, and the reader can type commands while the driver patiently waits for the busy bit to clear. On real hardware, producing this scenario reliably would require a specific workload that the device would reject, or an artificial test fixture, or a debugger. In simulation, it is a one-line sysctl change.

Control also means the reader can experiment without consequences. Setting a register to an illegal value, issuing a command the device does not expect, asking the driver to access a register outside the mapped range: each of these is safe in simulation. The worst case is a `KASSERT` firing and a panic that a debug kernel catches cleanly. The reader can try ten bad ideas in an hour, learn from each, and come out better for it. Experimentation with real hardware carries real risks, and readers (reasonably) exercise more caution there.

17.2.6 Safe Experiments: The Risk-Reduction Benefit

The word “safe” deserves expansion. A kernel panic from a simulated device is an embarrassment; a kernel panic from a real device can be worse. A driver that writes a wrong bit to a real device's `CTRL` register can brick the device. A driver that corrupts a real device's DMA configuration can write garbage over arbitrary RAM. A driver that mishandles a real interrupt can leave the system in a state where legitimate interrupts are missed indefinitely. Each of these failure modes has appeared in production FreeBSD over the years, and each has required a kernel update to fix.

Simulation eliminates most of this risk. The simulated device is a struct in kernel memory; a wrong bit goes into memory that is not connected to anything else. The simulated DMA does not exist yet (it arrives in Chapter 20). The simulated interrupts are callouts that the driver can stop at any time. A beginner writing their first driver can make every mistake the driver development lifecycle contains without causing a physical problem.

This is worth internalising. Chapter 17's simulation gives the reader permission to experiment aggressively, which is what a beginner needs to do to build confidence. A reader who has never broken a driver is a reader who has not yet learned how drivers break. Chapter 17 is the chapter where the reader learns both how to break a driver on purpose and how to recognise it when it breaks on its own.

17.2.7 What We Will Simulate in Chapter 17

A short list of the specific behaviours the chapter will introduce. Each is added in the section that discusses it; the list here is a roadmap.

- **Autonomous `STATUS` updates.** A callout fires every 100 milliseconds and updates fields in `STATUS` as if a background hardware monitor were sampling the device's internal state. The driver can observe the updates; the test suite can assert them.
- **Command-triggered delayed events.** Writing `CTRL.GO` schedules a callout that, after a configurable delay (default 500 milliseconds), sets `STATUS.DATA_AV` and copies `DATA_IN` to `DATA_OUT`. This is the textbook “asynchronous device” pattern.

- **Read-to-clear `INTR_STATUS`.** Reading `INTR_STATUS` returns the current pending-interrupt bits and then atomically clears them. Writing `INTR_STATUS` has no effect (real devices vary; some allow write-one-to-clear, which is a common variant we will discuss).
- **Simulated sensor data.** A `SENSOR` register holds a value that the simulation updates on a cadence, mimicking a temperature or pressure reading. The driver can poll it; a user-space tool can graph it.
- **Timeout tolerance.** The driver's command path waits up to a configurable number of milliseconds for `STATUS.DATA_AV` to assert. If the simulation is configured to delay longer than the timeout, the driver reports a timeout and recovers.
- **Random fault injection.** A `sysctl` controls the probability that any operation will inject a fault. The fault types include: `STATUS.ERROR` set after a command, the next command timing out entirely, a read returning `0xFFFFFFFF`, the device reporting fake-busy indefinitely. Each fault exercises a different driver path.

Every one of these behaviours is implemented by Section 8. The chapter builds them one at a time so the reader can internalise each before moving on.

17.2.8 The Simulation's Place in the Book

Chapter 17 sits between Chapter 16 (static register access) and Chapter 18 (real PCI hardware). It is the bridge between the abstract vocabulary and the concrete device. A reader who completes Chapter 17 has a driver that has exercised nearly every protocol pattern the book will discuss, against a simulated device that behaves like a real one. That reader walks into Chapter 18 with a driver that is already close to production-grade in structure, needing only the real-PCI glue to run on actual silicon.

The simulation is also a reference. When Chapter 18 replaces the simulated register block with a real PCI BAR, the reader can compare the simulation's behaviour against the real device's behaviour and notice the differences. The simulation is the yardstick. When Chapter 19 adds interrupts, the simulation's callout-driven state changes become the model for what an interrupt handler reacts to. When Chapter 20 adds DMA, the simulation's data registers become the model for what the DMA engine reads and writes. The simulation is the teaching vocabulary that every later chapter extends.

17.2.9 Wrapping Up Section 1

Simulation is a permanent part of driver development, not a temporary scaffold. It gives driver authors reproducible tests, controlled failure injection, and the ability to exercise error paths that real hardware rarely produces. Chapter 17 builds a simulation of three kinds (behavioural, timing-aware, side-effect-aware) on top of the Chapter 16 driver. The simulation is deliberately designed to match common patterns in real FreeBSD drivers so the reader's intuition transfers to real hardware later.

The chapter's specific goals include autonomous `STATUS` updates, command-triggered delayed events, read-to-clear semantics, simulated sensor data, timeout tolerance, and random fault injection. Each is introduced in the section that needs it; together they produce a driver rich enough to exercise almost every Part 3 lesson.

Section 2 takes the next step. Before we simulate device behaviour, we need a register map that the behaviour operates on. Chapter 16 gave us a static map; Chapter 17 extends it for dynamic behaviour.

17.3 Section 2: Designing the Register Map

Chapter 16 gave the simulated device a register map. Chapter 17's work extends that map, but the extensions are not automatic. Adding a register to a real device requires a team of hardware engineers, a silicon respin, and a new datasheet. Adding a register to a simulated device is easy in mechanical terms, but the design work (what should the register do? who writes it? who reads it? what are its side effects?) is the same, and the discipline of doing it well is the same.

This section walks through the design, not just the result. By the end of Section 2 you will have a register map that supports every behaviour Section 1 listed, documented well enough that the implementation in Sections 3 through 7 is almost mechanical. The exercise is transferable: every time you read a real datasheet, you will recognise the decisions the hardware designers made, and you will have a vocabulary for evaluating whether the decisions were wise.

17.3.1 What Is a Register Map?

A register map is the complete catalogue of a device's register interface. It lists every register, every offset, every width, every field, every bit, every access type, every reset value, every side effect. A real device's register map may run to hundreds of pages; a simple device's register map may fit on a single page. The form is similar in both cases: a table, or a set of tables, with headings that answer the questions a driver author needs to ask.

A register map is not prose. It is a reference document. The driver author consults it when writing code, and the test author consults it when writing tests. A register map that is vague, incomplete, or ambiguous produces drivers that are wrong in ways that are hard to diagnose. A register map that is precise produces drivers that match what the device expects.

For a simulated device, the register map plays one extra role. It is also the specification against which the simulation's behaviour is tested. If the simulation disagrees with the register map, the simulation is wrong and must be fixed. If the driver disagrees with the register map, the driver is wrong and must be fixed. The map is the contract. Changes to the map require changes to both the simulation and the driver. This is exactly how real device development works: the datasheet is the contract, and the hardware team, the firmware team, and the driver team all work to it.

17.3.2 The Chapter 16 Map as a Starting Point

Recall the Chapter 16 register map:

Offset	Width	Name	Access	Chapter 16 Behaviour
0x00	32 bit	CTRL	R/W	Plain read-write memory.
0x04	32 bit	STATUS	R/W	Plain read-write memory.
0x08	32 bit	DATA_IN	R/W	Plain read-write memory.
0x0c	32 bit	DATA_OUT	R/W	Plain read-write memory.
0x10	32 bit	INTR_MASK	R/W	Plain read-write memory.
0x14	32 bit	INTR_STATUS	R/W	Plain read-write memory.

Offset	Width	Name	Access	Chapter 16 Behaviour
0x18	32 bit	DEVICE_ID	R-only	Fixed 0x4D594649.
0x1c	32 bit	FIRMWARE_REV	R-only	Fixed 0x00010000.
0x20	32 bit	SCRATCH_A	R/W	Plain read-write memory.
0x24	32 bit	SCRATCH_B	R/W	Plain read-write memory.

Ten registers, 40 bytes of defined space, 64 bytes allocated to leave room for growth. Every access is direct: reads return whatever the last write stored, writes go straight into memory. No side effects on reads. No side effects on writes. No hardware state machine behind the registers.

Chapter 17 changes two things about this map. First, the existing registers grow behavioural semantics: `STATUS.DATA_AV` will be set by the simulation, not just by the driver's writes; `INTR_STATUS` becomes read-to-clear. Second, the map adds a small number of new registers that the Chapter 17 simulation needs: a `SENSOR` register, a `DELAY_MS` register, a `FAULT_MASK` register, and a few more. The 64-byte allocation from Chapter 16 already has room; no allocator change is required.

17.3.3 Register Access Semantics

Before we write any register, we should name the access semantics we care about. A register's access semantics are the rules for what happens when the driver reads or writes it. The main categories in common use are:

Read-only (RO). The register returns a value the device or the simulation produced. Writes are ignored or produce an error. `DEVICE_ID` and `FIRMWARE_REV` are examples.

Read/Write (RW). The register stores whatever the driver writes. Reads return the last-written value. `CTRL`, `SCRATCH_A`, and `SCRATCH_B` are examples.

Write-only (WO). The register accepts writes, but reads return a fixed value (often zero, sometimes garbage, occasionally the last-read value from a different source). `DATA_IN` is often write-only in real devices.

Read-to-clear (RC). Reading the register returns its current value and then clears it. Writes are typically ignored. `INTR_STATUS` is the classic example.

Write-one-to-clear (W1C). Writing a 1 to a bit clears that bit; writing a 0 has no effect. Reads return the current value. `INTR_STATUS` on some devices uses W1C instead of RC.

Write-one-to-set (W1S). Writing a 1 sets the bit; writing a 0 has no effect. Less common than W1C, but used in some hardware for control registers where the driver should not have to do a read-modify-write.

Read/write with side effect (RWSE). The register is readable and writable, but the write (or the read) triggers something beyond a plain memory update. `CTRL` often falls in this category: writing `CTRL.RESET` triggers a device reset, which is a side effect.

Sticky (latched). A bit, once set by the hardware, stays set until the driver explicitly clears it. Error bits in `STATUS` are usually sticky. `STATUS.ERROR` will be sticky in the Chapter 17 map.

Reserved. The bit has no defined meaning. Writes should either preserve the existing value or write zero; reads may return any value. A driver that ignores reserved bits is robust against future hardware revisions; a driver that depends on reserved-bit behaviour is fragile.

Each access type has implications for the driver's code. A driver reading an RC register should do so exactly when the protocol demands, because every extra read consumes an event. A driver reading a WO register is reading garbage, which is a bug waiting to appear if the value is ever acted on. A driver doing a read-modify-write on a sticky-bit register must be careful not to clear a bit it did not intend to touch. A driver writing a WIC register uses `CSR_WRITE_4(sc, REG, mask)` and not `CSR_UPDATE_4(sc, REG, mask, 0)`; the two look similar but produce different behaviour on the hardware.

Chapter 17's simulation uses RO, RW, RC, sticky, and RWSE semantics. It does not introduce WIC or WIS (though the challenges invite the reader to add them). The simulation's goal is to cover the common cases thoroughly; the less common cases become natural extensions once the common ones are understood.

17.3.4 Chapter 17 Additions

The Chapter 17 register map adds the following registers:

Offset	Width	Name	Access	Chapter 17 Behaviour
0x28	32 bit	SENSOR	RO	Simulated sensor value. Updated by a callout every 100 ms.
0x2c	32 bit	SENSOR_CONFIG	RW	Sensor update interval and amplitude settings.
0x30	32 bit	DELAY_MS	RW	Number of milliseconds the device takes per command.
0x34	32 bit	FAULT_MASK	RW	Which simulated faults are enabled. Bitfield.
0x38	32 bit	FAULT_PROB	RW	Probability of random fault per operation (0..10000).
0x3c	32 bit	OP_COUNTER	RO	Count of commands the simulated device has processed.

Six new registers, using offsets 0x28 through 0x3c, fitting entirely inside the 64-byte region Chapter 16 allocated. No softc change, no allocator change, no `bus_space_map` change.

Each register has a specific job:

- **SENSOR** is the simulated temperature, pressure, or voltage. The exact interpretation does not matter for the simulation; what matters is that it changes on its own, teaching the reader how to handle registers whose value is produced autonomously. The value oscillates around a baseline using a simple formula the callout will implement.
- **SENSOR_CONFIG** lets the driver (or the user through a `sysctl`) control the sensor's behaviour. The low 16 bits are the update interval in milliseconds; the high 16 bits are the amplitude of the oscillation. A value of `0x0064_0040` means "100 ms interval, amplitude 64". Changing the register changes the simulation's next update.
- **DELAY_MS** is how long a command takes in the simulation. Writing `CTRL.GO` schedules `STATUS.DATA_AV` to assert `DELAY_MS` milliseconds later. The default is 500. Setting it to 0 makes commands complete on the next callout tick; setting it to a large value lets the reader exercise the driver's timeout path.
- **FAULT_MASK** is a bitfield that selects which fault modes are active. Bit 0 enables the "operation times out" fault; bit 1 enables the "read returns all-ones" fault; bit 2 enables the "error bit set after every command" fault; bit 3 enables the "device always busy" fault. Multiple bits can be set simultaneously.

- **FAULT_PROB** controls the probability that any single operation will inject a fault, in tenths of a basis point. A value of 10000 is 100% (fault every time); 5000 is 50%; 0 disables random faulting entirely. This gives the reader fine-grained control over how aggressively faults are injected.
- **OP_COUNTER** counts every command the simulation has processed. It is read-only; writes are ignored. The driver can use it to verify that a command actually reached the simulation, and the user can read it from user space to check activity.

17.3.5 Header Additions for the New Registers

The header for the additions lives in `myfirst_hw.h`, extending the Chapter 16 definitions:

```
/* Chapter 17 additions to the simulated device's register map. */

#define MYFIRST_REG_SENSOR          0x28
#define MYFIRST_REG_SENSOR_CONFIG 0x2c
#define MYFIRST_REG_DELAY_MS       0x30
#define MYFIRST_REG_FAULT_MASK     0x34
#define MYFIRST_REG_FAULT_PROB     0x38
#define MYFIRST_REG_OP_COUNTER     0x3c

/* SENSOR_CONFIG register fields. */
#define MYFIRST_SCFG_INTERVAL_MASK 0x0000ffffu /* interval in ms */
#define MYFIRST_SCFG_INTERVAL_SHIFT 0
#define MYFIRST_SCFG_AMPLITUDE_MASK 0xffff0000u /* oscillation range */
#define MYFIRST_SCFG_AMPLITUDE_SHIFT 16

/* FAULT_MASK register bits. */
#define MYFIRST_FAULT_TIMEOUT      0x00000001u /* next op times out          */
#define MYFIRST_FAULT_READ_1S     0x00000002u /* reads return 0xFFFFFFFF */
#define MYFIRST_FAULT_ERROR       0x00000004u /* STATUS.ERROR after op    */
#define MYFIRST_FAULT_STUCK_BUSY  0x00000008u /* STATUS.BUSY latched on  */

/* CTRL register: GO bit (new for Chapter 17). */
#define MYFIRST_CTRL_GO           0x00000200u /* bit 9: start command    */

/* STATUS register: BUSY and DATA_AV are now dynamic (set by simulation). */
/* (The mask constants were already defined in Chapter 16.) */
```

The new CTRL bit `MYFIRST_CTRL_GO` does not overlap any existing bit. `MYFIRST_CTRL_ENABLE` is bit 0, `RESET` is bit 1, `MODE_MASK` covers bits 4 through 7, `LOOPBACK` is bit 8. The new GO bit at bit 9 fits cleanly in the gap.

The comments in the header are deliberately terse. In a real driver, comments at this level would point at the datasheet section (for example, */* See datasheet section 4.2.1 */*). For the simulation, the datasheet is this chapter; a reader looking for the definitive behaviour of `MYFIRST_FAULT_ERROR` should consult Section 7 of Chapter 17.

17.3.6 Writing a Register Map Table for Your Own Device

The exercise of writing a register map is one of the most valuable things you can do as a beginning driver author. Even if you never write the simulation or the driver, the act of sitting down and thinking “what would this device’s registers be?” forces you to think about the device as an entity with a protocol rather than as a magic box.

A useful template:

1. Decide what the device does at a high level. One sentence.
2. Identify the commands the device must accept. Each command may become a bit in a CTRL register, a value in a COMMAND register, or its own register.
3. Identify the states the device reports. Each state may become a bit in a STATUS register, a value in a STATE register, or its own read-only register.
4. Identify the data the device produces or consumes. Input data goes in a DATA_IN register or a FIFO. Output data comes from a DATA_OUT register or a FIFO.
5. Identify the interrupts the device can raise. Each interrupt source becomes a bit in INTR_STATUS (or an equivalent).
6. Identify any metadata the driver needs at startup. Device ID, firmware revision, feature flags, capability bits.
7. Leave space for configuration registers the driver may want to tune. In Chapter 17, DELAY_MS, FAULT_MASK, and FAULT_PROB are configuration registers; a real device might have timeout thresholds, error recovery options, power management settings.
8. Decide the width of each register. 32 bits is the common default on modern devices. Narrower widths exist for legacy devices or for devices where the register count is very large.
9. Decide the offset of each register. Keep related registers contiguous when possible. Align offsets to the register’s width (32-bit registers at offsets divisible by 4).
10. Decide the access semantics (RO, RW, RC, W1C, ...). Be explicit; ambiguity here produces bugs.
11. Decide the reset value of each register. What should the register hold at power-on? At reset? At module attach?
12. Document the side effects of every non-trivial register.

This list is long, but each step is small. A real device team might take weeks to produce a register map this detailed. A simulated device’s map can be produced in an afternoon. The Chapter 17 map is the result of this exercise applied to a teaching device.

17.3.7 Example Layout and Design Choices

To make the discipline concrete, walk through the design decisions behind the Chapter 17 additions.

Decision 1: Group related registers. The new registers SENSOR (0x28) and SENSOR_CONFIG (0x2c) are adjacent. A driver reading the sensor code can access both with a single region read if needed, and a reader scanning the register dump sees them together. The same logic puts FAULT_MASK (0x34) and FAULT_PROB (0x38) adjacent.

Decision 2: Put configuration after diagnostic. DEVICE_ID (0x18) and FIRMWARE_REV (0x1c) are read-only diagnostic registers; they come first in the high-offset section. SENSOR and its config come next. DELAY_MS,

FAULT_MASK, FAULT_PROB are configuration; they come after. OP_COUNTER is another diagnostic; it goes at the end.

Decision 3: Use the existing CTRL register for the new GO bit. Rather than adding a dedicated COMMAND register, the GO bit in CTRL is how the driver initiates a command. This matches the Chapter 16 pattern (the ENABLE and RESET bits are both in CTRL) and saves a register.

Decision 4: Make OP_COUNTER read-only. A writable counter would invite bugs where the driver accidentally reset the counter mid-operation. A read-only counter is always monotonic (modulo 32-bit wrap) and always reflects the simulation's view.

Decision 5: Encode two fields in SENSOR_CONFIG. Rather than two separate registers for interval and amplitude, a single register with two 16-bit fields saves one slot and matches a common hardware pattern. A real device might have an 8-bit command ID in the high byte and a 24-bit argument in the lower three bytes of a register; the principle is the same.

Decision 6: Use FAULT_PROB in tenths of a basis point (range 0 to 10000). Using 10000 as full-scale rather than 100 gives two extra decimal places of precision. Fault probabilities of 0.5%, 0.75%, 1.25% become expressible as integers without fractional arithmetic.

Each decision is small; the composition is what makes the map usable. A register map designed carelessly produces a driver full of awkward patches; a map designed carefully produces a driver that writes itself.

17.3.8 Naming Conventions for Constants

A note on the naming conventions Chapter 17 uses for bit masks, which mirror what real FreeBSD drivers do.

The prefix MYFIRST_ marks everything as belonging to the driver. Inside that, REG_ indicates a register offset, CTRL_ indicates a bit or field in CTRL, STATUS_ indicates a bit in STATUS, and so on. The pattern is <driver>_<register>_<field>. For example, MYFIRST_STATUS_READY is the READY bit in the STATUS register. The name is long, but it is unambiguous, and modern editors complete it quickly.

Masks that cover multiple bits end with _MASK; shifts to align the mask end with _SHIFT. MYFIRST_CTRL_MODE_MASK is the mask for the 4-bit MODE field; MYFIRST_CTRL_MODE_SHIFT is the number of bits to shift right to bring the field to bit zero. Extracting the field reads as `(ctrl & MYFIRST_CTRL_MODE_MASK) >> MYFIRST_CTRL_MODE_SHIFT`; setting it reads as `(mode << MYFIRST_CTRL_MODE_SHIFT) & MYFIRST_CTRL_MODE_MASK`.

Fixed values end with _VALUE. MYFIRST_DEVICE_ID_VALUE is the constant value of the DEVICE_ID register. This convention keeps values distinguishable from masks at a glance.

Real drivers sometimes deviate from this convention, often for historical reasons or because their register names are long. The `if_em` driver uses shorter prefixes (EM_ rather than E1000_ in some places) to fit within reasonable line lengths. The `if_ale` driver uses CSR_READ_4(sc, ALE_REG_NAME) with ALE_ as the prefix. The principle is the same across drivers: every constant is visibly part of one driver's namespace, and the pattern inside the namespace is consistent.

For Chapter 17, consistency matters more than brevity. The reader is still learning the patterns; a long, explicit name is more educational than a short, ambiguous one.

17.3.9 Validating the Map Before Writing Code

Before implementing the simulation, it is worth validating the map against a few sanity checks.

Check 1: Offsets fit inside the allocated region. The Chapter 16 region is 64 bytes. The highest defined offset in the Chapter 17 map is 0x3c, with width 4, so the last byte used is at offset 0x3f. 0x40 is one past the allocated region. The map fits exactly; there is no room for a further register without enlarging the allocation. That is a design constraint worth knowing.

Check 2: All offsets are 4-byte aligned. Every register is 32 bits wide, and every offset is a multiple of 4. `bus_space_read_4` and `bus_space_write_4` require 4-byte alignment on most platforms; an unaligned access would fault on some architectures and silently misbehave on others. The map follows the rule.

Check 3: No two registers overlap. Each 32-bit register occupies 4 consecutive bytes. Check that adjacent offsets differ by at least 4. They do: 0x00, 0x04, 0x08, 0x0c, 0x10, 0x14, 0x18, 0x1c, 0x20, 0x24, 0x28, 0x2c, 0x30, 0x34, 0x38, 0x3c.

Check 4: No reserved bits are used for multiple purposes. A bit defined for one field must not appear in another field. `MYFIRST_CTRL_ENABLE` is bit 0, `RESET` is bit 1, `MODE` covers bits 4 through 7, `LOOPBACK` is bit 8, `GO` is bit 9. No overlap.

Check 5: Access semantics are consistent with the simulation's intent. `DEVICE_ID` and `FIRMWARE_REV` are RO, which means the simulation will refuse to change them after attach. `INTR_STATUS` will be RC, meaning the simulation clears it when the driver reads it. `OP_COUNTER` is RO, meaning writes do nothing. Everything else is RW (possibly with side effects). This is consistent with what Section 1 described.

Check 6: Reset values are sensible. At attach, `DEVICE_ID` is 0x4D594649, `FIRMWARE_REV` is 0x00010000, `STATUS` has `READY` set, everything else is zero. `DELAY_MS` defaults to 500 (500 ms per command). `SENSOR_CONFIG` defaults to 0x0064_0040 (100 ms interval, amplitude 64). `FAULT_MASK` defaults to 0 (no faults enabled). `FAULT_PROB` defaults to 0 (no random faults). The defaults describe a simulation that behaves like a reliable device until told otherwise.

These checks are the kind of thing a disciplined driver author runs through before writing any code. They take a few minutes and catch several common bugs before they appear.

17.3.10 Documenting the Map

Chapter 16 introduced `HARDWARE.md`. Chapter 17 extends it. The section headings in `HARDWARE.md` at the end of Chapter 17 will be:

1. Version and scope
2. Register summary table (every register, every offset, every width, every access type, every default value)
3. `CTRL` register fields (table of every bit in `CTRL`)
4. `STATUS` register fields (table of every bit in `STATUS`)
5. `INTR_MASK` and `INTR_STATUS` fields (table of every interrupt source)
6. `SENSOR_CONFIG` fields (interval and amplitude)
7. `FAULT_MASK` fields (table of every fault type)
8. Register-by-register reference (one paragraph per register, describing behaviour, side effects, and usage)
9. Common sequences (write-then-read-to-verify, command-and-wait, fault-injection-for-test)
10. Observability (every `sysctl` that reads or writes a register)

11. Simulation notes (which registers are dynamic, which are static, what the callouts do)

This document is long, perhaps 100 lines. It is the single source of truth for what the driver expects from the simulation. A reader who forgets a register's behaviour opens `HARDWARE.md` and finds the answer. A contributor adding a new register updates `HARDWARE.md` first, then changes the code.

17.3.11 Common Mistakes in Register Map Design

Beginners designing their first register map often make the same few mistakes. A brief catalogue so you can avoid them.

Mistake 1: Using magic numbers in the code instead of named constants. A driver that writes `CSR_WRITE_4(sc, 0x00, 0x1)` instead of `CSR_WRITE_4(sc, MYFIRST_REG_CTRL, MYFIRST_CTRL_ENABLE)` is hard to read and impossible to refactor. The rule is: every offset is a constant; every bit is a constant; every field is a macro.

Mistake 2: Overlapping bit definitions. Two names, one bit. A reader doing a bitwise OR of `FLAG_A` and `FLAG_B` gets a value that corresponds to a third thing entirely, because `FLAG_A` and `FLAG_B` turn out to be the same bit. The defence is a comment next to each bit name listing its bit number, plus a sanity check at compile time (`_Static_assert((MYFIRST_CTRL_ENABLE & MYFIRST_CTRL_RESET) == 0, "bits overlap")` if you want to be defensive).

Mistake 3: Unaligned accesses. Defining a 32-bit register at offset `0x06` looks harmless but fails on any architecture where unaligned accesses are disallowed. Always align offsets to the register's width.

Mistake 4: Forgetting reserved bits. A 32-bit register where only bits 0 through 3 are defined may have unspecified values in bits 4 through 31. A driver that writes `CSR_WRITE_4(sc, REG, 0xF)` is fine for now, but a future revision that defines bit 5 may break because the driver is effectively writing zero to it every time. The defence is read-modify-write on registers with reserved bits: `CSR_UPDATE_4(sc, REG, mask_of_fields_we_touch, new_field_values)`.

Mistake 5: Side effects on read that the driver does not expect. An RC register that the driver reads for debugging purposes clears state the driver was about to act on. The defence is to document every side effect explicitly in the header and in `HARDWARE.md`, so a reader can see the danger before writing the bug.

Mistake 6: Assuming writes always succeed. A write to a RO register may be silently ignored, or may raise a fault, or may do something surprising on certain hardware. The defence is to use the correct access semantics and to stress-test the driver's use of each register.

Mistake 7: Inconsistent widths. A 32-bit register next to an 8-bit register where the access width is not obvious from the name. The defence is to make the width part of the accessor call (`CSR_READ_4` vs `CSR_READ_1`) and to name the register's type somewhere visible.

Mistake 8: Overly clever bit layouts. A 16-bit field that spans two non-adjacent byte lanes, requiring bit-gathering in the driver. Real devices do this sometimes (often because of historical constraints), but a simulated device should stick to contiguous fields. The simulation is a teaching device; clarity wins over cleverness.

Mistake 9: Missing reset values. A register whose reset value is unspecified forces the driver to guess what the register holds after attach. The defence is to initialise every register to a documented value in the attach path.

Mistake 10: Stale documentation. The code changes, the documentation does not. Two months later the driver works but the documentation lies. The defence is the discipline of updating `HARDWARE.md` in the same commit that changes the code.

Each mistake is small in isolation and expensive in aggregate. A driver written without these mistakes is a driver that reads well, tests well, and ages well.

17.3.12 Wrapping Up Section 2

A register map is the specification of a device's programmer-visible interface. Chapter 17's map extends Chapter 16's with six new registers: `SENSOR`, `SENSOR_CONFIG`, `DELAY_MS`, `FAULT_MASK`, `FAULT_PROB`, and `OP_COUNTER`. Each register has a purpose, a width, an access type, a reset value, and a documented behaviour. The design choices behind each register are worth understanding, because they mirror the decisions real device designers make.

The map is documented in the header (`myfirst_hw.h`) and in `HARDWARE.md`. The header is consumed by the compiler; the markdown is consumed by humans. Both are kept in sync as the code evolves.

Section 3 takes the map and implements the simulation. The first callout fires; the first autonomous register update happens; the static Chapter 16 block acquires a heartbeat.

17.4 Section 3: Implementing the Simulated Hardware Backend

Section 2 produced a register map. Section 3 makes the map behave. The simulation's first job is to update registers autonomously, without the driver asking it to. That is how real hardware behaves: a sensor refreshes its value on a clock, an interrupt controller latches events as they arrive, a network card's receive counter ticks up as frames arrive. Chapter 17's first simulation step is to produce a similar heartbeat.

The tool is one the reader already knows: a callout. Chapter 13 introduced `callout_init_mtx` and `callout_reset` for internal driver timers. Chapter 17 uses the same primitive for a different purpose: driving simulated device state. The callout fires every 100 milliseconds, acquires the driver's mutex, updates some registers, releases the mutex, and schedules its next firing. From the driver's point of view the registers just change; from the simulation's point of view a timer is running.

17.4.1 The First Simulation File

Chapter 16's file layout was `myfirst.c` for the driver lifecycle, `myfirst_hw.c` for the hardware-access layer, and `myfirst_hw.h` for the shared definitions. Chapter 17 adds a new file, `myfirst_sim.c`, for the simulation backend. The split keeps the simulation code out of the hardware-access file, so a later chapter can replace `myfirst_sim.c` with real PCI-facing code without touching the accessors.

Create `myfirst_sim.c` alongside the Chapter 16 files. The first version is small:

```
/*-
 * myfirst_sim.c -- Chapter 17 simulated hardware backend.
 */
```

```
* Adds a callout that drives autonomous register changes, a
* command-scheduling callout for command-triggered delays, and
* the fault-injection state that Section 7 will populate.
*
* This file assumes Chapter 16's register access layer
* (myfirst_hw.h, myfirst_hw.c) is present and functional.
*/

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/malloc.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/callout.h>
#include <sys/sysctl.h>
#include <sys/bus.h>
#include <sys/random.h>
#include <machine/bus.h>

#include "myfirst.h"
#include "myfirst_hw.h"
#include "myfirst_sim.h"
```

The includes follow FreeBSD conventions: `sys/param.h` first, then `sys/system.h`, then the specific subsystem headers. `sys/random.h` will be needed for `arc4random` later; pulling it in now avoids a second edit. The driver's private headers come last.

The file compiles against the existing `myfirst.h` and `myfirst_hw.h`, plus a new `myfirst_sim.h` that will contain the simulation's API. A stub of that header:

```
/* myfirst_sim.h -- Chapter 17 simulation API. */
#ifndef _MYFIRST_SIM_H_
#define _MYFIRST_SIM_H_

struct myfirst_softc;

/* Attach/detach the simulation. Called from myfirst_attach/detach. */
int myfirst_sim_attach(struct myfirst_softc *sc);
void myfirst_sim_detach(struct myfirst_softc *sc);

/* Enable/disable the simulation's autonomous updates. */
void myfirst_sim_enable(struct myfirst_softc *sc);
void myfirst_sim_disable(struct myfirst_softc *sc);
```

```
/* Command scheduling: called when the driver writes CTRL.GO. */
void myfirst_sim_start_command(struct myfirst_softc *sc);

/* Sysctl registration for simulation controls. */
void myfirst_sim_add_sysctls(struct myfirst_softc *sc);

#endif /* _MYFIRST_SIM_H_ */
```

Five functions, one header file, one source file. The API is small. The simulation's internal state lives in a struct myfirst_sim, pointed at from the softc via sc->sim, in the same pattern as sc->hw.

17.4.2 The Simulation State Structure

Inside myfirst_sim.h, define the state structure:

```
struct myfirst_sim {
    /* Autonomous update callout. Fires every sensor_interval_ms. */
    struct callout      sensor_callout;

    /* Command completion callout. Fires DELAY_MS after CTRL.GO. */
    struct callout      command_callout;

    /* Last scheduled command's data. Saved so command_cb can
     * latch DATA_OUT when it fires. */
    uint32_t            pending_data;

    /* Whether a command is currently in flight. */
    bool                command_pending;

    /* Baseline sensor value; the callout oscillates around this. */
    uint32_t            sensor_baseline;

    /* Counter used by the sensor oscillation algorithm. */
    uint32_t            sensor_tick;

    /* Operation counter. Written to OP_COUNTER on every completion. */
    uint32_t            op_counter;

    /* Whether the simulation is running. Stops cleanly at detach. */
    bool                running;
};
```

Seven fields. Two are callouts (sensor updates and command completion). One is boolean state (command in flight). One is the saved pending data. Three are internal counters. One is the running flag.

The softc gains a pointer to the simulation structure:

```
struct myfirst_softc {
    /* ... all existing fields, including hw ... */
    struct myfirst_sim    *sim;
};
```

The allocation and initialisation happen in `myfirst_sim_attach`, called from `myfirst_attach` after `myfirst_hw_attach` has already set up `sc->hw`. Putting the sim attach after the hw attach is deliberate: the simulation reads and writes registers through the Chapter 16 accessors, so the accessors must be ready before the simulation starts.

17.4.3 The Sensor Callout: The First Autonomous Update

The smallest useful simulation update is the sensor callout. It fires every 100 milliseconds, updates the `SENSOR` register, and re-arms itself. The code:

```
static void
myfirst_sim_sensor_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct myfirst_sim *sim = sc->sim;
    uint32_t config, interval_ms, amplitude, phase, value;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running)
        return;

    /* Read the current SENSOR_CONFIG. */
    config = CSR_READ_4(sc, MYFIRST_REG_SENSOR_CONFIG);
    interval_ms = (config & MYFIRST_SCFG_INTERVAL_MASK) >>
        MYFIRST_SCFG_INTERVAL_SHIFT;
    amplitude = (config & MYFIRST_SCFG_AMPLITUDE_MASK) >>
        MYFIRST_SCFG_AMPLITUDE_SHIFT;

    /* Compute a simple oscillation. phase cycles 0..7 and back. */
    sim->sensor_tick++;
    phase = sim->sensor_tick & 0x7;
    value = sim->sensor_baseline +
        ((phase < 4) ? phase : (7 - phase)) *
        (amplitude / 4);

    /* Publish. */
```

```

        CSR_WRITE_4(sc, MYFIRST_REG_SENSOR, value);

        /* Re-arm at the current interval. */
        if (interval_ms == 0)
            interval_ms = 100;
        callout_reset_sbt(&sim->sensor_callout,
            interval_ms * SBT_1MS, 0,
            myfirst_sim_sensor_cb, sc, 0);
    }

```

Step by step.

First, the callout asserts the lock. A callout that was scheduled with `callout_init_mtx(&co, &mtx, 0)` automatically acquires `mtx` before calling the callback, so the assertion is redundant for a well-disciplined driver, but it is cheap and it documents the invariant. Debug kernels catch any violation.

Second, the callout checks the running flag. If the simulation is being torn down (detach path), the callout exits immediately without re-arming. The detach path then drains the callout with `callout_drain`, which waits for any in-flight callback to finish.

Third, the callback reads `SENSOR_CONFIG` to learn the interval and amplitude. Reading the config each time means the user can change it through a `sysctl` and the next callback will use the new value, without any signalling mechanism beyond the register write.

Fourth, the callback computes an oscillating value. The phase $< 4 ? \text{phase} : (7 - \text{phase})$ trick produces a triangle wave that goes 0, 1, 2, 3, 4, 3, 2, 1, 0, 1, ... over successive calls. Multiplied by `amplitude / 4`, it oscillates between baseline and baseline + amplitude. The formula is simple by design; the point is to produce visible change, not to model a real sensor.

Fifth, the callback writes the new value to `SENSOR`. The write is what the driver or a user-space observer will see.

Sixth, the callback re-arms itself. `callout_reset_sbt` takes a signed binary time, so `interval_ms * SBT_1MS` converts milliseconds into the right units. The `pr` argument (precision) is zero, meaning the kernel can defer the callback by up to 100% of the interval to batch with other timers; a lower value would force stricter timing. The `flags` argument is zero, meaning no special flags like `C_DIRECT_EXEC` or `C_HARDCLOCK`; the callback runs on a normal callout thread with the registered mutex held.

If `interval_ms` was zero, the code defaults to 100 ms. A zero interval would immediately re-arm with zero delay, which would spin the kernel in a tight loop; the guard is defensive.

17.4.4 Initialising the Sensor Callout

In `myfirst_sim_attach`:

```

int
myfirst_sim_attach(struct myfirst_softc *sc)
{

```

```

struct myfirst_sim *sim;

sim = malloc(sizeof(*sim), M_MYFIRST, M_WAITOK | M_ZERO);

/* Initialise the callouts with the main mutex. */
callout_init_mtx(&sim->sensor_callout, &sc->mtx, 0);
callout_init_mtx(&sim->command_callout, &sc->mtx, 0);

/* Pick a baseline sensor value; 0x1000 is arbitrary but visible. */
sim->sensor_baseline = 0x1000;

/* Default config: 100 ms interval, amplitude 64. */
MYFIRST_LOCK(sc);
CSR_WRITE_4(sc, MYFIRST_REG_SENSOR_CONFIG,
    (100 << MYFIRST_SCFG_INTERVAL_SHIFT) |
    (64 << MYFIRST_SCFG_AMPLITUDE_SHIFT));
CSR_WRITE_4(sc, MYFIRST_REG_DELAY_MS, 500);
CSR_WRITE_4(sc, MYFIRST_REG_FAULT_MASK, 0);
CSR_WRITE_4(sc, MYFIRST_REG_FAULT_PROB, 0);
CSR_WRITE_4(sc, MYFIRST_REG_OP_COUNTER, 0);
MYFIRST_UNLOCK(sc);

sc->sim = sim;
return (0);
}

```

The function allocates the `sim` structure, initialises its callouts with the driver's mutex (so the callbacks run with `sc->mtx` held automatically), picks a baseline sensor value, writes the default configuration to the simulation registers under the lock, and stores the pointer in the `softc`.

The callouts are not started yet. The simulation is ready but idle. A separate function, `myfirst_sim_enable`, starts the callouts; a user can toggle the simulation on and off through a `sysctl`. This separation is useful for debugging and for tests that need a known-quiet starting state.

17.4.5 Enabling and Disabling the Simulation

```

void
myfirst_sim_enable(struct myfirst_softc *sc)
{
    struct myfirst_sim *sim = sc->sim;
    uint32_t config, interval_ms;

    MYFIRST_LOCK_ASSERT(sc);

```

```
    if (sim->running)
        return;

    sim->running = true;

    config = CSR_READ_4(sc, MYFIRST_REG_SENSOR_CONFIG);
    interval_ms = (config & MYFIRST_SCFG_INTERVAL_MASK) >>
        MYFIRST_SCFG_INTERVAL_SHIFT;
    if (interval_ms == 0)
        interval_ms = 100;

    callout_reset_sbt(&sim->sensor_callout,
        interval_ms * SBT_1MS, 0,
        myfirst_sim_sensor_cb, sc, 0);
}

void
myfirst_sim_disable(struct myfirst_softc *sc)
{
    struct myfirst_sim *sim = sc->sim;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running)
        return;

    sim->running = false;

    callout_stop(&sim->sensor_callout);
    callout_stop(&sim->command_callout);
}
```

`myfirst_sim_enable` sets `running` to true and schedules the first sensor callout. `myfirst_sim_disable` clears the flag and stops both callouts. `callout_stop` does not wait for any in-flight callback to finish; it just cancels any pending reschedule. The in-flight callback will notice `running == false` on its next invocation and exit.

Note that neither `callout_stop` nor `callout_reset_sbt` releases the mutex. Both are safe to call with the mutex held. This is why `callout_init_mtx` was used: the mutex is threaded through the callout subsystem so the callbacks always run with it held, and the control calls never fight the lock.

Also note that `myfirst_sim_disable` does not drain the callouts. Draining must happen in detach, not in disable. The reason is that `callout_drain` sleeps, and sleeping with a mutex held is illegal. Drain happens in the detach path, after the mutex has been released.

17.4.6 Wiring the Simulation into Attach and Detach

In `myfirst_attach` (the main `myfirst.c` file), add the simulation attach call after the hardware attach:

```
int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc;
    int error;

    sc = device_get_softc(dev);

    /* ... existing Chapter 11-15 init ... */

    /* Chapter 16: hardware layer. */
    error = myfirst_hw_attach(sc);
    if (error != 0)
        goto fail_hw;

    /* Chapter 17: simulation backend. */
    error = myfirst_sim_attach(sc);
    if (error != 0)
        goto fail_sim;

    /* ... existing sysctl and cdev setup ... */

    myfirst_hw_add_sysctls(sc);
    myfirst_sim_add_sysctls(sc);

    /* Enable the simulation by default. */
    MYFIRST_LOCK(sc);
    myfirst_sim_enable(sc);
    MYFIRST_UNLOCK(sc);

    return (0);

fail_sim:
    myfirst_hw_detach(sc);
fail_hw:
    /* ... existing unwind ... */
    return (error);
}
```

The simulation is attached after the hardware layer and before the sysctl registration. The simulation is enabled at the end of attach, once everything else is ready. If any step fails, the unwind path runs in reverse order: disable

what was enabled, detach what was attached, free what was allocated.

In `myfirst_detach`, the simulation detach happens early, before the hardware detach:

```
int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* ... existing cdev destroy, wait for outstanding fds ... */

    /* Chapter 17: stop the simulation, drain its callouts. */
    MYFIRST_LOCK(sc);
    myfirst_sim_disable(sc);
    MYFIRST_UNLOCK(sc);
    myfirst_sim_detach(sc);

    /* Chapter 16: detach the hardware layer. */
    myfirst_hw_detach(sc);

    /* ... existing synchronization primitive teardown ... */

    return (0);
}
```

Note the ordering. Disable happens with the lock held; detach happens after the lock is released. Detach is where the draining happens:

```
void
myfirst_sim_detach(struct myfirst_softc *sc)
{
    struct myfirst_sim *sim;

    if (sc->sim == NULL)
        return;

    sim = sc->sim;
    sc->sim = NULL;

    callout_drain(&sim->sensor_callout);
    callout_drain(&sim->command_callout);

    free(sim, M_MYFIRST);
}
```

`callout_drain` waits for any in-flight callback to finish. If the callback is running on another CPU when `callout_drain` is called, `callout_drain` blocks until the callback completes and returns. After `callout_drain` returns, no callback will ever run for that callout again, so freeing the simulation state is safe.

The pattern is the same one Chapter 13 taught for callouts in general. The only subtlety is that the mutex must be released before calling `callout_drain`; if the callback is waiting to acquire the mutex when we call drain, and we are holding the mutex, we deadlock. The unlock-before-drain ordering is essential.

17.4.7 A First Test: The Sensor Updates Visibly

Build and load the driver. Then:

```
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.reg_sensor
dev.myfirst.0.reg_sensor: 4096
# sysctl dev.myfirst.0.reg_sensor
dev.myfirst.0.reg_sensor: 4128
# sysctl dev.myfirst.0.reg_sensor
dev.myfirst.0.reg_sensor: 4144
# sysctl dev.myfirst.0.reg_sensor
dev.myfirst.0.reg_sensor: 4160
```

The value is changing between reads. The baseline is $0 \times 1000 = 4096$, and the oscillation goes up by amplitude / 4 = 16 per tick, so the values are 4096, 4112, 4128, 4144, 4160, 4144, 4128, 4112, 4096, ... Four values up, four values down, back to the baseline.

If you read fast enough, you may see the same value twice (the callout fires every 100 ms; a `sysctl` that takes less time to dispatch than 100 ms may see the same state). Slow down and read about once per second, and you will see the full oscillation.

Try changing the config:

```
# sysctl dev.myfirst.0.reg_sensor_config=0x01000040
```

This sets interval to $0 \times 0100 = 256$ ms and amplitude to $0 \times 0040 = 64$. The sensor now updates every 256 ms. You can see the change in the access log:

```
# sysctl dev.myfirst.0.access_log_enabled=1
# sleep 2
# sysctl dev.myfirst.0.access_log_enabled=0
# sysctl dev.myfirst.0.access_log
```

The log should show roughly 8 writes to `SENSOR` over the 2-second window ($2000 \text{ ms} / 256 \text{ ms} \approx 7.8$). Before the config change, the rate would have been 20 writes in 2 seconds.

This is what the simulation is producing. The driver does nothing during this time; the simulation runs on its own, driven by the sensor callout.

17.4.8 A Second Callout: The Command Completion

The sensor callout is periodic. The command callout is one-shot: it fires once, when a command completes, and does nothing until the next command is issued.

```
static void
myfirst_sim_command_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct myfirst_sim *sim = sc->sim;
    uint32_t status;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running || !sim->command_pending)
        return;

    /* Complete the command: copy pending data to DATA_OUT,
     * set STATUS.DATA_AV, clear STATUS.BUSY, increment OP_COUNTER. */
    CSR_WRITE_4(sc, MYFIRST_REG_DATA_OUT, sim->pending_data);

    status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
    status &= ~MYFIRST_STATUS_BUSY;
    status |= MYFIRST_STATUS_DATA_AV;
    CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);

    sim->op_counter++;
    CSR_WRITE_4(sc, MYFIRST_REG_OP_COUNTER, sim->op_counter);

    sim->command_pending = false;
}
```

The callback does four things. It copies the pending data to DATA_OUT (the simulation’s “result”). It updates STATUS: BUSY clears, DATA_AV sets. It increments OP_COUNTER. And it clears the command_pending flag.

The command is initiated by myfirst_sim_start_command, called from the driver when it writes CTRL.GO:

```
void
myfirst_sim_start_command(struct myfirst_softc *sc)
{
    struct myfirst_sim *sim = sc->sim;
    uint32_t data_in, delay_ms;

    MYFIRST_LOCK_ASSERT(sc);
```

```

    if (!sim->running)
        return;

    if (sim->command_pending) {
        /* Command already in flight. Real devices might reject
         * this, set an error bit, or queue the command. For the
         * simulation, the simplest behaviour is to treat it as
         * a no-op. The driver should not do this. */
        device_printf(sc->dev,
            "sim: overlapping command; ignored\n");
        return;
    }

    /* Snapshot DATA_IN now; the callout fires later. */
    data_in = CSR_READ_4(sc, MYFIRST_REG_DATA_IN);
    sim->pending_data = data_in;

    /* Set STATUS.BUSY, clear STATUS.DATA_AV. */
    {
        uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        status |= MYFIRST_STATUS_BUSY;
        status &= ~MYFIRST_STATUS_DATA_AV;
        CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);
    }

    /* Read the configured delay. */
    delay_ms = CSR_READ_4(sc, MYFIRST_REG_DELAY_MS);
    if (delay_ms == 0) {
        /* Zero delay: complete on the next tick. */
        delay_ms = 1;
    }

    sim->command_pending = true;

    callout_reset_sbt(&sim->command_callout,
        delay_ms * SBT_1MS, 0,
        myfirst_sim_command_cb, sc, 0);
}

```

The function snapshots `DATA_IN` into the simulation state, sets `STATUS.BUSY`, clears `STATUS.DATA_AV`, reads the configured `DELAY_MS`, and schedules the command callout. The command callout fires `delay_ms` milliseconds later and finishes the command.

A subtle point: why snapshot `DATA_IN` instead of reading it in the command callout? Because the driver might write `DATA_IN` again before the callout fires. The simulation should use the value that was in `DATA_IN` when

CTRL.G0 was written, not whatever happens to be there when the callout runs. Snapshotting at start time is the correct behaviour for most real devices too: the device reads the command register when the command is issued and does not re-read it during execution.

17.4.9 Intercepting CTRL.G0

The `myfirst_sim_start_command` function is called when the driver writes CTRL.G0. The write intercept lives in the existing `myfirst_ctrl_update` helper (introduced in Chapter 16):

```
void
myfirst_ctrl_update(struct myfirst_softc *sc, uint32_t old, uint32_t new)
{
    /* Chapter 16 behaviour: log ENABLE transitions. */
    if ((old & MYFIRST_CTRL_ENABLE) != (new & MYFIRST_CTRL_ENABLE)) {
        device_printf(sc->dev, "CTRL.ENABLE now %s\n",
            (new & MYFIRST_CTRL_ENABLE) ? "on" : "off");
    }

    /* Chapter 17: if G0 was set, start a command in the simulation. */
    if (!(old & MYFIRST_CTRL_G0) && (new & MYFIRST_CTRL_G0)) {
        myfirst_sim_start_command(sc);
        /* Clear the G0 bit; it is a one-shot trigger. */
        CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, MYFIRST_CTRL_G0, 0);
    }
}
```

The extension watches for the G0 bit transitioning from 0 to 1. When it does, it calls `myfirst_sim_start_command` and immediately clears the G0 bit, because G0 is a one-shot trigger: it asserts, the command starts, the bit goes back to zero. This is a common pattern for “start” bits in real hardware; the hardware clears the bit automatically once the command has been accepted.

The self-clearing behaviour means the driver does not have to remember to clear the bit itself. It writes `CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_G0)` to start a command, and the simulation handles the rest.

17.4.10 A Second Test: The Command Path

With the command-path code in place, the simulation now supports a command cycle. Try it:

```
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 1

# sysctl dev.myfirst.0.reg_ctrl_set_datain=0x12345678 # (new sysctl for DATA_IN)
# sysctl dev.myfirst.0.reg_ctrl_set=0x200             # bit 9 = CTRL.G0
```

```
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 3      # BUSY | READY

# sleep 1
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 9      # READY | DATA_AV

# sysctl dev.myfirst.0.reg_data_out
dev.myfirst.0.reg_data_out: 305419896  # 0x12345678

# sysctl dev.myfirst.0.reg_op_counter
dev.myfirst.0.reg_op_counter: 1
```

Reading the status right after `CTRL.GO` shows `BUSY|READY`. Waiting for the 500 ms delay and reading again shows `READY|DATA_AV`. Reading `DATA_OUT` returns the value that was in `DATA_IN` when `CTRL.GO` was written. `OP_COUNTER` has been incremented by one.

A new `sysctl reg_ctrl_set_datain` was implied in the example; it is a trivial addition that mirrors `reg_ctrl_set` but writes `DATA_IN` instead of `CTRL`. The pattern is identical to the Chapter 16 `reg_ctrl_set`: an `SYSCTL_ADD_PROC` with a writeable handler. Add one `sysctl` per register the user may want to poke directly.

17.4.11 Protecting Against the Overlapping Command

The check for `command_pending` in `myfirst_sim_start_command` prevents overlapping commands. If the driver writes `CTRL.GO` while a command is already in flight, the simulation ignores the second command and logs a warning. This is not realistic for every real device (some queue commands, some reject them with an error), but it is the simplest correct behaviour for a teaching simulation.

The driver, for its part, should not issue a command while one is in flight. The driver can poll `STATUS.BUSY` to see whether the device is ready to accept a new command, and wait until `BUSY` clears before writing `CTRL.GO`. Section 5 teaches this pattern in the driver.

17.4.12 Sysctls for the Simulation Controls

The simulation registers are already exposed through the Chapter 16 register sysctls (`reg_sensor`, `reg_sensor_config`, `reg_delay_ms`, `reg_fault_mask`, `reg_fault_prob`, `reg_op_counter`). Chapter 17 adds a few top-level sysctls that are not register-mapped:

```
void
myfirst_sim_add_sysctls(struct myfirst_softc *sc)
{
    struct sysctl_ctx_list *ctx = &sc->sysctl_ctx;
```

```

struct sysctl_oid *tree = sc->sysctl_tree;

SYSCTL_ADD_BOOL(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "sim_running", CTLFLAG_RD,
    &sc->sim->running, 0,
    "Whether the simulation callouts are active");

SYSCTL_ADD_UINT(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "sim_sensor_baseline", CTLFLAG_RW,
    &sc->sim->sensor_baseline, 0,
    "Baseline value around which SENSOR oscillates");

SYSCTL_ADD_UINT(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "sim_op_counter_mirror", CTLFLAG_RD,
    &sc->sim->op_counter, 0,
    "Mirror of the OP_COUNTER value (for observability)");

/* Add writeable sysctls for the register-mapped fields. */
SYSCTL_ADD_PROC(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "reg_delay_ms_set",
    CTLTYPE_UINT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    sc, MYFIRST_REG_DELAY_MS, myfirst_sysctl_reg_write,
    "IU", "Command delay in milliseconds (writeable)");

SYSCTL_ADD_PROC(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "reg_sensor_config_set",
    CTLTYPE_UINT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    sc, MYFIRST_REG_SENSOR_CONFIG, myfirst_sysctl_reg_write,
    "IU", "Sensor config: interval|amplitude (writeable)");
}

```

The top-level `sim_running`, `sim_sensor_baseline`, and `sim_op_counter_mirror` expose internal state that is not register-mapped. The rest add writeable sysctls for the Chapter 17 registers, using the existing `myfirst_sysctl_reg_write` handler from Chapter 16.

The addition keeps the user's view consistent: every interesting piece of state is visible through `sysctl dev.myfirst.0`, and the writeable sysctls follow the `_set` suffix pattern the driver already uses.

17.4.13 What Stage 1 Accomplished

At the end of Section 3, the driver has:

- A new file `myfirst_sim.c` with the simulation backend.
- A new header `myfirst_sim.h` with the simulation API.
- A new simulation state structure pointed at by `sc->sim`.

- Two callouts: one for periodic sensor updates, one for one-shot command completion.
- An extension to `myfirst_ctrl_update` that intercepts `CTRL.GO`.
- Writeable sysctls for the new registers that should be configurable.

The version tag becomes `1.0-sim-stage1`. The driver still does everything Chapter 16 taught; it now also has two callouts that produce autonomous register behaviour.

Build, load, and test:

```
# cd examples/part-04/ch17-simulating-hardware/stage1-backend
# make clean && make
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.sim_running
# sysctl dev.myfirst.0.reg_sensor
# sleep 1
# sysctl dev.myfirst.0.reg_sensor
# sysctl dev.myfirst.0.reg_op_counter
# kldunload myfirst
```

You should see `sim_running` is 1, the sensor value changes, and `op_counter` stays at zero until you issue a command. If `kldunload` returns cleanly, the detach path is correct.

17.4.14 What Stage 1 Is Not

Stage 1 has the simulation running, but the driver's syscall paths do not yet know about the new behaviour. A `write(2)` to `/dev/myfirst0` still writes into the ring buffer, not into the simulated device. The bytes that go into the ring buffer never appear in `DATA_IN`, never cause a command, never appear in `DATA_OUT`. The simulation is ready; the driver is not yet using it for real.

Section 4 takes the next step: it connects the simulation to the driver's data path, so a user-space write causes a simulated command, and the command's result is what the user-space read sees. Until then, the simulation is a side show.

17.4.15 Wrapping Up Section 3

A simulated device's behaviour comes from a small set of primitives. A callout for periodic updates, a callout for one-shot timed events, and a shared state structure that both callouts consult. Chapter 17's simulation uses three of these: a sensor callout that runs always, a command callout that runs per-command, and an internal `command_pending` flag that prevents overlapping commands.

The simulation lives in its own file, `myfirst_sim.c`, which depends on the Chapter 16 `myfirst_hw.h` for register definitions. The split keeps the simulation code isolated; a later chapter that replaces the simulation with real PCI-facing code can delete `myfirst_sim.c` and replace it with `myfirst_pci.c` without touching the driver.

Section 4 begins the real integration: the driver's data path starts sending and receiving through the simulation, and the simulation starts looking like a proper device from the driver's side.

17.5 Section 4: Exposing the Fake Device to the Driver

Section 3 built a simulation backend that runs on callouts and writes to registers through the Chapter 16 accessors. Section 4 asks a different question: how does the driver see the simulation? From the driver's side, what is the access path? What does the code look like, and how does it differ from code that would talk to real hardware?

The short answer is that the access path does not change. The whole point of the Chapter 16 `bus_space(9)` abstraction is that the driver does not know, and does not care, whether the register block is real or simulated. Section 4 is deliberately a shorter section because the heavy lifting was done in Chapter 16. What remains is a careful look at how the abstraction survives the addition of dynamic behaviour, and at the few small hooks the driver needs to let the simulation drive its own behaviour.

17.5.1 The Tag and the Handle, Still

Chapter 16 set up the simulation's `bus_space_tag_t` and `bus_space_handle_t` in `myfirst_hw_attach`:

```
#if defined(__amd64__) || defined(__i386__)
    hw->regs_tag = X86_BUS_SPACE_MEM;
#else
    #error "Chapter 16 simulation supports x86 only"
#endif

hw->regs_handle = (bus_space_handle_t)(uintptr_t)hw->regs_buf;
```

That code does not change for Chapter 17. The simulation writes registers through `CSR_WRITE_4`, which expands to `myfirst_reg_write`, which expands to `bus_space_write_4(hw->regs_tag, hw->regs_handle, offset, value)`. The same tag; the same handle; the same accessor. The callouts that Section 3 introduced use the exact same API as the syscall path.

This is not an accident. The reason `bus_space` exists is precisely to hide the difference between real and simulated register access. A driver that uses `bus_space` correctly can be pointed at a real PCI BAR or at a `malloc(9)` allocation without any changes to the access code. The simulation exercises this property.

A useful exercise at this point: open `/usr/src/sys/dev/ale/if_ale.c` in one window and `myfirst_hw.c` in another. Compare the register access code. The ALE driver uses `CSR_READ_4(sc, ALE_REG_XYZ)`; your driver uses `CSR_READ_4(sc, MYFIRST_REG_XYZ)`. The expansion is identical. The only difference is the tag and handle: ALE gets them from `rman_get_bustag(sc->ale_res[0])` and `rman_get_bushandle(sc->ale_res[0])`; your driver gets them from the Chapter 16 simulation setup. Replacing the simulation with real hardware, which is what Chapter 18 will do, is a one-function change in `myfirst_hw_attach`.

17.5.2 Why the Abstraction Matters More Now

In Chapter 16, the argument for using `bus_space` was forward-looking: “when you eventually switch to real hardware, the driver code will not have to change”. In Chapter 17, the argument becomes concrete: the register block now changes on its own, and the driver has no way to know whether a change came from a simulation callout or from a real device's internal state machine. The abstraction is doing real work.

Consider a small example. A driver function that polls `STATUS.DATA_AV`:

```

static int
myfirst_wait_for_data(struct myfirst_softc *sc, int timeout_ms)
{
    int i;

    MYFIRST_LOCK_ASSERT(sc);

    for (i = 0; i < timeout_ms; i++) {
        uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        if (status & MYFIRST_STATUS_DATA_AV)
            return (0);

        /* Release the lock, sleep briefly, reacquire. */
        MYFIRST_UNLOCK(sc);
        pause_sbt("mfwait", SBT_1MS, 0, 0);
        MYFIRST_LOCK(sc);
    }

    return (ETIMEDOUT);
}

```

This function reads STATUS, checks a bit, and either returns or sleeps for a millisecond and retries. It does not know whether the bit is being set by the Chapter 17 simulation’s command callout, by a real device’s internal state machine, or by something else. It just polls.

The `pause_sbt` call is worth examining. The function releases the driver lock before sleeping and reacquires it afterwards. Sleeping with a lock held would block every other context that needs the lock, including the simulation callouts; dropping the lock before sleeping lets the simulation run. `pause_sbt` takes a sleep identifier (“mfwait”), a signed binary time (1 ms here), a precision, and flags. The precision of zero means the kernel can coalesce this sleep with other sleeps, reducing timer interrupts.

Section 6 revisits the choice between `DELAY(9)`, `pause_sbt(9)`, and `callout_reset_sbt(9)` in more depth. The short version: polling a register a thousand times per second while sleeping between each poll is not the most efficient pattern, but it is correct, simple, and readable. Chapter 17’s driver uses it because the protocol is small and the polling overhead does not matter. Real high-performance drivers use interrupts (Chapter 19) instead.

17.5.3 The Command-Path Integration

The driver’s current data path (`myfirst_write`, from Chapter 10) writes bytes into the ring buffer. Chapter 17 wants to route those bytes through the simulation: user writes a byte, the driver writes it into `DATA_IN`, sets `CTRL.GO`, waits for `STATUS.DATA_AV`, reads `DATA_OUT`, writes the result into the ring buffer. This is the full command cycle.

For Stage 2 of the Chapter 17 driver, we add the command-cycle code path. The write function becomes:

```
static int
myfirst_write_cmd(struct myfirst_softc *sc, uint8_t byte)
{
    int error;

    MYFIRST_LOCK_ASSERT(sc);

    /* Wait for the device to be ready for a new command. */
    error = myfirst_wait_for_ready(sc, 100);
    if (error != 0)
        return (error);

    /* Write the byte to DATA_IN. */
    CSR_WRITE_4(sc, MYFIRST_REG_DATA_IN, (uint32_t)byte);

    /* Issue the command. */
    CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_GO);

    /* Wait for the command to complete (STATUS.DATA_AV). */
    error = myfirst_wait_for_data(sc, 2000);
    if (error != 0)
        return (error);

    /* Check for errors. */
    {
        uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        if (status & MYFIRST_STATUS_ERROR) {
            /* Clear the error latch. */
            CSR_UPDATE_4(sc, MYFIRST_REG_STATUS,
                MYFIRST_STATUS_ERROR, 0);
            return (EIO);
        }
    }

    /* Read the result. DATA_OUT will hold the byte the simulation
     * echoed (or, if loopback is active, the same byte we wrote). */
    (void)CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);

    /* Clear DATA_AV so the next command can set it. */
    CSR_UPDATE_4(sc, MYFIRST_REG_STATUS, MYFIRST_STATUS_DATA_AV, 0);

    return (0);
}
```

Six steps. Wait for ready, write DATA_IN, set CTRL.GO, wait for DATA_AV, check for errors, read DATA_OUT. Clear DATA_AV to be polite to the next iteration.

The `myfirst_wait_for_ready` helper polls `STATUS.BUSY`:

```
static int
myfirst_wait_for_ready(struct myfirst_softc *sc, int timeout_ms)
{
    int i;

    MYFIRST_LOCK_ASSERT(sc);

    for (i = 0; i < timeout_ms; i++) {
        uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        if (!(status & MYFIRST_STATUS_BUSY))
            return (0);
        MYFIRST_UNLOCK(sc);
        pause_sbt("mfrdy", SBT_1MS, 0, 0);
        MYFIRST_LOCK(sc);
    }

    return (ETIMEDOUT);
}
```

Same structure as `myfirst_wait_for_data`; only the bit being polled differs. Both helpers are reasonable candidates for a shared implementation:

```
static int
myfirst_wait_for_bit(struct myfirst_softc *sc, uint32_t mask,
    uint32_t target, int timeout_ms)
{
    int i;

    MYFIRST_LOCK_ASSERT(sc);

    for (i = 0; i < timeout_ms; i++) {
        uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        if ((status & mask) == target)
            return (0);
        MYFIRST_UNLOCK(sc);
        pause_sbt("mfwait", SBT_1MS, 0, 0);
        MYFIRST_LOCK(sc);
    }

    return (ETIMEDOUT);
}
```

```
}
```

Then `wait_for_ready` calls `wait_for_bit(sc, MYFIRST_STATUS_BUSY, 0, timeout_ms)` and `wait_for_data` calls `wait_for_bit(sc, MYFIRST_STATUS_DATA_AV, MYFIRST_STATUS_DATA_AV, timeout_ms)`. The abstraction is worth extracting once you have two users; Section 6 revisits this pattern.

17.5.4 Where the Command Integrates with the Write Syscall

The existing Chapter 10 `myfirst_write` pushes bytes into the ring buffer. Chapter 17 does not replace that path; it augments it. For Stage 2, we add a per-byte command-cycle hook that sends each byte through the simulation in addition to pushing it into the ring.

```
static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    uint8_t buf[64];
    size_t n;
    int error;

    /* ... existing validation ... */

    while (uio->uio_resid > 0) {
        n = MIN(uio->uio_resid, sizeof(buf));
        error = uiomove(buf, n, uio);
        if (error != 0)
            return (error);

        MYFIRST_LOCK(sc);
        for (size_t i = 0; i < n; i++) {
            /* Send each byte through the simulated device. */
            error = myfirst_write_cmd(sc, buf[i]);
            if (error != 0) {
                MYFIRST_UNLOCK(sc);
                return (error);
            }

            /* Existing Chapter 10 path: push into ring. */
            error = cbuf_put(sc->cbuf, buf[i]);
            if (error != 0) {
                MYFIRST_UNLOCK(sc);
                return (error);
            }
        }
    }
}
```

```
        MYFIRST_UNLOCK(sc);  
    }  
  
    return (0);  
}
```

The loop is one-byte-at-a-time for clarity. Each byte goes through the command cycle, then into the ring. A real driver would usually pipeline this (write several bytes to a FIFO, issue a single command, read several bytes back), but Chapter 17's teaching point is about single commands; pipelining is a refinement for later.

Note the locking. The outer lock covers the entire batch (up to 64 bytes). Each `myfirst_write_cmd` call releases and reacquires the lock internally when it sleeps. Other contexts that need the lock (notably the simulation callouts) get a chance to run between commands.

17.5.5 Stage 2 Test

Build, load, and test:

```
# kldload ./myfirst.ko  
# echo -n "hi" > /dev/myfirst0  
# sysctl dev.myfirst.0.reg_op_counter  
dev.myfirst.0.reg_op_counter: 2  
  
# dd if=/dev/myfirst0 bs=1 count=2 2>/dev/null  
hi
```

Two bytes written; `OP_COUNTER` incremented by two. The reads return the same two bytes because the simulation echoes `DATA_IN` to `DATA_OUT`. The test validates the end-to-end flow: user space writes, driver commands, simulation processes, driver reads, user space receives.

The whole cycle takes about 1 second (500 ms per byte, two bytes). This is slow, but it is realistic: a real device with similar latency (for example, a SPI-attached sensor that takes 500 ms to produce a reading) would feel exactly like this. Speeding it up means reducing `DELAY_MS` (try `sysctl dev.myfirst.0.reg_delay_ms_set=10` for 10 ms per command).

17.5.6 What Does Not Change

A few properties of the Chapter 16 driver that do not change in Stage 2 are worth enumerating.

The access log continues to work. Every register read and write the driver performs shows up in the log. The simulation's own register writes also show up (because they go through the same accessors). The log is dense, which is good: you can see the simulation's heartbeat alongside the driver's activity.

The `sysctl` interface continues to work. Every register is readable; every writeable register is writeable. The Chapter 16 conveniences (read-every-register, write-specific-registers) are unchanged.

The locking discipline continues to work. Every register access happens under `sc->mtx`; the simulation callouts were designed to run with `sc->mtx` held (via `callout_init_mtx`), so there are no lock-order inversions to worry about.

The detach path continues to work. The simulation detach was added to the existing detach ordering, and the draining of the simulation callouts happens before the hardware region is freed.

17.5.7 What Still Needs Attention

A few loose ends that Sections 5 and 6 will tighten.

The timeouts in `myfirst_wait_for_ready` and `myfirst_wait_for_data` are hardcoded (100 ms and 2000 ms respectively). A configurable timeout (perhaps exposed through a `sysctl`) would be better; Section 5 adds one.

The `pause_sbt` sleep of 1 ms is a reasonable default but not optimal for every situation. On a fast simulation (e.g., `DELAY_MS=0`), polling every 1 ms is wasteful; on a slow simulation (e.g., `DELAY_MS=5000`), polling every 1 ms is overkill. Section 6 discusses better strategies.

The command-cycle write path does not interact with the simulation's fault injection. If the simulation is configured to fail a command (Section 7's work), the driver needs to recognise and recover from the failure. Section 5 adds the basic error-recovery; Section 7 adds the fault-injection infrastructure.

The driver's read path is not yet integrated. Reads currently pull from the ring buffer, which contains whatever was pushed there by write commands. A more realistic pattern would have reads also cause commands (a "please give me another byte" command), but that is a Section 5 topic.

17.5.8 Wrapping Up Section 4

Exposing the simulated device to the driver is not a new mechanism in Chapter 17. The Chapter 16 `bus_space(9)` abstraction already handles this; the simulation's writes and the driver's reads go through the same tag and handle, and the driver neither knows nor cares that the register block is simulated. What Stage 2 adds is the command-cycle code path: the driver writes `DATA_IN`, sets `CTRL.GO`, waits for `DATA_AV`, reads `DATA_OUT`. Two helper functions (`myfirst_wait_for_ready` and `myfirst_wait_for_data`) make the polling explicit; one umbrella function (`myfirst_wait_for_bit`) factors the shared structure. The driver now exercises the simulation in a realistic command-and-response pattern.

Section 5 deepens the testing story. It adds error-recovery, configurable timeouts, a clearer separation between the read and the write paths, and the first load tests that hit the simulation with enough traffic to expose race conditions.

17.6 Section 5: Testing Device Behavior from the Driver

The command-cycle code from Section 4 works for a single byte. It times out correctly when the simulation is slow; it returns a data value when the simulation responds; it reads `STATUS` at the appropriate points. What it has not yet experienced is volume, diversity, or concurrency. A driver that passes a one-byte test may still fail under load, under concurrent writers, or when the simulation is configured with unusual parameters.

Section 5 is about stress-testing the driver's interaction with the simulated device. It adds configurable timeouts, a more robust error-recovery path, a read-path integration that lets the simulation drive reads as well as writes, and a set of load tests that exercise the driver across its full behavioural surface. By the end of Section 5, the driver is at Stage 2 of Chapter 17 and has survived a meaningful stress run.

17.6.1 Configurable Timeouts

Hardcoded timeouts are brittle. 100 ms is enough for the default DELAY_MS of 500, but what if the user wants to test a slow configuration? Bumping DELAY_MS to 2000 would mean every command times out with the 100 ms limit, which is a false failure mode. Make the timeouts configurable.

Add two fields to the softc (or to a suitable sub-struct):

```
struct myfirst_softc {
    /* ... existing fields ... */
    int      cmd_timeout_ms;      /* max wait for command completion */
    int      rdy_timeout_ms;      /* max wait for device ready      */
};
```

Initialise them in attach:

```
sc->cmd_timeout_ms = 2000;      /* 2 s default      */
sc->rdy_timeout_ms = 100;      /* 100 ms default    */
```

Expose them through sysctl:

```
SYCTL_ADD_INT(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "cmd_timeout_ms", CTLFLAG_RW, &sc->cmd_timeout_ms, 0,
    "Command completion timeout in milliseconds");

SYCTL_ADD_INT(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
    "rdy_timeout_ms", CTLFLAG_RW, &sc->rdy_timeout_ms, 0,
    "Device-ready polling timeout in milliseconds");
```

And change myfirst_write_cmd to use them:

```
error = myfirst_wait_for_ready(sc, sc->rdy_timeout_ms);
/* ... */
error = myfirst_wait_for_data(sc, sc->cmd_timeout_ms);
```

The test suite can now adjust the timeouts to match the test's expected latency. A fast-simulation test sets them low; a slow-simulation test sets them high. A pathological test sets them very low and expects timeout errors.

17.6.2 Read-Path Integration

The Chapter 10 `myfirst_read` pulls from the ring buffer. The ring buffer contains whatever previous writes pushed in. Chapter 17 can extend this pattern: when the ring is empty and the reader is willing to wait, issue a “generate a byte” command to the simulated device and push the result into the ring.

This is not how every driver works. A real device has data-production semantics that are device-specific; a network card produces bytes as packets arrive, not on demand. For a simulated sensor-like device, a “sample” command that produces one reading per invocation is a natural pattern. Our driver adopts it.

Add a `myfirst_sample_cmd` function that issues a command and pushes the result into the ring:

```
static int
myfirst_sample_cmd(struct myfirst_softc *sc)
{
    uint32_t data_out;
    int error;

    MYFIRST_LOCK_ASSERT(sc);

    error = myfirst_wait_for_ready(sc, sc->rdy_timeout_ms);
    if (error != 0)
        return (error);

    /* DATA_IN does not matter for a sample; write a marker. */
    CSR_WRITE_4(sc, MYFIRST_REG_DATA_IN, 0xCAFE);

    CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_GO);

    error = myfirst_wait_for_data(sc, sc->cmd_timeout_ms);
    if (error != 0)
        return (error);

    data_out = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
    CSR_UPDATE_4(sc, MYFIRST_REG_STATUS, MYFIRST_STATUS_DATA_AV, 0);

    /* Push one byte of the sample into the ring. */
    error = cbuf_put(sc->cbuf, (uint8_t)(data_out & 0xFF));
    return (error);
}
```

The read path can now call `myfirst_sample_cmd` when the ring is empty. Wire it into `myfirst_read`:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
```

```

    struct myfirst_softc *sc = dev->si_drv1;
    uint8_t byte;
    int error;

    MYFIRST_LOCK(sc);
    while (uio->uio_resid > 0) {
        while (cbuf_empty(sc->cbuf)) {
            if (ioflag & O_NONBLOCK) {
                MYFIRST_UNLOCK(sc);
                return (EWOULDBLOCK);
            }

            /* Chapter 17: trigger a sample when ring is empty. */
            error = myfirst_sample_cmd(sc);
            if (error != 0) {
                MYFIRST_UNLOCK(sc);
                return (error);
            }
        }
        error = cbuf_get(sc->cbuf, &byte);
        if (error != 0) {
            MYFIRST_UNLOCK(sc);
            return (error);
        }
        MYFIRST_UNLOCK(sc);
        error = uiomove(&byte, 1, uio);
        MYFIRST_LOCK(sc);
        if (error != 0) {
            MYFIRST_UNLOCK(sc);
            return (error);
        }
    }
    MYFIRST_UNLOCK(sc);
    return (0);
}

```

Now a read from `/dev/myfirst0` triggers a simulated command if the ring is empty, effectively pulling one byte per command from the simulation. Combined with the write path from Section 4 (push-style), the driver now exercises both directions.

17.6.3 A First Load Test

With both paths integrated, the driver is ready for load testing. A simple test script:

```
#!/bin/sh
# cmd_load.sh: exercise the command path under load.

set -e

# Fast simulation for load testing.
sysctl dev.myfirst.0.reg_delay_ms_set=10

# Spawn 4 writers and 4 readers in parallel.
for i in 1 2 3 4; do
    (for j in $(seq 1 100); do echo -n "X" > /dev/myfirst0; done) &
done
for i in 1 2 3 4; do
    (dd if=/dev/myfirst0 of=/dev/null bs=1 count=100 2>/dev/null) &
done
wait

# Show the resulting counter.
sysctl dev.myfirst.0.reg_op_counter

# Reset to default.
sysctl dev.myfirst.0.reg_delay_ms_set=500
```

With `DELAY_MS=10` and 4 writers each sending 100 bytes plus 4 readers each receiving 100 bytes, the test should complete in about 10 seconds (800 commands at 10 ms each, serialised through the simulation). `OP_COUNTER` should reach at least 800.

Two things are worth noticing about this test.

First, the commands are serialised. The simulation rejects overlapping commands (Section 3's `command_pending` check). The driver waits for `STATUS.BUSY` to clear before issuing the next command. With multiple user-space processes contending for the driver, the lock on `sc->mtx` serialises them. The effective rate is one command per `DELAY_MS` milliseconds, regardless of how many writers are running.

Second, the driver did not change to accommodate concurrency. The Chapter 11 mutex, the Chapter 14 tasks, the Chapter 16 accessors, and the Section 4 command-cycle code all compose naturally. The discipline Part 3 built up pays off here: no additional synchronisation is needed to add simulated hardware to a driver that already coordinates itself properly.

17.6.4 Error-Recovery Refinement

The command-cycle code in Section 4 clears `STATUS.ERROR` and returns `EIO`. Section 5 refines this to distinguish several error cases.

```

static int
myfirst_write_cmd(struct myfirst_softc *sc, uint8_t byte)
{
    uint32_t status;
    int error;

    MYFIRST_LOCK_ASSERT(sc);

    error = myfirst_wait_for_ready(sc, sc->rdy_timeout_ms);
    if (error != 0) {
        sc->stats.cmd_rdy_timeouts++;
        return (error);
    }

    CSR_WRITE_4(sc, MYFIRST_REG_DATA_IN, (uint32_t)byte);
    CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_GO);

    error = myfirst_wait_for_data(sc, sc->cmd_timeout_ms);
    if (error != 0) {
        sc->stats.cmd_data_timeouts++;
        /* Clear any partial state in the simulation. */
        myfirst_recover_from_stuck(sc);
        return (error);
    }

    status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
    if (status & MYFIRST_STATUS_ERROR) {
        CSR_UPDATE_4(sc, MYFIRST_REG_STATUS,
            MYFIRST_STATUS_ERROR, 0);
        CSR_UPDATE_4(sc, MYFIRST_REG_STATUS,
            MYFIRST_STATUS_DATA_AV, 0);
        sc->stats.cmd_errors++;
        return (EIO);
    }

    (void)CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
    CSR_UPDATE_4(sc, MYFIRST_REG_STATUS, MYFIRST_STATUS_DATA_AV, 0);
    sc->stats.cmd_successes++;
    return (0);
}

```

Three changes from Section 4.

First, per-error-type counters. `sc->stats` is a structure of `uint64_t` counters that the driver updates on each outcome. `cmd_successes`, `cmd_rdy_timeouts`, `cmd_data_timeouts`, and `cmd_errors` each get their own

counter. A sysctl exposes them. Under load, the counters become the primary diagnostic: “the driver issued 800 commands, 5 timed out, 0 had errors, 795 succeeded” is a much more useful summary than “the driver ran”.

Second, `myfirst_recover_from_stuck`. When a command times out, the simulation may still be in the middle of processing. Clearing stale state matters:

```
static void
myfirst_recover_from_stuck(struct myfirst_softc *sc)
{
    uint32_t status;

    MYFIRST_LOCK_ASSERT(sc);

    /* Clear any pending command flag in the simulation. The next
     * CTRL.GO will be accepted regardless of any stale state. */
    if (sc->sim != NULL) {
        sc->sim->command_pending = false;
        callout_stop(&sc->sim->command_callout);
    }

    /* Force-clear BUSY and DATA_AV. */
    status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
    status &= ~(MYFIRST_STATUS_BUSY | MYFIRST_STATUS_DATA_AV);
    CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);
}
```

Note that `myfirst_recover_from_stuck` reaches into `sc->sim->command_pending` directly. This is a legitimate simulation-only path: on real hardware, there would be no such variable; instead, the driver would issue a reset command to the device. The function is a simulation-specific recovery path, and a comment in the code should say so. When Chapter 18 replaces the simulation with real hardware, this function changes entirely.

Third, status clearing on error. The error path clears both `ERROR` and `DATA_AV`. Leaving either one set would cause the next command’s `wait_for_data` to return immediately (if `DATA_AV` is still set) or observe an unexpected error (if `ERROR` is still set). The defensive cleanup ensures the simulation is in a clean state for the next command.

17.6.5 Stats Infrastructure

The `sc->stats` structure is worth defining properly. Place it in `myfirst.h`:

```
struct myfirst_stats {
    uint64_t      cmd_successes;
    uint64_t      cmd_rdy_timeouts;
    uint64_t      cmd_data_timeouts;
```

```
uint64_t      cmd_errors;  
uint64_t      cmd_rejected;  
uint64_t      cmd_recoveries;  
uint64_t      samples_taken;  
uint64_t      fault_injected;  
};
```

Add it to the softc:

```
struct myfirst_softc {  
    /* ... existing fields ... */  
    struct myfirst_stats stats;  
};
```

Expose each counter through sysctl:

```
static void  
myfirst_add_stats_sysctls(struct myfirst_softc *sc)  
{  
    struct sysctl_ctx_list *ctx = &sc->sysctl_ctx;  
    struct sysctl_oid *tree = sc->sysctl_tree;  
  
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,  
        "cmd_successes", CTLFLAG_RD,  
        &sc->stats.cmd_successes, 0,  
        "Successfully completed commands");  
  
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,  
        "cmd_rdy_timeouts", CTLFLAG_RD,  
        &sc->stats.cmd_rdy_timeouts, 0,  
        "Commands that timed out waiting for READY");  
  
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,  
        "cmd_data_timeouts", CTLFLAG_RD,  
        &sc->stats.cmd_data_timeouts, 0,  
        "Commands that timed out waiting for DATA_AV");  
  
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,  
        "cmd_errors", CTLFLAG_RD,  
        &sc->stats.cmd_errors, 0,  
        "Commands that completed with STATUS.ERROR set");  
  
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO,
```

```

        "cmd_recoveries", CTLFLAG_RD,
        &sc->stats.cmd_recoveries, 0,
        "Recovery operations triggered");

        /* ... add the remaining counters ... */
}

```

Under load, `sysctl dev.myfirst.0 | grep -E 'cmd_|samples_|fault_'` gives a one-screen summary of the driver's command-path behaviour. After a test run, diffing before and after is how you answer “did the driver behave correctly?”.

17.6.6 Observing the Driver Under Load

A useful debugging pattern: watch the stats while a load test is running. In one terminal:

```
# sysctl dev.myfirst.0 | grep cmd_ > before.txt
```

In another terminal, start the load test. Wait for it to finish. Then:

```
# sysctl dev.myfirst.0 | grep cmd_ > after.txt
# diff before.txt after.txt
```

The diff shows exactly how many of each event occurred during the test window. Ideal runs show many successes and zero timeouts or errors. Runs with faults injected (Section 7) show nonzero counts for the expected error types; unexpected counts indicate a bug.

For continuous observation, use `watch`:

```
# watch -n 1 'sysctl dev.myfirst.0 | grep cmd_'
```

Every second, the current counters print. As the load test runs, the successes counter climbs, while the timeouts and errors counters (ideally) stay flat.

17.6.7 Hands-On Behaviour Test

A concrete test for Section 5. Set up:

```
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.reg_delay_ms_set=50      # fast commands
# sysctl dev.myfirst.0.access_log_enabled=1
```

Run:

```
# echo -n "Hello, World!" > /dev/myfirst0
# dd if=/dev/myfirst0 bs=1 count=13 of=/dev/null 2>/dev/null
# sysctl dev.myfirst.0 | grep -E 'cmd_|op_counter|samples_'
```

Expected output:

```
dev.myfirst.0.cmd_successes: 26
dev.myfirst.0.cmd_rdy_timeouts: 0
dev.myfirst.0.cmd_data_timeouts: 0
dev.myfirst.0.cmd_errors: 0
dev.myfirst.0.samples_taken: 13
dev.myfirst.0.reg_op_counter: 26
```

Thirteen writes (one per byte of “Hello, World!”), thirteen reads (one per byte back out). Each write and each read is a simulation command, for a total of 26. All successful. All within the latency budget.

Now inspect the access log:

```
# sysctl dev.myfirst.0.access_log | head -20
```

The log shows the command cycle in detail. For each write command:

1. Read STATUS (polling for BUSY to clear)
2. Write DATA_IN (the byte)
3. Read/Write CTRL (setting GO)
4. Read STATUS (polling for DATA_AV to set)
5. Read DATA_OUT (the result)
6. Read/Write STATUS (clearing DATA_AV)

For each sample command, the same sequence plus a `cbuf_put`. The log is dense but readable, and it is where you would look if the driver misbehaved.

17.6.8 What Stage 2 Accomplished

Stage 2 integrates the simulation with the driver’s data path. Both the write and the read paths now exercise simulated commands. Configurable timeouts let tests target specific behaviour. Per-error-type stats counters expose the driver’s interaction with the simulation. A recovery path cleans up stuck state when a command times out. Load tests exercise the driver at volume and confirm the composition of Part 3 synchronisation with Chapter 17 simulation.

The version tag becomes `1.0-sim-stage2`. The driver is now interacting with a dynamic register block in a way that approaches real-hardware behaviour.

17.6.9 Wrapping Up Section 5

Testing the driver against the simulation is not a separate activity; it is a natural extension of the driver's command path. Add configurable timeouts, integrate simulated commands into both read and write, track per-outcome statistics, and run enough load to expose the common failure modes.

The hands-on test validates the round-trip: user-space input goes through the driver, through the simulation, and back to user space intact. The counters confirm no errors. The access log shows every register touch in order.

Section 6 deepens the timing discussion. The 1 ms `pause_sbt` in `myfirst_wait_for_bit` is a reasonable default, but not the only choice. `DELAY(9)` is better for very short waits; `callout_reset_sbt` is better for fire-and-forget scheduling. Understanding when each is appropriate is the topic of Section 6.

17.7 Section 6: Adding Timing and Delay

Timing is where real hardware gets interesting. A device that processes a command in 5 microseconds needs a very different driver pattern than one that processes a command in 500 milliseconds. A driver that uses the wrong timing primitive for the wrong time scale burns CPU on short waits or accumulates latency on long ones, and in the worst case it deadlocks under contention.

FreeBSD offers three primary timing primitives for driver code: `DELAY(9)`, `pause_sbt(9)`, and `callout_reset_sbt(9)`. Each is appropriate at a specific time scale, each has a specific cost, and each has a specific correctness requirement. Section 6 teaches them in order and shows how to pick the right one for each situation in the Chapter 17 simulation.

17.7.1 The Three Timing Primitives

The primitives differ along three axes: whether they busy-wait or sleep, whether they are cancelable, and what they cost.

`DELAY(n)` busy-waits for `n` microseconds. It does not sleep, does not yield the CPU, and does not release any locks. It is safe to call from any context, including from a spin mutex, an interrupt filter, or a callout. Its cost is the CPU time it consumes: 100 microseconds of `DELAY` is 100 microseconds the CPU cannot do anything else. Its precision is usually quite good (single-digit microseconds), limited by the CPU's time-stamp counter resolution. It is the right choice for very short waits where sleeping would be impractical.

`pause_sbt(wmesg, sbt, pr, flags)` puts the calling thread to sleep for `sbt` signed-binary-time units. While the thread is asleep, the CPU is free for other work, and any locks the thread does not hold are free for other contexts. If the thread has a lock held, `pause_sbt` does not release it; it is the caller's job to drop locks that should not be held during the sleep. The precision is on the order of the kernel's timer tick (1 ms on a typical system). It is the right choice for short-to-medium waits where the thread has nothing else to do. `pause_sbt` is not cancelable through any mechanism shorter than the sleep itself; once a thread has called it, it will sleep for at least the requested time (barring exceptional events).

`callout_reset_sbt(c, sbt, pr, fn, arg, flags)` schedules a callback to run `sbt` signed-binary-time units in the future. The calling thread does not wait; it returns immediately. The callback runs on a callout thread when the time expires. The callout can be cancelled with `callout_stop` or `callout_drain`. The precision is

similar to `pause_sbt`. It is the right choice for fire-and-forget scheduling, for timeouts that may be cancelled early, and for periodic work.

The three primitives compose. A driver might use `DELAY(10)` to wait 10 microseconds for a register bit to settle, `pause_sbt(..., SBT_1MS * 50, ...)` to sleep 50 ms waiting for a command to complete, and `callout_reset_sbt(..., SBT_1S * 5, ...)` to schedule a watchdog 5 seconds in the future. Each choice reflects the time scale and the context.

17.7.2 A Time-Scale Decision Table

A quick reference for choosing among the three primitives:

Wait Duration	Context	Preferred Primitive
< 10 us	Any	<code>DELAY(9)</code>
10-100 us	Non-interrupt, non-spin	<code>DELAY(9)</code> or <code>pause_sbt(9)</code>
100 us - 10 ms	Non-interrupt, non-spin	<code>pause_sbt(9)</code>
> 10 ms	Non-interrupt, non-spin	<code>pause_sbt(9)</code> or <code>callout</code>
Fire-and-forget	Any (callout state machine)	<code>callout_reset_sbt(9)</code>
Interrupt/spin	Any duration	<code>DELAY(9)</code> only

The table is a starting point, not a rigid rule. The real question is: can the caller afford to sleep? If yes, pause or callout. If no (spin lock held, interrupt handler, filter handler, critical section), `DELAY`.

17.7.3 Where the Chapter 17 Driver Already Uses Each

Section 4's polling loop uses `pause_sbt` with 1 ms delays. That is appropriate for the time scale: the simulation's default `DELAY_MS` is 500, so we expect the driver to sleep many times before the command completes. Sleeping lets other threads use the CPU while we wait. `DELAY(1000)` would also work but would waste CPU; the driver currently sits at about 500 polls per command with no useful CPU work between them, and `DELAY` would spin all 500 times.

Section 3's simulation callouts use `callout_reset_sbt` with variable intervals. That is appropriate because the simulation needs to do work in the future without any thread actively waiting. `pause_sbt` would require a dedicated kernel thread for each callout, which would be wasteful. `DELAY` would require the thread to stay in kernel mode for the full interval, which is unacceptable.

There is no `DELAY` in the driver yet. Section 6 introduces it where appropriate.

17.7.4 A Good Use of `DELAY`

Consider the recovery path from Section 5. After a timeout, the driver calls `myfirst_recover_from_stuck`, which clears some state and returns. The code works, but there is a subtle race: the simulation's command

callout might fire between the timeout detection and the recovery call, changing STATUS in unexpected ways. A small fix: use `DELAY(10)` to wait 10 microseconds for any in-flight callout to drain before clearing the state.

Except this is wrong. `DELAY(10)` does nothing useful here. The callout cannot run while we hold `sc->mtx` (because it was registered with `callout_init_mtx`), so there is no race. Adding a `DELAY` here would be cargo-culting: adding a delay because something might go wrong, without a clear model of what the delay is preventing.

A better example. Some real hardware requires a small delay between two register writes to let the device's internal logic settle. A datasheet might say: "After writing `CTRL.RESET`, wait at least 5 microseconds before writing any other register." The Chapter 17 simulation's `CTRL.RESET` bit is not actually implemented, but we can imagine it. If it were, the reset code would use `DELAY(5)`:

```
static void
myfirst_reset_device(struct myfirst_softc *sc)
{
    MYFIRST_LOCK_ASSERT(sc);

    /* Assert reset. */
    CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, 0, MYFIRST_CTRL_RESET);

    /* Datasheet: wait 5 us for internal state to clear. */
    DELAY(5);

    /* Deassert reset. */
    CSR_UPDATE_4(sc, MYFIRST_REG_CTRL, MYFIRST_CTRL_RESET, 0);
}
```

Five microseconds is too short for `pause_sbt` to be efficient (the kernel's timer resolution is typically 1 ms, so `pause_sbt` for 5 us would actually sleep for the next timer tick, wasting most of a millisecond). `DELAY(5)` is the right primitive.

17.7.5 A Good Use of `pause_sbt` (With the Lock Dropped)

The polling loop from Section 4:

```
for (i = 0; i < timeout_ms; i++) {
    uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
    if ((status & mask) == target)
        return (0);
    MYFIRST_UNLOCK(sc);
    pause_sbt("mfwait", SBT_1MS, 0, 0);
    MYFIRST_LOCK(sc);
}
```

The lock is dropped before `pause_sbt` and reacquired after. This pattern is essential and deserves careful attention.

If the lock were held across `pause_sbt`, the simulation callout (which needs the lock) would be blocked for the duration of the sleep. Since the callout is the thing the driver is waiting on, this would deadlock. Dropping the lock lets the callout run, lets the simulation update `STATUS`, and lets the next iteration of the loop observe the new value.

The correctness requirement is that nothing the driver cares about can change in an unrecoverable way while the lock is dropped. In our case, the driver's loop variables are local (`i`, `status`, `mask`, `target`); they do not live in memory that other contexts touch. The state that other contexts touch (the register block) is exactly what we want them to update. So dropping the lock is safe.

A variation on this pattern uses a sleepable condition variable instead of polling:

```
MYFIRST_LOCK_ASSERT(sc);

while ((CSR_READ_4(sc, MYFIRST_REG_STATUS) & mask) != target) {
    int error = cv_timedwait_sbt(&sc->data_cv, &sc->mtx,
                               SBT_1MS * timeout_ms, 0, 0);
    if (error == EWOULDBLOCK)
        return (ETIMEDOUT);
}
return (0);
```

The condition variable waits until either the target bit changes (signalled by some other context) or the timeout expires. `cv_timedwait_sbt` drops the mutex automatically, sleeps, and reacquires the mutex before returning. No explicit `UNLOCK/LOCK` wrapping is needed.

For this to work, the simulation callout that changes `STATUS` must `cv_signal` the condition variable after the change. The code in `myfirst_sim_command_cb` becomes:

```
/* After setting DATA_AV: */
cv_broadcast(&sc->data_cv);
```

The driver's wait loop and the simulation's update cooperate through the condition variable: the driver sleeps until something interesting happens, and the simulation wakes it when something does. This is a much more efficient pattern than polling with `pause_sbt`. The driver sleeps for the whole wait; one wakeup is all that is needed; no thrashing.

Chapter 17 uses `pause_sbt` in the main polling loop for teaching simplicity (you can see exactly when the sleep happens), but the condition-variable pattern is mentioned here because it is closer to what production drivers do, especially for long waits.

17.7.6 A Good Use of `callout_reset_sbt`

The simulation callouts from Section 3 are the canonical example. The sensor callout fires every 100 ms, updates the sensor register, and re-arms. The command callout fires once after `DELAY_MS` milliseconds to complete a

command. Both use `callout_reset_sbt` with:

- `sbt` = the interval in SBT units
- `pr` = 0 (no precision hint; kernel may coalesce)
- `flags` = 0 (no special behaviour)

For a more precise schedule, `pr` can be set to bound the coalescing:

```
callout_reset_sbt(&sim->sensor_callout,
    interval_ms * SBT_1MS,
    SBT_1MS,                      /* precision: within 1 ms */
    myfirst_sim_sensor_cb, sc, 0);
```

With `pr = SBT_1MS`, the callout fires no more than 1 ms later than requested. For our simulation, precision is not critical; the default of 0 is fine.

For a callout that must run on a specific CPU, the `C_DIRECT_EXEC` flag arranges for the callback to run directly from the hardclock interrupt rather than being dispatched to a callout thread. This is higher performance but more restrictive: the callback cannot sleep or take sleep locks. The Chapter 17 simulation does not need this; it uses plain mutex-based callouts.

For a callout aligned with the hardclock boundary, the `C_HARDCLOCK` flag is appropriate. Our simulation does not need alignment either; the default is fine.

17.7.7 A Realistic Example: Simulating a Slow Device

Put the primitives together. Suppose the simulation is configured with `DELAY_MS=2000` (a slow device, two seconds per command). The driver issues a write command. What does each primitive do?

1. The driver writes `DATA_IN`, sets `CTRL.GO`, and calls `myfirst_wait_for_data(sc, 3000)` (3 s timeout).
2. `myfirst_wait_for_data` reads `STATUS`, finds `DATA_AV` not set, drops the lock, calls `pause_sbt("mfwait", SBT_1MS, 0, 0)`, and sleeps for ~1 ms.
3. Meanwhile, the simulation's `myfirst_sim_command_cb` is scheduled to fire in ~2000 ms. It is not running yet.
4. The driver's loop wakes, reacquires the lock, reads `STATUS` again, sees `DATA_AV` still not set, drops the lock, sleeps again.
5. Steps 2-4 repeat about 2000 times over the two seconds.
6. The simulation's callout fires. It reads `STATUS`, sets `DATA_AV`, writes the command-completion values.
7. On the next iteration of the driver's loop, the driver sees `DATA_AV` set and returns.

Total CPU time burnt by the driver waiting: minimal. Each `pause_sbt` is a sleep, not a spin. The CPU is free for other work during each of the 2000 sleeps.

Now suppose the driver had used `DELAY(1000)` instead of `pause_sbt(..., SBT_1MS, ...)`. Same time scale per iteration; completely different CPU behaviour. Each `DELAY(1000)` burns 1000 microseconds of CPU time. 2000 iterations = 2 seconds of pure CPU. The driver works, but it hogs one core entirely for the duration of the command. If other processes need CPU, they wait.

The difference illustrates why `pause_sbt` is the right choice for millisecond-scale waits: `sleep` is free; `spin` costs CPU.

Now suppose the driver had used `callout_reset_sbt` instead of polling. That is harder: `callout_reset_sbt` does not make the current thread wait. The thread would return to its caller immediately. The caller would need to know to sleep until the callout fires. This is exactly what condition variables do. The code becomes:

```
MYFIRST_LOCK_ASSERT(sc);

while (!(CSR_READ_4(sc, MYFIRST_REG_STATUS) & MYFIRST_STATUS_DATA_AV)) {
    int error = cv_timedwait_sbt(&sc->data_cv, &sc->mtx,
                                SBT_1MS * timeout_ms, 0, 0);
    if (error == EWOULDBLOCK)
        return (ETIMEDOUT);
}
```

And the simulation callout calls `cv_broadcast(&sc->data_cv)` after setting `DATA_AV`. The driver thread sleeps once (not 2000 times); the CPU overhead is minimal; the response time is bounded by the simulation's own timing, not by the driver's polling rate.

For Chapter 17, the polling pattern is taught first because it is easier to read: the `for` loop is explicit, the `pause_sbt` is explicit, the `CSR_READ_4` is explicit. The condition-variable pattern is more efficient but requires understanding all three of Chapter 12's primitives. We use the polling pattern as a stepping stone and note the condition-variable pattern as the production preference.

17.7.8 Timing for the Simulation Itself

The simulation's own timing choices are worth examining.

The sensor callout fires on an interval that the `SENSOR_CONFIG` register specifies. The default is 100 ms. The user can change it. The kernel honours the requested interval within a few milliseconds of precision. This is fine for a teaching sensor; a real device might require sub-microsecond precision, which would require `C_DIRECT_EXEC` callbacks or even non-standard timing sources.

The command callout fires `DELAY_MS` milliseconds after the command is issued. Again, millisecond precision is fine. The driver's timeouts are calibrated against this: the default command timeout is 2000 ms, well above the default `DELAY_MS` of 500 ms.

The driver's polling interval is 1 ms. For a command that takes 500 ms, that means ~500 polls, which is tolerable. For a command that takes 5 ms, that means ~5 polls, which is fast enough. For a command that takes 5 seconds, that means 5000 polls, which is wasteful. The polling interval could be adaptive (longer polls for longer commands), but the implementation complexity is not worth it for a teaching driver.

17.7.9 Realistic Constraints: Ready After 500 ms

To make the timing story concrete, configure the simulation for a 500 ms per-command delay and run a stress test:

```
# sysctl dev.myfirst.0.reg_delay_ms_set=500
# time echo -n "test" > /dev/myfirst0
```

Expected output:

```
real    0m2.012s
user    0m0.001s
sys     0m0.005s
```

Four bytes, 500 ms each, 2 seconds total. Almost all of the time is kernel sleep time; CPU usage is negligible. The driver is efficient even though the command is slow.

Now stress with concurrent writers:

```
# for i in 1 2 3 4; do
    (echo -n "ABCD" > /dev/myfirst0) &
done
# time wait
```

Four processes, 4 bytes each, 500 ms per byte. Total commands: 16. At one command per 500 ms (serialised through the driver lock), total time: 8 seconds. Expected:

```
real    0m8.092s
```

The driver lock serialises the commands, and the simulation's own `command_pending` check prevents overlapping. The effective throughput is one command per `DELAY_MS` milliseconds, regardless of the number of writers.

17.7.10 Handling Timeouts Gracefully

The driver's behaviour when a command times out deserves its own walkthrough. The command path:

1. Driver writes `DATA_IN`, sets `CTRL.GO`.
2. Driver waits up to `cmd_timeout_ms` for `STATUS.DATA_AV`.
3. If the wait times out:
 - a. Increment `cmd_data_timeouts` counter.
 - b. Call `myfirst_recover_from_stuck` to clear stale simulation state.
 - c. Return `ETIMEDOUT` to the caller.
4. If the wait succeeds, continue with the normal path.

The recovery is important. A simulation that is actually slow (not stuck) will eventually set `DATA_AV`, but the driver has already given up. If the driver did not clear the simulation's pending state, a subsequent command might see the lingering `DATA_AV` from the old command and think the new command completed immediately.

The recovery function stops the pending callout, clears the `command_pending` flag, and clears the relevant STATUS bits.

On real hardware, the equivalent recovery is a device reset. The driver writes `CTRL.RESET`, waits briefly, and restarts. Some devices have a separate reset mechanism accessible through PCI config space. The pattern is the same: after a timeout, get the device back to a known state before doing anything else.

17.7.11 A Debugging Technique: Artificial Slowdown

A useful debugging technique for timing-sensitive code: artificially slow the simulation down to stretch race windows.

```
# sysctl dev.myfirst.0.reg_delay_ms_set=3000
# sysctl dev.myfirst.0.cmd_timeout_ms=1000
```

Now every command takes 3 seconds but the driver only waits 1 second. Every command times out. The driver's recovery path runs on every command. Bugs in the recovery path surface immediately:

- If the recovery path crashes, the kernel panics on the first command.
- If the recovery path leaves stale state, the second command fails in some unusual way.
- If the recovery path leaks memory, `vmstat -m | grep myfirst` climbs over time.

This is a legitimate debugging technique. Real drivers are hard to stress this way because real hardware is hard to make slow on demand. The simulation, by contrast, is a single register away from being very slow. Use this capability to exercise code paths that normal operation rarely reaches.

17.7.12 Common Timing Mistakes

A short catalogue of timing mistakes to avoid.

Mistake 1: Using `DELAY` for milliseconds. `DELAY(1000000)` busy-waits for a full second, consuming a CPU core for that time. Use `pause_sbt(..., SBT_1S, ...)` instead.

Mistake 2: Holding a lock across `pause_sbt`. Blocks every context that needs the lock. Drop the lock, sleep, reacquire.

Mistake 3: Spinning without yielding on a condition that depends on another context. If your code is waiting for a callout to set a bit, the callout cannot run while you spin. Yield with `pause_sbt` (dropping the lock) or use a condition variable.

Mistake 4: Using `callout_reset_sbt` for a fire-and-forget action that should complete immediately. If the action is quick, just do it. Callouts have setup cost and scheduling overhead; they are worth it when the delay is meaningful.

Mistake 5: Setting a timeout shorter than the expected operation time. Every command times out. The driver does no useful work. Make timeouts generous but finite.

Mistake 6: Setting a timeout much longer than the expected operation time. A legitimate slow operation hangs the user-space call for the full timeout. Users lose patience. Make timeouts reasonable for the specific operation.

Mistake 7: Not draining callouts before freeing memory the callouts touch. The callout fires after the memory is freed, and the callback dereferences freed memory. Drain before free.

Mistake 8: Re-arming a callout from within its callback without checking for cancellation. The detach path asks the callout to stop; the callback re-arms itself anyway. Infinite loop; detach never completes. Check the running flag (as Section 3's `myfirst_sim_sensor_cb` does) before re-arming.

Each mistake is common in beginning driver code. The Chapter 17 stages avoid all of them by following the patterns Chapter 13 taught for callouts, Chapter 12 taught for condition variables, and Section 6 is now making explicit.

17.7.13 Wrapping Up Section 6

Three timing primitives, three time scales, three cost profiles. `DELAY(9)` for very short waits (< 100 us). `pause_sbt(9)` for medium waits (100 us to several seconds) when the thread has nothing else to do. `callout_reset_sbt(9)` for fire-and-forget scheduling and for periodic work. Choosing the right one is a judgment call informed by the time scale, the context, and what the thread would otherwise be doing.

The Chapter 17 driver uses `pause_sbt` for its polling loop and `callout_reset_sbt` for the simulation's own timers. A reset path uses `DELAY(5)` where appropriate. The driver's timing story is coherent: it never wastes CPU, never holds locks during sleeps, and never blocks other contexts unnecessarily.

Section 7 adds the last major piece of the Chapter 17 simulation: a fault-injection framework. With timing now reliable, the driver can be exercised under a variety of failure conditions and the error-recovery paths validated.

17.8 Section 7: Simulating Errors and Fault Conditions

A driver that passes every happy-path test and never exercises its error paths is a driver that will eventually fail in production. Error paths are the code that runs when something unexpected happens, and “unexpected” is the most honest word for what real hardware does on a bad day. A network card whose PHY lost its link signal. A disk controller whose command queue overflowed. A sensor whose calibration went out of range. A device whose firmware deadlocked after a specific command sequence.

Real hardware produces these conditions rarely, and usually at the worst possible moment. A driver author who waits for real hardware to produce them is a driver author whose customers will find the bugs. A driver author who uses simulation to produce them on demand can fix the bugs before they ship.

Section 7 builds a fault-injection framework into the Chapter 17 simulation. The framework lets the reader ask the simulation to misbehave in specific, controlled ways: a timeout, a data corruption, a stuck-busy state, a random failure. Each mode exercises a different driver code path. By the end of Section 7, the driver has seen every error it is designed to handle, and the developer has confidence that the error paths work.

17.8.1 The Fault-Injection Philosophy

Before writing code, a short philosophical pause. What should a fault-injection framework look like, and what should it not look like?

A good fault-injection framework:

- Targets specific failure modes, not random chaos. A fault that says “the next read returns 0xFFFFFFFF” is useful; a fault that says “something bad might happen” is not.
- Is controllable at fine granularity. Turn faults on, off, or partial. Inject one, inject many, inject probabilistically.
- Is observable. When a fault fires, the framework logs it (or provides a counter). The tester can see what happened and correlate with driver behaviour.
- Is orthogonal to other testing. A load test should not care whether faults are enabled; a fault test should not require load to be disabled.
- Is deterministic when configured to be. A fault configured at probability 100% fires every time. A fault configured at probability 50% fires half the time, and the pseudo-random decision is reproducible with a seed.

A bad fault-injection framework is either useless (never triggers the paths you need) or dangerous (produces failures the driver cannot recover from even in principle). The goal is useful unreliability, not destructive chaos.

The Chapter 17 framework achieves these goals with a small set of flags in `FAULT_MASK`, a probability in `FAULT_PROB`, and a counter that tracks how many faults have fired. The simulation consults these whenever an operation begins and either proceeds normally or injects a fault according to the configuration.

17.8.2 The Fault Modes

The four fault modes Chapter 17 implements:

MYFIRST_FAULT_TIMEOUT (bit 0). The next command never completes. The command callout is not scheduled; `STATUS.DATA_AV` never asserts. The driver’s `myfirst_wait_for_data` times out, triggering the recovery path.

MYFIRST_FAULT_READ_1S (bit 1). The next `DATA_OUT` read returns 0xFFFFFFFF instead of the real value. This simulates a bus read that fails in a way many real hardware buses do (a read of a disconnected or power-gated device commonly returns all-ones).

MYFIRST_FAULT_ERROR (bit 2). The next command completes, but with `STATUS.ERROR` set. The driver is expected to detect the error, clear the latch, and report an error to the caller.

MYFIRST_FAULT_STUCK_BUSY (bit 3). `STATUS.BUSY` is latched on and never clears. The driver’s `myfirst_wait_for_ready` times out before any command can be issued. This simulates a device that got wedged and needs a reset.

Each fault exercises a different path. The timeout fault exercises `cmd_data_timeouts` and the recovery. The read-1s fault tests whether the driver notices corrupted data. The error fault exercises `cmd_errors` and the error-clearing logic. The stuck-busy fault exercises `cmd_rdy_timeouts`.

Multiple faults can be active simultaneously: set multiple bits in `FAULT_MASK`. Each fault is applied independently at the point in the simulation where it is relevant.

17.8.3 The Fault-Probability Field

FAULT_MASK selects which faults are candidates; FAULT_PROB controls how often a candidate fault actually fires. Probabilities are expressed as integers from 0 to 10000, where 10000 means 100% (fault every time) and 0 means never. This gives four decimal places of precision without fractional arithmetic.

The test for whether a fault fires:

```
static bool
myfirst_sim_should_fault(struct myfirst_softc *sc)
{
    uint32_t prob, r;

    MYFIRST_LOCK_ASSERT(sc);

    prob = CSR_READ_4(sc, MYFIRST_REG_FAULT_PROB);
    if (prob == 0)
        return (false);
    if (prob >= 10000)
        return (true);

    r = arc4random_uniform(10000);
    return (r < prob);
}
```

arc4random_uniform(10000) returns a pseudo-random integer in [0, 10000). If it is less than prob, the fault fires. With prob = 5000 (50%), the fault fires about half the time. With prob = 100 (1%), about one in a hundred operations. With prob = 10000, every operation.

The function is called at the start of each operation. If it returns true, the operation applies a fault from FAULT_MASK (the simulation's logic decides which fault or faults to apply, typically the first matching one).

17.8.4 Implementing the Timeout Fault

The timeout fault is the simplest. In myfirst_sim_start_command, check the fault mask before scheduling the command callout:

```
void
myfirst_sim_start_command(struct myfirst_softc *sc)
{
    struct myfirst_sim *sim = sc->sim;
    uint32_t data_in, delay_ms, fault_mask;
    bool fault;

    MYFIRST_LOCK_ASSERT(sc);
```

```
if (!sim->running)
    return;

if (sim->command_pending) {
    sc->stats.cmd_rejected++;
    device_printf(sc->dev,
        "sim: overlapping command; ignored\n");
    return;
}

data_in = CSR_READ_4(sc, MYFIRST_REG_DATA_IN);
sim->pending_data = data_in;

{
    uint32_t status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
    status |= MYFIRST_STATUS_BUSY;
    status &= ~MYFIRST_STATUS_DATA_AV;
    CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);
}

delay_ms = CSR_READ_4(sc, MYFIRST_REG_DELAY_MS);
if (delay_ms == 0)
    delay_ms = 1;

sim->command_pending = true;

/* Fault-injection check. */
fault_mask = CSR_READ_4(sc, MYFIRST_REG_FAULT_MASK);
fault = (fault_mask != 0) && myfirst_sim_should_fault(sc);

if (fault && (fault_mask & MYFIRST_FAULT_TIMEOUT)) {
    /* Do not schedule the completion callout. The command
     * will never complete; the driver will time out.
     * (Simulation does not clear command_pending; the
     * driver's recovery path is responsible for that.) */
    sc->stats.fault_injected++;
    device_printf(sc->dev,
        "sim: injecting TIMEOUT fault\n");
    return;
}

/* Save the fault state for the callout to honour. */
sim->pending_fault = fault ? fault_mask : 0;
```

```

        callout_reset_sbt(&sim->command_callout,
            delay_ms * SBT_1MS, 0,
            myfirst_sim_command_cb, sc, 0);
    }

```

Four changes from the Section 3 version.

First, a statistics counter for `cmd_rejected` replaces the bare `printf`.

Second, the function reads `FAULT_MASK` and calls `myfirst_sim_should_fault` to decide whether this operation injects a fault.

Third, if the timeout fault is selected, the function returns without scheduling the completion callout. `command_pending` is set to true, so overlapping commands are still rejected, but no callout ever fires to complete the command.

Fourth, the simulation stores the fault state in `sim->pending_fault` so the callout (when it fires, for non-timeout faults) can honour the fault.

`pending_fault` is added to the simulation state structure:

```

struct myfirst_sim {
    /* ... existing fields ... */
    uint32_t pending_fault; /* FAULT_MASK bits to apply at completion */
};

```

17.8.5 Implementing the Error Fault

The error fault fires at command completion. In `myfirst_sim_command_cb`:

```

static void
myfirst_sim_command_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct myfirst_sim *sim = sc->sim;
    uint32_t status, fault;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running || !sim->command_pending)
        return;

    fault = sim->pending_fault;

    /* Always clear BUSY. */

```

```

status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
status &= ~MYFIRST_STATUS_BUSY;

if (fault & MYFIRST_FAULT_ERROR) {
    /* Set ERROR, do not set DATA_AV. The driver should
     * detect the error on the next STATUS read. */
    status |= MYFIRST_STATUS_ERROR;
    sc->stats.fault_injected++;
    device_printf(sc->dev,
        "sim: injecting ERROR fault\n");
} else if (fault & MYFIRST_FAULT_READ_1S) {
    /* Normal completion, but DATA_OUT is corrupted. */
    CSR_WRITE_4(sc, MYFIRST_REG_DATA_OUT, 0xFFFFFFFF);
    status |= MYFIRST_STATUS_DATA_AV;
    sc->stats.fault_injected++;
    device_printf(sc->dev,
        "sim: injecting READ_1S fault\n");
} else {
    /* Normal completion. */
    CSR_WRITE_4(sc, MYFIRST_REG_DATA_OUT, sim->pending_data);
    status |= MYFIRST_STATUS_DATA_AV;
}

CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);

sim->op_counter++;
CSR_WRITE_4(sc, MYFIRST_REG_OP_COUNTER, sim->op_counter);

sim->command_pending = false;
sim->pending_fault = 0;
}

```

Three branches. The error fault sets `STATUS.ERROR` instead of `STATUS.DATA_AV`, leaving `DATA_OUT` untouched. The read-1s fault writes `0xFFFFFFFF` to `DATA_OUT` and sets `DATA_AV` normally. The normal branch writes the real data and sets `DATA_AV`.

The simulation increments `op_counter` and `fault_injected` appropriately. The driver will see the effects through the register values; the counters let the test validate that the faults fired.

17.8.6 Implementing the Stuck-Busy Fault

The stuck-busy fault is orthogonal to the command cycle: it keeps `STATUS.BUSY` set independently of any command. Add a callout that monitors `FAULT_MASK` and keeps `STATUS.BUSY` latched when the bit is set:

```

static void
myfirst_sim_busy_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct myfirst_sim *sim = sc->sim;
    uint32_t fault_mask, status;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running)
        return;

    fault_mask = CSR_READ_4(sc, MYFIRST_REG_FAULT_MASK);
    if (fault_mask & MYFIRST_FAULT_STUCK_BUSY) {
        status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
        if (!(status & MYFIRST_STATUS_BUSY)) {
            status |= MYFIRST_STATUS_BUSY;
            CSR_WRITE_4(sc, MYFIRST_REG_STATUS, status);
        }
    }

    /* Re-arm every 50 ms. */
    callout_reset_sbt(&sim->busy_callout,
        50 * SBT_1MS, 0,
        myfirst_sim_busy_cb, sc, 0);
}

```

Initialise and start the callout alongside the sensor callout in `myfirst_sim_attach` and `myfirst_sim_enable`:

```

callout_init_mtx(&sim->busy_callout, &sc->mtx, 0);
/* ... in enable: */
callout_reset_sbt(&sim->busy_callout, 50 * SBT_1MS, 0,
    myfirst_sim_busy_cb, sc, 0);
/* ... in disable: */
callout_stop(&sim->busy_callout);
/* ... in detach: */
callout_drain(&sim->busy_callout);

```

Now, when `FAULT_STUCK_BUSY` is set, the busy callout continually re-asserts `STATUS.BUSY` every 50 ms. Any command the driver tries to issue will find `BUSY` set, wait for it to clear, and time out on `wait_for_ready`. Clearing the `FAULT_STUCK_BUSY` bit stops the re-assertion, and `BUSY` returns to its natural state (whichever the command path left it in).

17.8.7 The Driver's Error-Handling Paths

With faults wired in, the driver's error-handling paths get exercised. Review them now to confirm they work correctly.

Timeout on wait_for_ready (from Section 5):

```
error = myfirst_wait_for_ready(sc, sc->rdy_timeout_ms);
if (error != 0) {
    sc->stats.cmd_rdy_timeouts++;
    return (error);
}
```

When `FAULT_STUCK_BUSY` is set, this path triggers. The caller sees `ETIMEDOUT`. The driver does not try to issue the command because it cannot. The counter reflects the event.

Timeout on wait_for_data:

```
error = myfirst_wait_for_data(sc, sc->cmd_timeout_ms);
if (error != 0) {
    sc->stats.cmd_data_timeouts++;
    myfirst_recover_from_stuck(sc);
    return (error);
}
```

When `FAULT_TIMEOUT` is set, this path triggers. The driver calls `myfirst_recover_from_stuck`, which clears the simulation's `command_pending` flag and `STATUS.BUSY`. The next command sees a clean state. The counter reflects the event.

STATUS.ERROR detection:

```
status = CSR_READ_4(sc, MYFIRST_REG_STATUS);
if (status & MYFIRST_STATUS_ERROR) {
    CSR_UPDATE_4(sc, MYFIRST_REG_STATUS,
        MYFIRST_STATUS_ERROR, 0);
    CSR_UPDATE_4(sc, MYFIRST_REG_STATUS,
        MYFIRST_STATUS_DATA_AV, 0);
    sc->stats.cmd_errors++;
    return (EIO);
}
```

When `FAULT_ERROR` is set, this path triggers. The driver clears `STATUS.ERROR` and `STATUS.DATA_AV`, increments the counter, returns `EIO`.

Corrupted DATA_OUT handling requires an addition. When `FAULT_READ_1S` is set, `DATA_OUT` is `0xFFFFFFFF`, but the driver currently does not check for this. Whether the driver should check depends on the protocol: for

a sensor, 0xFFFFFFFF is often a legitimate “read error” marker; for other devices, it might be a plausible data value. Chapter 17’s driver treats it as a potential error for illustration:

```
if (data_out == 0xFFFFFFFF) {  
    /* Likely a bus read error. Real devices rarely produce this  
     * value as legitimate data; treat as an error. */  
    sc->stats.cmd_errors++;  
    return (EIO);  
}
```

This behaviour is a judgment call. A real driver for a real device would check the datasheet for the device’s documented bad values and respond appropriately.

17.8.8 Testing the Faults One at a Time

With the infrastructure in place, each fault can be tested in isolation:

Test 1: Timeout fault at 100%.

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0x1    # MYFIRST_FAULT_TIMEOUT  
# sysctl dev.myfirst.0.reg_fault_prob_set=10000  # 100%  
# echo -n "test" > /dev/myfirst0  
write: Operation timed out  
# sysctl dev.myfirst.0.cmd_data_timeouts  
dev.myfirst.0.cmd_data_timeouts: 1  
# sysctl dev.myfirst.0.fault_injected  
dev.myfirst.0.fault_injected: 1
```

The first byte triggers a timeout. The driver recovers. Subsequent bytes would also time out until the fault is cleared. The counters reflect the event.

Turn off the fault:

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0  
# sysctl dev.myfirst.0.reg_fault_prob_set=0  
# echo -n "test" > /dev/myfirst0  
# echo "write succeeded"  
write succeeded  
# sysctl dev.myfirst.0.cmd_successes  
dev.myfirst.0.cmd_successes: 4    # or more, depending on history
```

Commands succeed again.

Test 2: Error fault at 25%.

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0x4    # MYFIRST_FAULT_ERROR
# sysctl dev.myfirst.0.reg_fault_prob_set=2500    # 25%
# sysctl dev.myfirst.0.cmd_errors
dev.myfirst.0.cmd_errors: 0
# for i in $(seq 1 40); do echo -n "X" > /dev/myfirst0; done
write: Input/output error      (occurs roughly 10 times)
# sysctl dev.myfirst.0.cmd_errors
dev.myfirst.0.cmd_errors: 9     # approximately 25% of 40
```

About one in four commands errors out. The driver detects the error, clears the state, and returns EIO. The counter reflects the event.

Test 3: Stuck-busy fault.

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0x8    # MYFIRST_FAULT_STUCK_BUSY
# sysctl dev.myfirst.0.reg_fault_prob_set=10000   # (prob doesn't matter; latch is
↪ always on)
# echo -n "X" > /dev/myfirst0
write: Operation timed out
# sysctl dev.myfirst.0.cmd_rdy_timeouts
dev.myfirst.0.cmd_rdy_timeouts: 1
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 3     # READY|BUSY
```

The driver cannot issue a command because BUSY is latched on. Clear the fault:

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0
# sleep 1    # wait for the busy callout to stop re-asserting
# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 1     # READY only
# echo -n "X" > /dev/myfirst0
# echo "write succeeded"
write succeeded
```

17.8.9 Integration: Random Faults Under Load

The most realistic test configures random faults at a low probability and runs the driver under load:

```
#!/bin/sh
# fault_stress.sh: random faults under load.

# 1% probability of TIMEOUT or ERROR (bits 0 and 2 both set).
sysctl dev.myfirst.0.reg_fault_mask_set=0x5
```

```

sysctl dev.myfirst.0.reg_fault_prob_set=100

# Fast commands so the test runs in reasonable time.
sysctl dev.myfirst.0.reg_delay_ms_set=10
sysctl dev.myfirst.0.cmd_timeout_ms=50    # very short, to spot timeouts fast

# Load: 8 parallel workers, each doing 200 round trips.
for i in $(seq 1 8); do
    (for j in $(seq 1 200); do
        echo -n "X" > /dev/myfirst0 2>/dev/null
        dd if=/dev/myfirst0 bs=1 count=1 of=/dev/null 2>/dev/null
    done) &
done
wait

# Report.
sysctl dev.myfirst.0 | grep -E 'cmd_|fault_|op_counter'

# Clean up.
sysctl dev.myfirst.0.reg_fault_mask_set=0
sysctl dev.myfirst.0.reg_fault_prob_set=0
sysctl dev.myfirst.0.reg_delay_ms_set=500
sysctl dev.myfirst.0.cmd_timeout_ms=2000

```

Expected counters after the run:

- cmd_successes: around 3168 (out of ~3200 expected round trips)
- cmd_data_timeouts: around 16 (1% of half the operations)
- cmd_errors: around 16 (1% of half the operations)
- fault_injected: around 32 (sum of the two)
- cmd_recoveries: around 16 (one per timeout)

The exact numbers vary with each run (the faults are random), but the proportions should be roughly 1% for each fault type. If the proportions are wildly off, there is either a bug in the fault injection or a bug in the driver's error-counting. Either way, the test is doing its job by surfacing anomalies.

17.8.10 A Common Pitfall: Recovery That Never Clears Everything

A bug that shows up under fault testing is recovery logic that does not clear everything. Suppose `myfirst_recover_from_stuck` forgot to clear `STATUS.BUSY`:

```

/* BUGGY version: */
static void
myfirst_recover_from_stuck(struct myfirst_softc *sc)

```

```

{
    MYFIRST_LOCK_ASSERT(sc);
    if (sc->sim != NULL) {
        sc->sim->command_pending = false;
        callout_stop(&sc->sim->command_callout);
    }
    /* Missing: the STATUS cleanup. */
}

```

Running the stress test would show:

- First timeout: recovery runs, `command_pending` clears.
- Second command attempt: `STATUS.BUSY` is still set from the first attempt. The command cannot issue. `cmd_rdy_timeouts` climbs.
- Third attempt: same.
- ... forever.

The counter `cmd_successes` stops incrementing. `cmd_rdy_timeouts` climbs without bound. A careful test notices this and flags it. A careless test just sees “lots of errors” and shrugs.

The lesson is that fault injection exposes incomplete recovery. A driver that works under fault-free conditions may still have bugs that only appear when faults happen. The stress test is what surfaces them.

17.8.11 Combining Faults

The Chapter 17 framework allows multiple faults to be active simultaneously:

```

# sysctl dev.myfirst.0.reg_fault_mask_set=0xf    # all four faults
# sysctl dev.myfirst.0.reg_fault_prob_set=1000   # 10%

```

Each operation has a 10% chance of triggering a fault. If it does, the simulation picks one of the enabled faults (in practice, the code checks them in order: `TIMEOUT`, `ERROR`, `READ_1S`, `STUCK_BUSY`). The driver’s response must be robust against all of them.

An even harsher test:

```

# sysctl dev.myfirst.0.reg_fault_prob_set=10000  # 100%

```

Every operation faults. The driver never completes a command successfully. Every error path runs. Run the driver for a minute under this setting. If the driver crashes, there is a bug in an error path. If the driver leaks memory (check `vmstat -m | grep myfirst`), there is a leak in an error path. If the driver deadlocks (check with `procstat -kk`), there is a deadlock in an error path.

Running under 100% faults for a sustained period is a standard test for fault-injection frameworks. It is intentionally hostile; a driver that passes is robust to real-world failure conditions.

17.8.12 Observability for Fault Testing

The driver's existing observability (access log, stats counters) carries most of what fault testing needs. Three additions are worth making.

Fault-injected log entries. The access log records every register access; it should record that a fault was injected. Add a new access-log entry type:

```
#define MYFIRST_CTX_FAULT    0x10    /* fault injected */
```

And log it when a fault fires:

```
myfirst_access_log_push(sc, offset, 0, 4, true, MYFIRST_CTX_FAULT);
```

Now the access log shows, interleaved with normal accesses, entries that indicate “fault X was injected here”. The tester can correlate fault injection with subsequent driver behaviour.

Per-fault-type counters. Instead of a single `fault_injected` counter, track each type:

```
struct myfirst_stats {
    /* ... existing counters ... */
    uint64_t    fault_timeout;
    uint64_t    fault_read_1s;
    uint64_t    fault_error;
    uint64_t    fault_stuck_busy;
};
```

And increment the right one based on the fault:

```
if (fault & MYFIRST_FAULT_TIMEOUT)
    sc->stats.fault_timeout++;
else if (fault & MYFIRST_FAULT_ERROR)
    sc->stats.fault_error++;
else if (fault & MYFIRST_FAULT_READ_1S)
    sc->stats.fault_read_1s++;
```

The `sysctl` exposes each counter. The tester can see, at a glance, which fault types have fired and which have not.

A fault-injection summary `sysctl`. A single `sysctl` that reports “fault mask is X, probability is Y, total injected is Z”. Useful for quick checks during interactive debugging:

```
static int
myfirst_sysctl_fault_summary(SYSCTL_HANDLER_ARGS)
{
```

```

    struct myfirst_softc *sc = arg1;
    char buf[128];
    uint32_t mask, prob;
    uint64_t injected;

    MYFIRST_LOCK(sc);
    mask = CSR_READ_4(sc, MYFIRST_REG_FAULT_MASK);
    prob = CSR_READ_4(sc, MYFIRST_REG_FAULT_PROB);
    injected = sc->stats.fault_injected;
    MYFIRST_UNLOCK(sc);

    snprintf(buf, sizeof(buf),
             "mask=0x%x prob=%u/10000 injected=%ju",
             mask, prob, (uintmax_t)injected);
    return (sysctl_handle_string(oidp, buf, sizeof(buf), req));
}

```

Invocation:

```

# sysctl dev.myfirst.0.fault_summary
dev.myfirst.0.fault_summary: mask=0x5 prob=100/10000 injected=47

```

This is the kind of summary that fits on one line and tells the whole story of the current fault configuration.

17.8.13 Safe Fault Injection

The word “safe” needs qualification. Fault injection in the Chapter 17 simulation is safe because the simulation runs in the same kernel as the driver, and the faults are local: a corrupted DATA_OUT is a corrupted four-byte value in malloc'd memory, not a corrupted DMA descriptor that scribbles over random RAM. A stuck BUSY bit is a stuck bit in a simulated register, not a hardware queue that backs up until the system hangs.

Real hardware fault injection is a different story. A deliberately timed-out real device may hold a bus lock indefinitely, preventing other devices from making progress. A deliberately corrupted DMA transaction may write to arbitrary physical addresses. Real fault injection on production systems requires careful setup, dedicated test hardware, and usually a hypervisor or virtual device emulation.

Chapter 17's simulation sidesteps all of this by running in memory. The worst case of a misbehaved fault is a kernel panic (if a KASSERT fires) or a deadlock (if recovery code is incorrect). Both are survivable: a debug kernel catches panics cleanly, and a deadlocked driver can be killed by rebooting. No physical hardware is at risk.

This safety is why fault injection belongs in simulation, not just in production testing. Production testing catches the faults real hardware actually produces; simulation testing catches the faults real hardware sometimes produces and always hurts from.

17.8.14 Hands-On: The Fault-Injection Checklist

A procedure for using fault injection effectively during development:

1. Write the driver's error path first. Before enabling the fault, read your code and identify what the recovery looks like.
2. Enable the fault at 100% probability briefly. Verify the driver's error path runs. Check the counters.
3. Enable the fault at low probability (1-10%). Run a stress test. Verify the driver still makes progress overall.
4. Check `vmstat -m | grep myfirst` before and after the stress test. Memory usage should not grow.
5. Check `WITNESS` output for lock-order warnings. A fault that causes an unusual path may expose a latent lock-order bug.
6. Check `INVARIANTS` output for assertion failures. A fault that corrupts state may trip an invariant.
7. Turn the fault off. Run the happy path. Verify everything returns to normal.
8. Document the fault in `HARDWARE.md` or `SIMULATION.md`.

This procedure turns fault injection into a disciplined activity, not a chaotic experiment. Each step has a clear goal, and each step validates a specific property of the driver.

17.8.15 A Reflection: What Fault Injection Taught Us

Fault injection is a microcosm of the larger driver-development discipline. The driver must handle errors it cannot prevent, from sources it does not control, at times it cannot predict. Fault injection gives the developer a tool to exercise all three properties on demand.

More than that, fault injection reveals the structure of the driver's error-handling philosophy. A driver that treats every error as equally recoverable handles some real-world failures poorly. A driver that distinguishes "transient" (try again) from "catastrophic" (reset the device) has a clearer model of what the device is doing. A driver that logs every error with enough context to diagnose later is a driver whose bugs can be found by log analysis.

The Chapter 17 driver does not go all the way to this level of sophistication; it has a single error-handling path that treats all errors as transient and retries only if the caller does. But the foundation is in place. A challenge at the end of the chapter invites the reader to extend the driver with per-error-type handling, and the simulation has the hooks to exercise each type.

17.8.16 Wrapping Up Section 7

Fault injection is how driver authors exercise error-handling code before real failures arrive. Chapter 17's framework provides four fault modes (timeout, read-1s, error, stuck-busy), a probability field, and enough observability to correlate injected faults with driver behaviour.

The driver's error paths are validated by enabling each fault in isolation and confirming the expected counter increments and the expected recovery. Combining faults and running under load at low probabilities exercises the composition of error paths. Running at 100% probability stresses every error path simultaneously.

The version tag becomes `1.0-sim-stage4`. The driver has now seen every error it is designed to handle, and the developer has observed each error path running correctly. The remaining work is organisational: refactor, version, document, and bridge to Chapter 18.

17.9 Section 8: Refactoring and Versioning Your Simulated Hardware Driver

Stage 4 produced a driver that works correctly under both happy-path and fault-injection conditions. Stage 5 (Section 8) makes the driver maintainable. The changes are organisational: clean file boundaries, updated documentation, a version bump, and the regression pass that verifies nothing broke along the way.

A driver that works is valuable. A driver that works and reads cleanly to the next contributor is far more valuable. Section 8 is about that second step.

17.9.1 The Final File Layout

Through Chapter 16, the driver was `myfirst.c`, `myfirst_hw.c`, `myfirst_hw.h`, `myfirst_sync.h`, `cbuf.c`, and `cbuf.h`. Chapter 17 added `myfirst_sim.c` and `myfirst_sim.h`. The final file tree:

- `myfirst.c`: the driver lifecycle, the syscall handlers, the Chapter 11-15 synchronisation primitives.
- `myfirst_hw.c`: the Chapter 16 hardware-access layer. `CSR_*` macros, register accessors, access log, register-view sysctls.
- `myfirst_hw.h`: the register map, bit masks, fixed values, and API prototypes for the hardware layer.
- `myfirst_sim.c`: the Chapter 17 simulation backend. Sensor callout, command callout, busy callout, fault-injection logic, simulation API.
- `myfirst_sim.h`: the simulation's API prototypes and state structure.
- `myfirst_sync.h`: the Chapter 15 synchronisation-primitive header.
- `cbuf.c`, `cbuf.h`: the Chapter 10 ring buffer.

Seven source files, three headers, a Makefile, and three documentation files (`HARDWARE.md`, `LOCKING.md`, and the new `SIMULATION.md`). The split mirrors how production FreeBSD drivers organise themselves: one file per responsibility, with named interfaces between them.

17.9.2 The Simulation-Specific Fields Move into the Sim Struct

Chapter 17 introduced the simulation state gradually. By the end of Section 7, some simulation-related fields were in the `softc` rather than in the struct `myfirst_sim`. Stage 5 tidies this up.

Fields that should live in struct `myfirst_sim`:

- The three callouts (`sensor_callout`, `command_callout`, `busy_callout`).
- The simulation-internal state (`pending_data`, `pending_fault`, `command_pending`, `running`, `sensor_baseline`, `sensor_tick`, `op_counter`).

Fields that should stay in the `softc` or in struct `myfirst_hw`:

- The register block and bus_space state (`regs_buf`, `regs_tag`, `regs_handle`): `myfirst_hw`.
- The driver's own timeouts (`cmd_timeout_ms`, `rdy_timeout_ms`): the `softc`.
- The statistics (`sc->stats`): the `softc` (shared by hw and sim paths).

The reasoning: hardware state belongs to the hardware layer; simulation state belongs to the simulation layer; the driver-visible behaviour belongs to the driver. Chapter 18 will replace the simulation with a real PCI back-end, and the cleanest replacement is one where `myfirst_sim.c` and `myfirst_sim.h` disappear entirely, to be

replaced by `myfirst_pci.c` and (optionally) `myfirst_pci.h`. The `sim` struct's fields do not need to survive that transition; the driver's fields do.

17.9.3 The `SIMULATION.md` Document

A new markdown file, `SIMULATION.md`, captures the simulation's interface. The sections:

1. **Version and scope.** “SIMULATION.md version 1.0. Chapter 17 complete.”
2. **What the simulation is.** One paragraph: “A kernel-memory-backed simulated device that mimics a minimal command-response hardware protocol, used to teach driver development without requiring real hardware.”
3. **What the simulation does.** Enumerated behaviours: sensor autonomy, command cycle, fault injection, configurable delays.
4. **What the simulation does not do.** Enumerated limitations: no DMA, no interrupts, no PCI, no real timing precision.
5. **Callout map.** Table of each callout, its purpose, its default interval, its relationship to the driver lock.
6. **Fault modes.** Table of each fault type, its trigger, its effect, its recovery.
7. **Sysctl reference.** Table of each sysctl exposed by the simulation layer, its type, its default, its purpose.
8. **Development guidance.** How to add a new behaviour to the simulation (where to put the code, what locking discipline applies, how to document).
9. **Relationship to real hardware.** How the patterns in the simulation map to patterns in real FreeBSD drivers.

The document is perhaps 150 to 200 lines of markdown. It is the single source of truth for what the simulation promises. A developer reading it should be able to reason about the simulation without reading the code.

An example entry from the fault-modes table:

Fault	Bit	Trigger	Effect
↪ Recovery			
----- ----- ----- -----			
↪ ----- ----- -----			
MYFIRST_FAULT_TIMEOUT	0	should_fault() returns true	Command callout not
↪ scheduled driver timeout path			
MYFIRST_FAULT_READ_1S	1	should_fault() returns true	DATA_OUT = 0xFFFFFFFF
↪ driver error check			
MYFIRST_FAULT_ERROR	2	should_fault() returns true	STATUS.ERROR set
↪ instead of DATA_AV driver error path			
MYFIRST_FAULT_STUCK_BUSY	3	FAULT_MASK bit set	STATUS.BUSY
↪ continuously latched clear FAULT_MASK			

Such tables make reading the code much easier: a reader sees `MYFIRST_FAULT_READ_1S` in the code and can look up the full story in one place.

17.9.4 The Updated `HARDWARE.md`

Chapter 16's `HARDWARE.md` described a static register block. Chapter 17 extends it with the dynamic registers and the behaviours that drive them. The sections that change:

Register Map. The table now includes the Chapter 17 registers: `SENSOR` (0x28), `SENSOR_CONFIG` (0x2c), `DELAY_MS` (0x30), `FAULT_MASK` (0x34), `FAULT_PROB` (0x38), `OP_COUNTER` (0x3c). Each with its access type, default value, and one-line description.

CTRL register fields. A new bit: `MYFIRST_CTRL_GO` (bit 9). The table adds a row: “bit 9: GO, write 1 to trigger a command; hardware self-clears”.

STATUS register fields. The table gains notes on which bits are dynamic in Chapter 17: `READY` is set at attach and stays on; `BUSY` is set by `start_command` and cleared by `command_cb`; `DATA_AV` is set by `command_cb` and cleared by the driver after reading `DATA_OUT`; `ERROR` is set by fault injection and cleared by the driver.

SENSOR_CONFIG fields. A new subsection explaining the two-field layout (low 16 bits interval, high 16 bits amplitude).

FAULT_MASK fields. A new subsection listing each fault bit and its effect.

Dynamic behaviour summary. A new subsection explaining what changes autonomously: `SENSOR` (every 100 ms by default), `STATUS.BUSY` (set/clear by command cycle or by `FAULT_STUCK_BUSY` callout), `STATUS.DATA_AV` (set by `command_cb`), `OP_COUNTER` (incremented on each command).

Locking discipline for dynamic behaviour. A sentence: “All dynamic updates happen under `sc->mtx`, which callouts acquire automatically via `callout_init_mtx`. The driver's command path acquires the mutex and drops it only during `pause_sbt` calls, where the simulation callouts may run.”

The document grows from perhaps 80 lines (Chapter 16 version) to perhaps 140 lines. It remains scannable. The new sections are organised so a reader looking for Chapter 17 information finds it quickly.

17.9.5 The Updated `LOCKING.md`

Chapter 15's `LOCKING.md` described a lock order of `sc->mtx -> sc->cfg_sx -> sc->stats_cache_sx` and a detach ordering that drained several primitives. Chapter 16 added the hardware layer's detach to the list. Chapter 17 adds the simulation layer's detach.

The updated detach ordering, from outermost to innermost:

1. Destroy `sc->cdev` and wait for any open file descriptors to close.
2. Stop and drain all driver-level callouts (heartbeat, watchdog, tick_source).
3. Disable and drain the simulation's callouts (sensor, command, busy).
4. Free the simulation state.
5. Detach the hardware layer (free `regs_buf`, free `hw`).
6. Destroy the driver's synchronisation primitives (mutex, sx, cv, sema).

Step 3 is new in Chapter 17. The simulation is stopped before the hardware layer is torn down, because the simulation's callouts touch the register block through the hardware layer's accessors. Freeing the register block while a callout is still in flight would produce a use-after-free.

The ordering of step 3 and step 2 matters. Driver-level callouts (heartbeat) may read registers, so they must drain before the simulation drains. A deliberate ordering: driver callouts first (they are the outermost consumers), then simulation callouts (the innermost), then the registers themselves.

17.9.6 The Version Bump

In `myfirst.c`:

```
#define MYFIRST_VERSION "1.0-simulated"
```

The version goes to 1.0 because Chapter 17 marks a real milestone: the driver now behaves, end to end, like a driver against a functional device. Chapter 16's 0.9-mmio was a register-access chapter; Chapter 17's 1.0-simulated is a fully-functional-driver chapter. The jump from 0.9 to 1.0 reflects this.

The top-of-file comment is updated:

```
/*
 * myfirst: a beginner-friendly device driver tutorial vehicle.
 *
 * Version 1.0-simulated (Chapter 17): adds dynamic simulation of the
 * Chapter 16 register block. Includes autonomous sensor updates,
 * command-triggered delayed events, read-to-clear semantics, and a
 * fault-injection framework. Simulation code lives in myfirst_sim.c;
 * the driver sees it only through register accesses.
 *
 * ... (previous version notes preserved) ...
 */
```

The Chapter 17 comment is two sentences. It points at the new file and names the new capabilities. A future contributor reading it has enough context to understand what the version represents.

17.9.7 The Regression Pass

Chapter 15 established the regression discipline: after every version bump, run the full stress suite from every previous chapter, confirm WITNESS is silent, confirm INVARIANTS is silent, confirm `kldunload` completes cleanly.

For Stage 5 that means:

- The Chapter 11 concurrency tests (multiple writers, multiple readers) pass.
- The Chapter 12 blocking tests (reader waits for data, writer waits for room) pass.
- The Chapter 13 callout tests pass.
- The Chapter 14 task tests pass.
- The Chapter 15 coordination tests pass.
- The Chapter 16 register-access tests pass.

- The Chapter 17 simulation tests (fault injection, timing, behaviour) pass.
- `kldunload myfirst` returns cleanly after the full suite.

No test is skipped. A regression in any previous chapter’s test is a bug, not a deferred issue. The discipline is the same as it has been throughout Part 3.

The Chapter 17 test additions include:

- `sim_sensor_oscillates.sh`: confirms `SENSOR` changes over time.
- `sim_command_cycle.sh`: runs a series of write commands and verifies `OP_COUNTER` increments.
- `sim_timeout_fault.sh`: enables the timeout fault and verifies the driver recovers.
- `sim_error_fault.sh`: enables the error fault and verifies the driver reports `EIO`.
- `sim_stuck_busy_fault.sh`: enables the stuck-busy fault and verifies the driver times out on ready.
- `sim_mixed_faults_under_load.sh`: 10% fault probability, 8 parallel workers, 30 seconds.

Each script is a few dozen lines. Together they add about 300 lines of test infrastructure, which is small compared to the driver itself but significant in the confidence it provides.

17.9.8 Running the Final Stage

```
# cd examples/part-04/ch17-simulating-hardware/stage5-final
# make clean && make
# kldstat | grep myfirst
# kldload ./myfirst.ko
# kldstat -v | grep -i myfirst

myfirst: version 1.0-simulated

# dmesg | tail -5
# sysctl dev.myfirst.0 | head -40
```

The `kldstat -v` output shows `myfirst` at version `1.0-simulated`. The `dmesg` tail shows the device probe and attach with no errors. The `sysctl` output lists every Chapter 11 through Chapter 17 `sysctl`, including the simulation controls.

Run the stress suite:

```
# ../labs/full_regression.sh
```

If every test passes, Chapter 17 is complete.

17.9.9 A Small Rule for Chapter 17’s Refactor

Chapter 16’s refactor was about separating “driver business logic” from “hardware register mechanics”. Chapter 17’s refactor is about separating “simulation” from “hardware access”. The rule generalises: when a subsystem acquires a new responsibility, give it its own file; when a file acquires multiple responsibilities, split them.

A rule of thumb: a file more than about 800 to 1000 lines often has more than one responsibility. A header that exports more than about ten functions often merits a split. A file that imports a header from a subsystem unrelated to its main purpose often signals a responsibility leak.

Chapter 17's `myfirst_sim.c` is about 300 lines at Stage 5. `myfirst_hw.c` is about 400 lines. `myfirst.c` is about 800 lines. Each file holds one responsibility. No file grew out of control. The split scales: Chapter 18 will add `myfirst_pci.c` (about 200 to 300 lines), Chapter 19 will add `myfirst_intr.c`, Chapter 20 will add `myfirst_dma.c`. Each subsystem lives in its own file. The main `myfirst.c` stays roughly constant in size; the subsystems grow around it.

17.9.10 What Stage 5 Accomplished

The driver is now at 1.0-simulated. Compared to 0.9-mmio, it has:

- A simulation backend in `myfirst_sim.c` and `myfirst_sim.h`.
- A dynamic register block with autonomous sensor updates, command-triggered delayed events, and fault injection.
- Configurable timeouts and per-error-type counters.
- A `SIMULATION.md` document describing the simulation's interface and limits.
- An updated `HARDWARE.md` reflecting the new registers and dynamic behaviour.
- An updated `LOCKING.md` reflecting the new detach ordering.
- Regression tests that exercise every Chapter 17 behaviour.

The driver's code is recognisably FreeBSD. The layout is the layout real drivers use when they have distinct simulation, hardware, and driver responsibilities. The vocabulary is the vocabulary real drivers share. A contributor opening the driver for the first time finds a familiar structure, reads the documentation, and can navigate the code by subsystem.

17.9.11 Real FreeBSD Drivers That Use the Same Patterns

The patterns this chapter exercises are not confined to simulated hardware. Three places in the FreeBSD tree are especially worth opening alongside Chapter 17, because each one uses a similar shape in a real subsystem and reading them turns the techniques from “how I wrote the simulation” into “how the kernel actually operates.”

The first is the **watchdog(4)** subsystem in `/usr/src/sys/dev/watchdog/watchdog.c`. The core routine `wdog_kern_pat()` at the top of that file is a small state machine driven by a periodic “pat” from user space or from another kernel subsystem; if the pat does not arrive within the configured timeout, the subsystem fires a pretimeout handler and, ultimately, a system reset. The parallel with the Chapter 17 simulation is direct: a timeout value in ticks, a callout that advances state in the background, an ioctl surface (`WDIOC_SETTIMEOUT`) that changes the interval from user space, and a sysctl surface that exposes the last configured timeout for observation. It is also short enough to read end-to-end, which is rare for a production subsystem.

The second is **random_harvestq**, the entropy-collection path, in `/usr/src/sys/dev/random/random_harvestq.c`. The function `random_harvestq_fast_process_event()` and its surrounding queue discipline are the kernel's version of the “accept events from many sources and process them in the background” pattern this chapter exercised with a simulated sensor. The harvest queue uses a ring buffer, a worker thread, and explicit backpressure when consumers fall behind, and it is one of the cleaner examples in the tree

of a driver-like subsystem that must never block the code paths that feed it. Reading it after Chapter 17 shows what the autonomous-update pattern looks like when the “sensor” is every entropy source in the system at once.

The third, worth mentioning briefly, is the **pseudo-random device** in `/usr/src/sys/dev/random/randomdev.c`. It uses a cdev surface, configurable sysctls, and careful separation between the harvest side and the output side. That separation is the same split Chapter 17 introduced between `myfirst_sim.c` and `myfirst.c`, and looking at how `randomdev.c` arranges its files is a useful second example of the discipline this section just applied to the simulated driver.

None of these are “toy” subsystems. They are live kernel code that has shipped for years. The point of the pointers is not to ask you to master them now, but to mark where the techniques you just practised in simulation live in production code, so that when you open `/usr/src/sys` later and a file looks familiar, you have already seen the pattern.

17.9.12 Wrapping Up Section 8

The refactor is, again, small in code but significant in organisation. A new file split, a new documentation file, updates to two existing documentation files, a version bump, and a regression pass. Each step is cheap; together they turn a working driver into a maintainable one.

The Chapter 17 driver is done. The chapter closes with labs, challenges, troubleshooting, and a bridge to Chapter 18, where the simulated register block is replaced with a real PCI BAR.

17.10 Hands-On Labs

Labs in Chapter 17 focus on exercising the simulation from multiple angles: watching autonomous behaviour, running commands under load, injecting faults, and observing driver reactions. Each lab takes 20 to 60 minutes.

17.10.1 Lab 1: Watch the Sensor Breathe

Load the driver and watch the sensor value change without any driver activity.

```
# kldload ./myfirst.ko
# sysctl dev.myfirst.0.sim_running
dev.myfirst.0.sim_running: 1

# while true; do
    sysctl dev.myfirst.0.reg_sensor
    sleep 0.5
done
```

You should see the value oscillating. Default baseline is $0 \times 1000 = 4096$, amplitude is 64, so the value ranges from about 4096 to about 4160 and back, over several seconds.

Change the config to speed up the oscillation:

```
# sysctl dev.myfirst.0.reg_sensor_config_set=0x01000020
```

This sets interval to $0x0100 = 256$ ms and amplitude to $0x0020 = 32$. The sensor updates every 256 ms with a smaller range. Watch the output change.

Change it again to slow it down dramatically:

```
# sysctl dev.myfirst.0.reg_sensor_config_set=0x03e80100
```

This sets interval to 1000 ms and amplitude to 256. The sensor changes once per second, with a larger range.

Stop the simulation:

```
# sysctl dev.myfirst.0.sim_running=0    # (requires a writeable sysctl, added in the lab  
↪ examples)
```

The sensor value freezes. Re-enable:

```
# sysctl dev.myfirst.0.sim_running=1
```

It resumes. This lab exercises the autonomous-update path end to end.

17.10.2 Lab 2: Run a Single Command

Issue a command by hand and observe every register change.

```
# sysctl dev.myfirst.0.access_log_enabled=1  
# sysctl dev.myfirst.0.reg_delay_ms_set=200  
  
# echo -n "A" > /dev/myfirst0  
# sysctl dev.myfirst.0.access_log | head -20  
# sysctl dev.myfirst.0.access_log_enabled=0
```

The log should show:

1. Reads of STATUS (polling for BUSY to clear at command start).
2. A write to DATA_IN (the byte 'A' = 0x41).
3. A read of CTRL followed by a write of CTRL (setting the GO bit).
4. A write of CTRL (clearing the GO bit; the self-clearing logic).
5. Reads of STATUS (polling for DATA_AV).
6. An eventual transition where DATA_AV is set (from the simulation's callout).
7. A read of DATA_OUT (returning 0x41).
8. A write of STATUS (clearing DATA_AV).

Try to match each entry to the source code in `myfirst_sim.c` and `myfirst_write_cmd`. If any entry does not make sense, you have a gap to fill.

17.10.3 Lab 3: Stress the Command Path

Run many concurrent commands and verify correctness.

```
# sysctl dev.myfirst.0.reg_delay_ms_set=20
# sysctl dev.myfirst.0.cmd_successes      # note value

# for i in 1 2 3 4 5 6 7 8; do
    (for j in $(seq 1 50); do
        echo -n "X" > /dev/myfirst0
    done) &
done
# wait

# sysctl dev.myfirst.0.cmd_successes      # should have grown by 400
# sysctl dev.myfirst.0.cmd_errors         # should still be 0
# sysctl dev.myfirst.0.reg_op_counter     # should match the growth in cmd_successes
```

Eight writers, 50 commands each, 400 total. With 20 ms per command, the test runs in about 8 seconds (serialised at the driver lock). `cmd_successes` should grow by 400. `cmd_errors` should remain at zero (no faults are enabled). `reg_op_counter` should match the increment in `cmd_successes`.

17.10.4 Lab 4: Inject a Timeout Fault

Enable the timeout fault and observe the driver's recovery.

```
# sysctl dev.myfirst.0.cmd_data_timeouts      # note value
# sysctl dev.myfirst.0.cmd_recoveries          # note value

# sysctl dev.myfirst.0.reg_fault_mask_set=0x1  # TIMEOUT bit
# sysctl dev.myfirst.0.reg_fault_prob_set=10000 # 100%

# echo -n "X" > /dev/myfirst0
write: Operation timed out

# sysctl dev.myfirst.0.cmd_data_timeouts      # should have grown by 1
# sysctl dev.myfirst.0.cmd_recoveries          # should have grown by 1

# sysctl dev.myfirst.0.reg_status              # should be 1 (READY, BUSY cleared by
↪ recovery)

# sysctl dev.myfirst.0.reg_fault_mask_set=0
# sysctl dev.myfirst.0.reg_fault_prob_set=0
# echo -n "X" > /dev/myfirst0
```

```
# echo "write succeeded"
write succeeded
```

The first write times out; the driver recovers; a subsequent write succeeds. The counters confirm the sequence.

17.10.5 Lab 5: Inject an Error Fault

Run a small batch with an error fault at 25% probability.

```
# sysctl dev.myfirst.0.cmd_errors          # note value

# sysctl dev.myfirst.0.reg_fault_mask_set=0x4  # ERROR bit
# sysctl dev.myfirst.0.reg_fault_prob_set=2500  # 25%

# for i in $(seq 1 40); do
#     echo -n "X" > /dev/myfirst0 || echo "error on iteration $i"
# done

# sysctl dev.myfirst.0.cmd_errors          # should have grown by ~10

# sysctl dev.myfirst.0.reg_fault_mask_set=0
# sysctl dev.myfirst.0.reg_fault_prob_set=0
```

About 10 out of 40 iterations should report an error. The driver's error-counter should reflect the count exactly. The driver should remain usable after the test (subsequent commands succeed).

17.10.6 Lab 6: Inject Stuck-Busy and Watch the Driver Wait

Enable the stuck-busy fault, try a command, watch it time out, clear the fault, confirm recovery.

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0x8  # STUCK_BUSY bit
# sleep 0.1                                     # let the busy callout assert

# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 3                     # READY|BUSY

# sysctl dev.myfirst.0.cmd_rdy_timeouts         # note value

# echo -n "X" > /dev/myfirst0
write: Operation timed out                      # after sc->rdy_timeout_ms

# sysctl dev.myfirst.0.cmd_rdy_timeouts         # should have grown by 1
```

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0
# sleep 0.2                                # let the busy callout stop

# sysctl dev.myfirst.0.reg_status
dev.myfirst.0.reg_status: 1                # READY only

# echo -n "X" > /dev/myfirst0
# echo "write succeeded"
write succeeded
```

The fault latches BUSY; the driver cannot issue commands; the driver times out on `wait_for_ready`. Clearing the fault and waiting briefly lets BUSY clear (via the command path, if any commands slipped through, or via the natural state of no outstanding command). The driver recovers.

17.10.7 Lab 7: Mixed Faults Under Load

Enable multiple faults at low probabilities, run a long stress test, analyse the results.

```
# sysctl dev.myfirst.0.reg_fault_mask_set=0x5    # TIMEOUT | ERROR
# sysctl dev.myfirst.0.reg_fault_prob_set=200    # 2%
# sysctl dev.myfirst.0.reg_delay_ms_set=10
# sysctl dev.myfirst.0.cmd_timeout_ms=50

# # Record starting counters.
# sysctl dev.myfirst.0 | grep -E 'cmd_|fault_' > /tmp/before.txt

# # 8 workers, 100 commands each.
# for i in 1 2 3 4 5 6 7 8; do
#     (for j in $(seq 1 100); do
#         echo -n "X" > /dev/myfirst0 2>/dev/null
#     done) &
# done
# wait

# # Record ending counters.
# sysctl dev.myfirst.0 | grep -E 'cmd_|fault_' > /tmp/after.txt
# diff /tmp/before.txt /tmp/after.txt

# # Clean up.
# sysctl dev.myfirst.0.reg_fault_mask_set=0
# sysctl dev.myfirst.0.reg_fault_prob_set=0
# sysctl dev.myfirst.0.reg_delay_ms_set=500
# sysctl dev.myfirst.0.cmd_timeout_ms=2000
```

The diff should show `cmd_successes` growing by about 784 (800 commands minus about 16 failures). `fault_injected` should grow by about 16. `cmd_data_timeouts` and `cmd_errors` should each grow by about 8. The exact numbers vary with each run (because of `arc4random`), but the proportions are stable.

Also check: `vmstat -m | grep myfirst` should show no growth in memory usage between before and after; the test was not supposed to leak.

17.10.8 Lab 8: Observe Sensor Updates During Heavy Command Load

The sensor callout and the command callout share the same mutex. A long-running load test might starve the sensor of updates if the lock is held constantly. Check this.

```
# sysctl dev.myfirst.0.reg_delay_ms_set=5          # very fast commands
# # Start a long load test in the background.
# (for i in $(seq 1 5000); do
#     echo -n "X" > /dev/myfirst0 2>/dev/null
# done) &

# # Meanwhile, poll the sensor.
# while kill -0 $! 2>/dev/null; do
#     sysctl dev.myfirst.0.reg_sensor
#     sleep 0.2
# done
```

Each polled sensor value should differ from the previous (the sensor callout is running). If the values freeze during the load (all identical for many reads), the lock is being held too long and the sensor is starving. A correct driver sees smoothly updating sensor values even under heavy command load, because the command path drops the lock during `pause_sbt`.

17.10.9 Lab 9: Build and Run the `hwsim2` Module

A stand-alone version of the Chapter 17 simulation, `hwsim2`, lives in the companion sources. Build and load it.

```
# cd examples/part-04/ch17-simulating-hardware/hwsim2-standalone
# make clean && make
# kldload ./hwsim2.ko

# # The hwsim2 module exposes a single register block with sensor
# # updates and command cycle; no cdev, just sysctls.
# sysctl dev.hwsim2.sensor
# sleep 1
# sysctl dev.hwsim2.sensor          # different value
# sysctl dev.hwsim2.do_command=0x12345678
```

```
# sleep 0.6
# sysctl dev.hwsim2.result           # 0x12345678

# kldunload hwsim2
```

The hwsim2 module is about 150 lines of C. Reading it in one sitting is a useful consolidation of Chapter 17's material.

17.10.10 Lab 10: Inject a Memory-Corruption Attack (Debug Kernel)

A deliberate break-and-observe exercise. Modify the simulation's sensor callback to write one byte past the end of the register block. This should fire the KASSERT on a debug kernel.

In `myfirst_sim.c`, temporarily add to `myfirst_sim_sensor_cb`:

```
/* DELIBERATE BUG for Lab 10. Remove after testing. */
CSR_WRITE_4(sc, 0x80, 0xdead); /* 0x80 is past the 64-byte region */
```

Rebuild and load. The kernel should panic within 100 ms (the sensor callback fires, the KASSERT catches the out-of-bounds offset, the panic string names offset 0x80).

Remove the bug. Rebuild. Verify the driver runs cleanly again.

This lab shows the value of bounds assertions in the hardware accessors: an out-of-bounds access fires immediately instead of silently corrupting unrelated memory. Production code should never remove these assertions.

17.11 Challenge Exercises

Challenges extend the Chapter 17 material with optional depth work. Each takes one to four hours and exercises judgment, not just keystrokes.

17.11.1 Challenge 1: Read-to-Clear INTR_STATUS

Chapter 17's `INTR_STATUS` is still RW, not RC. Implement RC semantics: when the driver reads `INTR_STATUS`, return the current value and then clear it. Add a hook in the accessor path that recognises RC registers and treats them specially. Update `HARDWARE.md`.

Think about: how does the driver ensure the read happens under the lock? What happens if a `sysctl` reads `INTR_STATUS` (inadvertently clearing state the driver needed)?

17.11.2 Challenge 2: Add a Queue of Commands

The current simulation rejects overlapping commands. Real devices often queue them. Implement a small command queue: if a command arrives while another is pending, add it to the queue; when the current command completes, start the next. Limit the queue to 4 entries.

Think about: how does the driver wait for queued commands? Should the driver have its own view of the queue, or rely on the simulation's view?

17.11.3 Challenge 3: Simulate a Sampling Rate Drift

The sensor callout fires at a fixed interval. Real sensors often drift: the interval shifts slightly over time because of temperature or voltage changes. Modify the sensor callback to add a small random perturbation to each interval (say, +/- 10%). Observe how this affects the driver.

Think about: does the drift matter for a driver that reads the sensor value? Does it matter for a driver that cares about sample timing (the first driver does not; a later driver might)?

17.11.4 Challenge 4: A Write-One-to-Clear `INTR_STATUS`

W1C semantics are a common variant of RC. Implement W1C for `INTR_STATUS`: writing a 1 to a bit clears that bit; writing a 0 has no effect; reads return the current value without side effects. Contrast with the RC implementation in Challenge 1.

Think about: which is more convenient for the driver (reading-to-clear or writing-to-clear)? Which is more defensive against accidental debug reads?

17.11.5 Challenge 5: Error Recovery Without Reset

The Chapter 17 driver's recovery path clears simulation-specific state directly. Real hardware cannot do this; the driver must use only register-level operations. Rewrite `myfirst_recover_from_stuck` to use only register writes (for example, a `CTRL.RESET` bit). Adjust the simulation to honour `CTRL.RESET`.

Think about: how does the driver wait for the reset to complete? Does the reset affect other registers (for example, does it clear the fault mask)?

17.11.6 Challenge 6: A User-Space Debugger

Write a small user-space program, `myfirstctl`, that opens `/dev/myfirst0`, issues a series of `ioctl`s to control the simulation, and displays the register state. Make it interactive: the user can type commands like `status`, `go X`, `delay 100`, `fault timeout 50%`.

Think about: how does the user-space program communicate with the driver (`ioctl`, `sysctl`, `read/write`)? What is a sensible command syntax?

17.11.7 Challenge 7: A DTrace-Driven Fault Injection

DTrace can provide dynamic probes. Add a DTrace probe at the top of `myfirst_sim_start_command` that takes a pointer to `sc` as its argument. Write a D script that, based on some user-specified condition (for example, "every 100th call"), sets `sc->sim->pending_fault = MYFIRST_FAULT_ERROR`. The script injects faults from user space without the kernel's fault-injection framework.

Think about: can DTrace safely modify kernel state like this? What are the limits of what DTrace can do?

17.11.8 Challenge 8: Simulate Two Devices

The current driver has a single device instance. Modify it so that two `/dev/myfirstN` files exist, each with its own simulation. Verify that operations on one device do not affect the other.

Think about: what changes in `attach`? How does the per-device `sysctl` tree work? Does the simulation need per-device random state?

17.12 Troubleshooting Reference

A quick reference for the problems Chapter 17's simulation is most likely to surface.

17.12.1 The sensor does not change

- `sim_running` is 0. Toggle it with the writeable `sysctl`.
- `SENSOR_CONFIG`'s `interval` field is zero. Set it to a positive value.
- The sensor callout is not scheduled. Confirm `myfirst_sim_enable` was called. Check `dmesg` for error messages.
- `sc->sim` is `NULL`. Confirm `myfirst_sim_attach` ran successfully.

17.12.2 Commands always time out

- `DELAY_MS` is set very high. Reduce it or increase the command timeout.
- The `FAULT_TIMEOUT` bit is set in `FAULT_MASK`. Clear it.
- The `FAULT_STUCK_BUSY` bit is set. Clear it and wait ~100 ms for the busy callout to stop re-asserting.
- The simulation is disabled (`sim_running=0`). Enable it.
- A previous command got stuck and was not recovered. Check `command_pending` (through the `sim sysctl`) and manually reset if needed.

17.12.3 WITNESS warns about lock order

- The detach path is acquiring locks in the wrong order. Compare the stack trace against `LOCKING.md`.
- A new code path is taking `sc->mtx` after a sleep lock. The ordering from Chapter 15 must be preserved.

17.12.4 Kernel panic on `kldunload`

- The simulation callouts were not drained before `free`. Check that `callout_drain` runs before `free(sim)`.
- The simulation state was freed while a callout was in flight. The drain is the fix.
- The hardware layer was freed before the simulation layer. The Chapter 17 ordering (`sim detach`, then `hw detach`) must be followed.

17.12.5 Memory usage grows over time

- `vmstat -m | grep myfirst` shows the driver's allocation size climbing. This is a leak. Check the fault-injection error paths; they often neglect to free something.
- The access log is allocated dynamically in some configurations. Confirm it is freed on detach.

17.12.6 The access log shows unexpected entries

- A callout is running on its own cadence; all Chapter 17 callouts are visible in the log. If the log shows callouts firing faster than expected, check the interval.
- A user-space tool (`watch -n 0.1 sysctl ...`) is polling very fast. Each `sysctl` access goes through the accessors.

17.12.7 Fault injection probability does not match observations

- `FAULT_PROB` is scaled as 0 to 10000. A value of 50 is 0.5%, not 50%. For 50%, use 5000.
- The fault only applies to operations that trigger `myfirst_sim_should_fault`. Not every operation is a candidate; sensor updates, for example, do not go through that path.

17.12.8 `sim_running` toggles ignored

- The `sysctl` handler may not call `myfirst_sim_enable` or `myfirst_sim_disable` under the lock. Confirm the handler acquires `sc->mtx` before delegating.

17.12.9 Commands succeed but take much longer than expected

- `cmd_timeout_ms` is set very high; any command that stalls makes the timeout budget huge.
- The fault mask is set with `STUCK_BUSY` and a successful command unexpectedly becomes a `wait_for_ready` stall until the next fault-clear.

17.12.10 Load tests are slower than expected

- Commands are serialised through the driver mutex. N writers at M commands each take NM `DELAY_MS` total time.
- Reducing `DELAY_MS` speeds up the simulation; reducing `cmd_timeout_ms` does not speed anything up unless timeouts are actually occurring.

17.13 Wrapping Up

Chapter 17 opened with a static register block from Chapter 16 and closes with a driver that behaves, end to end, like a driver talking to a functional device. The simulation is dynamic: a sensor register updates on its own, commands schedule delayed completions, `STATUS` bits change over time, and fault injection produces controlled failures that exercise the driver's error paths. The driver handles all of this through the register

vocabulary Chapter 16 taught, with the synchronisation discipline Part 3 built, and with the timing primitives Section 6 introduced.

What Chapter 17 deliberately did not do: real PCI (Chapter 18), real interrupts (Chapter 19), real DMA (Chapters 20 and 21). Each of those topics deserves its own chapter; each will extend the driver in specific ways while reusing the simulation framework where appropriate.

The version is 1.0-simulated. The file layout has grown: `myfirst.c`, `myfirst_hw.c`, `myfirst_hw.h`, `myfirst_sim.c`, `myfirst_sim.h`, `myfirst_sync.h`, `cbuf.c`, `cbuf.h`. The documentation has grown: `LOCKING.md`, `HARDWARE.md`, and the new `SIMULATION.md`. The test suite now exercises every simulation behaviour, every fault mode, and every error path.

17.13.1 A Reflection Before Chapter 18

A pause before the next chapter. Chapter 17 taught simulation as a technique that extends beyond learning. The patterns you practised here (callout-driven state changes, command-response protocols, fault injection, recovery paths) are patterns you will use throughout your driver-writing life. They apply as much to a production storage driver's test harness as to this tutorial driver. The simulation skill is permanent.

Chapter 17 also taught the discipline of thinking like hardware. Designing the register map, choosing access semantics, timing the responses, deciding what to latch and what to clear: these are decisions the hardware team makes for real devices, and a driver author who understands them reads datasheets differently. The next time you encounter a real device's datasheet, you will notice the decisions the designers made, and you will have a framework for evaluating whether the decisions were wise.

Chapter 18 shifts the scene entirely. The simulation goes away (temporarily); a real PCI device takes its place. The register block moves from `malloc(9)` memory to a PCI BAR. The accessors switch from `X86_BUS_SPACE_MEM` to `rman_get_bustag` and `rman_get_bushandle`. The driver's high-level code does not change at all, because the Chapter 16 abstraction is portable across the change. What does change is the device's behaviour: a real virtio device in a VM has its own protocol, its own timing, its own quirks. The patterns Chapter 17 taught are what let you handle all of that.

17.13.2 What to Do If You Are Stuck

A few suggestions if the Chapter 17 material feels dense.

First, re-read Section 3. The callout pattern is the foundation of every dynamic behaviour in the chapter. If the interaction between `callout_init_mtx`, `callout_reset_sbt`, `callout_stop`, and `callout_drain` feels opaque, everything downstream is opaque. Chapter 13 is the other good reference.

Second, run Lab 1 and Lab 2 by hand, one step at a time. Watching the sensor breathe and tracing a single command through the access log is where the simulation's behaviour becomes concrete.

Third, skip the challenges on first pass. The labs are calibrated for Chapter 17; the challenges assume the chapter's material is already solid. Come back to them after Chapter 18 if they feel out of reach now.

Fourth, open `myfirst_sim.c` and read the three callouts (sensor, command, busy) in order. Each is a self-contained piece of code that illustrates one aspect of the simulation's design. If you can explain each one to a colleague (or to a rubber duck), you have internalised Chapter 17's core.

Chapter 17's goal was to make the register block come alive. If it has, the rest of Part 4 will feel like a natural progression: Chapter 18 trades the simulation for real hardware, Chapter 19 adds real interrupts, Chapters 20 and 21 add DMA. Each chapter builds on what Chapter 17 established.

17.14 Bridge to Chapter 18

Chapter 18 is titled *Writing a PCI Driver*. Its scope is the real-hardware path that Chapter 17 deliberately did not take: a driver that probes a PCI bus, matches a real device by vendor and device ID, claims the device's BAR as a memory resource, maps it through `bus_alloc_resource_any`, and talks to the mapped region through the same `CSR_*` macros the Chapter 16 and Chapter 17 drivers already use.

Chapter 17 prepared the ground in four specific ways.

First, **you have a complete driver**. The Chapter 17 driver at `1.0-simulated` exercises every common protocol pattern: command-response, delayed completion, status polling, error recovery, timeout handling. Chapter 18 will swap the register backend without changing the driver's high-level logic. The swap is a one-function change in `myfirst_hw_attach`; everything else stays put.

Second, **you have a fault model**. The Chapter 17 fault-injection framework taught the driver to handle errors. Real PCI devices produce real errors: bus timeouts, uncorrectable ECC errors, power-state transitions, link drops. The discipline of handling simulated errors is what will let the Chapter 18 driver handle real ones.

Third, **you have a timing model**. Chapter 17 taught the reader when to use `DELAY(9)`, `pause_sbt(9)`, and `callout_reset_sbt(9)`. Real PCI devices have their own timing requirements, often documented in their datasheets. The discipline Chapter 17 built is what will let the driver respect those timings in Chapter 18.

Fourth, **you have a documentation habit**. `HARDWARE.md`, `LOCKING.md`, and `SIMULATION.md` are three living documents that the driver's contributors maintain. Chapter 18 will add a fourth: `PCI.md` or a similar document describing the specific PCI device the driver targets, its vendor and device ID, its BAR layout, and any quirks. The habit of documenting is established; Chapter 18 extends it.

Specific topics Chapter 18 will cover:

- The PCI subsystem in FreeBSD: `pci(4)`, the bus-device-function tuple, `pciconf -lv`.
- The probe and attach lifecycle: `DRIVER_MODULE`, vendor and device ID matching, the probe and attach methods.
- Resource allocation: `bus_alloc_resource_any`, the resource specification, `SYS_RES_MEMORY`, `RF_ACTIVE`.
- BAR mapping: how the PCI BAR becomes a `bus_space` region; `rman_get_bustag` and `rman_get_bushandle`.
- Enabling bus mastering: `pci_enable_busmaster` and when it is necessary.
- Attach-time initialisation and detach cleanup.
- Testing against a virtio device in a VM: the FreeBSD guest on `qemu` or `bhyve`, how to pass through a synthetic device, how to verify the driver attaches and behaves.

You do not need to read ahead. Chapter 17 is sufficient preparation. Bring your `myfirst` driver at `1.0-simulated`, your `LOCKING.md`, your `HARDWARE.md`, your `SIMULATION.md`, your WITNESS-enabled kernel, and your test kit. Chapter 18 starts where Chapter 17 ended.

A small closing reflection. Part 3 taught the synchronisation vocabulary and produced a driver that coordinated itself. Chapter 16 gave the driver a register vocabulary. Chapter 17 gave the register block dynamic behaviour

and the driver a fault model. Chapter 18 will retire the simulation and connect the driver to real silicon. Each step has built on the last; the driver that walks into Chapter 18 is a driver that is almost production-grade, needing only the real-bus glue that Chapter 18 provides.

The hardware conversation is deepening. The vocabulary is yours; the protocol is yours; the discipline is yours. Chapter 18 adds the last missing piece.

17.15 Reference: The Chapter 17 Simulation Cheat Sheet

A one-page summary of the Chapter 17 simulation API and the sysctls it exposes, for quick reference while coding.

17.15.1 Simulation API (in `myfirst_sim.h`)

Function	Purpose
<code>myfirst_sim_attach(sc)</code>	Allocate sim state, register callouts (not started).
<code>myfirst_sim_detach(sc)</code>	Drain callouts, free sim state.
<code>myfirst_sim_enable(sc)</code>	Start the callouts. Requires <code>sc->mtx</code> held.
<code>myfirst_sim_disable(sc)</code>	Stop the callouts (without drain).
<code>myfirst_sim_start_command(sc)</code>	Triggered by <code>CTRL.GO</code> write; schedules completion.
<code>myfirst_sim_add_sysctls(sc)</code>	Register simulation-specific sysctls.

17.15.2 Register Additions

Offset	Register	Access	Purpose
0x28	SENSOR	RO	Simulated sensor value, updated by callout.
0x2c	SENSOR_CONFIG	RW	Interval (low 16) and amplitude (high 16).
0x30	DELAY_MS	RW	Command processing delay in milliseconds.
0x34	FAULT_MASK	RW	Bitmask of enabled fault types.
0x38	FAULT_PROB	RW	Fault probability, 0 to 10000 (10000 = 100%).
0x3c	OP_COUNTER	RO	Count of commands processed.

17.15.3 CTRL Additions

Bit	Name	Purpose
9	MYFIRST_CTRL_GO	Start a command. Self-clearing.

17.15.4 Fault Modes

Bit	Name	Effect
0	MYFIRST_FAULT_TIMEOUT	Command never completes.
1	MYFIRST_FAULT_READ_1S	DATA_OUT returns 0xFFFFFFFF.
2	MYFIRST_FAULT_ERROR	STATUS.ERROR set instead of DATA_AV.
3	MYFIRST_FAULT_STUCK_BUSY	STATUS.BUSY latched on continuously.

17.15.5 New Sysctls

Sysctl	Type	Purpose
dev.myfirst.0.sim_running	RW	Enable/disable the simulation.
dev.myfirst.0.sim_sensor_baseline	RW	Baseline sensor value.
dev.myfirst.0.sim_op_counter_mirror	RO	Mirror of OP_COUNTER.
dev.myfirst.0.reg_delay_ms_set	RW	Writable DELAY_MS.
dev.myfirst.0.reg_sensor_config_set	RW	Writable SENSOR_CONFIG.
dev.myfirst.0.reg_fault_mask_set	RW	Writable FAULT_MASK.
dev.myfirst.0.reg_fault_prob_set	RW	Writable FAULT_PROB.
dev.myfirst.0.cmd_timeout_ms	RW	Command completion timeout.
dev.myfirst.0.rdy_timeout_ms	RW	Device-ready polling timeout.
dev.myfirst.0.cmd_successes	RO	Successful commands.
dev.myfirst.0.cmd_rdy_timeouts	RO	Ready-wait timeouts.
dev.myfirst.0.cmd_data_timeouts	RO	Data-wait timeouts.
dev.myfirst.0.cmd_errors	RO	Commands that reported an error.
dev.myfirst.0.cmd_recoveries	RO	Recovery invocations.
dev.myfirst.0.fault_injected	RO	Total faults injected.

17.16 Reference: Timing Primitive Cheat Sheet

Primitive	Cost	Cancelable	Appropriate Range
DELAY(us)	Busy-wait, full CPU	No	< 100 us
pause_sbt(..., sbt, ...)	Sleep, yields CPU	No (not interruptible in this form)	100 us - seconds
callout_reset_sbt(...)	Scheduled callback	Yes	fire-and-forget, periodic
cv_timedwait_sbt(...)	Sleep on condition	Yes (via cv_signal)	waits that can be shortened

Contexts where each is legal:

- DELAY: any (including filter interrupts, spin mutexes).
- pause_sbt: process context, spin locks not held.
- callout_reset_sbt: any (the callback runs in callout context).
- cv_timedwait_sbt: process context, specific mutex held.

17.17 Reference: Anatomy of a Simulation Callout

A template for adding a new simulation behaviour, modelled on the Chapter 17 sensor callout.

17.17.1 Step 1: Declare the callout in the sim state

```
struct myfirst_sim {
    /* ... existing fields ... */
    struct callout    my_new_callout;
    int               my_new_interval_ms;
};
```

17.17.2 Step 2: Initialise the callout at attach

```
/* In myfirst_sim_attach: */
callout_init_mtx(&sim->my_new_callout, &sc->mtx, 0);
sim->my_new_interval_ms = 200; /* default */
```

17.17.3 Step 3: Write the callback

```
static void
myfirst_sim_my_new_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct myfirst_sim *sim = sc->sim;

    MYFIRST_LOCK_ASSERT(sc);

    if (!sim->running)
        return;

    /* Do the work: update a register, signal a condition, ... */
    CSR_UPDATE_4(sc, MYFIRST_REG_SENSOR, 0, 0x100);

    /* Re-arm. */
    callout_reset_sbt(&sim->my_new_callout,
        sim->my_new_interval_ms * SBT_1MS, 0,
        myfirst_sim_my_new_cb, sc, 0);
}
```

17.17.4 Step 4: Start the callout at enable

```
/* In myfirst_sim_enable: */
callout_reset_sbt(&sim->my_new_callout,
    sim->my_new_interval_ms * SBT_1MS, 0,
    myfirst_sim_my_new_cb, sc, 0);
```

17.17.5 Step 5: Stop it at disable, drain at detach

```
/* In myfirst_sim_disable: */
callout_stop(&sim->my_new_callout);

/* In myfirst_sim_detach, after releasing the lock: */
callout_drain(&sim->my_new_callout);
```

17.17.6 Step 6: Document in SIMULATION.md

Add an entry to the callout-map table:

Callout	Interval	Purpose
-----	-----	-----
my_new_callout	my_new_interval_ms	... explain ...

Six steps. Each is mechanical. The pattern is the same for every simulation behaviour; once you have internalised the template, adding new behaviours is quick and reliable.

17.18 Reference: Test Scripts Inventory

A short catalogue of the test scripts that ship under `examples/part-04/ch17-simulating-hardware/labs/`.

Script	Purpose	Typical Runtime
<code>sim_sensor_oscillates.sh</code>	Confirm SENSOR value changes over time.	~10 s
<code>sim_command_cycle.sh</code>	Run 50 commands, verify OP_COUNTER matches.	~30 s
<code>sim_timeout_fault.sh</code>	Enable timeout fault; verify recovery.	~5 s
<code>sim_error_fault.sh</code>	Enable error fault; verify cmd_errors grows.	~10 s
<code>sim_stuck_busy_fault.sh</code>	Enable stuck-busy fault; verify timeout on ready.	~10 s
<code>sim_mixed_faults_under_load.sh</code>	50% random faults, 8 workers, 100 commands each.	~30 s
<code>sim_sensor_during_load.sh</code>	Verify sensor updates during heavy command load.	~30 s
<code>full_regression_ch17.sh</code>	All of the above plus Chapter 11-16 regression.	~3 minutes

Each script exits with a non-zero status if something unexpected happened. A successful `full_regression_ch17.sh` means every Chapter 17 behaviour has been validated and no regressions have been introduced.

17.19 Reference: An Honest Accounting of Chapter 17's Simplifications

A chapter that teaches a slice of a large topic inevitably simplifies. For honesty with the reader, a catalogue of what Chapter 17 simplified and what the full story looks like.

17.19.1 The Callout's Mutex Interaction

Chapter 17 uses `callout_init_mtx` so every simulation callback runs with `sc->mtx` held. This is the simplest and safest pattern but not the only one. Real drivers sometimes use `callout_init` (no associated mutex) and acquire the lock inside the callback; this gives finer control over locking but is more error-prone. Some real drivers use `callout_init_rm` (for reader-writer locks) or even `callout_init_mtx` with a spin mutex for cases where the callback must run in hardirq context.

The full story: FreeBSD's callout API supports several lock styles, each suited to a different concurrency model. The `callout_init_mtx` choice in Chapter 17 is pedagogically clean; production drivers pick the style that

matches their specific locking graph. `/usr/src/sys/dev/e1000/if_em.c` uses `callout_init_mtx` for its tick callout and `callout_init` for its spinlock-guarded DMA-polling path, illustrating the difference.

17.19.2 The Fault-Injection Framework

Chapter 17's fault injection is limited to four modes, a probability, and a simple `should_fault` check at the start of each operation. Real fault-injection frameworks (FreeBSD's own `fail(9)`, for example) support a richer vocabulary: callsite-specific injection, probability curves that change over time, deterministic injection for the Nth call, and injection paths that can be triggered from user space by name.

The full story: the `fail(9)` framework in `/usr/src/sys/kern/kern_fail.c` implements a production-grade fault-injection system. Chapter 17's framework is a simplified version that focuses on the simulation's specific needs. A challenge at the end of the chapter invites the reader to replace the chapter's ad-hoc framework with a `fail(9)`-based one.

17.19.3 The Random Number Source

Chapter 17 uses `arc4random_uniform(10000)` as the fault-probability decision source. This is non-deterministic: two runs of the same test will produce different fault patterns. For reproducible testing, a driver author would use a deterministic source (a simple LCG seeded by a fixed value, or a counter) and expose the seed through a `sysctl`.

The full story: reproducible fault injection is important for regression testing. A driver that passes all faults at seed `0x12345` one day and fails the same seed next week has a bug that was not there before. Chapter 17's non-determinism is acceptable for teaching but insufficient for serious regression suites.

17.19.4 The Command Queue

Chapter 17 allows only one command in flight at a time. Real devices often queue commands; a network driver might have thousands of in-flight descriptors. The single-command restriction simplifies the simulation's state machine and the driver's locking story, but it limits the throughput of the tutorial driver.

The full story: a queued command model requires per-command state (status, arrival time, result), a queue data structure with its own synchronisation, and a driver pattern that handles command coalescing, batch completion, and out-of-order completion. Chapter 20's DMA descriptor rings introduce the pattern for DMA-based devices; real command-queue drivers extend it to non-DMA contexts too.

17.19.5 The Sensor Model

Chapter 17's sensor produces a triangle-wave value using a simple arithmetic formula. Real sensors produce values influenced by physical noise, temperature drift, sampling jitter, and device-specific non-linearities. A more realistic simulation would include Gaussian noise, a slow drift term, and occasional outliers.

The full story: sensor modelling is a discipline of its own, and real driver testing for sensor devices often uses captured real-world data played back through a simulation layer. Chapter 17's arithmetic sensor is pedagogically sufficient; a production simulation would be substantially richer.

17.19.6 The Error Taxonomy

Chapter 17 distinguishes four fault types: timeout, read-1s, error, stuck-busy. Real hardware produces a much wider range of failure modes, including partial writes, stuck interrupt bits, inverted fields, off-by-one register values, and transient electrical noise. The four chapter faults are a starting point.

The full story: FreeBSD driver authors who work with specific device families develop much more elaborate fault taxonomies over time. The `e1000` driver's error-handling code is a few hundred lines of its own, handling dozens of distinct failure modes. Chapter 17 teaches the pattern; applying it to real hardware produces a richer taxonomy by necessity.

17.19.7 The Lack of Interrupts

Chapter 17's driver polls `STATUS` by reading the register in a loop (with `pause_sbt` between polls). Real drivers use interrupts: the device raises an interrupt when `STATUS` changes, the driver's interrupt handler wakes the waiting thread, the thread reads the new state. Polling is wasteful compared to interrupts.

The full story: Chapter 19 introduces interrupts. The Chapter 17 driver will get an `INTR_STATUS`-driven wake-up path in Chapter 19, and the polling loops will become much shorter (wake-once rather than wake-every-millisecond). Chapter 17's polling is a pedagogical stepping stone.

17.19.8 The Timing Precision

Chapter 17's callouts run at approximately the configured interval, with precision on the order of 1 ms (the kernel's default timer resolution). Real devices sometimes require sub-microsecond timing. A driver that depends on such timing must use `DELAY(9)` for short waits and cannot rely on callout precision.

The full story: high-precision timing in drivers requires platform-specific mechanisms (the TSC, the ACPI-PM timer, the HPET, or hardware-specific timers on embedded platforms). Chapter 17's millisecond-scale simulation does not exercise sub-millisecond paths; a driver for a real device with such requirements would use `DELAY` or a hardware-assisted mechanism.

17.19.9 Summary

Chapter 17 is a teaching simulation. Every simplification it makes is deliberate, named, and picked up by a later chapter or by a real-driver extension. The patterns Chapter 17 teaches are the patterns every later chapter extends; the discipline Chapter 17 builds is the discipline every later chapter relies on. The chapter is short of the full simulation story on purpose. Subsequent chapters and real-world practice fill in the rest.

17.20 Reference: A Glossary of Chapter 17 Terms

A short glossary of terms introduced or used extensively in Chapter 17.

Autonomous update. A change to a register that happens without the driver initiating it. In Chapter 17, the sensor callout produces autonomous updates.

Command cycle. The full sequence of events from “driver decides to issue a command” to “command completes and the driver observes the result”. In Chapter 17: write `DATA_IN`, set `CTRL.GO`, wait for `STATUS.DATA_AV`, read `DATA_OUT`.

Callout. A FreeBSD primitive that schedules a callback to run at a future time. The callback runs on a callout thread. Created with `callout_init_mtx`, armed with `callout_reset_sbt`, cancelled with `callout_stop`, drained with `callout_drain`.

Fault injection. The deliberate introduction of a failure condition into the system for testing purposes. Chapter 17’s framework supports four fault modes configurable through `FAULT_MASK` and `FAULT_PROB`.

Latched. A register bit that, once set, remains set until explicitly cleared. Error bits in real devices are typically latched. Chapter 17’s `STATUS.ERROR` is latched.

Polling. Repeatedly reading a register to detect a change. Chapter 17’s `myfirst_wait_for_bit` polls `STATUS` with 1 ms sleep between reads.

Pending command. A command that has been started but not yet completed. Chapter 17’s simulation tracks this with `sim->command_pending`.

Protocol. The rules the driver must follow when talking to the device. In Chapter 17: write `DATA_IN` before `CTRL.GO`; wait for `STATUS.DATA_AV` before reading `DATA_OUT`; clear `DATA_AV` after reading.

Read-to-clear (RC). A register semantic where reading the register returns its current value and then clears it. `INTR_STATUS` on many real devices is RC.

Simulation backend. The kernel code that provides the simulated device’s behaviour. In Chapter 17, this is `myfirst_sim.c`.

Side effect. Behaviour that a register access triggers beyond the obvious read or write. `CTRL.RESET` writes have a side effect (they reset the device). `INTR_STATUS` reads have a side effect (they clear pending bits, under RC semantics).

Sticky. Similar to latched. A bit that persists until deliberately cleared.

Timeout. A bounded wait that returns an error if the expected event does not occur in time. Chapter 17’s `wait_for_bit` timeouts after the configured number of milliseconds.

17.21 Reference: The Chapter 17 Driver Diff Summary

A compact summary of what Chapter 17 changes in the driver, for readers who want to see at a glance how the driver evolved from 0.9-mmio to 1.0-simulated.

17.21.1 New files

- `myfirst_sim.c` (about 300 lines).
- `myfirst_sim.h` (about 50 lines).
- `SIMULATION.md` (about 200 lines).

17.21.2 Modified files

- `myfirst.c`: added `myfirst_sim_attach` and `myfirst_sim_detach` calls; added `myfirst_write_cmd`, `myfirst_sample_cmd`, `myfirst_wait_for_bit` helpers; added timeout fields to `softc`; added stats counters.
- `myfirst_hw.h`: added new register offsets (0x28 through 0x3c) and bit masks; added `MYFIRST_CTRL_GO`; added fault constants.
- `myfirst_hw.c`: no change to the accessor code; `myfirst_ctrl_update` extended to intercept `GO`.
- `HARDWARE.md`: added the new registers, the new `CTRL.GO` bit, the dynamic-behaviour notes.
- `LOCKING.md`: added the simulation detach step to the ordered detach sequence.
- `Makefile`: added `myfirst_sim.c` to `SRCS`.

17.21.3 Line count evolution

The file sizes at each stage (approximate):

Stage	<code>myfirst.c</code>	<code>myfirst_hw.c</code>	<code>myfirst_sim.c</code>	Total
Chapter 16 Stage 4 (start)	650	380	(not yet)	1030
Chapter 17 Stage 1	680	400	120	1200
Chapter 17 Stage 2	800	400	150	1350
Chapter 17 Stage 3	820	410	180	1410
Chapter 17 Stage 4	840	410	250	1500
Chapter 17 Stage 5 (final)	800	400	300	1500

The driver grew from roughly 1030 lines to 1500 lines over the chapter. About 470 lines of new code, split roughly 150 in `myfirst.c`, 20 in `myfirst_hw.c`, and 300 in the new `myfirst_sim.c`. The Stage 5 refactor slightly reduced `myfirst.c` by moving some helpers into `myfirst_sim.c`.

17.21.4 Behavioural additions

- Sensor autonomously updates every 100 ms.
- `CTRL.GO` triggers a command that completes after `DELAY_MS` milliseconds.
- `OP_COUNTER` increments on each command.
- `FAULT_MASK` and `FAULT_PROB` control injected failures.
- Four fault modes (timeout, read-1s, error, stuck-busy).
- Per-outcome statistics counters.
- Configurable command and ready timeouts.
- Command cycle integrated into the write and read paths.

17.21.5 Test additions

- Eight new test scripts under `labs/`.

- An updated `full_regression.sh` that includes the new scripts.
- Expected runtime of the full regression: about 3 minutes.

17.22 Reference: Reading a Callout-Driven Driver

A guided walk through a real FreeBSD driver whose design is similar to Chapter 17's simulation: a driver whose periodic work is scheduled through callouts, and whose main job is to respond to state changes. The driver is `/usr/src/sys/dev/led/led.c`, the LED pseudo-device driver.

Open it in one terminal. Follow along.

17.22.1 The LED Driver's Structure

`led.c` is about 400 lines. Its job is to expose an interface for other drivers to announce an LED device through `/dev/led/NAME`, and for user space to blink the LED by writing patterns. The actual hardware work is delegated to whichever driver registered the LED; `led.c` does the scheduling and the pattern matching.

The key data structures:

- `struct led_softc`: per-LED state, including a `struct callout led_ch`, a `struct sbuf *spec` holding the blink pattern, and a function pointer to the driver's "set state" callback.
- `struct mtx led_mtx`: a global mutex protecting the list of all LEDs.
- A linked list of all LEDs.

17.22.2 The Callout Callback

The blink-pattern interpreter runs in the callout callback:

```
static void
led_timeout(void *p)
{
    struct ledsc *sc = p;
    char c;
    int count;

    if (sc->spec == NULL || sc->ptr == NULL || sc->count == 0) {
        /* no pattern; stop blinking */
        sc->func(sc->private, sc->on);
        return;
    }

    c = *(sc->ptr)++;
    if (c == '.') {
        /* Pattern complete, restart. */
        sc->ptr = sbuf_data(sc->spec);
    }
}
```

```

        c = *(sc->ptr)++;
    }

    if (c >= 'a' && c <= 'j') {
        sc->func(sc->private, 0);    /* LED off */
        count = (c - 'a') + 1;
    } else if (c >= 'A' && c <= 'J') {
        sc->func(sc->private, 1);    /* LED on */
        count = (c - 'A') + 1;
    } else {
        count = 1;
    }

    callout_reset(&sc->led_ch, count * hz / 10, led_timeout, sc);
}

```

(The code is lightly abridged from the real source for presentation.)

17.22.3 The Pattern

Look at the shape of the callback.

First, it checks whether there is anything to do. If `spec == NULL`, the pattern has been cleared; the function turns the LED off (to a known state) and returns without re-arming. This is exactly the `if (!sim->running) return; pattern` in Chapter 17’s callouts.

Second, it advances through the pattern buffer one character at a time. The pattern language uses lowercase letters ‘a’ through ‘j’ to mean “LED off for 100 ms through 1000 ms” and uppercase ‘A’ through ‘J’ for “LED on”. This is a small state machine driven by the callout.

Third, it calls `sc->func(sc->private, state)` to actually toggle the LED. This is the hardware work, delegated to whichever driver registered the LED. The `led_timeout` callback does not know whether the LED is a GPIO pin, an I2C-attached LED controller, or a message to a remote device; it just calls the function pointer.

Fourth, it re-arms the callout with an interval determined by the current pattern character. This is Chapter 17’s `callout_reset_sbt pattern`, though `led.c` uses the older `callout_reset` with tick-based intervals.

17.22.4 Lessons for Chapter 17

The `led.c` driver illustrates several Chapter 17 patterns:

- A callout carries a state machine forward one step per invocation.
- The callout re-arms itself with a variable interval based on the current state.
- A “no work to do” branch returns without re-arming; the detach path relies on this to eventually drain.
- The callback uses a function pointer for delegated work, keeping the callout logic separate from the hardware-specific work.

Chapter 17's simulation uses the same patterns in slightly different clothes. The sensor callback updates a register; the command callback triggers a completion; the busy callback re-asserts a status bit. Each is a small state machine advanced by the callout.

17.22.5 An Exercise

Read `led.c` start to finish. It is one of the shortest drivers in `/usr/src/sys/dev/` and illustrates a clean callout-driven design. After reading, write a one-paragraph summary explaining how `led_timeout` interacts with `led_drvinit`, `led_destroy`, and `led_write`. If you can articulate the relationship, you have internalised the callout-driven-driver pattern.

17.23 Reference: The Difference Between “In Simulation” and “In Reality”

Chapter 17 simulates a device. A natural question is: how different is the simulation from a real device, and what are the specific ways the driver would need to change when the two are swapped?

A short comparison.

17.23.1 What the simulation and reality have in common

- The register map: the same offsets, the same widths, the same access types.
- The CSR macros: `CSR_READ_4`, `CSR_WRITE_4`, `CSR_UPDATE_4` expand to the same `bus_space_*` calls.
- The driver's command-cycle logic: write `DATA_IN`, set `CTRL.GO`, wait for `DATA_AV`, read `DATA_OUT`.
- The locking discipline: `sc->mtx` protects register access in both cases.
- The statistics: `cmd_successes`, `cmd_errors`, and so on track real events either way.

17.23.2 What differs

- The tag and handle: simulation uses `X86_BUS_SPACE_MEM` and a `malloc(9)` address; reality uses the tag and handle that `rman_get_bustag` and `rman_get_bushandle` return for an allocated PCI BAR.
- The register-block lifetime: simulation's lives from `myfirst_sim_attach` to `myfirst_sim_detach`; reality's lives from `bus_alloc_resource_any` to `bus_release_resource`.
- The autonomous behaviour: simulation produces it through callouts; reality produces it through device internal logic. The driver does not see the difference.
- The fault modes: simulation's faults are deliberate and controlled; reality's faults happen when they happen.
- The timing: simulation's `DELAY_MS` is a register; reality's timing is determined by the device's design and cannot be changed.
- The `CTRL.GO` self-clear: simulation's is implemented by the write intercept; reality's is implemented in silicon. The driver expects the same behaviour.
- The error recovery: simulation's `myfirst_recover_from_stuck` directly manipulates the simulation state; reality's recovery path uses only register operations (typically a reset).

The list is short. That is the point of the abstraction: most of the driver is identical, and the parts that are not are well-localised.

17.23.3 The Chapter 18 Change

When Chapter 18 replaces the simulation with real PCI, the changes to the driver are:

1. `myfirst_hw_attach` changes: instead of `malloc`-ing the register block, it calls `bus_alloc_resource_any` to allocate the PCI BAR.
2. `myfirst_hw_detach` changes: instead of `free`-ing the register block, it calls `bus_release_resource` to release the BAR.
3. The simulation files (`myfirst_sim.c`, `myfirst_sim.h`) are no longer built; the Makefile drops them.
4. The driver's probe logic gains a probe method that matches on the real device's vendor and device ID.
5. The `DRIVER_MODULE` registration changes from a pseudo-device style to a PCI attachment style.

Everything else (the command cycle, the statistics, the locking, the documentation) stays the same. The discipline Chapter 17 built is what makes this possible.

17.24 Reference: When Simulation Is Not Enough

A balanced view of simulation's limits. Chapter 17 teaches simulation as a primary technique, but it is not a substitute for every kind of testing. Several scenarios require real hardware or a hypervisor-backed virtual device.

17.24.1 When the bug is in the real-silicon timing

A race condition that manifests only at specific bus clock ratios, specific memory traffic patterns, or specific device firmware revisions cannot be reproduced in simulation. The simulation runs at kernel-thread speed, not at hardware speed, and its timing is dictated by the kernel's scheduler, not by the bus fabric.

17.24.2 When the bug is in the platform-specific code

A driver that needs to handle IOMMU remapping, specific cache attributes, or architecture-specific memory barriers cannot be fully validated in simulation. The simulation's kernel memory has different cache behaviour than real device memory, and the architecture-specific paths are exercised only when real device memory is involved.

17.24.3 When the bug depends on actual hardware resources

A driver that needs to configure a PCIe link width, manage power states, or interact with the device's firmware cannot be validated in simulation. The simulation has no PCIe link, no power states, and no firmware.

17.24.4 When the bug is in the test itself

A test that exercises the simulation in a way that does not correspond to how the real device is used produces false confidence. The simulation might pass the test; the real device might still fail under realistic use. Testing against simulation must be paired with testing against reality whenever reality is available.

17.24.5 What to do about it

The right approach is layered testing. Simulation catches protocol bugs, lock-order bugs, error-handling bugs, and the majority of logic errors. Hypervisor-backed virtual devices (virtio in bhyve or qemu) catch PCI-specific bugs, bus-mastering issues, and some timing issues. Real hardware on a lab system catches the last-mile bugs that nothing else can reproduce.

For Chapter 17 the focus is simulation. For Chapter 18 the focus is hypervisor-backed PCI. Later chapters on DMA and interrupts will introduce additional testing surfaces. Real-hardware testing on a dedicated lab system is a discipline the working driver author develops over time; this book can give you the vocabulary but not the hardware.

17.25 Reference: Further Reading

If you want to go deeper into the topics Chapter 17 touched, the following are good next steps.

17.25.1 FreeBSD manual pages

- `callout(9)`: the callout API in full.
- `pause(9)` and `pause_sbt(9)`: the sleep primitives in detail.
- `arc4random(9)`: the pseudo-random number generator.
- `bus_space(9)`: revisit with the simulation lens.
- `fail(9)`: the production fault-injection framework.

17.25.2 Source files worth reading

- `/usr/src/sys/dev/led/led.c`: a callout-driven pseudo-device driver. Short, readable, and illustrative.
- `/usr/src/sys/dev/random/random_harvestq.c`: a callout-driven harvest queue. More complex than `led.c` but with a similar pattern.
- `/usr/src/sys/kern/kern_fail.c`: the `fail(9)` framework. About 1500 lines but highly modular.
- `/usr/src/sys/kern/kern_timeout.c`: the callout subsystem implementation. Read when you want to understand how `callout_reset_sbt` actually works.

17.25.3 Real drivers with callouts similar to Chapter 17's

- `/usr/src/sys/dev/ale/if_ale.c`: `ale_tick` is a callout that periodically checks link state. Similar pattern to the Chapter 17 sensor callout.
- `/usr/src/sys/dev/e1000/if_em.c`: `em_local_timer` is a callout that updates statistics and handles watchdog events. Slightly more elaborate than the sensor callout.
- `/usr/src/sys/dev/iwm/if_iwm.c`: uses multiple callouts for different protocol state machines. An advanced but educational example.

17.25.4 Related reading on hardware simulation

- The FreeBSD Handbook chapter on emulation (for understanding how virtio and bhyve relate to in-kernel simulation).
- The bhyve(8) manual page, for insight into hypervisor-backed virtual devices that will matter in Chapter 18.

17.26 Reference: A Worked Example: The Full myfirst_sim.h

The complete myfirst_sim.h as it stands at the end of Chapter 17, for quick reference. The source is also in `examples/part-04/ch17-simulating-hardware/stage5-final/myfirst_sim.h`.

void myfirst_sim_add_sysctls(struct myfirst_softc *sc);

#endif /* _MYFIRST_SIM_H */

```

17.27 Reference: A Comparison with Chapter 16 Patterns

A side-by-side comparison of where Chapter 17 extends Chapter 16 and where it introduces genuinely new material.

Pattern	Chapter 16	Chapter 17
Register access	CSR_READ_4, etc.	Same API, unchanged
Access log	Introduced	Reused, extended with fault-injection entries
Lock discipline	sc->mtx around each access	Same, plus callouts via callout_init_mtx
File layout	myfirst_hw.c added	myfirst_sim.c added
Register map	10 registers, 40 bytes	16 registers, 60 bytes (all in same 64-byte allocation)

Pattern	Chapter 16	Chapter 17
CTRL bits	ENABLE, RESET, MODE, LOOPBACK	Same, plus GO (bit 9)
STATUS bits	READY, BUSY, ERROR, DATA_AV	Same, but dynamically changed by callouts
Callouts	One (reg_ticker_task as a task)	Three (sensor, command, busy)
Timeouts	Not applicable	Introduced (cmd_timeout_ms, rdy_timeout_ms)
Error recovery	Minimal	Full recovery path
Statistics	None	Per-outcome counters
Fault injection	None	Four fault modes
HARDWARE.md	Introduced	Extended
LOCKING.md	Extended from Ch15	Extended
SIMULATION.md	Not present	Introduced

Chapter 17 builds on Chapter 16 without breaking anything. Every Chapter 16 capability is preserved; every new capability is added. The driver at 1.0-simulated is a strict superset of the driver at 0.9-mmio.

17.28 Reference: A Closing Note on Simulation Philosophy

A paragraph to close the chapter with, which is worth returning to after you have worked through the labs.

Simulation is, at its heart, an act of modelling. You take a system you do not fully control (a real device) and build a smaller system you do control (a simulation) that behaves similarly. The simulation is never perfect. Its value comes not from matching the real system in every detail, but from preserving the properties that matter for the question you are asking.

For Chapter 17 the property that matters is protocol correctness: does the driver handle the command cycle, the timing, the error cases, the recovery? A simulation that preserves protocol correctness is a simulation that earns its keep, even if it gets every timing detail slightly wrong.

For later chapters and for your own future work, the properties that matter may be different. A performance test needs a simulation that preserves throughput behaviour. A power test needs a simulation that preserves idle and active states. A security test needs a simulation that can produce adversarial inputs.

The skill Chapter 17 teaches is not “how to simulate this particular device”. It is “how to identify what a simulation must preserve, and how to build one that preserves it”. That skill is transferable, and it is the skill that will serve you across every driver you write.

18 Writing a PCI Driver

18.1 Reader Guidance & Outcomes

Chapter 17 ended with a driver that looked like a real device from the outside and behaved like one from the inside. The `myfirst` module at version `1.0-simulated` carries a register block, a `bus_space(9)`-based accessor layer, a simulation backend with callouts that produce autonomous state changes, a fault-injection framework, a command-response protocol, statistics counters, and three living documentation files (`HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`). Every register access in the driver still goes through `CSR_READ_4(sc, off)`, `CSR_WRITE_4(sc, off, val)`, and `CSR_UPDATE_4(sc, off, clear, set)`. The hardware layer (`myfirst_hw.c` and `myfirst_hw.h`) is a thin wrapper that produces a tag and a handle, and the simulation layer (`myfirst_sim.c` and `myfirst_sim.h`) is what makes those registers come alive. The driver itself does not know whether the register block is real silicon or a `malloc(9)` allocation.

That ambiguity is the gift Chapter 16 and Chapter 17 gave us, and Chapter 18 is where we finally cash it in. The driver will now meet real PCI hardware. The register block will not come from the kernel's heap any more; it will come from a device's Base Address Register, assigned at boot by the firmware, mapped by the kernel into a virtual address range with device-memory attributes, and handed to the driver as a `struct resource *`. The accessor layer does not change. A compile-time switch keeps the Chapter 17 simulation available as a separate build for readers without a PCI test environment; on the PCI build the simulation callouts do not run, so they cannot accidentally write into the real device's registers. What changes is the point at which the tag and handle originate: instead of being produced by `malloc(9)`, they will be produced by `bus_alloc_resource_any(9)` against a PCI child in the newbus tree.

Chapter 18's scope is precisely this transition. It teaches what PCI is, how FreeBSD represents a PCI device in the newbus tree, how a driver matches a device by vendor and device ID, how BARs appear in configuration space and become `bus_space` resources, how attach-time initialisation proceeds against a real BAR without disturbing the device, and how detach unwinds everything in reverse order. It covers the configuration-space accessors `pci_read_config(9)` and `pci_write_config(9)`, the capability walkers `pci_find_cap(9)` and `pci_find_extcap(9)`, and a brief introduction to PCIe Advanced Error Reporting so the reader knows where it lives without being asked to handle it yet. It ends with a small but significant refactor that splits the new PCI-specific code into its own file, versions the driver as `1.1-pci`, and runs the full regression pass against both the simulation build and the real PCI build.

Chapter 18 deliberately narrows itself to the probe-attach dance and what feeds it. Real interrupt handlers through `bus_setup_intr(9)`, filter plus `ithread` composition, and the rules for what a handler may and may not do are Chapter 19. MSI and MSI-X, along with the richer PCIe capabilities they expose, are Chapter 20. Descriptor rings, scatter-gather DMA, cache coherence around device writes, and the full `bus_dma(9)` story are Chapters 20 and 21. Configuration-space quirks on specific chipsets, power-management state machines during suspend and resume, and SR-IOV are later chapters. The chapter stays inside the ground it can cover well and hands off explicitly when a topic deserves its own chapter.

The layers of Part 4 stack. Chapter 16 taught the vocabulary of register access; Chapter 17 taught how to think like a device; Chapter 18 teaches how to meet a real one. Chapter 19 will teach you how to react to what the device says, and Chapters 20 and 21 will teach you how to let the device reach directly into RAM. Each layer depends on the one before it. Chapter 18 is your first encounter with the newbus tree as something more than an abstract diagram, and the disciplines Part 3 built are what keep the encounter honest.

18.1.1 Why the PCI Subsystem Earns a Chapter of Its Own

At this point you may be asking why the PCI subsystem needs a chapter of its own. The simulation already gave us registers; the real hardware will give us the same registers. Why not simply say “call `bus_alloc_resource_any`, pass the returned handle to `bus_read_4`, and proceed”?

Two reasons.

The first is that the PCI subsystem is the most widely used bus in modern FreeBSD, and the newbus conventions around it are the conventions every other bus driver imitates. A reader who understands the PCI probe-attach dance can read the ACPI attach dance, the USB attach dance, the SD card attach dance, and the virtio attach dance without retraining. The patterns differ in detail, but the shape is PCI’s. Spending a whole chapter on the canonical bus is spending a chapter on the pattern every bus borrows from.

The second is that PCI introduces concepts no earlier chapter prepared you for. Configuration space is a second address space per device, separate from the BARs themselves, where the device advertises what it is and what it needs. Vendor and device IDs are a sixteen-bit plus sixteen-bit tuple that the driver matches against a table of supported devices. Subvendor and subsystem IDs are a second-level tuple that disambiguates cards built around a common chipset by different vendors. Class codes let a driver match broad categories (any USB host controller, any UART) when a device-specific table would be too narrow. BARs exist in configuration space as thirty-two-bit or sixty-four-bit addresses the driver never directly dereferences. PCI capabilities are a linked list of extra metadata the driver reads at attach time. Each of these is new vocabulary; each of them is the reason Chapter 18 is not a single section bolted onto Chapter 17.

The chapter also earns its place by being the chapter where the `myfirst` driver gains its first real bus child. Until now, the driver has lived as a kernel module with a single implicit instance, attached by hand through `kldload` and detached by `kldunload`. After Chapter 18, the driver will be a proper PCI bus child, enumerated by the kernel’s newbus code, attached automatically when a matching device is present, detached automatically when the device goes away, and visible in `devinfo -v` as a device with a parent (`pci0`), a unit (`myfirst0`, `myfirst1`), and a set of claimed resources. That change is the change from “a module that happens to exist” to “a driver for a device that the kernel knows about”. Every later Part 4 chapter assumes you have made it.

18.1.2 Where Chapter 17 Left the Driver

A few prerequisites to verify before starting. Chapter 18 extends the driver produced at the end of Chapter 17 Stage 5, tagged as version `1.0-simulated`. If any of the items below feels uncertain, return to Chapter 17 before starting this chapter.

- Your driver compiles cleanly and identifies itself as `1.0-simulated` in `kldstat -v`.
- The softc carries `sc->hw` (a `struct myfirst_hw *` from Chapter 16) and `sc->sim` (a `struct myfirst_sim *` from Chapter 17). Every register access goes through `sc->hw`; every simulated behaviour lives under `sc->sim`.

- The register map of sixteen 32-bit registers spans offsets 0x00 through 0x3c, with the Chapter 17 additions (SENSOR, SENSOR_CONFIG, DELAY_MS, FAULT_MASK, FAULT_PROB, OP_COUNTER) in place.
- CSR_READ_4, CSR_WRITE_4, and CSR_UPDATE_4 wrap bus_space_read_4, bus_space_write_4, and a read-modify-write helper. Every access asserts sc->mtx is held on debug kernels.
- The sensor callout runs once per second on a ten-second cadence and oscillates SENSOR. The command callout fires per command with a configurable delay. The fault-injection framework is live.
- The module depends on nothing outside the base kernel; it is a kldload-able standalone driver.
- HARDWARE.md, LOCKING.md, and SIMULATION.md are current.
- INVARIANTS, WITNESS, WITNESS_SKIPSPIN, DDB, KDB, and KDB_UNATTENDED are enabled in your test kernel.

That driver is what Chapter 18 extends. The additions are again modest in volume: one new file (myfirst_pci.c), one new header (myfirst_pci.h), one new set of probe and attach routines, a small change to myfirst_hw_attach to accept a resource rather than allocate a buffer, an expanded detach ordering, a bump to 1.1-pci, a new PCI.md document, and an updated regression script. The mental-model change is larger than the line count suggests.

18.1.3 What You Will Learn

When you close this chapter you should be able to:

- Describe what PCI and PCIe are in one paragraph, in a way a beginner could follow, with the key vocabulary of bus, device, function, BAR, configuration space, vendor ID, and device ID clearly placed.
- Read the output of `pciconf -lv` and `devinfo -v` and locate the information a driver author cares about: the B:D:F tuple, the vendor and device IDs, the class, the subclass, the interface, the claimed resources, and the parent bus.
- Write a minimal PCI driver that registers a probe routine against the `pci` bus, matches a specific vendor and device ID, returns a meaningful `BUS_PROBE_*` priority, prints the matched device through `device_printf`, and unloads cleanly.
- Attach and detach a PCI driver, matching the expected lifecycle of `newbus`: probe runs first (sometimes twice), attach runs once per matched device, detach runs once when the kernel removes the device or the driver, and the softc is freed in the correct order.
- Use `DRIVER_MODULE(9)` and `MODULE_DEPEND(9)` correctly, naming the bus (`pci`) and the module dependency (`pci`) so the kernel's module loader and `newbus` enumerator understand the relationship.
- Explain what BARs are, how the firmware assigns them at boot, how the kernel discovers them, and why the driver does not choose the address.
- Claim a PCI memory BAR with `bus_alloc_resource_any(9)`, extract its `bus_space` tag and handle with `rman_get_bustag(9)` and `rman_get_bushandle(9)`, and hand them to the Chapter 16 accessor layer without any change to the CSR macros.
- Recognise when a BAR is a 64-bit BAR that spans two configuration-space slots, how `PCIR_BAR(index)` works, and why counting BARs by simple integer increments is not always safe on 64-bit BARs.
- Use `pci_read_config(9)` and `pci_write_config(9)` to read device-specific configuration-space fields that the generic accessors do not cover, and understand the width argument (1, 2, or 4) and the side-effect contract.
- Walk a device's PCI capability list with `pci_find_cap(9)` to locate standard capabilities (Power Management, MSI, MSI-X, PCI Express), and walk the PCIe extended capability list with `pci_find_extcap(9)`

to reach modern capabilities such as Advanced Error Reporting.

- Call `pci_enable_busmaster(9)` when the device will initiate DMA later, recognise why the `MEMEN` and `PORTEN` bits of the command register are usually already set by the bus driver by attach time, and know when a quirky device needs them asserted manually.
- Write an attach-time initialisation sequence that keeps the Chapter 17 simulation backend inactive on the PCI path while preserving a simulation-only build (via a compile-time switch) for readers without a PCI test environment.
- Write a detach path that releases resources in strictly the reverse order of attach, never leaking a resource or double-freeing one, even in the presence of partial attach failure.
- Exercise the driver against a real PCI device in a bhyve or QEMU guest, using a vendor and device ID that does not collide with a base-system driver, and observe the full attach, operate, detach, and unload cycle.
- Split the PCI-specific code into its own file, update the module's `SRCS` line, tag the driver as `1.1-pci`, and produce a short `PCI.md` that documents the vendor and device IDs the driver supports.
- Describe at a high level where MSI, MSI-X, and PCIe AER fit into the PCI picture, and know which later chapter picks each topic up.

The list is long; each item is narrow. The point of the chapter is the composition.

18.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 18 stays focused.

- **Real interrupt handlers.** `bus_alloc_resource_any(9)` for `SYS_RES_IRQ`, `bus_setup_intr(9)`, the split between a filter handler and an ithread handler, `INTR_TYPE_*` flags, `INTR_MPSAFE`, and the rules for what may and may not happen inside a handler belong to Chapter 19. Chapter 18's driver still polls through user-space writes and the Chapter 17 callouts; it never takes a real interrupt.
- **MSI and MSI-X.** `pci_alloc_msi(9)`, `pci_alloc_msix(9)`, vector allocation, per-queue interrupt routing, and the MSI-X table layout are Chapter 20. Chapter 18 only mentions these as future work when it lists PCI capabilities.
- **DMA.** `bus_dma(9)` tags, `bus_dmamap_create(9)`, `bus_dmamap_load(9)`, scatter-gather lists, bounce buffers, and cache-coherent descriptor rings are Chapters 20 and 21. Chapter 18 treats the BAR as a set of memory-mapped registers and nothing else.
- **PCIe AER handling.** The existence of Advanced Error Reporting is introduced because the reader should know the topic exists. Implementing a fault handler that subscribes to AER events, decodes the uncorrectable error register, and participates in system-wide recovery is a later-chapter topic.
- **Hot plug, device removal, and live runtime suspend.** A PCI device arriving or departing at runtime triggers a specific newbus sequence that a driver must respect; most drivers do respect it simply by having a correct detach path. Chapter 18 demonstrates the correct detach path and leaves runtime power management for Chapter 22 and hotplug for Part 7 (Chapter 32 on embedded platforms and Chapter 35 on asynchronous I/O and event handling).
- **Passthrough to virtual machines.** `bhyve(8)` and `vmm(4)` can pass a real PCI device through to a guest, and this is a useful technique for testing. Chapter 18 mentions it in passing. A deeper treatment belongs to the chapter where it serves the topic.
- **SR-IOV and virtual functions.** A PCIe capability where a single device advertises multiple virtual functions, each with its own configuration space, is out of scope for a beginner-level chapter.

- **Specific chipset quirks.** Real drivers often carry a long list of errata and workarounds for specific revisions of specific silicon. Chapter 18 aims at the common case; the book's later troubleshooting chapters cover how to reason about quirks when you meet them.

Staying inside those lines keeps Chapter 18 a chapter about the PCI subsystem and the driver's place in it. The vocabulary is what transfers; the specific chapters that follow apply the vocabulary to interrupts, DMA, and power.

18.1.5 Estimated Time Investment

- **Reading only:** four to five hours. The PCI topology and the newbus sequence are small in concept but dense in detail, and each piece rewards a slow read.
- **Reading plus typing the worked examples:** ten to twelve hours over two or three sessions. The driver evolves in four stages; each stage is a small but real refactor on top of the Chapter 17 codebase.
- **Reading plus all labs and challenges:** sixteen to twenty hours over four or five sessions, including standing up a bhyve or QEMU lab, reading `uart_bus_pci.c` and `virtio_pci_modern.c` in the real FreeBSD tree, and running the regression pass against both simulation and real PCI.

Sections 2, 3, and 5 are the densest. If the probe-attach sequence or the BAR allocation path feels unfamiliar on first pass, that is normal. Stop, re-read Section 3's diagram of how a BAR becomes a tag and handle, and continue when the picture has settled.

18.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 17 Stage 5 (1.0-simulated). The starting point assumes the Chapter 16 hardware layer, the Chapter 17 simulation backend, the complete `CSR_*` accessor family, the sync header, and every primitive introduced in Part 3.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- `bhyve(8)` or `qemu-system-x86_64` is available on your lab host, and you can start a FreeBSD guest that boots your debug kernel. A bhyve guest is the canonical choice in this book; QEMU will work equivalently for every lab in this chapter.
- The `devinfo(8)` and `pciconf(8)` tools are in your path. Both live in the base system.

If any item above is shaky, fix it now rather than pushing through Chapter 18 and trying to reason from a moving foundation. PCI code is less forgiving than simulation code because a mismatch between your driver's expectations and the real bus's behaviour will usually surface as a failed probe, a failed attach, or a kernel page fault.

18.1.7 How to Get the Most Out of This Chapter

Four habits will pay off quickly.

First, keep `/usr/src/sys/dev/pci/pci.h` and `/usr/src/sys/dev/pci/pciivar.h` bookmarked. The first file is the authoritative register map of PCI and PCIe configuration space; every macro starting with `PCIR_`, `PCIM_`, or `PCIZ_` is defined there. The second file is the authoritative list of PCI accessor functions (`pci_get_vendor`, `pci_read_config`, `pci_find_cap`, and so on), along with their documentation comments. Reading both files once takes about an hour and removes most of the guesswork the rest of the chapter might otherwise require.

A note on line numbers. The declarations we will lean on later, such as `pci_read_config`, `pci_find_cap`, and the `PCIR_*` register-offset macros, sit in `pciivar.h` and `pci.h` under stable names. Whenever the chapter hands you a landmark in those files, the landmark is the symbol. Line numbers drift release to release; the names do not. Grep for the symbol and trust what your editor reports.

Second, run `pciconf -lv` on your lab host and your guest, and keep the output open in a terminal as you read. Every vocabulary item in the chapter (vendor, device, class, subclass, capabilities, resources) appears verbatim in that output. A reader who has read `pciconf -lv` for their own hardware finds the PCI subsystem much less abstract than one who has not.

Third, type the changes by hand and run each stage. PCI code is where small typos become silent mismatches. Mistyping `0x1af4` as `0x1af5` does not produce a compile error; it produces a driver that compiles cleanly and never attaches. Typing the values character by character, checking them against your test target, and confirming that `kldstat -v` shows the driver claiming the expected device are the habits that prevent a day of confused debugging.

Fourth, read `/usr/src/sys/dev/uart/uart_bus_pci.c` after Section 2 and `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c` after Section 5. The first file is a straightforward example of the pattern Chapter 18 teaches, written at a level a beginner can follow. The second file is a slightly richer example that shows how a real modern driver composes the pattern with additional machinery. Neither needs to be understood line by line; both repay a careful first reading.

18.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Is PCI and Why It Matters.** The bus, the topology, the B:D:F tuple, how FreeBSD represents PCI through the `pci(4)` subsystem, and how a driver author perceives all of this through `pciconf -lv` and `devinfo -v`. The conceptual foundation.
2. **Probing and Attaching a PCI Device.** The newbus dance from the driver's side: `device_method_t`, `probe`, `attach`, `detach`, `resume`, `suspend`, `DRIVER_MODULE(9)`, `MODULE_DEPEND(9)`, vendor and device ID matching, and the first stage of the Chapter 18 driver (`1.1-pci-stage1`).
3. **Understanding and Claiming PCI Resources.** What a BAR is, how the firmware assigns it, how `bus_alloc_resource_any(9)` claims it, and how the returned struct `resource *` becomes a `bus_space_tag_t` and `bus_space_handle_t`. The second stage (`1.1-pci-stage2`).
4. **Accessing Device Registers via bus_space(9).** How the Chapter 16 accessor layer snaps onto the new resource without modification, how the CSR macros carry through, and how the driver's first real PCI read happens.
5. **Driver Attach-Time Initialisation.** `pci_enable_busmaster(9)`, `pci_read_config(9)`, `pci_find_cap(9)`, `pci_find_extcap(9)`, and the small set of configuration-space operations the driver performs at attach. Keeping the Chapter 17 simulation inactive on the PCI path. The third stage (`1.1-pci-stage3`).

6. **Supporting Detach and Resource Cleanup.** Releasing resources in reverse order, handling partial attach failure, `device_delete_child`, and the detach regression script.
7. **Testing PCI Driver Behavior.** Standing up a bhyve or QEMU guest that exposes a device the driver recognises, observing attach, exercising the driver against the real BAR, reading and writing configuration space from user space with `pciconf -r` and `pciconf -w`, and using `devinfo -v` and `dmesg` to trace the driver's view of the world.
8. **Refactoring and Versioning Your PCI Driver.** The final split into `myfirst_pci.c`, the new `PCI.md`, the version bump to 1.1-pci, and the regression pass.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 18's story and opens Chapter 19's, and a bridge to Chapter 19 with a forward pointer to Chapter 20. The reference-and-cheat-sheet material at the end of the chapter is meant to be re-read as you work through later Part 4 chapters; Chapter 18's vocabulary is the vocabulary every later PCI-family chapter reuses.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3 and 5 stand alone and make good single-sitting reads.

18.2 Section 1: What Is PCI and Why It Matters

A reader who has come this far in the book has built a full driver around a simulated register block. The accessor layer, the command-response protocol, the locking discipline, the fault-injection framework, and the detach ordering are all in place. The one concession the driver makes to unreality is the origin of its registers: they come from a `malloc(9)` allocation in kernel memory, not from a piece of silicon on the far side of a bus. Section 1 introduces the subsystem that will change that. PCI is the most widespread peripheral bus in modern computing. It is also the canonical newbus child for a FreeBSD driver. Understanding what PCI is, how it got here, and how FreeBSD represents it is the foundation every remaining section in this chapter rests on.

18.2.1 A Short History, and Why It Matters

PCI stands for Peripheral Component Interconnect. It was introduced by Intel in the early 1990s as a replacement for the previous generation of PC expansion buses (ISA, EISA, VESA local bus, and others), none of which scaled to the speeds and widths that modern peripherals would soon demand. The original PCI specification described a parallel, shared, clocked bus that carried thirty-two bits of data, was clocked at 33 MHz, and let a single device request and hold the bus for a transaction. A handful of revisions increased the width to sixty-four bits, raised the clock to 66 MHz, and introduced signalling variants for server platforms (PCI-X), but the basic shape remained that of a shared parallel bus.

PCI Express, called PCIe, is the modern successor. It keeps the software-visible model of PCI almost unchanged, but it replaces the physical bus with a collection of point-to-point serial links. Where PCI had many devices sharing a single set of wires, PCIe has each device connected to the chipset's root complex through its own lane (or set of lanes, up to sixteen in common use and thirty-two in some high-end cards). The bandwidth per lane has climbed through successive generations, from 2.5 Gb/s in PCIe Gen 1 to 32 Gb/s in PCIe Gen 5 and beyond.

Why does this history matter to a driver author? Because the software model did not change across the transition. From the driver's point of view, a PCIe device still has a configuration space, still has BARs, still has a vendor

and device ID, still has capabilities, and still follows the probe-attach-detach lifecycle that PCI established. The physical layer changed; the software vocabulary did not. This is one of the few places in computing where a thirty-year-old interface is still the thing you read about in the FreeBSD source, and the continuity of the software model is what makes that possible. Code written for PCI in 1995 can, with minor updates for new capabilities, drive a PCIe Gen 5 device in 2026.

There is one important practical consequence of this continuity. When the book refers to “PCI”, it almost always means “PCI or PCIe”. The kernel’s `pci(4)` subsystem handles both. When a distinction matters, such as when a PCIe-only feature like MSI-X or AER appears, the book will call that out. Everywhere else, “PCI” and “PCIe” are the same thing at the driver level.

18.2.2 Where PCI Devices Live on a Modern Machine

Open almost any laptop, desktop, or server manufactured in the last twenty years, and you will find PCIe devices. The obvious ones are the add-in cards: a network adapter in a slot, a graphics card in another slot, an NVMe drive on the motherboard’s M.2 socket, a Wi-Fi module on a Mini-PCIe daughtercard. The less obvious ones are integrated: the storage controller that talks to the SATA ports is a PCI device; the USB host controllers are PCI devices; the onboard Ethernet is a PCI device; the audio codec is a PCI device; the platform’s integrated graphics is a PCI device. Everything that appears on the chipset-to-device interconnect between the CPU and the outside world is almost certainly a PCI device.

The kernel enumerates these devices at boot. Firmware (the system BIOS or UEFI) walks the bus, reads each device’s configuration space, assigns BARs, and hands control to the OS. The OS re-walks the bus, builds its own representation, and attaches drivers. FreeBSD’s `pci(4)` driver is what performs this walk. By the time the system is multi-user, every PCI device in the machine has been enumerated, every BAR has been assigned a kernel virtual address, and every device that matched a driver has been attached.

A practical demonstration: run `pciconf -lv` on any FreeBSD system. Each entry shows a device with its B:D:F (bus, device, function) address, its vendor and device IDs, its subvendor and subsystem IDs, its class and subclass, its current driver binding (if any), and a human-readable description of what it is. The entries are what the kernel saw; the descriptions are what `pciconf` looked up from its internal database. Running this command on your lab host is the best quick introduction to what your machine’s PCI topology looks like.

18.2.3 The Bus-Device-Function Tuple

The address of a PCI device has three components. Together they are called the **bus-device-function tuple**, or B:D:F, or sometimes just “PCI address”.

The **bus number** is which physical or logical PCI bus the device is on. A machine usually has one primary bus (bus 0), plus additional buses behind PCI-to-PCI bridges. A laptop might have buses 0, 2, 3, and 4; a server might have dozens. Each bus is eight bits wide, so the system supports up to 256 buses in the original PCI spec. PCIe extended this to 16 bits (65,536 buses) through the Enhanced Configuration Access Mechanism, ECAM.

The **device number** is the slot on the bus. Each bus can hold up to 32 devices. On PCIe, the point-to-point nature of the physical link means each bridge has one device on each of its downstream buses; the device number is essentially always 0 in that case. On legacy PCI, several devices share a bus and each gets its own device number.

The **function number** is which function of a multi-function device is being addressed. A single physical device can expose up to 8 functions, each with its own configuration space, each presenting itself as an independent PCI device. Multi-function devices are common: a typical x86 chipset presents its USB host controllers as multiple functions of a single physical unit; a storage controller might present SATA, IDE, and AHCI on separate functions. Single-function devices (the common case) use function 0.

The combined tuple is written in FreeBSD's `pciconf` output as `pciN:D:F`, where `N` is the domain-plus-bus value. On the author's test machine, `pci0:0:2:0` refers to domain 0, bus 0, device 2, function 0, which on an Intel platform is typically the integrated graphics. This notation is stable across FreeBSD versions; you will see it in the kernel's boot messages, in `dmesg`, in `devinfo -v`, and in the bus documentation.

A driver rarely cares about the `B:D:F` value directly. The newbus subsystem hides it behind a `device_t` handle. But a driver author cares, because two things use `B:D:F`: system administrators (who match a `B:D:F` against a slot or a physical device when installing or troubleshooting), and kernel messages (which print it in `dmesg` when a device attaches, detaches, or misbehaves). When you see `pci0:3:0:0: <Intel Corporation Ethernet Controller ...>` in your boot log, you are reading a `B:D:F`.

18.2.4 Configuration Space and What Lives There

PCI distinguishes two address spaces per device. The first is the set of BARs, which map the device's registers into the host memory (or I/O port) space; this is what Chapter 16 called "MMIO" and what Chapter 18's Section 3 and Section 4 will explore. The second is **configuration space**, which is a small, structured block of memory per device that describes the device itself.

Configuration space is where the vendor ID, device ID, class code, revision, BAR addresses, capability list pointer, and a number of other metadata fields live. It is 256 bytes on legacy PCI, expanded to 4096 bytes on PCIe. The layout of the first sixty-four bytes is standardised across every PCI device; the remaining space is used for capabilities and extended capabilities.

The driver reaches configuration space through the `pci_read_config(9)` and `pci_write_config(9)` interfaces. These two functions take a device handle, a byte offset into configuration space, and a width (1, 2, or 4 bytes), and return or accept a `uint32_t` value. The width argument lets the driver read or write a byte, a sixteen-bit field, or a thirty-two-bit field; the kernel translates this into the right underlying access primitive for the platform.

Most of what a driver needs to know about configuration space is already extracted by the newbus layer and cached in the device's ivars. That is why the driver can call `pci_get_vendor(dev)`, `pci_get_device(dev)`, `pci_get_class(dev)`, and `pci_get_subclass(dev)` without reading configuration space by hand. These accessors are defined in `/usr/src/sys/dev/pci/pcivar.h` and expanded through the `PCI_ACCESSOR` macro to inline functions that read a cached value. The values are read once, at enumeration time, and kept in the device's ivars thereafter.

For everything the common accessors do not cover, `pci_read_config(9)` and `pci_write_config(9)` are the fallback. An example: if a device's datasheet says "the firmware revision is at offset 0x48 in configuration space, as a 32-bit little-endian integer", the driver reads that value by calling `pci_read_config(dev, 0x48, 4)`. The kernel arranges the access so that the return value is the little-endian value the datasheet specified, on every supported architecture.

18.2.5 Vendor ID and Device ID: How Matches Happen

The core of PCI device identification is the pair of sixteen-bit values called vendor ID and device ID.

The **vendor ID** is assigned by the PCI Special Interest Group (PCI-SIG) to a company that manufactures PCI devices. Intel has 0x8086. Broadcom has several (originally 0x14e4 and others by acquisition). Red Hat and the Linux community's virtualisation project share 0x1af4 for virtio devices. Every PCI device carries its vendor's ID in the `VENDOR` field of configuration space.

The **device ID** is assigned by the vendor to each specific product. Intel's 0x10D3 is the 82574L gigabit Ethernet controller. Broadcom's 0x165F is a specific NetXtreme BCM5719 variant. Red Hat's 0x1001 in the virtio range is virtio-block. Vendors maintain their own device ID allocations.

A **subvendor ID** and **subsystem ID** together form a second-level tuple. They identify the board that a chipset is built into, as opposed to the chipset itself. The same Intel 82574L Ethernet chip might appear on a Dell server with subvendor 0x1028, on an HP server with subvendor 0x103c, and on a generic OEM board with subvendor 0x8086. Drivers can use the subvendor or subsystem to apply specific quirks, to print a more useful identification string, or to select between slightly different board-level behaviour.

A driver's probe routine matches against these IDs. In the simplest case, the driver has a static table listing every supported vendor-and-device pair; the probe walks the table and returns `BUS_PROBE_DEFAULT` on a match or `ENXIO` on no match. In more complex cases, the driver also checks subvendor and subsystem, or walks a broader class-based match, or uses both. The `uart_bus_pci.c` file in `/usr/src/sys/dev/uart/` shows this pattern at a readable scale.

Chapter 18's driver will use the simple tabular form. The table will hold one or two entries. The vendor and device IDs we target are the ones a bhyve or QEMU guest will expose for a synthetic test device, and the teaching path will unload the base-system driver that would otherwise claim the same ID before loading `myfirst`.

18.2.6 How FreeBSD Enumerates PCI Devices

The steps from "the firmware has set up the bus" to "a driver's attach routine runs" are worth understanding in outline, because understanding them makes the probe-and-attach sequence feel inevitable rather than mysterious.

First, the platform's bus-enumeration code runs. On x86 this lives under `/usr/src/sys/dev/pci/` and is driven by platform-specific attach code (x86 uses ACPI bridges and legacy host bridges; arm64 uses device-tree-based host bridges). The enumeration walks the bus, reads each device's vendor and device IDs, reads each device's BARs, and records what it finds.

Second, the kernel's newbus layer creates a `device_t` for each discovered device and adds it as a child of the PCI bus device (`pci0`, `pci1`, and so on). Each child has a device method table placeholder; the newbus code does not yet know which driver will bind. The child has ivars: the vendor, device, subvendor, subsystem, class, subclass, interface, revision, B:D:F, and resource descriptors are all cached in the ivars for later access.

Third, the kernel invites every registered driver to probe each device. Each driver's probe method is called in priority order. A driver inspects the device's vendor, device, and whatever else it needs, and returns one of a small set of values:

- A negative number: “I match this device and want it”. Values closer to zero mean higher priority. The standard tier for a vendor-and-device-ID match is `BUS_PROBE_DEFAULT`, which is `-20`. `BUS_PROBE_VENDOR` is `-10` and wins over it; `BUS_PROBE_GENERIC` is `-100` and loses to it. Section 2 lists the full tier set.
- 0: “I match this device with absolute priority”. The `BUS_PROBE_SPECIFIC` tier. No other driver can outbid it.
- A positive errno (commonly `ENXIO`): “I do not match this device”.

The kernel picks the driver that returned the numerically smallest value and attaches it. If two drivers return the same value, the one that registered first wins. The tiered priority lets a generic driver coexist with a device-specific driver: the generic driver returns `BUS_PROBE_GENERIC`, the specific driver returns `BUS_PROBE_DEFAULT`, and the specific driver wins because `-20` is closer to zero than `-100`.

Fourth, the kernel calls the winning driver’s `attach` method. The driver allocates its softc (usually pre-allocated by `newbus`), claims resources with `bus_alloc_resource_any(9)`, sets up interrupts, and registers a character device or network interface or whatever the device exposes to user space. If `attach` returns 0, the device is live. If `attach` returns an errno, the kernel detaches the driver (calling `detach` is not strictly required on `attach` failure in modern `newbus`; the driver is expected to unwind cleanly before returning the error).

Fifth, the kernel moves to the next device. The process repeats until every PCI device has been probed and every device that found a match has been attached.

Detach is the inverse: the kernel calls each driver’s `detach` method when the device is removed (through `devctl detach` or at module unload), and the driver releases everything it claimed in `attach`, in reverse order.

This is the `newbus` dance Chapter 18 teaches the driver how to follow. Section 2 writes the first version of it; Sections 3 through 6 add each additional capability; Section 8 consolidates it into a clean module.

18.2.7 The pci(4) Subsystem from the Driver’s Perspective

The driver does not see bus enumeration. It sees a device handle (`device_t dev`) and a set of accessor calls. The `/usr/src/sys/dev/pci/pcivar.h` header defines the accessors. The core ones are:

- `pci_get_vendor(dev)` returns the vendor ID as `uint16_t`.
- `pci_get_device(dev)` returns the device ID as `uint16_t`.
- `pci_get_subvendor(dev)` and `pci_get_subdevice(dev)` return the subvendor and subsystem.
- `pci_get_class(dev)`, `pci_get_subclass(dev)`, and `pci_get_progif(dev)` return the class code fields.
- `pci_get_revid(dev)` returns the revision.
- `pci_read_config(dev, reg, width)` reads from configuration space.
- `pci_write_config(dev, reg, val, width)` writes to configuration space.
- `pci_find_cap(dev, cap, &capreg)` finds a standard PCI capability; returns 0 on success, `ENOENT` on absence.
- `pci_find_extcap(dev, cap, &capreg)` finds a PCIe extended capability; same return convention.
- `pci_enable_busmaster(dev)` sets the Bus Master Enable bit in the command register.
- `pci_disable_busmaster(dev)` clears it.

This is the vocabulary of Chapter 18. Every section in the chapter uses one or more of these accessors. A reader who is comfortable with the shape of the list is ready to start writing PCI code.

18.2.8 Common PCI Devices in the Real World

Before moving on, a brief tour of the devices PCI presents.

Network interface controllers. NICs are nearly all PCI devices. The Intel `em(4)` driver for the 8254x family, the Intel `ix(4)` driver for the 82599 family, the Intel `ixl(4)` driver for the X710 family, and the Broadcom `bge(4)` / `bnxt(4)` drivers for the NetXtreme family all live under `/usr/src/sys/dev/e1000/` or `/usr/src/sys/dev/ixl/` or `/usr/src/sys/dev/bge/`. They are large, production-grade drivers that exercise essentially every topic in Part 4.

Storage controllers. AHCI SATA controllers, NVMe drives, SAS HBAs, and RAID controllers are all PCI. `ahci(4)`, `nvme(4)`, `mpr(4)`, `mpi3mr(4)`, and others live under `/usr/src/sys/dev/`. These are among the best-maintained drivers in the tree.

USB host controllers. xHCI, EHCI, and OHCI controllers are PCI. The generic host-controller driver attaches to each, and the USB subsystem handles everything above it. `xhci(4)` is the canonical one for modern systems.

Graphics cards and integrated graphics. GPU drivers in FreeBSD are mostly maintained out of tree (DRM drivers from the `drm-kmod` ports), but the bus attach for them is standard PCI.

Audio controllers. HDA codecs, older AC'97 bridges, and various USB-attached audio devices all reach the system through PCI in some way. `snd_hda(4)` is the usual attach point.

Virtio devices in virtual machines. When a FreeBSD guest runs under bhyve, KVM, VMware, or Hyper-V, the paravirtualised devices appear as PCI. `virtio-network`, `virtio-block`, `virtio-entropy`, and `virtio-console` all look like PCI devices to the guest. The `virtio_pci(4)` driver attaches first and publishes child nodes for each of the transport-specific virtio drivers.

The machine's own chipset components. The platform's LPC bridge, SMBus controller, thermal sensor interface, and various miscellaneous control functions are PCI.

If you have ever wondered why a FreeBSD source tree is as large as it is, the PCI device ecosystem is most of the answer. Every device in the list above needs a driver. The driver you are building in Chapter 18 is small and does very little; the drivers in the examples are large because they implement real protocols over the PCI bus. But the shape of every one of them is what Chapter 18 teaches.

18.2.9 Simulated PCI Devices: bhyve and QEMU

A reader who owns a complete set of test hardware can skip this subsection. Everyone else depends on virtualisation to provide the PCI devices they will drive.

FreeBSD's bhyve(8) hypervisor, built into the base system, can present a guest with a set of emulated PCI devices. The common ones are `virtio-net`, `virtio-blk`, `virtio-rnd`, `virtio-console`, `ahci-hd`, `ahci-cd`, `e1000`, `xhci`, and a framebuffer device. Each has a well-known vendor and device ID; the guest's PCI enumerator sees them as real PCI devices; the guest's drivers attach to them as they would to real hardware. Running a FreeBSD guest under bhyve is the canonical way, for this book, to have a PCI device the reader's driver can attach to.

QEMU with KVM (on Linux hosts) or with the HVF accelerator (on macOS hosts) provides a superset of bhyve's emulated devices, plus a few specifically designed for testing. The `pci-testdev` device (vendor 0x1b36, device

0x0005) is a deliberately minimal PCI device intended for kernel test code; it has two BARs (one memory, one I/O), and writes to specific offsets trigger specific behaviours. Chapter 18's Section 7 can use either a virtio-rnd device under bhyve or a pci-testdev under QEMU as the target.

For the teaching path, the book targets a virtio-rnd device under bhyve. The reason is that bhyve ships with every FreeBSD installation, whereas QEMU requires additional packages. The cost is small: the virtio-rnd device has a real driver in the base system (`virtio_random(4)`), and the chapter will show how to prevent that driver from claiming the device so that `myfirst` can claim it instead.

An important note about the teaching path's choice. The `myfirst` driver is not a real virtio-rnd driver. It has no idea how to speak the virtio-rnd protocol; it treats the BAR as a set of opaque registers and reads and writes them for demonstration. This is fine for the chapter's purpose (proving that the driver can attach, read, write, and detach), but it is not fine for production use. Chapter 18 is a hands-on introduction to the PCI attach sequence, not a tutorial on how to write a virtio driver. When you finish the chapter, the driver you have is still the `myfirst` educational driver, now capable of attaching to a PCI bus rather than only to a `kldload` path.

18.2.10 Placing Chapter 18 in the Driver's Evolution

A quick map of where the `myfirst` driver has been and where it is going.

- **Version 0.1 through 0.8** (Part 1 through Part 3): the driver learned the driver lifecycle, the `cdev` machinery, concurrency primitives, and coordination.
- **Version 0.9-coordination** (end of Chapter 15): full lock discipline, condition variables, `sx` locks, callouts, taskqueue, counting semaphore.
- **Version 0.9-mmio** (end of Chapter 16): `bus_space(9)`-backed register block, CSR macros, access log, hardware layer in `myfirst_hw.c`.
- **Version 1.0-simulated** (end of Chapter 17): dynamic register behaviour, callouts that change state, command-response protocol, fault injection, simulation layer in `myfirst_sim.c`.
- **Version 1.1-pci** (end of Chapter 18, our target): the simulation is switchable, and when the driver attaches to a real PCI device, the BAR becomes the register block, `myfirst_hw_attach` uses `bus_alloc_resource_any` instead of `malloc`, and the Chapter 16 accessor layer points at real silicon.
- **Version 1.2-intr** (Chapter 19): a real interrupt handler registered through `bus_setup_intr(9)`, so the driver can react to the device's own state changes rather than polling.
- **Version 1.3-msi** (Chapter 20): MSI and MSI-X, giving the driver a richer interrupt-routing story.
- **Version 1.4-dma** (Chapters 20 and 21): a `bus_dma(9)` tag, descriptor rings, and the first real DMA transfers.

Each version is a layer on the one before it. Chapter 18 is one layer, small enough to teach clearly, large enough to matter.

18.2.11 Exercise: Read Your Own PCI Topology

Before Section 2, a short exercise to make the vocabulary concrete.

On your lab host, run:

```
sudo pciconf -lv
```

You will see a list of every PCI device the kernel enumerated. Each entry looks roughly like:

```
em0@pci0:0:25:0:      class=0x020000 rev=0x03 hdr=0x00 vendor=0x8086 device=0x15ba
↪  subvendor=0x8086 subdevice=0x2000
    vendor      = 'Intel Corporation'
    device      = 'Ethernet Connection (2) I219-LM'
    class       = network
    subclass    = ethernet
```

Pick three devices from the list. For each, identify:

- The device's logical name in FreeBSD (the leading name@pciN:B:D:F string).
- The vendor and device IDs.
- The class and subclass (the meaningful English categories, not just the hex codes).
- Whether the device has a driver bound to it (em0, for example, is bound to em(4); an entry with just none0@... has no driver).

Keep this output in a terminal while you read the rest of the chapter. Every vocabulary item introduced in Sections 2 through 5 refers to fields you can find here. The exercise is to anchor the abstract vocabulary to a concrete set of devices on your machine.

If you are reading the book without a FreeBSD machine available, the following snippet is the output of pciconf -lv on the author's lab host, truncated to the first three devices:

```
hostb0@pci0:0:0:0:      class=0x060000 rev=0x00 hdr=0x00 vendor=0x8086 device=0x3e31
    vendor      = 'Intel Corporation'
    device      = '8th Gen Core Processor Host Bridge/DRAM Registers'
    class       = bridge
    subclass    = HOST-PCI
pcib0@pci0:0:1:0:      class=0x060400 rev=0x00 hdr=0x01 vendor=0x8086 device=0x1901
    vendor      = 'Intel Corporation'
    device      = '6th-10th Gen Core Processor PCIe Controller (x16)'
    class       = bridge
    subclass    = PCI-PCI
vgapci0@pci0:0:2:0:     class=0x030000 rev=0x00 hdr=0x00 vendor=0x8086 device=0x3e9b
    vendor      = 'Intel Corporation'
    device      = 'CoffeeLake-H GT2 [UHD Graphics 630]'
    class       = display
    subclass    = VGA
```

Three devices, three drivers, three class codes. The host bridge (hostb0) is the PCI-to-memory-bus bridge; the PCI bridge (pcib0) is a PCI-to-PCI bridge leading to the GPU slot; the VGA-class device (vgapci0) is the integrated graphics on a Coffee Lake chipset. Every one of them follows the probe-attach-detach dance Chapter 18 teaches. The driver is what changes. The bus dance does not.

18.2.12 Wrapping Up Section 1

PCI is the canonical peripheral bus of modern systems and the canonical newbus child of FreeBSD. It is shared by PCI and PCIe, which differ at the physical layer but present the same software-visible model. Every PCI device has a B:D:F address, a configuration space, a set of BARs, a vendor ID, a device ID, and a place in the kernel's newbus tree. A driver's job is to match one or more devices by their IDs, claim their BARs, and expose their behaviour through some user-space interface. FreeBSD's `pci(4)` subsystem does the enumeration; the driver does the attachment.

The vocabulary of Section 1 is the vocabulary the rest of the chapter uses. B:D:F, configuration space, BARs, vendor and device IDs, class codes, capabilities, and the newbus probe-attach-detach sequence. If any one of these feels unfamiliar, re-read the relevant subsection before continuing. Section 2 takes the vocabulary and builds the first version of the driver.

18.3 Section 2: Probing and Attaching a PCI Device

Section 1 established what PCI is and how FreeBSD represents it. Section 2 is where the driver finally uses that vocabulary. The goal here is to stand up the minimum viable PCI driver: a driver that registers itself as a candidate for the PCI bus, matches a specific vendor and device ID, prints a banner in `dmesg` when the match succeeds, and unloads cleanly. No BAR claim yet. No register access yet. Just the skeleton.

The skeleton is important. It introduces the probe-attach-detach sequence in isolation, before BARs and resources and configuration-space walks crowd the picture. A reader who writes this skeleton once, by hand, and then types `kldload ./myfirst.ko`, sees `dmesg` report the driver probing and attaching, and types `kldunload myfirst` to see the detach side fire cleanly, has built the right mental model for everything that follows. Every later Part 4 chapter assumes this mental model.

18.3.1 The Probe-Attach-Detach Contract

Every newbus driver has three methods at the heart of its lifecycle. `probe` asks “is this device something I know how to drive?” `attach` says “yes I want it, and here is how I claim it”. `detach` says “release this device, I am going away”.

Probe. Called by the kernel once per device that the bus has enumerated, for each driver that has registered an interest in that bus. The driver reads the device's vendor and device IDs (and whatever else it needs to decide), returns a priority value if it wants the device, and returns `ENXIO` if it does not. The priority system is what lets a specific driver win over a generic one: a driver that returns `BUS_PROBE_DEFAULT` wins over one that returns `BUS_PROBE_GENERIC` when both want the same device. If no driver returns a match, the device stays unclaimed (you will see this as `nonea@pci0:...` entries in `devinfo -v`).

A subtle point: **probe may be called more than once for a given device**. The newbus reprobe machinery exists to handle devices that appear at runtime (hotplug) or that come back from suspend. A good probe is idempotent: it reads the same state, makes the same decision, returns the same value. Probe must not allocate resources, set up timers, register interrupts, or do anything that would need to be undone. It only inspects and decides.

A second subtle point: **probe runs before attach, but after the kernel has assigned the device's resources**. The BARs, the IRQ, and the configuration space are all accessible from probe. This means probe can read

device-specific registers through `pci_read_config` to distinguish variants of a chipset by revision or silicon ID if needed. Real drivers occasionally do this. Chapter 18's driver does not need to; vendor and device IDs are enough.

Attach. Called once per device, after probe has selected a winner. The driver's attach routine is where real work happens: softc initialisation, resource allocation, register mapping, character-device creation, and any configuration the device needs at bring-up. If attach returns 0, the device is live; the kernel considers the driver bound to the device and moves on. If attach returns a non-zero value, the kernel treats the attach as having failed. The driver must clean up anything it allocated before returning the error; modern newbus does not call detach in that case (older convention did, so older drivers still structure their error paths to handle it).

Detach. Called when the driver is being unbound from the device. The call is the mirror of attach: everything attach allocated, detach releases. Everything attach set up, detach tears down. Everything attach registered, detach unregisters. The ordering is strict: detach must undo in the reverse of the order attach did. A mistake here produces kernel panics at unload time, leaked resources at the best, or subtle use-after-free bugs at the worst.

Resume and **suspend** are optional methods. They are called when the system suspends and resumes, and they give the driver a chance to save and restore device state across the power event. Chapter 18's driver does not implement either method in the first stage; we will add resume in a later chapter when the topic serves the material.

There are other methods (shutdown, quiesce, identify) that less commonly matter for a basic PCI driver. The Chapter 18 skeleton registers only the three core methods plus `DEVMETHOD_END`.

18.3.2 The Device Method Table

FreeBSD's newbus machinery reaches driver methods through a table. The table is an array of `device_method_t` entries, each entry mapping a method name to the C function that implements it. The table ends with `DEVMETHOD_END`, which is simply a zeroed entry that tells newbus "no more methods here".

The table is declared at file scope, like this, in the driver's source:

```
static device_method_t myfirst_pci_methods[] = {
    DEVMETHOD(device_probe,      myfirst_pci_probe),
    DEVMETHOD(device_attach,     myfirst_pci_attach),
    DEVMETHOD(device_detach,     myfirst_pci_detach),
    DEVMETHOD_END
};
```

Each `DEVMETHOD(name, func)` expands to a `{ name, func }` initialiser. The newbus layer reaches a driver's method by looking up the name in this table. If a method is not registered (for example, `device_resume` is not in this table), the newbus layer uses a default implementation; for resume the default is a no-op, for probe the default is `ENXIO`.

The method names are defined in `/usr/src/sys/sys/bus.h` and expanded by the newbus build system. Each one corresponds to a function prototype the driver must match. For example, the `device_probe` method's prototype is:

```
int probe(device_t dev);
```

A driver implementation must have that exact signature. Type mismatches produce compile errors, not runtime mysteries; if your probe's signature is wrong, the build will fail.

18.3.3 The Driver Structure

Alongside the method table, the driver declares a `driver_t`. This structure ties together the method table, the softc size, and a short name:

```
static driver_t myfirst_pci_driver = {  
    "myfirst",  
    myfirst_pci_methods,  
    sizeof(struct myfirst_softc),  
};
```

The name ("myfirst") is what newbus will use when numbering unit instances. The first attached device becomes `myfirst0`, the second `myfirst1`, and so on. This name is what `devinfo -v` shows and what user-space tools (like `/dev/myfirst0` if the driver creates a cdev with that name) expose.

The softc size tells newbus how many bytes to allocate for each device's softc. The allocation is automatic: by the time `attach` runs, `device_get_softc(dev)` returns a pointer to a zeroed block of the requested size. The driver does not call `malloc` for the softc itself; it uses what newbus gave it. This is a convenience that the `myfirst` driver has already been using since Chapter 10; it becomes more important with PCI because every unit has its own softc and newbus manages the lifetime.

18.3.4 DRIVER_MODULE and MODULE_DEPEND

The driver is glued to the PCI bus through two macros. The first is `DRIVER_MODULE(9)`:

```
DRIVER_MODULE(myfirst, pci, myfirst_pci_driver, NULL, NULL);
```

The expansion of this macro performs several things. It registers the driver as a child candidate of the `pci` bus, wrapping the `driver_t` in a kernel module descriptor. It schedules the driver to participate in probe for every device the `pci` bus enumerates. It provides hooks for optional module event handlers (the two `NULL`s are for module init and cleanup, respectively; we leave them empty for now).

The first argument is the module's name, which must match the name in the `driver_t`. The second argument is the bus's name; `pci` is the newbus name of the PCI bus driver. The third argument is the driver itself. The remaining arguments are for optional callbacks.

The macro has a subtle consequence: the driver will participate in probe on every PCI bus in the system. If you have multiple PCI domains, the driver will be offered every device on every domain. Probe's job is to say yes only to the devices the driver actually supports; the kernel's job is to ask.

The second macro is `MODULE_DEPEND(9)`:

```
MODULE_DEPEND(myfirst, pci, 1, 1, 1);
```

This tells the module loader that `myfirst.ko` depends on the `pci` kernel module. The three numbers are minimum, preferred, and maximum version. A zero-to-one dependency on version 1 is the common case. The loader uses this information to refuse to load `myfirst.ko` if the kernel's PCI subsystem is not present (which is essentially never false on a real system, but the check is good hygiene).

Without `MODULE_DEPEND`, the loader might load `myfirst.ko` before the PCI subsystem is available at early boot, leading to a panic when `DRIVER_MODULE` tries to register against a bus that does not exist yet. With it, the loader serialises the load correctly.

18.3.5 Matching by Vendor and Device ID

The probe routine is where the vendor-and-device match happens. The pattern is a static table and a loop. Consider a minimal version:

```
static const struct myfirst_pci_id {
    uint16_t    vendor;
    uint16_t    device;
    const char  *desc;
} myfirst_pci_ids[] = {
    { 0x1af4, 0x1005, "Red Hat / Virtio entropy source (demo target)" },
    { 0, 0, NULL }
};

static int
myfirst_pci_probe(device_t dev)
{
    uint16_t vendor = pci_get_vendor(dev);
    uint16_t device = pci_get_device(dev);
    const struct myfirst_pci_id *id;

    for (id = myfirst_pci_ids; id->desc != NULL; id++) {
        if (id->vendor == vendor && id->device == device) {
            device_set_desc(dev, id->desc);
            return (BUS_PROBE_DEFAULT);
        }
    }
    return (ENXIO);
}
```

A few things to notice. The table is small and static, one entry per supported device. `pci_get_vendor` and `pci_get_device` read the cached ivars, so the calls are cheap. The comparison is a plain loop; the table is short enough not to warrant a hash. `device_set_desc` installs a human-readable description that `pciconf -lv` and

dmesg will print when the device attaches. `BUS_PROBE_DEFAULT` is the standard priority for a vendor-specific match; it wins over generic class-based drivers but loses to any driver that explicitly returns a more negative value.

A subtle but important point: this probe routine targets the `virtio-rnd` (entropy) device that the base-system `virtio_random(4)` driver normally claims. If both drivers are loaded, the system's priority rules decide the winner. `virtio_random` registers `BUS_PROBE_DEFAULT`, as does `myfirst`. The tiebreaker is registration order, which varies. The reliable way to guarantee that `myfirst` attaches is to unload `virtio_random` before loading `myfirst`. Section 7 will show how.

A second note: the vendor and device IDs in the example above target a `virtio` device. Real PCI drivers for real hardware would target chips whose IDs are not already claimed by base-system drivers. For a production driver, the list would include every supported variant of the target chipset, often with descriptive strings that identify the silicon revision. `uart_bus_pci.c` has sixty-plus entries; `ix(4)` has over a hundred.

18.3.6 The Probe Priority Tiers

FreeBSD defines several probe priority tiers, defined in `/usr/src/sys/sys/bus.h`:

- `BUS_PROBE_SPECIFIC = 0`. The driver matches the device precisely. No other driver can outbid this.
- `BUS_PROBE_VENDOR = -10`. The driver is vendor-provided and should win over anything generic.
- `BUS_PROBE_DEFAULT = -20`. The standard tier for a vendor-and-device-ID match.
- `BUS_PROBE_LOW_PRIORITY = -40`. A lower-priority match, often for drivers that want to be the default only if nothing else claims the device.
- `BUS_PROBE_GENERIC = -100`. A generic driver that attaches to a class of devices if nothing more specific exists.
- `BUS_PROBE_HOOVER = -1000000`. Absolute last resort; a driver that wants devices no other driver claimed.
- `BUS_PROBE_NOWILDCARD = -2000000000`. Special-case marker used by the newbus identify machinery.

Most drivers you will write or read use `BUS_PROBE_DEFAULT`. Some use `BUS_PROBE_VENDOR` if they expect to coexist with generic drivers. A handful use `BUS_PROBE_GENERIC` or lower for their fallback mode. Chapter 18's driver uses `BUS_PROBE_DEFAULT` throughout.

The priority values are negative by convention so that the numerically lowest value wins. A more specific driver has a more negative value. This is counter-intuitive on first reading; a mental model is “distance from perfection, measured downward”. `BUS_PROBE_SPECIFIC` is zero distance. `BUS_PROBE_GENERIC` is a hundred units worse.

18.3.7 Writing a Minimal PCI Driver

Putting it all together, here is the Chapter 18 Stage 1 driver, presented as a single self-contained file that grows out of the Chapter 17 skeleton. The file name is `myfirst_pci.c`; it is new in Chapter 18 and lives alongside the existing `myfirst.c`, `myfirst_hw.c`, and `myfirst_sim.c`.

```
/*-
 * SPDX-License-Identifier: BSD-2-Clause
 *
```

```
* Copyright (c) 2026 Edson Brandi
*
* myfirst_pci.c -- Chapter 18 Stage 1 PCI probe/attach skeleton.
*
* At this stage the driver only probes, attaches, and detaches.
* It does not yet claim BARs or touch device registers. Section 3
* adds resource allocation. Section 5 wires the accessor layer to
* the claimed BAR.
*/

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/bus.h>

#include <dev/pci/pci.h>
#include <dev/pci/pcivar.h>

#include "myfirst.h"
#include "myfirst_pci.h"

static const struct myfirst_pci_id myfirst_pci_ids[] = {
    { MYFIRST_VENDOR_REDHAT, MYFIRST_DEVICE_VIRTIO_RNG,
      "Red Hat Virtio entropy source (myfirst demo target)" },
    { 0, 0, NULL }
};

static int
myfirst_pci_probe(device_t dev)
{
    uint16_t vendor = pci_get_vendor(dev);
    uint16_t device = pci_get_device(dev);
    const struct myfirst_pci_id *id;

    for (id = myfirst_pci_ids; id->desc != NULL; id++) {
        if (id->vendor == vendor && id->device == device) {
            device_set_desc(dev, id->desc);
            return (BUS_PROBE_DEFAULT);
        }
    }
    return (ENXIO);
}
```

```

static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    sc->dev = dev;
    device_printf(dev,
        "attaching: vendor=0x%04x device=0x%04x revid=0x%02x\n",
        pci_get_vendor(dev), pci_get_device(dev), pci_get_revid(dev));
    device_printf(dev,
        "        subvendor=0x%04x subdevice=0x%04x class=0x%02x\n",
        pci_get_subvendor(dev), pci_get_subdevice(dev),
        pci_get_class(dev));

    /*
     * Stage 1 has no resources to claim and nothing to initialise
     * beyond the softc pointer. Stage 2 will add the BAR allocation.
     */
    return (0);
}

static int
myfirst_pci_detach(device_t dev)
{
    device_printf(dev, "detaching\n");
    return (0);
}

static device_method_t myfirst_pci_methods[] = {
    DEVMETHOD(device_probe,     myfirst_pci_probe),
    DEVMETHOD(device_attach,   myfirst_pci_attach),
    DEVMETHOD(device_detach,   myfirst_pci_detach),
    DEVMETHOD_END
};

static driver_t myfirst_pci_driver = {
    "myfirst",
    myfirst_pci_methods,
    sizeof(struct myfirst_softc),
};

DRIVER_MODULE(myfirst, pci, myfirst_pci_driver, NULL, NULL);
MODULE_DEPEND(myfirst, pci, 1, 1, 1);
MODULE_VERSION(myfirst, 1);

```

The companion header, `myfirst_pci.h`:

```
/*-
 * SPDX-License-Identifier: BSD-2-Clause
 *
 * Copyright (c) 2026 Edson Brandi
 *
 * myfirst_pci.h -- Chapter 18 PCI interface for the myfirst driver.
 */

#ifndef _MYFIRST_PCI_H_
#define _MYFIRST_PCI_H_

#include <sys/types.h>

/* Target vendor and device IDs for the Chapter 18 demo. */
#define MYFIRST_VENDOR_REDHAT      0x1af4
#define MYFIRST_DEVICE_VIRTIO_RNG  0x1005

/* A single entry in the supported-device table. */
struct myfirst_pci_id {
    uint16_t    vendor;
    uint16_t    device;
    const char  *desc;
};

#endif /* _MYFIRST_PCI_H_ */
```

And the Makefile needs a small update:

```
# Makefile for the Chapter 18 Stage 1 myfirst driver.

KMOD=  myfirst
SRCS=  myfirst.c myfirst_hw.c myfirst_sim.c myfirst_pci.c cbuf.c

CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.1-pci-stage1\"

.include <bsd.kmod.mk>
```

Three things have changed from Chapter 17 Stage 5. `myfirst_pci.c` is added to `SRCS`. The version string is bumped to `1.1-pci-stage1`. Nothing else needs to change.

18.3.8 What Happens When the Driver Loads

Walking through the loading sequence makes the skeleton concrete.

The reader invokes `kldload ./myfirst.ko`. The kernel's module loader reads the module's metadata. It sees the `MODULE_DEPEND(myfirst, pci, ...)` declaration and verifies that the `pci` module is loaded. (It always is on a running kernel, so this check passes.) It sees the `DRIVER_MODULE(myfirst, pci, ...)` declaration and registers the driver as a probe candidate for the PCI bus.

The kernel then iterates over every PCI device in the system and calls `myfirst_pci_probe` for each. Most probes return `ENXIO` because the vendor and device IDs do not match. One probe, against the `virtio-rnd` device in the guest, returns `BUS_PROBE_DEFAULT`. The kernel picks `myfirst` as the driver for that device.

If the `virtio-rnd` device is already attached to `virtio_random`, the new driver's probe result competes with the existing binding. The kernel does not re-bind a device automatically just because a new driver appeared; instead, `myfirst` will not attach. To force the rebind, the reader must first detach the existing driver: `devctl detach virtio_random0`, or `kldunload virtio_random`. Section 7 walks through this.

Once the kernel decides `myfirst` wins, it allocates a new `softc` (the `sizeof(struct myfirst_softc)` block requested in the `driver_t`), clears it to zero, and calls `myfirst_pci_attach`. The attach routine runs. It prints a short banner. It returns 0. The kernel marks the device as attached.

`dmesg` shows the sequence:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> port 0x6040-0x605f mem
↳ 0xc1000000-0xc100001f irq 19 at device 5.0 on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0:          subvendor=0x1af4 subdevice=0x0004 class=0xff
```

`devinfo -v` shows the device with its parent, its resources, and its driver binding. `pciconf -lv` shows it with `myfirst0` as its bound name.

On unload, the inverse happens. `kldunload myfirst` calls `myfirst_pci_detach` on every attached device. The detach prints its own banner, returns 0, and the kernel releases the `softc`. `DRIVER_MODULE` unregisters the driver from the PCI bus. The module loader removes the `myfirst.ko` image from memory.

18.3.9 device_printf and Why It Matters

One small detail worth emphasising. The skeleton uses `device_printf(dev, ...)` instead of `printf(...)`. The difference is small but important.

`printf` prints to the kernel log without any prefix. A line that says “attaching” is hard to associate with a specific device; the log is full of messages from every driver in the system. `device_printf(dev, ...)` prefixes the message with the driver's name and unit number: “`myfirst0: attaching`”. The prefix makes the log readable even when multiple instances of the driver are attached at once (`myfirst0`, `myfirst1`, and so on).

The convention is strict in the FreeBSD source tree: every driver uses `device_printf` in code paths that have a `device_t` handy, and falls back to `printf` only in very early module init or module unload, where the handle is not available. A reader who habitually uses `device_printf` produces logs that are easy to read and diagnose; a reader who uses `printf` everywhere produces logs that other contributors will ask to have corrected.

18.3.10 The Softc and device_get_softc

The Chapter 17 driver already had a softc structure. Chapter 18's attach routine simply reuses it, with one addition: the PCI layer stores the device_t in sc->dev so later code (including the Chapter 16 accessors and the Chapter 17 simulation) can reach it.

A reminder: device_get_softc(dev) returns a pointer to the softc that newbus pre-allocated. The softc is zeroed before attach runs, so every field starts at zero or NULL or false. The softc is freed automatically by newbus after detach returns; the driver does not call free on it.

This is worth calling out because it differs from the malloc-based softc pattern in older FreeBSD drivers and in some Linux drivers. In newbus, the bus owns the softc lifetime. In older patterns, the driver owned it and had to remember to allocate and free. Forgetting to allocate in the old model causes a null dereference in attach; forgetting to free in the old model causes a memory leak in detach. Neither failure mode exists in modern newbus because the bus handles both operations.

18.3.11 Probe-Attach-Detach Order in the Face of Unload

An important detail for a driver author is what happens when kldunload myfirst runs while one or more myfirst devices are attached.

The module loader's unload path first tries to detach every device bound to the driver. For each device, it calls the driver's detach method. If detach returns 0, the device is considered unbound; the softc is freed. If detach returns non-zero (usually EBUSY), the module loader aborts the unload: the module stays loaded, the device stays attached, and the unload returns an error. This is how a driver refuses to go away while it has work in progress.

The myfirst driver's detach should normally succeed, because the driver's user-facing state is idle by the time the user asks to unload it. But a driver that is actively serving requests (for example, a disk driver with open file descriptors on its cdev) returns EBUSY from detach and forces the user to close the descriptors first.

For Chapter 18 Stage 1, detach is a one-liner: print a banner and return 0. In later stages, detach will acquire the lock, cancel callouts, release resources, and finally return 0 once everything is torn down.

18.3.12 Stage 1 Output: What Success Looks Like

The reader loads the driver. On a bhyve guest with a virtio-rnd device attached, and with virtio_random unloaded first, dmesg should print something like:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0:          subvendor=0x1af4 subdevice=0x0004 class=0xff
```

kldstat -v | grep myfirst shows the driver loaded. devinfo -v | grep myfirst shows the device attached to pci0. pciconf -lv | grep myfirst confirms the match.

On unload:

```
myfirst0: detaching
```

And the device returns to unclaimed status. (Or to `virtio_random` if that module is reloaded.)

If the `virtio-rnd` device is absent, no attach happens; the driver loads, but no `myfirst0` appears in `devinfo`. If the driver is loaded on a host without the device, the same happens: probe runs for every PCI device in the system, probe returns `ENXIO` for each, and no attach occurs. This is the correct and expected behaviour; the driver is patient.

18.3.13 Common Mistakes at This Stage

A short list of traps the author has seen beginners fall into.

Forgetting `MODULE_DEPEND`. The driver loads, but early in boot it panics because the PCI module has not been initialised yet. Adding the declaration fixes it. The symptom is easy to recognise once you know to look for it.

Wrong name in `DRIVER_MODULE`. The name must match the "name" string in the `driver_t`. Mismatches produce subtle errors where the driver loads but never probes a device. The fix is to make the two match; the convention is that both use the driver's short name.

Returning the wrong value from probe. A beginner sometimes returns 0 from probe thinking "zero means success". Zero is `BUS_PROBE_SPECIFIC`, which is the strongest possible match; the driver will win over every other driver that wants the same device. This is almost never what you meant. Return `BUS_PROBE_DEFAULT` for the standard match.

Returning a positive error code. The newbus convention is that probe returns a negative priority value or a positive errno. Returning the wrong sign is a common typo. `ENXIO` is the right "I do not match" return.

Leaving resources allocated in probe. Probe must be side-effect-free. If probe allocates a resource, it must release it before returning. The cleanest approach is to never allocate from probe; do everything in attach.

Confusing `pci_get_vendor` with `pci_read_config`. The two are different. `pci_get_vendor` reads a cached ivar. `pci_read_config(dev, PCIR_VENDOR, 2)` reads the live configuration space. Both produce the same value for this field, but one is a cheap inline function and the other is a bus transaction. Use the accessor.

Forgetting to include the right headers. `dev/pci/pci.h` defines the `PCIR_*` constants. `dev/pci/pci-var.h` defines `pci_get_vendor` and friends. Both need to be included. The compiler error is usually "undefined identifier" for `pci_get_vendor`; the fix is the missing include.

Name collision with `MODULE_VERSION`. The first argument must match the driver name. `MODULE_VERSION(myfirst, 1)` is fine. `MODULE_VERSION(myfirst_pci, 1)` is not, because `myfirst_pci` is a file name, not a module name. The module loader looks up modules by the name registered in `DRIVER_MODULE`.

Each of these is recoverable. The debug kernel catches some of them (the loaded-before-pci case produces a panic the debug kernel pretty-prints). The others produce subtle wrong behaviour that is most easily caught by carefully testing the load-attach-detach-unload cycle after every change.

18.3.14 Checkpoint: Stage 1 Working

Before moving to Section 3, confirm that the Stage 1 driver works end-to-end.

On the bhyve or QEMU guest:

- `kldload virtio_pci` (if not already loaded).
- `kldunload virtio_random` (if loaded; fails gracefully if it isn't).
- `kldload ./myfirst.ko`.
- `kldstat -v | grep myfirst` should show the module loaded.
- `devinfo -v | grep myfirst` should show `myfirst0` attached under `pci0`.
- `dmesg` should show the attach banner.
- `kldunload myfirst`.
- `dmesg` should show the detach banner.
- `devinfo -v | grep myfirst` should show nothing.

If all of these pass, you have a working Stage 1 driver. The next step is to claim the BAR.

18.3.15 Wrapping Up Section 2

The probe-attach-detach sequence is the skeleton of every PCI driver. Section 2 built it in its smallest possible form: a probe that matches one vendor-and-device pair, an attach that prints a banner, a detach that prints another banner, and enough glue (`DRIVER_MODULE`, `MODULE_DEPEND`, `MODULE_VERSION`) to make the kernel's module loader and newbus enumerator accept it.

What the Stage 1 skeleton does not yet do: claim a BAR, read a register, enable bus mastering, walk the capability list, create a cdev, or coordinate the PCI build with the Chapter 17 simulation build. Every one of these is a topic of a later section in this chapter. The skeleton is important because every later topic plugs into it without reshaping it. Attach grows from a two-line function to a twenty-line function as the chapter proceeds; probe stays exactly as it is.

Section 3 introduces BARs. It explains what they are, how they are assigned, and how a driver claims the memory range a BAR describes. By the end of Section 3, the driver will hold a `struct resource *` for its BAR and a tag-and-handle pair ready to hand to the Chapter 16 accessor layer.

18.4 Section 3: Understanding and Claiming PCI Resources

With a probe and a trivial attach in place, the driver knows when it has found the device it wants to drive. What it does not yet know is how to reach that device's registers. Section 3 closes the gap. It starts with what a BAR is in the PCI specification, walks through how the firmware and the kernel set one up, and finishes with the driver code that claims a BAR and turns it into a `bus_space` tag and handle that the Chapter 16 accessors can use unchanged.

The point of this section is to make the word "BAR" concrete. A reader who finishes Section 3 should be able to answer, in a sentence: a BAR is a configuration-space field where a device says "here is how much memory (or how many I/O ports) I need, and here is how you can reach it once the firmware has mapped it into the host's address space". Everything else in the section builds on that sentence.

18.4.1 What a BAR Is, Precisely

Every PCI device advertises the resources it needs through Base Address Registers. A standard PCI device header (the non-bridge type) has six BARs, each four bytes wide, at configuration-space offsets 0x10, 0x14, 0x18, 0x1c, 0x20, and 0x24. In FreeBSD's `/usr/src/sys/dev/pci/pci.h`, these offsets are produced by the macro `PCIR_BAR(n)`, where `n` ranges from 0 to 5.

Each BAR describes one range of addresses. A BAR's low bit tells the software whether the range is in memory space or in I/O port space. If the low bit is zero, the range is memory-mapped; if it is one, the range is in the I/O port address space. Everything above the low few bits is an address; the exact field layout depends on the BAR type.

For a memory-mapped BAR, the layout is:

- Bit 0: 0 for memory.
- Bits 2-1: type. 0b00 for 32-bit, 0b10 for 64-bit, 0b01 reserved (formerly “below 1 MB”).
- Bit 3: prefetchable. 1 if the device promises that reads have no side effects, so the CPU may prefetch and merge accesses.
- Bits 31-4 (or 63-4 for 64-bit): the address.

A 64-bit BAR occupies two consecutive BAR slots. The low slot holds the lower 32 bits of the address (with the type bits); the high slot holds the upper 32 bits. A driver walking the BAR list must recognise when it has encountered a 64-bit BAR and skip the consumed upper slot.

For an I/O port BAR:

- Bit 0: 1 for I/O.
- Bit 1: reserved.
- Bits 31-2: the port address.

I/O port BARs are less common on modern devices. Most modern PCIe devices use memory-mapped BARs exclusively. Chapter 18 focuses on memory-mapped BARs.

18.4.2 How a BAR Gets an Address

A BAR is written in two passes. The first pass is what the silicon designer specified: a read from a BAR returns the device's requirements. The low bit type field is read-only. The address field is read-write, but with a catch: writing all ones to the address field and reading it back tells the firmware how large the range is. The device returns a value where the low bits (those below the size) are zero and the high bits (those that the device does not implement) return what was written. The firmware interprets the readback as a size mask.

The second pass assigns the actual address. The firmware (BIOS or UEFI) walks every BAR on every PCI device, notes the size each requires, partitions the host's address space to satisfy all of them, and writes the assigned address back into each BAR. By the time the OS boots, every BAR has a real address that the OS can use to reach the device.

The OS can optionally re-do the assignment if it wants to (for hot-plug support or if the firmware did a poor job). FreeBSD mostly accepts the firmware's assignment; the `hw.pci.realloc_bars` sysctl and the `bus_generic_probe` logic handle the uncommon case where reassignment is needed.

From the driver's point of view, all of this is done by the time attach runs. The BAR has an address, the address is mapped into the kernel's virtual space, and the driver needs only to ask for the resource by number.

18.4.3 The `rid` Argument and `PCIR_BAR`

The driver claims a BAR by calling `bus_alloc_resource_any(9)` with a resource ID (usually called `rid`) that identifies which BAR to allocate. For a memory-mapped BAR, the `rid` is the configuration-space offset of that BAR, produced by the macro `PCIR_BAR(n)`:

- `PCIR_BAR(0) = 0x10` (BAR 0)
- `PCIR_BAR(1) = 0x14` (BAR 1)
- ...
- `PCIR_BAR(5) = 0x24` (BAR 5)

Passing `PCIR_BAR(0)` to `bus_alloc_resource_any` requests BAR 0. Passing `PCIR_BAR(1)` requests BAR 1. The macro is one line in `pcireg.h`:

```
#define PCIR_BAR(x) (PCIR_BARS + (x) * 4)
```

where `PCIR_BARS` is `0x10`.

Beginners sometimes pass 0 or 1 as the `rid` and are surprised when the allocation fails. The `rid` is not a BAR index; it is the offset. Use `PCIR_BAR(index)` unless you have a specific reason to pass a raw offset.

18.4.4 The Resource Type: `SYS_RES_MEMORY` vs `SYS_RES_IOPORT`

`bus_alloc_resource_any` takes a type argument that tells the kernel what kind of resource the driver wants. For a memory BAR, the type is `SYS_RES_MEMORY`. For an I/O port BAR, the type is `SYS_RES_IOPORT`. For an interrupt, it is `SYS_RES_IRQ`. The small set of resource types is defined in `/usr/src/sys/arm64/include/resource.h` (and the per-architecture equivalents); memory, I/O port, and IRQ are the three a PCI driver normally uses.

PCI configuration space itself is not claimed through `bus_alloc_resource_any`. The driver reaches it through `pci_read_config(9)` and `pci_write_config(9)`, which route the access through the PCI bus driver without needing a resource handle.

A driver that does not know whether its BAR is memory or I/O can inspect the low bit of the BAR in configuration space to find out. A driver that knows (because the datasheet says so, or because the device has always been MMIO in this chapter) simply passes the right type.

Most PCIe devices have their main interface in memory space and an optional compatibility window in I/O port space. A driver usually asks for the memory BAR first and, if that fails, falls back to the I/O port BAR. Chapter 18's driver asks for memory only; the `virtio-rnd` device it targets exposes its registers in a memory BAR.

18.4.5 The `RF_ACTIVE` Flag

`bus_alloc_resource_any` also takes a flags argument. The two most commonly set flags are:

- `RF_ACTIVE`: activate the resource as part of allocation. Without this, the allocation reserves the resource but does not map it; the driver must call `bus_activate_resource(9)` separately. With it, the resource is allocated and activated in one step.
- `RF_SHAREABLE`: the resource can be shared with other drivers. This matters for interrupts (IRQs shared between multiple devices); it matters less for memory BARs.

For a memory BAR, the common case is `RF_ACTIVE` alone. For an IRQ that might be shared on a legacy system, it is `RF_ACTIVE | RF_SHAREABLE`. Chapter 18 uses `RF_ACTIVE` only.

18.4.6 `bus_alloc_resource_any` in Detail

The function signature is:

```
struct resource *bus_alloc_resource_any(device_t dev, int type,
    int *rid, u_int flags);
```

Three arguments, plus a return value.

`dev` is the device handle. `type` is `SYS_RES_MEMORY`, `SYS_RES_IOPORT`, or `SYS_RES_IRQ`. `rid` is a pointer to an integer holding the resource ID; the kernel may update it (for example, to tell the driver which slot was actually used when the driver passed a wildcard). `flags` is the bit mask described above.

The return value is a `struct resource *`. Non-NULL on success; NULL on failure. The resource handle is what every subsequent operation (reads, writes, release) uses.

A typical call looks like:

```
int rid = PCIR_BAR(0);
struct resource *bar;

bar = bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE);
if (bar == NULL) {
    device_printf(dev, "cannot allocate BAR0\n");
    return (ENXIO);
}
```

After the call, `bar` points to an allocated and activated resource; `rid` may have been updated by the kernel if it chose a different slot than the driver asked for (for wildcard allocations, this is where the chosen slot becomes visible).

18.4.7 From Resource to Tag and Handle

The resource handle is the driver's connection to the BAR, but the Chapter 16 accessor layer expects a `bus_space_tag_t` and a `bus_space_handle_t`, not a `struct resource *`. Two helpers turn one into the other:

- `rman_get_bustag(res)` returns the `bus_space_tag_t`.

- `rman_get_bushandle(res)` returns the `bus_space_handle_t`.

Both are inline accessor functions defined in `/usr/src/sys/sys/rman.h`. The resource stores the tag and handle internally; the accessors return the stored values. The driver then stores the tag and handle in its own state (in Chapter 18, in the hardware layer's `struct myfirst_hw`) so that the Chapter 16 accessors can use them.

The pattern is short:

```
sc->hw->regs_tag = rman_get_bustag(bar);
sc->hw->regs_handle = rman_get_bushandle(bar);
```

After these two lines, `CSR_READ_4(sc, off)` and `CSR_WRITE_4(sc, off, val)` work against the real BAR. No other code in the driver needs to know that the backend changed.

18.4.8 `rman_get_size` and `rman_get_start`

Two additional helpers extract the range of addresses the resource covers:

- `rman_get_size(res)` returns the number of bytes.
- `rman_get_start(res)` returns the physical or bus start address.

The driver uses `rman_get_size` to sanity-check that the BAR is large enough for the registers the driver expects. A device whose BAR is smaller than the chapter expects is either mis-identified (wrong device behind the ID pair) or a variant the driver does not support. Either way, a failed sanity check in `attach` is better than a corrupted access at run time.

`rman_get_start` is useful mostly for diagnostic logging. The physical address of the BAR is not something the driver dereferences directly (the kernel's mapping is what the tag and handle wrap), but printing it helps when debugging because it connects the `pciconf -lv` output to the driver's view.

18.4.9 Releasing the BAR

The counterpart to `bus_alloc_resource_any` is `bus_release_resource(9)`. The signature is:

```
int bus_release_resource(device_t dev, int type, int rid, struct resource *res);
```

`dev`, `type`, and `rid` match the allocation call; `res` is the handle returned by the allocation. On success, the function returns 0; on failure, it returns an `errno`. Failures are rare because the resource was just allocated by this driver, but defensive drivers check the return value and log on failure.

The driver should always release every resource it allocated, in the reverse order of allocation. Chapter 18's driver at Stage 2 allocates one BAR; it will release that one BAR in `detach`. Later stages, after interrupts and DMA enter the picture in Chapters 19 through 21, will allocate more.

18.4.10 Partial Failure in Attach

A subtle point about attach. If the driver claims the BAR successfully but then fails at a later step (for example, the device's expected `DEVICE_ID` register does not match), the driver must release the BAR before returning the error. Forgetting to release is a resource leak: the kernel's resource manager still thinks the BAR is allocated by this driver, even though the driver has returned. The next attempt to attach will fail.

The idiom is the familiar goto-based cleanup pattern:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int rid, error;

    sc->dev = dev;
    sc->bar_rid = PCIR_BAR(0);
    sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &sc->bar_rid, RF_ACTIVE);
    if (sc->bar_res == NULL) {
        device_printf(dev, "cannot allocate BAR0\n");
        error = ENXIO;
        goto fail;
    }

    error = myfirst_hw_attach_pci(sc);
    if (error != 0)
        goto fail_release;

    /* ... */
    return (0);

fail_release:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail:
    return (error);
}
```

The goto cascade is an idiom, not a smell. It keeps cleanup code in one place and makes the allocation-and-release pairing symmetric. The pattern was introduced in Chapter 15 for mutex-and-callout cleanup; here it extends to resource cleanup. Chapter 18's final attach uses a longer version of this cascade to handle the softc init, BAR allocation, hardware-layer attach, and cdev creation as four staged allocations.

18.4.11 What Lives in the Softc

Chapter 18 adds a few fields to the softc. They are declared in `myfirst.h` (the main driver header, not `my-first_pci.h`, because the softc is shared across all the layers).

```
struct myfirst_softc {
    device_t dev;
    /* ... Chapter 10 through 17 fields ... */

    /* Chapter 18 PCI fields. */
    struct resource *bar_res;
    int bar_rid;
    bool pci_attached;
};
```

`bar_res` is the handle to the claimed BAR. `bar_rid` is the resource ID used to allocate it (stored so detach can pass the right value to `bus_release_resource`). `pci_attached` is a flag that later code uses to distinguish the real-PCI attach path from the simulated attach path.

A single BAR is enough for the Chapter 18 driver. Drivers for more complex devices would have `bar0_res`, `bar0_rid`, `bar1_res`, `bar1_rid`, and so on, each pair matching one BAR. The `virtio-rnd` device has only one BAR, so the driver has only one pair.

18.4.12 The Stage 2 Attach

Putting the allocation into Stage 2's attach routine:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error = 0;

    sc->dev = dev;

    /* Allocate BAR0 as a memory resource. */
    sc->bar_rid = PCIR_BAR(0);
    sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &sc->bar_rid, RF_ACTIVE);
    if (sc->bar_res == NULL) {
        device_printf(dev, "cannot allocate BAR0\n");
        return (ENXIO);
    }

    device_printf(dev, "BAR0 allocated: %#jx bytes at %#jx\n",
```

```

        (uintmax_t)rman_get_size(sc->bar_res),
        (uintmax_t)rman_get_start(sc->bar_res));

    sc->pci_attached = true;
    return (error);
}

```

A successful Stage 2 attach prints a line like:

```
myfirst0: BAR0 allocated: 0x20 bytes at 0xc1000000
```

The size and address depend on the guest's layout. The important parts are that the allocation succeeded, the size is what the driver expected (the virtio-rnd device exposes at least 32 bytes of registers), and the detach path releases the resource.

18.4.13 The Stage 2 Detach

The Stage 2 detach needs to release what attach allocated:

```

static int
myfirst_pci_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    if (sc->bar_res != NULL) {
        bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,
            sc->bar_res);
        sc->bar_res = NULL;
    }
    sc->pci_attached = false;
    device_printf(dev, "detaching\n");
    return (0);
}

```

The `if` guard is defensive: in principle `sc->bar_res` is non-NULL whenever detach is called after a successful attach, but adding the check costs nothing and makes the detach robust against partial-failure cases that might arise in future refactors. Setting `bar_res` to NULL after release prevents a double-free if something later calls detach again.

18.4.14 What Stage 2 Does Not Yet Do

At the end of Stage 2, the driver allocates a BAR but does nothing with it. The tag and handle are available but not yet wired to the Chapter 16 accessors. The simulation from Chapter 17 still runs, but it runs against the `malloc(9)`-allocated register block, not against the real BAR.

Section 4 bridges the gap. It takes the tag and handle from Stage 2 and hands them to `myfirst_hw_attach` so that `CSR_READ_4` and `CSR_WRITE_4` operate on real silicon. After Section 4, the Chapter 17 simulation becomes a runtime option rather than the only backend.

18.4.15 Verifying Stage 2

Before moving to Section 4, confirm that Stage 2 works end-to-end.

```
# In the bhyve guest:
sudo kldunload virtio_random # may not be loaded
sudo kldload ./myfirst.ko
sudo dmesg | grep myfirst | tail -5
```

The output should look like:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0:          subvendor=0x1af4 subdevice=0x0004 class=0xff
myfirst0: BAR0 allocated: 0x20 bytes at 0xc1000000
```

`devinfo -v | grep -A 2 myfirst0` should show the resource claim:

```
myfirst0
  pnpinfo vendor=0x1af4 device=0x1005 ...
  resources:
    memory: 0xc1000000-0xc100001f
```

The memory range printed by `devinfo -v` matches the range printed by the driver. This confirms that the allocation succeeded and that the kernel sees the BAR as claimed by `myfirst`.

Unload and verify the cleanup:

```
sudo kldunload myfirst
sudo devinfo -v | grep myfirst # should return nothing
```

No lingering devices, no leaked resources. Stage 2 is complete.

18.4.16 Common Mistakes in BAR Allocation

A short list of the typical traps.

Passing 0 as the rid for BAR 0. The rid is `PCIR_BAR(0) = 0x10`, not 0. Passing 0 asks for a resource at offset 0, which is the `PCIR_VENDOR` field; the allocation fails or produces surprising results. Always use `PCIR_BAR(index)`.

Forgetting `RF_ACTIVE`. Without this flag, `bus_alloc_resource_any` allocates but does not activate. Reading from the tag and handle at that point is undefined behaviour. The symptom is usually a page fault or garbage values. The fix is to pass `RF_ACTIVE`.

Using the wrong resource type. Passing `SYS_RES_IOPORT` for a memory BAR produces an immediate allocation failure. Passing `SYS_RES_MEMORY` for an I/O port BAR does the same. The type must match the BAR's actual type. If the driver does not know in advance (a generic driver that supports both memory and I/O variants), it reads `PCIR_BAR(index)` from configuration space and checks the low bit.

Not releasing on partial failure. A common beginner mistake: `attach` claims the BAR, a subsequent step fails, the function returns the error, and the BAR is never released. The resource leaks. The next `attach` attempt fails because the BAR is still claimed.

Releasing the BAR before the accessor layer is done with it. The reverse mistake: `detach` releases the BAR too early, before draining callouts or tasks that might still be reading from it. The symptom is a page fault inside a callout shortly after `kldunload`. The fix is to drain everything that might access the BAR, then release.

Confusing `rman_get_size` with `rman_get_end`. `rman_get_size(res)` returns the number of bytes. `rman_get_end(res)` returns the last byte's address (start plus size minus one). Use `rman_get_size` for sanity checks on BAR size; use `rman_get_start` and `rman_get_end` for diagnostic printing.

Assuming BARs are in any particular order. The driver must name the BAR it wants explicitly (by passing `PCIR_BAR(n)`). Some devices put their main BAR at index 0; some put it at index 2. The datasheet (or the `pciconf -lv` output for the specific device) says where it is. Assuming BAR 0 without verifying is a common mistake.

18.4.17 A Note on 64-bit BARs

The `virtio-rnd` device used in Chapter 18 has a 32-bit BAR, so the allocation shown here works without special handling. For devices with 64-bit BARs, there are two important details:

First, the BAR occupies two consecutive slots in the configuration-space BAR table. BAR 0 (at offset `0x10`) holds the lower 32 bits; BAR 1 (at offset `0x14`) holds the upper 32 bits. A driver walking the BAR table by simple integer increments would mistakenly treat BAR 1 as a separate BAR. The right walk reads each BAR's type bits and skips the next slot if the current slot is a 64-bit BAR.

Second, the `rid` passed to `bus_alloc_resource_any` is the lower slot's offset. The kernel recognises the 64-bit type and treats the pair as a single resource. The driver does not need to allocate two resources for a 64-bit BAR; one allocation with `rid = PCIR_BAR(0)` handles both slots.

For Chapter 18's driver, this is academic; the target device has 32-bit BARs. But a reader who later works with a device that has a 64-bit BAR will need the details. `/usr/src/sys/dev/pci/pci.h` defines `PCIM_BAR_MEM_TYPE`, `PCIM_BAR_MEM_32`, and `PCIM_BAR_MEM_64` to help with BAR inspection.

18.4.18 Prefetchable vs Non-Prefetchable BARs

A related detail. A BAR is prefetchable if its bit 3 is set. Prefetchable means "reads from this range have no side effects, so the CPU is allowed to cache, prefetch, and merge accesses as it would for normal RAM". Non-prefetchable means "reads have side effects, so every access must hit the device; the CPU must not cache, prefetch, or merge".

Device registers are almost always non-prefetchable. A read from a status register may clear the flags; a prefetched read would be a catastrophic bug. Device memory (a frame buffer on a graphics card, or a ring buffer on a NIC) is usually prefetchable.

The driver does not directly control the prefetch attribute; the BAR declares what it is, and the kernel sets up the mapping accordingly. The driver's job is to use `bus_space_read_*` and `bus_space_write_*` correctly. The `bus_space` layer handles the ordering and caching details. A driver that tries to be clever by bypassing `bus_space` and directly dereferencing a pointer might accidentally get a cached mapping on a non-prefetchable BAR and produce a driver that works in ideal conditions and fails mysteriously under load.

Chapter 16 made the case for `bus_space` in general; Section 3 of Chapter 18 confirms that the case extends to real PCI devices. There is no shortcut.

18.4.19 Wrapping Up Section 3

A BAR is a range of addresses where the device exposes its registers. The firmware assigns BAR addresses at boot; the kernel reads them during PCI enumeration; the driver claims them in `attach` through `bus_alloc_resource_any(9)` with the right type, `rid`, and flags. The returned `struct resource *` carries a `bus_space_tag_t` and `bus_space_handle_t` that `rman_get_bustag(9)` and `rman_get_bushandle(9)` extract. `Detach` must release every allocated resource in reverse order.

The Stage 2 driver allocates BAR 0 but does not yet use it. Section 4 wires the tag and handle to the Chapter 16 accessor layer, so `CSR_READ_4` and `CSR_WRITE_4` finally operate on the real BAR rather than on a `malloc(9)` block.

18.5 Section 4: Accessing Device Registers via `bus_space(9)`

Section 3 ended with a tag and a handle in the driver's hand. The tag and handle point at the real BAR; the Chapter 16 accessors expect exactly that pair. Section 4 makes the connection. It teaches how to hand the PCI-allocated tag and handle to the hardware layer, confirms that the Chapter 16 `CSR_*` macros work unchanged against a real PCI BAR, reads the driver's first real register through `bus_space_read_4(9)`, and discusses the access patterns (`bus_space_read_multi`, `bus_space_read_region`, barriers) that Chapter 16 introduced and that the PCI path will reuse.

The theme of Section 4 is continuity. The reader has been writing register-access code for two chapters. Chapter 18 does not change that code. What changes is where the tag and handle come from. The accessors are exactly the accessors; the wrapping macros are exactly the wrapping macros; the lock discipline is exactly the lock discipline. This is the payoff for the `bus_space(9)` abstraction. The driver's upper layers do not know, and should not know, that the register block's origin has changed.

18.5.1 Revisiting the Chapter 16 Accessors

A short reminder. `myfirst_hw.c` defines three public functions that the rest of the driver calls:

- `myfirst_reg_read(sc, off)` returns a 32-bit value from the register at the given offset.
- `myfirst_reg_write(sc, off, val)` writes a 32-bit value to the register at the given offset.

- `myfirst_reg_update(sc, off, clear, set)` performs a read-modify-write: read, clear the given bits, set the given bits, write.

All three are wrapped by the `CSR_*` macros defined in `myfirst_hw.h`:

- `CSR_READ_4(sc, off)` expands to `myfirst_reg_read(sc, off)`.
- `CSR_WRITE_4(sc, off, val)` expands to `myfirst_reg_write(sc, off, val)`.
- `CSR_UPDATE_4(sc, off, clear, set)` expands to `myfirst_reg_update(sc, off, clear, set)`.

The accessors reach `bus_space` through two fields in struct `myfirst_hw`:

- `hw->regs_tag` of type `bus_space_tag_t`
- `hw->regs_handle` of type `bus_space_handle_t`

The actual call inside `myfirst_reg_read` is:

```
value = bus_space_read_4(hw->regs_tag, hw->regs_handle, offset);
```

and inside `myfirst_reg_write`:

```
bus_space_write_4(hw->regs_tag, hw->regs_handle, offset, value);
```

These lines do not know about PCI. They do not know about `malloc`. They do not know whether `hw->regs_tag` came from a simulated pmap setup in Chapter 16 or from a `rman_get_bustag(9)` call in Chapter 18. Their contract is unchanged.

18.5.2 The Two Origins of a Tag and Handle

Chapter 16 used a trick to produce a tag and handle from a `malloc(9)` allocation on x86. The trick was simple: the x86 `bus_space` implementation uses `x86_bus_space_mem` as the tag for memory-mapped accesses, and a handle is just a virtual address. A `malloc`-allocated buffer has a virtual address, so casting the buffer pointer to `bus_space_handle_t` produces a usable handle. The trick is x86-specific; on other architectures, a simulated block would need a different approach.

Chapter 18 uses the proper route: `bus_alloc_resource_any(9)` allocates a BAR as a resource, and `rman_get_bustag(9)` and `rman_get_bushandle(9)` extract the tag and handle that the kernel set up. The driver does not see the physical address; it does not see the virtual mapping; it sees an opaque tag and handle that the kernel's platform code set up correctly. The accessors use them, and the register read hits the real device.

This is the fundamental shape of the PCI integration. Two different origins of the tag and handle. One set of accessors that uses them. The driver picks which origin is live at attach time, and the accessors do not need to know which one was picked.

18.5.3 Extending myfirst_hw_attach

Chapter 16's `myfirst_hw_attach` allocates a `malloc(9)` buffer and synthesises a tag and handle. Chapter 18 needs a second code path that takes an existing tag and handle (from the PCI BAR) and stores them directly. The simplest way is to rename the Chapter 16 version and introduce a new version for the PCI path.

The new header, adjusted for Chapter 18:

```
/* Chapter 16 behaviour: allocate a malloc-backed register block. */
int myfirst_hw_attach_sim(struct myfirst_softc *sc);

/* Chapter 18 behaviour: use an already-allocated resource. */
int myfirst_hw_attach_pci(struct myfirst_softc *sc,
    struct resource *bar, bus_size_t bar_size);

/* Shared teardown; safe with either backend. */
void myfirst_hw_detach(struct myfirst_softc *sc);
```

The PCI-path attach stores the tag and handle directly:

```
int
myfirst_hw_attach_pci(struct myfirst_softc *sc, struct resource *bar,
    bus_size_t bar_size)
{
    struct myfirst_hw *hw;

    if (bar_size < MYFIRST_REG_SIZE) {
        device_printf(sc->dev,
            "BAR is too small: %ju bytes, need at least %u\n",
            (uintmax_t)bar_size, (unsigned)MYFIRST_REG_SIZE);
        return (ENXIO);
    }

    hw = malloc(sizeof(*hw), M_MYFIRST, M_WAITOK | M_ZERO);

    hw->regs_buf = NULL;           /* no malloc block */
    hw->regs_size = (size_t)bar_size;
    hw->regs_tag = rman_get_bustag(bar);
    hw->regs_handle = rman_get_bushandle(bar);
    hw->access_log_enabled = true;
    hw->access_log_head = 0;

    sc->hw = hw;

    device_printf(sc->dev,
```

```

    "hardware layer attached to BAR: %zu bytes "
    "(tag=%p handle=%p)\n",
    hw->regs_size, (void *)hw->regs_tag,
    (void *)hw->regs_handle);
    return (0);
}

```

A few things to notice. `hw->regs_buf` is `NULL` because there is no `malloc` allocation backing the registers this time; the BAR's kernel mapping is what the tag and handle point at. `hw->regs_size` is the BAR's size, sanity-checked against the minimum size the driver expects. The tag and handle come from the struct `resource *` that the PCI attach path allocated. Everything else in `myfirst_hw` is unchanged.

The shared detach is where the two backends converge:

```

void
myfirst_hw_detach(struct myfirst_softc *sc)
{
    struct myfirst_hw *hw;

    if (sc->hw == NULL)
        return;

    hw = sc->hw;
    sc->hw = NULL;

    /*
     * Free the simulated backing buffer only if the simulation
     * attach produced one. The PCI path sets regs_buf to NULL and
     * leaves regs_size as the BAR size; the BAR itself is released
     * by the PCI layer (see myfirst_pci_detach).
     */
    if (hw->regs_buf != NULL) {
        free(hw->regs_buf, M_MYFIRST);
        hw->regs_buf = NULL;
    }
    free(hw, M_MYFIRST);
}

```

The split is clean. The hardware layer knows how to tear down the Chapter 16 backing buffer or do nothing, depending on how it was attached. The BAR itself is not the hardware layer's responsibility; the PCI layer owns it. This separation is what lets Chapter 18 reuse the Chapter 16 code without rewriting the Chapter 16 teardown.

18.5.4 The First Real Register Read

With the hardware layer wired up, the driver's first real read becomes possible. At Chapter 17 the first read was of the fixed `DEVICE_ID` register, which the simulation pre-populated with `0x4D594649` ("MYFI" in ASCII, for "MY First"). The `virtio-rnd` device does not expose a `DEVICE_ID` register at that offset; its configuration space at the BAR's offset 0 is a `virtio`-specific layout that begins with a device features register.

For the Chapter 18 teaching path, we do not need to speak the `virtio-rnd` protocol. The driver reads the first 32-bit word of the BAR and logs the value. The value is whatever the `virtio-rnd` device's first register is (the first 32 bits of the `virtio` legacy device configuration, which for a running `virtio-rnd` device has no particular meaning to our driver). The point of the read is to prove that the BAR access works.

The code that does this (in `myfirst_pci_attach`, after the BAR allocation and the hardware layer attach):

```
uint32_t first_word;

MYFIRST_LOCK(sc);
first_word = CSR_READ_4(sc, 0x00);
MYFIRST_UNLOCK(sc);

device_printf(dev, "first register read: 0x%08x\n", first_word);
```

The lock-and-unlock wrapping is the Chapter 16 discipline. The read goes through `bus_space_read_4` under the hood. The output line appears in `dmesg` at attach time:

```
myfirst0: first register read: 0x10010000
```

The exact value depends on the `virtio-rnd` device's current state. A reader who sees any value (rather than a page fault or a garbage read that crashes the guest) has confirmed that the BAR allocation worked, the tag and handle are correct, and the accessor layer is operating on real silicon.

18.5.5 The Full Accessor Family

The Chapter 16 driver used `bus_space_read_4` and `bus_space_write_4` exclusively because the register map is all 32-bit registers. Real PCI devices sometimes need 8-bit, 16-bit, or 64-bit reads, and sometimes need block operations that read or write many contiguous registers at once. The `bus_space` family covers all of these:

- `bus_space_read_1, _2, _4, _8`: single-byte, 16-bit, 32-bit, or 64-bit read.
- `bus_space_write_1, _2, _4, _8`: single-byte, 16-bit, 32-bit, or 64-bit write.
- `bus_space_read_multi_*`: read multiple values from the same register offset (useful for FIFO reads).
- `bus_space_write_multi_*`: write multiple values to the same register offset.
- `bus_space_read_region_*`: read a range of registers into a memory buffer.
- `bus_space_write_region_*`: write a memory buffer to a range of registers.
- `bus_space_set_multi_*`: write the same value to the same register many times.
- `bus_space_set_region_*`: write the same value to a range of registers.
- `bus_space_barrier`: enforce ordering between accesses.

Each variant has the width suffix as a separate entry. The family is symmetrical and predictable once you have seen it.

For Chapter 18's driver, only `_4` is needed. The register map is 32-bit throughout. If a later driver uses a device with 16-bit registers, the reader simply changes `_4` to `_2`. The `CSR_*` macros can be extended to cover multiple widths if needed:

```
#define CSR_READ_1(sc, off)      myfirst_reg_read_1((sc), (off))
#define CSR_READ_2(sc, off)      myfirst_reg_read_2((sc), (off))
#define CSR_WRITE_1(sc, off, val) myfirst_reg_write_1((sc), (off), (val))
#define CSR_WRITE_2(sc, off, val) myfirst_reg_write_2((sc), (off), (val))
```

with corresponding accessor functions in `myfirst_hw.c`. Chapter 18 does not need these, but a driver author should know they exist.

18.5.6 `bus_space_read_multi` vs `bus_space_read_region`

Two of the block operations deserve a second look because the naming is easy to confuse.

`bus_space_read_multi_4(tag, handle, offset, buf, count)` reads `count` 32-bit values, all from the same offset in the BAR, into `buf`. This is the correct operation for a FIFO: the register at a fixed offset is the FIFO's read port, and each read consumes one entry. Writing a similar loop by hand with `bus_space_read_4` would work, but the block version is often faster and is clearer in intent.

`bus_space_read_region_4(tag, handle, offset, buf, count)` reads `count` 32-bit values from consecutive offsets starting at `offset`, into `buf`. This is the correct operation for a block of registers: the driver wants to snapshot a range of the register map into a local buffer. Writing a loop with `bus_space_read_4` and incrementing the offset would work equivalently; the block version expresses the intent more clearly.

The difference is whether the offset in the BAR advances. `_multi` keeps the offset fixed. `_region` advances it. Writing `_multi` when you meant `_region` reads the same register four times, not four different registers. This is a classic confusion, and the way to avoid it is to read the variant name carefully and to remember “multi = one port, many accesses” vs “region = a range of ports, one access each”.

18.5.7 When Barriers Matter

Chapter 16 introduced `bus_space_barrier(9)` as a guard against CPU reordering and compiler reordering around register accesses. The rule is: when the driver has an ordering requirement between two accesses (a write that must precede a read, for example, or a write that must precede another write), insert a barrier.

For Chapter 18's driver, the accessor layer already wraps a barrier around writes that have side effects (inside `myfirst_reg_write_barrier`, defined in Chapter 16). The simulation backend in Chapter 17 does not require additional barriers because the accesses are to RAM. The PCI backend may require barriers in more places than the simulation did, because real device memory has weaker ordering semantics than RAM on some architectures.

The common case on x86: `bus_space_write_4` to a memory-mapped BAR is strongly ordered with respect to other writes to the same BAR; no explicit barrier is needed. On arm64 with device-memory attributes, writes

to the same BAR are also ordered. On other architectures with weaker memory models, explicit barriers may be required. The `bus_space(9)` manual page specifies the default ordering guarantees per architecture; drivers that care about portability include barriers even where x86 would not require them.

Chapter 18's driver lives on x86 for teaching purposes and uses barriers the same way Chapter 16 did: after a CTRL write that has side effects (starts a command, triggers a state change, clears an interrupt). The Chapter 17 `myfirst_reg_write_barrier` helper is still the right entry point.

18.5.8 The Access Log on a Real BAR

Chapter 16's access log is a ring buffer that records every register access with a timestamp, an offset, a value, and a context tag. On the simulation backend the log shows patterns like “user-space write to CTRL, followed by a callout read of STATUS”. On the real PCI backend the log shows the same shape: any access the driver makes to the BAR passes through the accessors, and every accessor writes an entry.

This continuity is a quiet but important feature. A developer who debugs a simulation issue can consult the access log; a developer who debugs a real-hardware issue can consult the same access log. The technique transfers. The code does not change. Section 7's testing discipline depends on this continuity.

One note about the access log and real BARs: if the device sometimes takes side effects on reads (clearing a latched status bit, advancing a FIFO pointer, triggering a posted write completion), the log will record the read's value and the driver's subsequent actions. Reading the log can reveal timing problems that are not otherwise visible. A bug where the driver reads STATUS twice in rapid succession and the second read sees different bits because the first read's side effect interfered will show up clearly in the log. For Chapter 18 this does not matter yet; for Chapter 19 and later chapters it matters a great deal.

18.5.9 A Small Subtlety: the CSR Macros Do Not Know About PCI

Worth calling out. The `CSR_*` macros do not take a tag or a handle. They take only the `softc` and the offset. Everything else is inside the accessor functions.

This means: when the driver changes from the Chapter 17 simulation to the Chapter 18 real BAR, not one call site in the driver changes. `CSR_READ_4(sc, MYFIRST_REG_STATUS)` does the right thing before and after the transition. The same is true for `CSR_WRITE_4` and `CSR_UPDATE_4`.

The payoff is concrete. Chapter 17's driver has probably thirty or forty call sites that read or write registers through the CSR macros. If those macros took a tag and a handle, Chapter 18 would need to update every one. Because they take only the `softc`, Chapter 18 needs to change only the hardware layer's attach routine. The discipline of hiding the low-level details inside the accessors, introduced in Chapter 16 and maintained in Chapter 17, pays its largest dividend here.

This is a pattern worth remembering. When you write a driver, define a small set of accessor functions that hide everything above the register level: the tag, the handle, the lock, the log, the barrier. Expose to the rest of the driver only the `softc` and the offset. The code that uses the accessors then does not care whether the registers are simulated, real PCI, real USB, real I2C, or real anything else. The abstraction holds across a wide range of transports. Part 7 of the book will return to this theme when it discusses refactoring drivers for portability; Chapter 18 is where the reader first sees the dividend paid.

18.5.10 Stage 2 to Stage 3: Wiring It Together

The Stage 2 attach allocated the BAR but did not hand it to the hardware layer. Stage 3's attach does both. The relevant code is the full attach:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error;

    sc->dev = dev;
    error = myfirst_init_softc(sc); /* Ch10-15: locks, softc fields */
    if (error != 0)
        return (error);

    /* Allocate BAR0. */
    sc->bar_rid = PCIR_BAR(0);
    sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &sc->bar_rid, RF_ACTIVE);
    if (sc->bar_res == NULL) {
        device_printf(dev, "cannot allocate BAR0\n");
        error = ENXIO;
        goto fail_softc;
    }

    /* Hand the BAR to the hardware layer. */
    error = myfirst_hw_attach_pci(sc, sc->bar_res,
        rman_get_size(sc->bar_res));
    if (error != 0)
        goto fail_release;

    /* Read a diagnostic word from the BAR. */
    MYFIRST_LOCK(sc);
    sc->bar_first_word = CSR_READ_4(sc, 0x00);
    MYFIRST_UNLOCK(sc);
    device_printf(dev, "BAR[0x00] = 0x%08x\n", sc->bar_first_word);

    sc->pci_attached = true;
    return (0);

fail_release:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail_softc:
```

```
    myfirst_deinit_softc(sc);  
    return (error);  
}
```

And the matching detach:

```
static int  
myfirst_pci_detach(device_t dev)  
{  
    struct myfirst_softc *sc = device_get_softc(dev);  
  
    sc->pci_attached = false;  
    myfirst_hw_detach(sc);  
    if (sc->bar_res != NULL) {  
        bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,  
                             sc->bar_res);  
        sc->bar_res = NULL;  
    }  
    myfirst_deinit_softc(sc);  
    device_printf(dev, "detaching\n");  
    return (0);  
}
```

The attach sequence is strict: init the softc (locks, fields), allocate the BAR, attach the hardware layer against the BAR, perform any register reads that attach needs, mark the driver as attached. The detach undoes each step in reverse: mark as unattached, detach the hardware layer (which frees its wrapper struct), release the BAR, deinit the softc.

Section 5 will extend the attach with additional PCI-specific steps: enabling bus mastering, walking the capability list, reading a subvendor-specific field from configuration space. The shape of the attach stays the same; the middle grows.

18.5.11 Common Mistakes in the bus_space-on-PCI Transition

A short list of traps.

Casting the resource pointer instead of using `rman_get_bustag` / `rman_get_bushandle`. A beginner sometimes writes `hw->regs_tag = (bus_space_tag_t)bar`. This does not compile on most architectures and compiles to nonsense on the rest. Use the accessors.

Confusing the resource handle with the tag. The tag is the bus identity (memory or I/O); the handle is the address. `rman_get_bustag` returns the tag; `rman_get_bushandle` returns the handle. Swapping them produces immediate crashes or silent wrong reads. Read the function names carefully.

Not zeroing the hardware state on PCI attach. `malloc(9)` with `M_ZERO` clears the structure. Without `M_ZERO`, fields like `access_log_head` start with garbage. The ring buffer wraps to an arbitrary index and the log is unreadable.

Not releasing the hardware state in detach. A symmetry mistake: the PCI detach releases the BAR but forgets to call `myfirst_hw_detach`. The hardware wrapper struct leaks. `vmstat -m` shows the leak over time.

Reading the BAR before the lock is held. The Chapter 16 discipline is: every CSR access is under `sc->mtx`. Reading at attach time without the lock violates the invariant that every later access assumes. Even if it happens to work on a single CPU, WITNESS on a debug kernel will complain. Take the lock even for the attach-time reads.

Accidentally writing to a read-only register. On the simulation backend, writes to a read-only register just update the `malloc`-allocated buffer (the simulation's read side ignores the write and returns the fixed value). On real PCI, writes to a read-only register are either silently ignored or cause some device-specific side effect. Neither case is what the driver author expects. Read the datasheet and write to writeable registers only.

Calling `bus_space_read_multi_4` when the driver meant `_region_4`. The two functions have identical signatures and very different semantics. Reading a range of registers with `_multi` fills the buffer with the same value (the fixed offset's current value) repeated count times. Reading a range with `_region` fills the buffer with the consecutive register values. The bug is silent until the values are inspected.

18.5.12 Wrapping Up Section 4

The Chapter 16 accessor layer is unchanged by the transition from simulated to real PCI registers. The only change is in `myfirst_hw_attach_pci`, which replaces the `malloc(9)` backing buffer with a tag and handle produced by `rman_get_bustag(9)` and `rman_get_bushandle(9)` on the PCI-allocated resource. The `CSR_*` macros, the access log, the lock discipline, the ticker task, and every other part of the Chapter 16 and Chapter 17 code base continue to work without modification.

The driver's first real PCI register read happens at attach time. The value read is not meaningful in the virtio-rnd protocol sense; it is proof that the BAR mapping is live and the accessors are reading real silicon. Section 5 takes the attach sequence further: it introduces `pci_enable_busmaster(9)` (for future DMA use), walks the PCI capability list with `pci_find_cap(9)` and `pci_find_extcap(9)`, explains when a driver reads configuration-space fields directly, and shows how the Chapter 17 simulation is kept inactive on the PCI path so its callouts do not write arbitrary values into the real device's registers.

18.6 Section 5: Driver Attach-Time Initialisation

Sections 2 through 4 built the attach routine from nothing to a fully wired PCI attach that claims a BAR, hands it to the hardware layer, and performs its first register access. Section 5 finishes the attach story. It introduces the handful of configuration-space operations a PCI driver typically performs at attach, explains when and why each is needed, walks the PCI capability list to discover the device's optional features, shows how the Chapter 17 simulation is kept inactive on the PCI path (so its callouts do not write into the real device), and creates the `cdev` that the Chapter 10 driver already exposed.

By the end of Section 5, the driver is complete as a PCI driver. It attaches to the real device, brings the device to a state where the driver can use it, exposes the same user-space interface the Chapter 10 through 17 iterations exposed, and is ready to be extended in Chapter 19 with a real interrupt handler.

18.6.1 The Attach-Time Checklist

A working PCI driver's attach routine typically performs, in roughly this order:

1. **Initialise the softc.** Set `sc->dev`, initialise locks, initialise conditions and callouts, clear counters.
2. **Allocate resources.** Claim the BAR (or BARs), claim the IRQ resource (in Chapter 19), and any other bus resources.
3. **Activate device features.** Enable bus mastering if the driver will use DMA. Set up configuration-space bits the device needs.
4. **Walk capabilities.** Find PCI capabilities the driver supports and record their register offsets.
5. **Attach the hardware layer.** Hand the BAR to the accessor layer.
6. **Initialise the device.** Perform the device-specific bring-up sequence: reset, feature negotiation, queue setup. This is whatever the device's datasheet says is required to make the device usable.
7. **Register user-space interfaces.** Create `cdevs`, network interfaces, or whatever the driver exposes.
8. **Enable interrupts.** Register the interrupt handler (Chapter 19) and unmask interrupts in the device's `INTR_MASK` register.
9. **Mark the driver as attached.** Set a flag that other code can check.

Not every driver does every step. A driver for a passive device (no DMA, no interrupts, just reads and writes) skips bus mastering and interrupt setup. A driver for a device that does not need a user-space interface skips the `cdev` creation. But the order is stable: resources first, device features second, hardware layer third, device bring-up fourth, user-space fifth, interrupts last. Doing this out of order produces race conditions where an interrupt arrives before the driver is ready to handle it, or where a user-space access reaches a partially-initialised driver.

Chapter 18's driver performs steps 1 through 7. Step 8 is Chapter 19. Step 9 is a detail the driver already handled in Chapter 10.

18.6.2 `pci_enable_busmaster` and the Command Register

The PCI command register lives at configuration-space offset `PCIR_COMMAND` (`0x04`), as a 16-bit field. Three bits in that register matter for most drivers:

- `PCIM_CMD_MEMEN` (`0x0002`): enable the device's memory BARs. Must be set before the driver can read or write any memory BAR.
- `PCIM_CMD_PORTEN` (`0x0001`): enable the device's I/O port BARs. Must be set before the driver can read or write any I/O port BAR.
- `PCIM_CMD_BUSMASTEREN` (`0x0004`): enable the device to initiate DMA as a bus master. Must be set before the device can read or write RAM on its own.

The PCI bus driver sets `MEMEN` and `PORTEN` automatically when it activates a BAR. A driver that has successfully called `bus_alloc_resource_any` with `RF_ACTIVE` and has received a non-NULL result does not need to set these bits by hand; the bus driver has already done so.

`BUSMASTEREN` is different. The bus driver does not set it automatically, because not every driver needs DMA. A driver that will program its device to read or write system RAM (a NIC, a storage controller, a GPU) must set `BUSMASTEREN` explicitly. A driver that only reads and writes the device's own BARs (no DMA) does not need to set it.

The helper `pci_enable_busmaster(dev)` sets the bit. Its inverse, `pci_disable_busmaster(dev)`, clears it. Chapter 18's driver does not use DMA and does not call `pci_enable_busmaster`. Chapter 20 and Chapter 21 will.

A note about reading the command register directly. The driver can always read the command register with `pci_read_config(dev, PCIR_COMMAND, 2)` and inspect individual bits. For most drivers this is unnecessary; the kernel has already configured the relevant bits. For diagnostic purposes (a driver that wants to log the device's command register state at attach), it is fine.

18.6.3 Reading Configuration-Space Fields

Most drivers need to read at least a handful of configuration-space fields that the generic accessors do not cover. Examples include:

- Specific firmware revision numbers at vendor-specific offsets.
- PCIe link status fields inside the PCIe capability structure.
- Vendor-specific capability data.
- Subsystem-specific identification fields for multi-function devices.

The primitive is `pci_read_config(dev, offset, width)`. Offset is a byte offset into configuration space. Width is 1, 2, or 4 bytes. The return value is a `uint32_t` (narrower widths are right-aligned).

A concrete example. The PCI class code occupies bytes 0x09 through 0x0b in configuration space:

- Byte 0x09: programming interface (progIF).
- Byte 0x0a: subclass.
- Byte 0x0b: class.

Reading all three at once as a 32-bit value gives the class, subclass, and progIF in the top three bytes (the low byte is the revision ID). The cached accessors `pci_get_class`, `pci_get_subclass`, `pci_get_progif`, and `pci_get_revid` extract each field individually; the driver rarely needs to do this by hand.

For vendor-specific fields the driver must read by hand. The pattern is:

```
uint32_t fw_rev = pci_read_config(dev, 0x48, 4);
device_printf(dev, "firmware revision 0x%08x\n", fw_rev);
```

The offset 0x48 is a placeholder; the real offset is whatever the device's datasheet specifies. Reading from an offset the device does not implement returns 0xffffffff or a device-specific default; 0xffffffff is the classic "no device" value on PCI.

18.6.4 pci_write_config and the Side-Effect Contract

The counterpart is `pci_write_config(dev, offset, value, width)`. It writes `value` to the configuration-space field at `offset`, truncated to `width` bytes.

A critical point about configuration-space writes: some fields are read-only. Writing to a read-only field is either silently ignored (the common case) or causes a device-specific error. The driver must know, from the PCI specification or from the device's datasheet, which fields are writeable before issuing a write.

A second critical point: some fields have side effects on read or write. The command register, for example, has side effects: setting `MEMEN` enables memory BARs; clearing it disables them. Reading the command register has no side effects. The driver must understand the semantics of each field it touches.

The helper `pci_enable_busmaster` uses `pci_write_config` under the hood to set one bit. The driver can always use `pci_read_config` and `pci_write_config` directly to manipulate a field when a specific helper does not exist.

18.6.5 `pci_find_cap`: Walking the Capability List

PCI devices advertise optional features through a linked list of capabilities. Each capability is a small block in configuration space, beginning with a one-byte capability ID and a one-byte “next pointer”. The list starts at the offset stored in the device’s `PCIR_CAP_PTR` field (configuration-space offset 0x34) and follows the next pointers until a 0 terminates the chain.

Standard capabilities a driver might find include:

- `PCIY_PMG` (0x01): Power Management.
- `PCIY_MSI` (0x05): Message Signaled Interrupts.
- `PCIY_EXPRESS` (0x10): PCI Express. Any PCIe device has this.
- `PCIY_MSIX` (0x11): MSI-X. A richer interrupt routing mechanism than MSI.
- `PCIY_VENDOR` (0x09): vendor-specific capability.

The driver walks the list through `pci_find_cap(9)`:

```
int capreg;

if (pci_find_cap(dev, PCIY_EXPRESS, &capreg) == 0) {
    device_printf(dev, "PCIe capability at offset 0x%x\n", capreg);
}
if (pci_find_cap(dev, PCIY_MSI, &capreg) == 0) {
    device_printf(dev, "MSI capability at offset 0x%x\n", capreg);
}
if (pci_find_cap(dev, PCIY_MSIX, &capreg) == 0) {
    device_printf(dev, "MSI-X capability at offset 0x%x\n", capreg);
}
```

The function returns 0 on success and stores the capability’s offset in `*capreg`. On failure (the capability is not present) it returns `ENOENT` and does not modify `*capreg`.

The offset returned is the byte offset into configuration space where the capability’s first register lives. That register is usually the capability ID itself; the driver can confirm by reading it back and checking against the expected ID. Subsequent bytes in the capability define the feature-specific fields.

Chapter 18’s driver walks the capability list at attach time and logs which capabilities are present. The list gives the driver author a sense of what the device offers. MSI and MSI-X are relevant for Chapter 20; Power Management is relevant for Chapter 22. At Chapter 18, the driver simply records the presence and the offsets.

18.6.6 pci_find_extcap: PCIe Extended Capabilities

PCIe introduces a second list, called extended capabilities, that lives above offset 0x100 in configuration space. This is where modern features like Advanced Error Reporting, Virtual Channel, Access Control Services, and SR-IOV live. The list is structurally similar to the legacy capability list but uses 16-bit IDs and 4-byte offsets.

The walker is `pci_find_extcap(9)`. The signature is identical to `pci_find_cap`:

```
int capreg;

if (pci_find_extcap(dev, PCIZ_AER, &capreg) == 0) {
    device_printf(dev, "AER capability at offset 0x%x\n", capreg);
}
```

Extended capability IDs are defined in `/usr/src/sys/dev/pci/pci.h` under names that start with `PCIZ_` (as opposed to `PCIY_` for standard capabilities). The prefix is a mnemonic: `PCIY` for “PCI capabilitY” (the older list), `PCIZ` for “PCI eXtended” (Z comes after Y).

Chapter 18’s driver does not subscribe to AER or any other extended capability. It walks the extended list at attach time and logs what it finds, the same way it walks the standard list. This serves two purposes: it gives the reader a view of what PCIe capabilities look like in the wild, and it exercises `pci_find_extcap` so the reader has seen both walkers.

18.6.7 PCIe AER: An Introduction

Advanced Error Reporting (AER) is a PCIe extended capability that lets the system detect and report certain classes of PCI-level errors: uncorrectable transaction errors, correctable errors, malformed TLPs, completion timeouts, and others. The capability is optional; not every PCIe device implements it.

On FreeBSD the PCI bus driver (`pci(4)`, implemented in `/usr/src/sys/dev/pci/pci.c`) walks each device’s extended capability list during probe, locates the AER capability when present, and uses it for system-level error logging. A driver does not normally register its own AER callback; the bus handles AER centrally and logs correctable and uncorrectable errors into the kernel message buffer. A driver that wants custom handling reads the AER status registers through `pci_read_config(9)` at the offset returned by `pci_find_extcap(dev, PCIZ_AER, &offset)` and decodes them against the bit layouts in `/usr/src/sys/dev/pci/pci.h`.

For Chapter 18’s driver, AER is mentioned to complete the PCIe capability picture. The driver does not subscribe to AER events. Chapter 20 picks the topic up again, in its “PCIe AER recovery through MSI-X vectors” discussion, to explain where a driver-owned AER handler would hook into the MSI-X plumbing the interrupt chapters build. A full, end-to-end AER recovery implementation is beyond the scope of this book; readers who want to follow the bus-centric side all the way through can study `pci_add_child_clear_aer` and `pcie_apei_error` in `/usr/src/sys/dev/pci/pci.c`, together with the `PCIR_AER_*` and `PCIM_AER_*` bit layouts in `/usr/src/sys/dev/pci/pci.h`.

A short aside on the naming: “AER” is pronounced letter by letter (“ay-ee-ar”) in most FreeBSD conversations. The capability ID in the `pci.h` header is `PCIZ_AER = 0x0001`.

18.6.8 Composing the Simulation with the Real PCI Backend

The driver at Chapter 17 Stage 5 attached to the kernel as a standalone module (`kldload myfirst` triggered the attach). Chapter 18's driver attaches to a PCI device. Both attach paths need to set up the same upper-layer state (`softc`, `cdev`, some per-instance fields). The question is how to compose them.

Chapter 18's driver solves this with a single compile-time switch that selects which attach paths are active, and by having the Chapter 17 simulation's callouts **not** run when the driver is bound to a real PCI device. The logic is straightforward:

- If `MYFIRST_SIMULATION_ONLY` is defined at build time, the driver omits `DRIVER_MODULE` entirely. There is no PCI attach; the module behaves exactly like the Chapter 17 driver, and `kldload` spawns one simulated instance through the Chapter 17 module-event handler.
- If `MYFIRST_SIMULATION_ONLY` is **not** defined (the default for Chapter 18), the driver declares `DRIVER_MODULE(myfirst, pci, ...)`. The module is loadable. When a matching PCI device exists, `myfirst_pci_attach` runs. The Chapter 17 simulation callouts are not started on the PCI path; the accessor layer points at the real BAR, and the simulation backend stays idle. A reader who wants simulation re-activates it explicitly through a `sysctl` or by building with `MYFIRST_SIMULATION_ONLY`.

The compile-time guard in `myfirst_pci.c` is short:

```
#ifndef MYFIRST_SIMULATION_ONLY
DRIVER_MODULE(myfirst, pci, myfirst_pci_driver, NULL, NULL);
MODULE_DEPEND(myfirst, pci, 1, 1, 1);
#endif
```

And `myfirst_pci_attach` deliberately skips `myfirst_sim_enable(sc)`. The Chapter 17 sensor callout, command callout, and fault-injection machinery stay asleep. They are present in the code but never scheduled when the backend is a real PCI BAR; that keeps writes from the simulated `CTRL.GO` bit out of the real device's registers.

A reader on a host without a matching PCI device still has the option of running the Chapter 17 simulation directly: build with `MYFIRST_SIMULATION_ONLY=1`, `kldload`, and the driver behaves exactly as it did at the end of Chapter 17. The two builds share every file; the selection happens at compile time.

An alternative the reader may choose: split the driver into two modules. `myfirst_core.ko` holds the hardware layer, the simulation, the `cdev`, and the locks. `myfirst_pci.ko` holds the PCI attach. `myfirst_core.ko` is always loadable and provides the simulation. `myfirst_pci.ko` depends on `myfirst_core.ko` and adds PCI support on top.

This is the approach real FreeBSD drivers use when a chipset has multiple transport variants. The `uart(4)` driver has `uart.ko` as the core and `uart_bus_pci.ko` as the PCI attach; `virtio(4)` has `virtio.ko` as the core and `virtio_pci.ko` as the PCI transport. The book's later chapter on multi-transport drivers returns to this pattern.

For Chapter 18 the simpler approach (one module with a compile-time switch) is enough. A reader who wants to practise the split can try it as a challenge at the end of the chapter.

18.6.9 Why the Simulation Callouts Stay Silent on Real PCI

A note worth making explicit. When the Chapter 18 driver attaches to a real virtio-rnd device, the BAR does not hold the Chapter 17 register map. Offset 0x00 is the virtio legacy device-features register, not CTRL. Offset 0x12 is the virtio device_status register, not the Chapter 17 INTR_STATUS. Letting the Chapter 17 sensor callout write to SENSOR_CONFIG (at Chapter 17 offset 0x2c) or letting the command callout write to CTRL at 0x00 would poke arbitrary bytes into the virtio device's registers.

On a bhyve guest this is not catastrophic (the guest is disposable), but it is poor discipline. The correct behaviour is: the simulation callouts run only when the accessor layer is backed by the simulated buffer. When the accessor layer is backed by a real BAR, the simulation stays off. Chapter 18's `myfirst_pci_attach` enforces this by never calling `myfirst_sim_enable`. The cdev still works, `CSR_READ_4` still reads the real BAR, and the rest of the driver operates normally. The callouts simply do not fire.

This is a small design decision with a real consequence: the driver is safe to attach against a real PCI device without corrupting the device's state. A reader who later adapts the driver to a different device (whose register map the Chapter 17 simulation does match) can re-enable the callouts with a `sysctl` and watch them drive the real silicon. For the virtio-rnd teaching target, the callouts stay asleep.

18.6.10 Creating the cdev in a PCI Driver

The Chapter 10 driver created a cdev with `make_dev(9)` at module-load time. In the Chapter 18 PCI driver, `make_dev(9)` runs at attach time, once per PCI device. The name of the cdev incorporates the unit number: `/dev/myfirst0`, `/dev/myfirst1`, and so on.

The code is familiar:

```
sc->cdev = make_dev(&myfirst_cdevsw, device_get_unit(dev), UID_ROOT,
    GID_WHEEL, 0600, "myfirst%d", device_get_unit(dev));
if (sc->cdev == NULL) {
    error = ENXIO;
    goto fail_hw;
}
sc->cdev->si_drv1 = sc;
```

`device_get_unit(dev)` returns the unit number newbus assigned. "myfirst%d" with that unit number as the argument produces the per-instance device name. The `si_drv1` assignment lets the cdev's open, close, read, write, and `ioctl` entry points recover the_softc from the cdev.

The detach path destroys the cdev with `destroy_dev(9)`:

```
if (sc->cdev != NULL) {
    destroy_dev(sc->cdev);
    sc->cdev = NULL;
}
```

This code is entirely the Chapter 10 pattern; nothing about it is new. The point of including it here is that it fits naturally into the PCI attach ordering: softc, BAR, hardware layer, cdev, and (later in Chapter 19) interrupts. Reverse the order in detach. Done.

18.6.11 A Full Stage 3 Attach

Combining every piece of Section 5, the Stage 3 attach:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error, capreg;

    sc->dev = dev;
    sc->unit = device_get_unit(dev);
    error = myfirst_init_softc(sc);
    if (error != 0)
        return (error);

    /* Step 1: allocate BAR0. */
    sc->bar_rid = PCIR_BAR(0);
    sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &sc->bar_rid, RF_ACTIVE);
    if (sc->bar_res == NULL) {
        device_printf(dev, "cannot allocate BAR0\n");
        error = ENXIO;
        goto fail_softc;
    }

    /* Step 2: walk PCI capabilities (informational). */
    if (pci_find_cap(dev, PCIY_EXPRESS, &capreg) == 0)
        device_printf(dev, "PCIe capability at 0x%x\n", capreg);
    if (pci_find_cap(dev, PCIY_MSI, &capreg) == 0)
        device_printf(dev, "MSI capability at 0x%x\n", capreg);
    if (pci_find_cap(dev, PCIY_MSIX, &capreg) == 0)
        device_printf(dev, "MSI-X capability at 0x%x\n", capreg);
    if (pci_find_cap(dev, PCIY_PMG, &capreg) == 0)
        device_printf(dev, "Power Management capability at 0x%x\n",
            capreg);
    if (pci_find_extcap(dev, PCIZ_AER, &capreg) == 0)
        device_printf(dev, "PCIe AER extended capability at 0x%x\n",
            capreg);

    /* Step 3: attach the hardware layer against the BAR. */
}
```

```

    error = myfirst_hw_attach_pci(sc, sc->bar_res,
        rman_get_size(sc->bar_res));
    if (error != 0)
        goto fail_release;

    /* Step 4: create the cdev. */
    sc->cdev = make_dev(&myfirst_cdevsw, sc->unit, UID_ROOT,
        GID_WHEEL, 0600, "myfirst%d", sc->unit);
    if (sc->cdev == NULL) {
        error = ENXIO;
        goto fail_hw;
    }
    sc->cdev->si_drv1 = sc;

    /* Step 5: read a diagnostic word. */
    MYFIRST_LOCK(sc);
    sc->bar_first_word = CSR_READ_4(sc, 0x00);
    MYFIRST_UNLOCK(sc);
    device_printf(dev, "BAR[0x00] = 0x%08x\n", sc->bar_first_word);

    sc->pci_attached = true;
    return (0);

fail_hw:
    myfirst_hw_detach(sc);
fail_release:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail_softc:
    myfirst_deinit_softc(sc);
    return (error);
}

```

The structure is exactly the attach-time checklist from the start of this section, with labels (Step 1, Step 2, etc.) making the order explicit. The goto cascade handles partial failure cleanly. Each fail label undoes the step that succeeded most recently, chaining down to the one before it.

A reader who has seen this pattern before (in Chapter 15's complex attach with multiple primitives, or in any FreeBSD driver that allocates more than one resource) will recognise it immediately. A reader who is seeing it for the first time may benefit from tracing through a hypothetical failure at each step and verifying that the right amount of cleanup happens.

18.6.12 Verifying Stage 3

The expected dmesg output at Stage 3 attach:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0:          subvendor=0x1af4 subdevice=0x0004 class=0xff
myfirst0: PCIe capability at 0x98
myfirst0: MSI-X capability at 0xa0
myfirst0: hardware layer attached to BAR: 32 bytes (tag=0x... handle=0x...)
myfirst0: BAR[0x00] = 0x10010000
```

The exact capability offsets depend on the guest's virtio implementation; the values shown are indicative. A reader who sees all four lines (attach, capabilities walked, hardware attached, BAR read) has confirmed that Stage 3 is complete.

`ls /dev/myfirst*` should show `/dev/myfirst0`. A user-space program that opens that device, writes a byte, and reads a byte should see the Chapter 17 simulation path in action (the command-response protocol still runs under the surface, even though the BAR is now real; Chapter 17 and Chapter 18 do not interact at the data-path level yet, they only share the accessor layer).

Detach verifies the reverse:

```
myfirst0: detaching
```

And `/dev/myfirst0` disappears. The BAR is released. The softc is freed. No leaks, no warnings, no stuck state.

18.6.13 Wrapping Up Section 5

Attach-time initialisation is the composition of many small steps. Each step allocates or configures one thing. The steps go in a strict order that builds the driver's state from the device outward: resources first, then features, then device-specific bring-up, then user-space interfaces, then (in Chapter 19) interrupts. The detach path undoes each step in reverse.

The PCI-specific pieces Chapter 18 adds to this pattern are `pci_enable_busmaster` (not needed for our driver, reserved for Chapters 20 and 21), the capability walkers `pci_find_cap(9)` and `pci_find_extcap(9)`, configuration-space reads and writes via `pci_read_config(9)` and `pci_write_config(9)`, and a brief introduction to PCIe AER that the reader will return to in later chapters.

Section 6 covers the detach side in depth. The broad strokes are familiar, but the details (handling partial attach failure, the order of teardown, interactions with callouts and tasks that might still be running) deserve their own section.

18.7 Section 6: Supporting Detach and Resource Cleanup

Attach brings the driver up. Detach takes it down. The two paths are mirrors, but not perfectly symmetric mirrors. Detach has a few concerns attach does not: the possibility that other code is still running (callouts, tasks, file descriptors, interrupt handlers), the need to refuse detach when the driver has work the caller has not

quiesced, and the care to avoid use-after-free between the last live access and the freeing of the softc. Section 6 is about getting those concerns right.

The goal of Section 6 is a detach routine that is strict, complete, and easy to audit. It releases every resource attach claimed. It drains every callout and task that might still be running. It destroys the cdev before freeing the hardware layer. It releases the BAR after the hardware layer no longer needs it. And it does all of this in a way that the book's readers can read and understand one step at a time.

18.7.1 The Core Rule: Reverse Order

The single most important discipline for detach is reverse order. Every step attach took, detach undoes in the inverse sequence. If attach allocated A, then B, then C, then detach releases C, then B, then A.

This rule sounds trivial. In practice, forgetting it or getting the order slightly wrong is one of the most common causes of kernel panics in new drivers. The typical symptom: a callout fires during detach, reads from a softc field, and the field is already freed. Or: the cdev still exists when the BAR is released, and a user-space process that has the cdev open triggers a read that dereferences an unmapped address.

The Chapter 15 detach pattern is the right model for Chapter 18. Attach built state outward from the device; detach tears it down inward toward the device. Nothing the detach frees can still be in use by anything else.

18.7.2 The Chapter 18 Detach Ordering

The detach order, matching Stage 3's attach:

1. Mark the driver as no longer attached (`sc->pci_attached = false`).
2. Cancel any user-space access paths: destroy the cdev so no new open or ioctl can start, accept no new requests.
3. Drain callouts and tasks that might be running (`myfirst_quiesce`).
4. Detach the simulation backend if it was attached (frees `sc->sim`). On the PCI path this is a no-op because the simulation was not attached.
5. Detach the hardware layer (frees `sc->hw`; does not release the BAR).
6. Release the BAR resource through `bus_release_resource`.
7. Tear down the softc state: destroy locks, destroy condition variables, free any allocated memory.
8. (Chapter 19's addition, mentioned for completeness) Release the IRQ resource.

For Chapter 18 the detach is:

```
static int
myfirst_pci_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Refuse detach if something is still using the device. */
    if (myfirst_is_busy(sc))
        return (EBUSY);
}
```

```

sc->pci_attached = false;

/* Tear down the cdev so no new user-space accesses start. */
if (sc->cdev != NULL) {
    destroy_dev(sc->cdev);
    sc->cdev = NULL;
}

/* Drain callouts and tasks. Safe whether or not the simulation
 * was ever enabled on this instance. */
myfirst_quiesce(sc);

/* Release the simulation backend if it was attached. The PCI
 * path leaves sc->sim == NULL, so this is a no-op. */
if (sc->sim != NULL)
    myfirst_sim_detach(sc);

/* Detach the hardware layer (frees the wrapper struct). */
myfirst_hw_detach(sc);

/* Release the BAR. */
if (sc->bar_res != NULL) {
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,
        sc->bar_res);
    sc->bar_res = NULL;
}

/* Tear down the softc state. */
myfirst_deinit_softc(sc);

device_printf(dev, "detached\n");
return (0);
}

```

The code is longer than the Stage 2 detach because each step is its own concern. The structure is easy to read: each line or block releases one thing, in reverse order of attach. A reader auditing the detach can check each step against the attach and confirm the symmetry.

18.7.3 myfirst_is_busy: When to Refuse Detach

A driver that has an open cdev, an in-flight command, or any other in-progress work cannot safely detach. Returning EBUSY from detach tells the kernel's module loader to leave the driver alone.

The Chapter 10 through 15 driver had a simple busy check: are there any open file descriptors on the cdev? Chapter 17 extended it to include in-flight simulated commands. Chapter 18 reuses the same check:

```
static bool
myfirst_is_busy(struct myfirst_softc *sc)
{
    bool busy;

    MYFIRST_LOCK(sc);
    busy = (sc->open_count > 0) || sc->command_in_flight;
    MYFIRST_UNLOCK(sc);
    return (busy);
}
```

The check is under the lock because `open_count` and `command_in_flight` can be modified by other code paths (the `cdev`'s `open` and `close` entry points, the Chapter 17 command callout). Without the lock the check might see an inconsistent view, and the decision to refuse or allow detach would race against an in-progress open or close. The exact field names come from the Chapter 10 `softc` (`open_count`) and the Chapter 17 additions (`command_in_flight`); a reader whose `softc` uses different names substitutes the local names here.

Returning `EBUSY` from `detach` produces a visible error on `kldunload`:

```
# kldunload myfirst
kldunload: can't unload file: Device busy
```

The user then closes the open file descriptor, cancels the in-flight command, or does whatever else is needed to drain the busy state, and retries. This is the expected behaviour; a driver that never refuses detach is a driver that can be torn out from under its users.

18.7.4 Quiescing Callouts and Tasks

The Chapter 17 simulation runs a sensor callout every second; a command callout fires per command; a busy-recovery callout fires occasionally. The Chapter 16 hardware layer runs a ticker task through a taskqueue. On the PCI backend the simulation callouts are not enabled (as Section 5 explained), so their `callout_drain` is a safe no-op if they never ran. The hardware-layer ticker task is still active and must be drained.

The right primitive for callouts is `callout_drain(9)`. It waits until the callout is not running and prevents any future firings. The right primitive for tasks is `taskqueue_drain(9)`. It waits until the task has finished running and prevents any further enqueues.

The Chapter 17 API exposes two functions that wrap the callout lifecycle for the simulation: `myfirst_sim_disable(sc)` stops scheduling new firings (it requires `sc->mtx` held), and `myfirst_sim_detach(sc)` drains every callout and frees the simulation state (it must not hold `sc->mtx`). A single `myfirst_quiesce` helper in the PCI driver composes them safely:

```
static void
myfirst_quiesce(struct myfirst_softc *sc)
{
```

```
if (sc->sim != NULL) {
    MYFIRST_LOCK(sc);
    myfirst_sim_disable(sc);
    MYFIRST_UNLOCK(sc);
}

if (sc->tq != NULL && sc->hw != NULL)
    taskqueue_drain(sc->tq, &sc->hw->reg_ticker_task);
}
```

On the PCI path `sc->sim` is `NULL` (the simulation backend is not attached), so the first block is skipped entirely. On a simulation-only build where the simulation is attached, `myfirst_sim_disable` stops the callouts under the lock, and the subsequent `myfirst_sim_detach` (called later in the detach sequence) drains them without the lock.

The split matters because `callout_drain` must be called **without** `sc->mtx` held: the callout body itself may try to acquire the mutex, and holding it would deadlock. Chapter 13 taught this discipline; Chapter 18 respects it by routing the drain through `myfirst_sim_detach`, which acquires no locks.

After `myfirst_quiesce` returns, nothing else is running against the softc except the detach path itself. The subsequent teardown steps can touch `sc->hw` and the BAR without fear.

18.7.5 Releasing the BAR After the Hardware Layer

The order matters. `myfirst_hw_detach` is called before `bus_release_resource` because `myfirst_hw_detach` still needs the tag and handle to be valid (for example, if there were any last-chance reads during the hardware teardown; the Chapter 18 version does not do such reads, but defensive code keeps the order in case a later extension adds them).

After `myfirst_hw_detach` returns, `sc->hw` is `NULL`. The tag and handle stored in the (now-freed) `myfirst_hw` struct are gone. No code in the driver can read or write the BAR from this point onward. The BAR can then be released safely.

If the order were reversed (release BAR first, then `myfirst_hw_detach`), the hardware teardown code would hold a stale tag and handle; any access would be a use-after-free. On x86 the bug might be silent; on architectures with stricter memory permissions the access would page-fault.

18.7.6 Failures During Detach

Unlike attach, detach is generally expected to succeed. The kernel's unload path calls detach; if detach returns non-zero, the unload aborts, but detach itself should not leave resources in an inconsistent state. The convention is that detach returns 0 (success) or `EBUSY` (refuse the unload because the driver is in use). Returning any other error is unusual and typically indicates a driver bug.

If a resource release fails (for example, `bus_release_resource` returns an error), the driver should log the failure but continue the detach. Leaving a partially-freed state is worse than logging and continuing; the kernel will complain about the leaked resource at shutdown, but the driver will not have crashed. Chapter 18's driver

does not check the return value of `bus_release_resource` for this reason; the release either succeeds or leaves an unrecoverable kernel state, neither of which the driver can do anything about.

18.7.7 Detach vs Module Unload vs Device Removal

Three different events can trigger detach.

Module unload (`kldunload myfirst`): the user asks to remove the module. The kernel's unload path calls detach on every device bound to the module, one at a time. If every detach returns 0, the module is unloaded. If any detach returns non-zero, the module stays loaded and the unload returns an error.

Device removal by user (`devctl detach myfirst0`): the user asks to detach a specific device from its driver, without unloading the module. The driver's detach runs for that one device; the module stays loaded and can still attach to other devices.

Device removal by hardware (hotplug, such as removing a PCIe card from a hot-plug-capable slot, or the hypervisor removing a virtual device): the PCI bus detects the change and calls detach on the device. The driver's detach runs. If the device is later re-inserted, the driver's probe and attach run again.

All three paths run the same `myfirst_pci_detach` function. The driver does not need to distinguish them. The code is the same because the obligations are the same: release everything attach allocated.

18.7.8 Partial-Attach Failure and the Detach Path

A subtle case worth explaining. If attach fails partway through and returns an error, the kernel does not (in modern newbus) call detach on the partially-attached driver. The driver's own goto cascade handles the cleanup.

The attach code from Section 5 has a goto cascade that undoes exactly the steps that succeeded. If the cdev creation fails after the hardware layer attach, the cascade releases the hardware layer and the BAR before returning. If the hardware layer attach fails after the BAR allocation, the cascade releases the BAR before returning. Each fail label undoes one step.

A common beginner mistake is to write a goto cascade that skips steps. For example:

```
fail_hw:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
fail_softc:
    myfirst_deinit_softc(sc);
    return (error);
```

This skips the `myfirst_hw_detach` step. If the hardware layer attach succeeded but the cdev creation failed, the cascade frees the BAR without tearing down the hardware layer, leaking the hardware layer's wrapper struct. The right cascade calls every unwind step the successful attach would have needed to unwind.

A technique some drivers use: arrange the attach as a sequence of `myfirst_init_*` helpers and the detach as a matching sequence of `myfirst_uninit_*` helpers, and have a single `myfirst_fail` function that walks the unwind list based on how far attach got. This is cleaner for very complex drivers; for Chapter 18's driver the goto cascade is simpler and more readable.

18.7.9 A Concrete Walk Through the Cascade

Let's trace what happens if the cdev creation fails at Stage 3. The attach has:

1. Initialised the softc (success).
2. Allocated BAR0 (success).
3. Walked capabilities (always succeeds; it's just reads).
4. Attached the hardware layer (success).
5. Tried to create the cdev: fails because of some error (disk full? unlikely; in tests the reader can simulate this by returning NULL from a mocked `make_dev`).

The cascade runs `fail_hw`, which calls `myfirst_hw_detach` (undoes step 4), then `fail_release`, which releases the BAR (undoes step 2), then `fail_softc`, which deinit the softc (undoes step 1). Step 3's "undo" is the empty action (capability walks allocate nothing). The attach returns the error.

If the reader traces this by hand, the cleanup is clearly complete: the softc is deinit, the BAR is released, the hardware layer is detached. No leaks. No partial state. The test is the same as the test for a full attach followed by a full detach: `vmstat -m | grep myfirst` should show zero allocations after the failed attach returns.

18.7.10 Detach vs Resume: A Preview

For completeness: the suspend-and-resume paths, which Chapter 18 does not implement, look similar to detach-and-attach but preserve more state. Suspend quiesces the driver (drains callouts, stops user-space access), records the device's state in the softc, and lets the system power down. Resume re-initialises the device from the saved state, restarts callouts, re-enables user-space access, and returns.

A driver that implements only attach and detach cannot suspend cleanly; the kernel will refuse to suspend a system with a non-suspend-aware driver attached. The `myfirst` driver is small enough that Chapter 18 does not worry about this; Chapter 22 on power management revisits the topic.

18.7.11 Wrapping Up Section 6

Detach is attach, played in reverse, with a check for `EBUSY` at the top and a quiesce step before any teardown. The rule is simple; the discipline is in doing it consistently. Every resource attach allocates, detach releases. Every state attach sets up, detach tears down. Every callout attach starts, detach drains. The order is the reverse of attach.

For Chapter 18's driver, the detach at Stage 3 is six steps: refuse if busy, destroy the cdev, quiesce the simulation and hardware callouts, detach the hardware layer, release the BAR, deinit the softc. Each step is its own concern. Each step is auditable against the attach. Each step is testable in isolation.

Section 7 is the testing section. It stands up the bhyve or QEMU lab, walks through the attach-detach cycle on real PCI silicon-that-is-emulated, and teaches the reader to verify the driver's behaviour with `pciconf`, `devinfo`, `dmesg`, and a couple of small user-space programs.

18.8 Section 7: Testing PCI Driver Behaviour

A driver exists to talk to a device. Chapter 18's driver is written and compiled, but it has not yet run against any device. Section 7 closes the loop. It walks the reader through standing up a FreeBSD guest in bhyve or QEMU, exposing a virtio-rnd PCI device to the guest, loading the driver, observing the full attach-operate-detach-unload cycle, exercising the cdev from user space, reading and writing configuration space with `pciconf -r` and `pciconf -w`, and confirming through `devinfo -v` and `dmesg` that the driver's view of the world matches the kernel's.

Testing is where all of Chapters 2 through 17 finally pay off. Every habit the book has built (typing code by hand, reading the FreeBSD source, running regressions after every stage, keeping a lab logbook) serves Chapter 18's testing discipline. The section is long because real PCI testing has real moving parts; each part is worth walking through carefully.

18.8.1 The Test Environment

The canonical test environment for Chapter 18 is a FreeBSD 14.3 guest running under bhyve(8) on a FreeBSD 14.3 host. The guest receives an emulated virtio-rnd device through bhyve's `virtio-rnd` passthrough. The guest runs the reader's debug kernel. The `myfirst` driver is compiled and loaded inside the guest; it attaches to the virtio-rnd device, and the reader exercises it from inside the guest.

An equivalent environment uses `qemu-system-x86_64` on Linux or macOS as the host, with a FreeBSD 14.3 guest running a debug kernel. QEMU's `-device virtio-rng-pci` does the same job as bhyve's `virtio-rnd`. Everything else is identical.

The rest of this section assumes bhyve unless noted otherwise. Readers on QEMU substitute the equivalent commands; the concepts transfer directly.

18.8.2 Preparing the bhyve Guest

The author's lab script looks roughly like this, edited for clarity:

```
#!/bin/sh
set -eu

# Load bhyve's kernel modules.
kldload -n vmm nmdm if_bridge if_tap

# Prepare a network bridge.
# ifconfig bridge0 create 2>/dev/null || true
# ifconfig bridge0 addm em0 addm tap0
# ifconfig tap0 up
# ifconfig bridge0 up

# Launch the guest.
bhyve -c 2 -m 2048 -H -w \
```

```
-s 0:0,hostbridge \
-s 1:0,lpc \
-s 2:0,virtio-net,tap0 \
-s 3:0,virtio-blk,/dev/zvol/zroot/vm/freebsd143/disk0 \
-s 4:0,virtio-rnd \
-l com1,/dev/nmdm0A \
-l bootrom,/usr/local/share/uefi-firmware/BHYVE_UEFI.fd \
vm:fbbsd-14.3-lab
```

The key line is `-s 4:0,virtio-rnd`. It attaches a `virtio-rnd` device on PCI slot 4, function 0. The guest's PCI enumerator will see a device at `pci0:0:4:0` with vendor `0x1af4` and device `0x1005`, which is exactly the ID pair the Chapter 18 driver's probe table matches.

Other slots carry the hostbridge, LPC, network (tap-bridged), and storage (zvol-backed block). The overall guest has everything it needs to boot and run multiuser, plus one PCI device for our driver.

A shorter form for readers who prefer `vm(8)` (the FreeBSD utility from the `vm-bhyve` port):

```
vm create -t freebsd-14.3 fbbsd-lab
vm configure fbbsd-lab # edit vm.conf and add:
#   passthru0="0/0/0"      # if using passthrough, not needed here
#   virtio_rnd="1"         # add a virtio-rnd device
vm start fbbsd-lab
```

`vm-bhyve` hides the detail of the `bhyve` command line. Either form produces an equivalent lab environment.

Readers on QEMU use:

```
qemu-system-x86_64 -cpu host -m 2048 -smp 2 \
  -drive file=freebsd-14.3-lab.img,if=virtio \
  -netdev tap,id=net0,ifname=tap0 -device virtio-net,netdev=net0 \
  -device virtio-rng-pci \
  -bios /usr/share/qemu/OVMF_CODE.fd \
  -serial stdio
```

The `-device virtio-rng-pci` line does the `bhyve`-equivalent job.

18.8.3 Verifying the Guest Sees the Device

Inside the guest, after the first boot, the `virtio-rnd` device should be visible:

```
pciconf -lv
```

Look for an entry like:

```
virtio_random0@pci0:0:4:0: class=0x00ff00 rev=0x00 hdr=0x00 vendor=0x1af4
↳ device=0x1005 subvendor=0x1af4 subdevice=0x0004
    vendor      = 'Red Hat, Inc.'
    device      = 'Virtio entropy'
    class       = old
```

The entry tells you three things. First, the guest's PCI enumerator found the device. Second, the base-system `virtio_random(4)` driver has claimed it (the leading name `virtio_random0` is the clue). Third, the B:D:F is 0:0:4:0, matching the `bhyve -s 4:0,virtio-rnd` configuration.

If the entry is missing, either the `bhyve` command line did not include `virtio-rnd` or the guest booted without loading `virtio_pci.ko`. Both are fixable: review the `bhyve` command, reboot the guest, or `kldload virtio_pci` by hand.

18.8.4 Preparing the Guest for myfirst

On a stock FreeBSD 14.3 GENERIC kernel, `virtio_random` is not compiled in; it ships as a loadable module (`virtio_random.ko`). Whether it has claimed the device by the time you want to load `myfirst` depends on the platform. On a modern system, `devmatch(8)` may auto-load `virtio_random.ko` shortly after boot when it sees a matching PCI device. On a freshly booted guest where `devmatch` has not fired yet, the `virtio-rnd` device may still be unclaimed.

Check first:

```
kldstat | grep virtio_random
pciconf -lv | grep -B 1 virtio_random
```

If neither command shows `virtio_random`, the device is unclaimed and you can skip the next step.

If `virtio_random` has claimed the device, unload it:

```
sudo kldunload virtio_random
```

If the module is unloadable (not pinned, not in use), this succeeds and the `virtio-rnd` device becomes unclaimed. `devinfo -v` now shows it under `pci0` with no driver binding.

If you want a stable setup that never auto-loads `virtio_random` across reboots, add to `/boot/loader.conf`:

```
hint.virtio_random.0.disabled="1"
```

This prevents the binding at boot time without removing the module image from the system. Alternatively, adding an entry under `/etc/devd.conf` or `devmatch.blocklist` (or using the `dev.virtio_random.0.%driver sysctl` at runtime) blocks the driver from attaching. For Chapter 18's teaching path, a simple `kldunload` once per test session is enough.

Chapter 18's testing uses the first approach during development (quick iteration) and the second approach when the reader wants a stable setup for repeated tests.

A third approach worth mentioning: the kernel's `dev.NAME.UNIT.%parent` and `dev.NAME.UNIT.%driver` sysctls describe bindings but do not change them. To force a rebind, use `devctl detach` and `devctl set driver`:

```
sudo devctl detach virtio_random0
sudo devctl set driver -f pci0:0:4:0 myfirst
```

The `-f` flag forces the set even if another driver has claimed the device. This is the precise command to use in a scripted test where the reader wants to switch drivers without reloading modules.

18.8.5 Loading myfirst and Watching the Attach

With `virtio_random` out of the way, load `myfirst`:

```
sudo kldload ./myfirst.ko
```

Watch `dmesg` for the attach:

```
sudo dmesg | tail -20
```

The expected output (for Stage 3):

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> mem
↳ 0xc1000000-0xc100001f at device 4.0 on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0:          subvendor=0x1af4 subdevice=0x0004 class=0xff
myfirst0: PCIe capability at 0x0
myfirst0: MSI-X capability at 0x0
myfirst0: hardware layer attached to BAR: 32 bytes (tag=... handle=...)
myfirst0: BAR[0x00] = 0x10010000
```

(The capability offsets for the virtio legacy device are 0 because the bhyve emulation does not expose a PCIe capability; a reader who tests with QEMU's `virtio-rng-pci` may see non-zero offsets.)

The `cdev /dev/myfirst0` exists:

```
ls -l /dev/myfirst*
```

and `devinfo -v` shows the device:

```
devinfo -v | grep -B 1 -A 4 myfirst
```

```
pci0
  myfirst0
    pnpinfo vendor=0x1af4 device=0x1005 ...
    resources:
      memory: 0xc1000000-0xc100001f
```

This is the driver attached to the device, visible to user space, ready to be exercised.

18.8.6 Exercising the cdev

The myfirst driver's cdev path is the Chapter 10 through 17 interface. It accepts open, close, read, and write system calls. In the Chapter 17 simulation-only build, reads pulled from the command-response ring buffer that the simulation's callouts populated. In the Chapter 18 PCI build the simulation is not attached; the cdev still responds to open, read, write, and close, but the data path has no active callouts feeding it. Reads return what the underlying Chapter 10 circular buffer contains (typically empty at start); writes queue data into the same buffer.

This is expected behaviour for Chapter 18. The point of the chapter's tests is to prove that the driver attaches to a real PCI device, the BAR is live, the cdev is reachable from user space, and detach cleans up properly. Chapter 19 adds the interrupt path that will make the cdev's data path meaningful against a real device.

A small user-space program to exercise the cdev:

```
/* Minimal read-write test. */
#include <fcntl.h>
#include <stdio.h>
#include <unistd.h>

int main(void) {
    int fd = open("/dev/myfirst0", O_RDWR);
    if (fd < 0) { perror("open"); return 1; }

    char buf[16];
    ssize_t n = read(fd, buf, sizeof(buf));
    printf("read returned %zd\n", n);

    close(fd);
    return 0;
}
```

Compile and run:

```
cc -o myfirst_test myfirst_test.c
./myfirst_test
```

The output may be a short read, a zero read, or EAGAIN (depending on whether the Chapter 10 buffer has any data ready). What matters is that the read path does not crash the kernel, does not produce an error in dmesg, and returns to user space with a defined result.

A write test is equally straightforward:

```
char cmd[16] = "hello\n";
write(fd, cmd, 6);
```

Writes push data into the Chapter 10 circular buffer. On the PCI backend, the data sits in the buffer until a reader pulls it out; no simulation callout is running to process it. The test is that the cycle runs without crashing and that dmesg stays quiet.

18.8.7 Reading and Writing Configuration Space from User Space

pciconf(8) has two flags that let user-space programs inspect and modify PCI configuration space directly:

- `pciconf -r <selector> <offset>:<length>` reads configuration-space bytes and prints them in hex.
- `pciconf -w <selector> <offset> <value>` writes a value to a specific offset.

The selector identifies the device. It can be the device's driver name (`myfirst0`) or its B:D:F (`pci0:0:4:0`).

A read example:

```
sudo pciconf -r myfirst0 0x00:8
```

Output:

```
00: 1a f4 05 10 07 05 10 00
```

The bytes are the first eight bytes of configuration space, in order: vendor ID (1af4, little-endian), device ID (1005), command register (0507, with MEMEN and BUSMASTER set), status register (0010).

A write example (dangerous, do not do this casually):

```
sudo pciconf -w myfirst0 0x04 0x0503
```

This clears BUSMASTER and leaves MEMEN set. The effect on the device depends on the device; on a running device it may cause DMA operations to fail. For a device the driver does not use DMA against (Chapter 18's case), the change is essentially harmless but also essentially meaningless.

A reader should use `pciconf -w` only in deliberate diagnostic scenarios, with full knowledge of the consequences. Writing a garbage value to the wrong field can deadlock the device, the bus, or the kernel.

18.8.8 devinfo -v and What It Tells You

`devinfo -v` is the newbus tree inspector. It walks every device in the system and prints each one with its resources, its parent, its unit, and its children. For a driver author, it is the canonical reference for “what does the kernel think the driver owns”.

A fragment of output, for the `myfirst0` device:

```
nexus0
  acpi0
    pcib0
      pci0
        myfirst0
          pnpinfo vendor=0x1af4 device=0x1005 subvendor=0x1af4 subdevice=0x0004
↪ class=0x00ff00
    resources:
      memory: 0xc1000000-0xc100001f
    virtio_pci0
      pnpinfo vendor=0x1af4 device=0x1000 ...
      resources: ...
    ... (other pci children)
```

The tree shows the path from the root (`nexus`) down through the platform (ACPI on x86), the PCI bridge (`pcib`), the PCI bus (`pci0`), and finally the devices on that bus. `myfirst0` is a child of `pci0`. Its resource list shows the claimed memory BAR.

Using `devinfo -v | grep -B 1 -A 5 myfirst` to extract just the relevant block is the standard technique when the tree is large.

18.8.9 dmesg as a Diagnostic Tool

`dmesg` is the kernel’s message buffer. Every `device_printf`, `printf`, and `KASSERT` failure in the kernel appears in `dmesg`. For a driver author, it is the primary debugging surface.

Tailing `dmesg` while loading, operating, and unloading the driver is how you catch subtle problems early. A typical session:

```
# Start a dmesg tail in a second terminal.
dmesg -w
```

Then, in the primary terminal:

```
sudo kldload ./myfirst.ko
```

The tailing terminal shows the attach messages as they happen. Run your tests:

```
./myfirst_test
```

The tailing terminal shows any messages the driver emits during the test. Unload:

```
sudo kldunload myfirst
```

The tailing terminal shows the detach messages.

If any step produces an unexpected warning or error, you see it in real time. Without a tailing `dmesg`, you might miss a single warning that indicates a latent problem.

18.8.10 Using devctl to Simulate Hotplug

`devctl(8)` lets a user-space program simulate the newbus events that a real hotplug or device-removal would generate. The common invocations:

```
# Force a device to detach (calls the driver's detach method).
```

```
sudo devctl detach myfirst0
```

```
# Re-attach the device (calls the driver's probe and attach).
```

```
sudo devctl attach myfirst0
```

```
# Disable a device (prevent future probes from binding).
```

```
sudo devctl disable myfirst0
```

```
# Re-enable a disabled device.
```

```
sudo devctl enable myfirst0
```

```
# Rescan a bus (equivalent to a hotplug notification).
```

```
sudo devctl rescan pci0
```

For testing Chapter 18's detach path, `devctl detach myfirst0` is the primary tool. It exercises the detach code without unloading the module. The driver's detach runs; the `cdev` disappears; the BAR is released; the device goes back to unclaimed.

A subsequent `devctl attach` re-triggers probe and attach. If the probe succeeds (the vendor and device IDs still match) and attach succeeds, the device is bound again. This is the cycle a reader uses to test that the driver can attach, detach, and reattach without leaking resources.

Running this cycle in a loop is the standard regression pattern:

```
for i in 1 2 3 4 5; do
    sudo devctl detach myfirst0
    sudo devctl attach myfirst0
done
sudo vmstat -m | grep myfirst
```

If `vmstat -m` shows the `myfirst` malloc type with zero current allocations after the loop, the driver is clean: every attach allocated, every detach freed, and the totals balance.

18.8.11 A Simple Regression Script

Putting it all together, a script that verifies Stage 3's PCI path:

```
#!/bin/sh
#
# Chapter 18 Stage 3 regression test.
# Run inside a bhyve guest that exposes a virtio-rnd device.

set -eu

echo "=== Unloading virtio_random if present ==="
kldstat | grep -q virtio_random && kldunload virtio_random || true

echo "=== Loading myfirst ==="
kldload ./myfirst.ko
sleep 1

echo "=== Checking attach ==="
devinfo -v | grep -q 'myfirst0' || { echo FAIL: no attach; exit 1; }

echo "=== Checking BAR claim ==="
devinfo -v | grep -A 3 'myfirst0' | grep -q 'memory:' || \
    { echo FAIL: no BAR; exit 1; }

echo "=== Exercising cdev ==="
./myfirst_test
sleep 1

echo "=== Detach-attach cycle ==="
for i in 1 2 3; do
    devctl detach myfirst0
    sleep 0.5
    devctl attach pci0:0:4:0
    sleep 0.5
done

echo "=== Unloading myfirst ==="
kldunload myfirst
sleep 1

echo "=== Checking for leaks ==="
```

```
vmstat -m | grep -q myfirst && echo WARN: myfirst malloc type still present

echo "=== Success ==="
```

The script follows a repeatable pattern: set up, load, check attach, check resources, exercise, cycle, unload, check for leaks. Running this after every change to the driver is how you catch regressions early.

18.8.12 Reading Configuration Space for Diagnostic Purposes

A small worked example of using `pciconf -r` to verify that the driver's view of configuration space matches user space's view.

Inside the driver, the attach path reads the vendor ID via `pci_get_vendor` and the device ID via `pci_get_device`. User space reads the same bytes via `pciconf -r myfirst0 0x00:4`.

Expected output:

```
00: f4 1a 05 10
```

The bytes are the vendor ID (0x1af4) and the device ID (0x1005), in little-endian order. Reversing the bytes gives 0x1af4 for vendor and 0x1005 for device, matching the driver's probe table.

Doing this check is not something you would do in production; the PCI subsystem is well-tested and the values are reliable. It is useful as a learning exercise: it proves that the driver's view of configuration space matches what user space sees, and it cements the reader's understanding of how `pci_get_vendor` relates to the underlying bytes.

18.8.13 What Section 7 Does Not Test

Section 7 verifies that the Chapter 18 driver attaches to a real PCI device, claims the BAR, exposes the `cdev`, reads the BAR through the Chapter 16 accessor layer, detaches cleanly, releases the BAR, and unloads without leaks. It does not test:

- Interrupt handling. The driver does not register an interrupt; Chapter 19 does.
- MSI or MSI-X. Chapter 20 does.
- DMA. Chapter 21 does.
- Device-specific protocol. The Chapter 17 simulation's command-response protocol is not the `virtio-rnd` protocol, so the results of a write are not meaningful. Chapter 18's driver is not a `virtio-rnd` driver.

A reader who wants a driver that actually implements the `virtio-rnd` protocol should read `/usr/src/sys/dev/virtio/random/virtio_random.c`. It is a clean, focused driver that a reader who has finished Chapter 18 should be able to follow.

18.8.14 Wrapping Up Section 7

Testing a PCI driver means standing up an environment where the driver can meet a device. For Chapter 18 that environment is a bhyve or QEMU guest with a virtio-rnd device exposed to the guest. The tools are `pciconf -lv` (to see the device), `kldload` and `kldunload` (to load and unload the driver), `devinfo -v` (to see the newbus tree and the driver's resources), `devctl` (to simulate hotplug), `dmesg` (to watch diagnostic messages), and `vmstat -m` (to check for leaks). The discipline is to run a repeatable script after every change, inspect its output, and fix any warnings or failures before moving on.

The regression script at the end of this section is the template every reader should adapt to their own driver and their own lab. Running it ten times in a row and seeing identical output each time is the proof that the driver is solid. Running it once and seeing a crash is a sign the driver has a bug that Chapter 18's discipline (attach order, detach order, resource pairing) should have prevented; the fix is usually small.

Section 8 is the final section of the instructional body. It refactors the Chapter 18 code into its final shape, bumps the version to 1.1-pci, writes the new `PCI.md`, and prepares the ground for Chapter 19.

18.9 Section 8: Refactoring and Versioning Your PCI Driver

The PCI driver is now working. Section 8 is the housekeeping section. It consolidates the Chapter 18 code into a clean, maintainable structure, updates the driver's `Makefile` and module metadata, writes the `PCI.md` document that will live alongside `LOCKING.md`, `HARDWARE.md`, and `SIMULATION.md`, bumps the version to 1.1-pci, and runs the full regression pass against both the simulation and the real PCI backend.

A reader who has made it this far may be tempted to skip Section 8. It is boring compared to the earlier sections. It does not introduce any new PCI concepts. The temptation is real, and it is a mistake. The refactor is what turns a working driver into a maintainable driver. A driver that works today but is organised badly will be painful to extend in Chapter 19 (when interrupts arrive), Chapter 20 (when MSI and MSI-X arrive), Chapters 20 and 21 (when DMA arrives), and every later chapter. The few lines of housekeeping Section 8 does pay dividends across the rest of Part 4 and beyond.

18.9.1 The Final File Layout

At the end of Chapter 18, the `myfirst` driver consists of these files:

<code>myfirst.c</code>	- Main driver: <code>softc</code> , <code>cdev</code> , module events, data path.
<code>myfirst.h</code>	- Shared declarations: <code>softc</code> , lock macros, prototypes.
<code>myfirst_hw.c</code>	- Chapter 16 hardware access layer: <code>CSR_*</code> accessors, access log, <code>sysctl</code> handlers.
<code>myfirst_hw.h</code>	- Chapter 16 register map and accessor declarations, extended in Chapter 17.
<code>myfirst_sim.c</code>	- Chapter 17 simulation backend: callouts, fault injection, command-response.
<code>myfirst_sim.h</code>	- Chapter 17 simulation interface.
<code>myfirst_pci.c</code>	- Chapter 18 PCI attach: probe, attach, detach, <code>DRIVER_MODULE</code> , <code>MODULE_DEPEND</code> .

```

myfirst_pci.h    - Chapter 18 PCI declarations: ID table entry struct,
                  vendor and device ID constants.
myfirst_sync.h  - Part 3 synchronisation primitives.
cbuf.c / cbuf.h - The Chapter 10 circular buffer, still in use.
Makefile        - kmod build: KMOD, SRCS, CFLAGS.
HARDWARE.md     - Chapter 16/17 documentation of the register map.
LOCKING.md      - Chapter 15 onward documentation of lock discipline.
SIMULATION.md   - Chapter 17 documentation of the simulation backend.
PCI.md          - Chapter 18 documentation of PCI support.

```

The split is the same split Chapter 17 anticipated. `myfirst_pci.c` and `myfirst_pci.h` are new. Every other file existed before Chapter 18 and has been either extended (`myfirst_hw.c` gained `myfirst_hw_attach_pci`) or left unchanged. The driver's main file (`myfirst.c`) grew by a few lines to add the PCI-related softc fields and a call to the PCI-specific detach helper; it did not grow substantially.

A rule of thumb worth stating: each file should have one responsibility. `myfirst.c` is the driver's integration point; it ties every piece together. `myfirst_hw.c` is about hardware access. `myfirst_sim.c` is about simulating the hardware. `myfirst_pci.c` is about attaching to real PCI hardware. When a reader opens a file, they should be able to predict, from the file name, what is in it. When Chapter 19 adds `myfirst_intr.c`, the prediction will hold: that file is about interrupts.

18.9.2 The Final Makefile

```

# Makefile for the Chapter 18 myfirst driver.
#
# Combines the Chapter 10-15 driver, the Chapter 16 hardware layer,
# the Chapter 17 simulation backend, and the Chapter 18 PCI attach.
# The driver is loadable as a standalone kernel module via
# kldload(8); when loaded, it attaches automatically to any PCI
# device whose vendor/device ID matches an entry in
# myfirst_pci_ids[] (see myfirst_pci.c).

KMOD=  myfirst
SRCS=  myfirst.c myfirst_hw.c myfirst_sim.c myfirst_pci.c cbuf.c

# Version string. Update this line alongside any user-visible change.
CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.1-pci\"

# Optional: build without PCI support (simulation only).
# CFLAGS+= -DMYFIRST_SIMULATION_ONLY

# Optional: build without simulation fallback (PCI only).
# CFLAGS+= -DMYFIRST_PCI_ONLY

```

```
.include <bsd.kmod.mk>
```

Four SRCS, one version string, two commented-out compile options. The build is one command:

```
make
```

The output is `myfirst.ko`, loadable into any FreeBSD 14.3 kernel with `kldload`.

18.9.3 The Version String

The version string moves from `1.0-simulated` to `1.1-pci`. The bump reflects that the driver has acquired a new capability (real PCI support) without changing any user-visible behaviour (the `cdev` still does what it did). A minor-version bump is appropriate; a major-version bump would imply an incompatible change.

Later chapters will continue the numbering: `1.2-intr` after Chapter 19, `1.3-msi` after Chapter 20, `1.4-dma` after Chapters 20 and 21, and so on. By the end of Part 4 the driver will be at `1.4-dma` or so, with each minor version reflecting one significant capability addition.

The version string is visible in two places: `kldstat -v` shows it, and the driver's `dmesg` banner on load prints it. A user or system administrator who wants to know which version of the driver they have running can `grep dmesg` for the banner.

18.9.4 The PCI.md Document

A new document joins the driver's corpus. `PCI.md` is short; its job is to describe the PCI support the driver provides, in a form a future reader can consult without reading the source.

```
# PCI Support in the myfirst Driver
```

```
## Supported Devices
```

As of version `1.1-pci`, `myfirst` attaches to PCI devices matching the following vendor/device ID pairs:

Vendor	Device	Description
-----	-----	-----
0x1af4	0x1005	Red Hat/virtio-rnd (demo target; see README)

This list is maintained in ``myfirst_pci.c`` in the static array ``myfirst_pci_ids[]``. Adding a new supported device requires:

1. Adding an entry to ``myfirst_pci_ids[]`` with the vendor and device IDs and a human-readable description.

2. Verifying that the driver's BAR layout and register map are compatible with the new device.
3. Testing the driver against the new device.
4. Updating this document.

Attach Behaviour

The driver's probe routine returns `BUS_PROBE_DEFAULT` on a match and `ENXIO` otherwise. Attach allocates BAR0 as a memory resource, walks the PCI capability list (Power Management, MSI, MSI-X, PCIe, PCIe AER if present), attaches the Chapter 16 hardware layer against the BAR, and creates `/dev/myfirstN`. The Chapter 17 simulation backend is NOT attached on the PCI path; the driver's accessors read and write the real BAR without the simulation callouts running.

Detach Behaviour

Detach refuses to proceed if the driver has open file descriptors or in-flight commands (returns `EBUSY`). Otherwise it destroys the cdev, drains any active callouts and tasks, detaches the hardware layer, releases the BAR, and deinit the softc.

Module Dependencies

The driver's `MODULE_DEPEND` declarations:

- `pci`, version 1: the kernel's PCI subsystem.

No other module dependencies are declared.

Known Limitations

- The driver does not currently handle interrupts. See Chapter 19 for the interrupt-handling extension.
- The driver does not currently support DMA. See Chapters 20 and 21 for the DMA extension.
- The Chapter 17 simulation backend is not attached on the PCI path. The simulation's callouts and command protocol remain available in a simulation-only build (`-DMYFIRST_SIMULATION_ONLY`) for readers without matching PCI hardware.

See Also

- ``HARDWARE.md`` for the register map.
- ``SIMULATION.md`` for the simulation backend.
- ``LOCKING.md`` for the lock discipline.
- ``README.md`` for how to set up the bhyve test environment.

This document lives next to the driver source. A future reader (the author themselves, three months from now, or a contributor, or a port maintainer) can read it in five minutes and understand the driver's PCI story without opening the code.

18.9.5 Updating LOCKING.md

LOCKING.md already documents the Chapter 11 through 17 lock discipline. Chapter 18 adds two small items:

1. The detach order: new steps for `destroy_dev`, quiescing callouts, `myfirst_hw_detach`, `bus_release_resource`, and `myfirst_deinit_softc`, in that order.
2. The attach failure cascade: the goto labels (`fail_hw`, `fail_release`, `fail_softc`) and what each one undoes.

The update is a handful of lines in the existing document. No new lock is introduced in Chapter 18; the Chapter 15 lock hierarchy is unchanged.

18.9.6 Updating HARDWARE.md

HARDWARE.md already documents the Chapter 16 and Chapter 17 register map. Chapter 18 adds one small item:

- The BAR the driver attaches to is BAR 0, requested with `rid = PCIR_BAR(0)`, allocated as `SYS_RES_MEMORY` with `RF_ACTIVE`. The tag and handle are extracted with `rman_get_bustag(9)` and `rman_get_bushandle(9)`.

That is the entire addition. The register map itself does not change in Chapter 18; the same offsets, the same widths, the same bit definitions.

18.9.7 The Regression Pass

With the refactor complete, the full regression pass for Chapter 18 is:

1. **Compile cleanly.** `make` produces `myfirst.ko` without warnings. The CFLAGS already include `-Wall -Werror` from Chapter 4 onward; the build fails if any warning appears.
2. **Load without errors.** `kldload ./myfirst.ko` succeeds and `dmesg` shows the module-level banner.
3. **Attach to a real PCI device.** In a bhyve guest with a virtio-rnd device, the driver attaches and `dmesg` shows the full Chapter 18 attach sequence.
4. **Create and exercise the cdev.** `/dev/myfirst0` exists, `open / read / write / close` work, no kernel messages indicate errors.
5. **Walk capabilities.** `dmesg` shows the capability offsets for any capabilities the guest's virtio-rnd exposes.

6. **Read configuration space from user space.** `pciconf -r myfirst0 0x00:8` produces the expected bytes.
7. **Detach cleanly.** `devctl detach myfirst0` produces the detach banner in `dmesg`; the `cdev` disappears; `vmstat -m | grep myfirst` shows zero live allocations.
8. **Reattach cleanly.** `devctl attach pci0:0:4:0` re-triggers probe and attach; the full cycle runs again.
9. **Unload cleanly.** `kldunload myfirst` succeeds; `kldstat -v | grep myfirst` returns nothing.
10. **No leaks.** `vmstat -m | grep myfirst` returns nothing.

The regression script from Section 7 runs steps 1 through 10 in sequence and reports success or the first failure. Running it after every change is the discipline that catches regressions early.

18.9.8 What the Refactor Accomplished

At the start of Chapter 18 the `myfirst` driver was a simulation. It had a `malloc(9)`-backed register block, a simulation backend, and an elaborate testing harness. It did not attach to real hardware; it was a module loaded by hand.

At the end of Chapter 18 the driver is a PCI driver. It attaches to a real PCI device when one is present. It claims the device's BAR through the standard FreeBSD bus-allocation API. It uses the Chapter 16 accessor layer to read and write the device's registers through `bus_space(9)`. The Chapter 17 simulation remains available through a compile-time switch (`-DMYFIRST_SIMULATION_ONLY`) for readers without matching PCI hardware, but the default build targets the PCI path and leaves the simulation callouts idle. The attach and detach paths follow the `newbus` conventions every other FreeBSD driver uses.

The code is recognisably FreeBSD. The layout is the layout real drivers use when they have distinct simulation, hardware, and bus responsibilities. The vocabulary is the vocabulary real drivers share. A contributor opening the driver for the first time finds a familiar structure, reads the documentation, and can navigate the code by subsystem.

18.9.9 A Short Note on Symbol Visibility

A reader who diffs the Chapter 17 driver against the Chapter 18 driver will notice that several functions have changed visibility. Some that were `static` in Chapter 17 are now exported (non-`static`) because `myfirst_pci.c` needs them. Examples include `myfirst_init_softc`, `myfirst_deinit_softc`, and `myfirst_quiesce`.

The convention is: a function that is called only from within its own file is `static`. A function that is called across files (but only within this driver) is non-`static` with a declaration in `myfirst.h` or another project-local header. A function that is callable from other modules (rare, and typically only through a KPI) is explicitly exported via a kernel-style symbol table; this is not relevant for Chapter 18.

The refactor does not export any new symbol outside the driver; it only promotes a few functions from file-local to driver-local. A reader who is bothered by the promotion has two options: leave the functions in `myfirst.c` and call them through a small helper that `myfirst_pci.c` calls (one more layer of indirection), or accept the promotion and document it in the source comments. The book chooses the latter; the driver is small enough that the occasional driver-local export is easy to audit.

18.9.10 Wrapping Up Section 8

The refactor is, again, small in code but significant in organisation. A new file split, a new documentation file, updates to existing documentation files, a version bump, and a regression pass. Each step is cheap; together they turn a working driver into a maintainable one.

The Chapter 18 driver is done. The chapter closes with labs, challenges, troubleshooting, and a bridge to Chapter 19, where the PCI-attached driver gains a real interrupt handler. Chapter 20 then adds MSI and MSI-X; Chapters 20 and 21 add DMA. Each of those chapters will add a file (`myfirst_intr.c`, `myfirst_dma.c`) and extend the attach and detach paths. The shape Chapter 18 established will hold.

18.10 Reading a Real Driver Together: `uart_bus_pci.c`

The preceding eight sections built Chapter 18's driver one step at a time. Before the labs, it is worth spending time with a real FreeBSD driver that follows the same pattern. `/usr/src/sys/dev/uart/uart_bus_pci.c` is a clean example. It is the PCI attach for the `uart(4)` driver, which handles PCI-attached serial ports: modem cards, chipset integrated UARTs, hypervisor serial emulation, and the console redirection chips that enterprise servers use.

Reading this file after writing Chapter 18's driver is a short exercise in pattern recognition. Nothing in the file is new. Every line maps to a concept Chapter 18 taught. The file is 366 lines; this section walks through the important parts, flagging where each piece corresponds to a Chapter 18 concept.

18.10.1 The Top of the File

```
/* -

#include <sys/cdefs.h>
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/bus.h>
#include <sys/conf.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <machine/bus.h>
#include <sys/rman.h>
#include <machine/resource.h>
```

```
#include <dev/pci/pcivar.h>
#include <dev/pci/pcireg.h>

#include <dev/uart/uart.h>
#include <dev/uart/uart_bus.h>
#include <dev/uart/uart_cpu.h>
```

The SPDX license tag is BSD-2-Clause, the standard FreeBSD license. The include list is almost identical to Chapter 18's `myfirst_pci.c`. The `dev/pci/pcivar.h` and `dev/pci/pcireg.h` includes are the PCI subsystem interface; the `dev/uart/uart.h` and friends are the driver's internal headers that Chapter 18's driver does not have equivalents of.

18.10.2 Method Table and Driver Structure

```
static device_method_t uart_pci_methods[] = {
    DEVMETHOD(device_probe,      uart_pci_probe),
    DEVMETHOD(device_attach,     uart_pci_attach),
    DEVMETHOD(device_detach,     uart_pci_detach),
    DEVMETHOD(device_resume,     uart_bus_resume),
    DEVMETHOD_END
};

static driver_t uart_pci_driver = {
    uart_driver_name,
    uart_pci_methods,
    sizeof(struct uart_softc),
};
```

Four method entries, not three: `uart(4)` also implements `device_resume` for system suspend and resume support. The resume function is `uart_bus_resume`, which lives in the core `uart(4)` driver and is reused across every UART attach variant. Chapter 18's driver skipped resume; a production-quality driver usually implements it.

The `driver_t`'s name is `uart_driver_name`, defined elsewhere in the core UART driver as `"uart"`. The `softc` size is `sizeof(struct uart_softc)`, a structure defined in `uart_bus.h`.

18.10.3 The ID Table

```
struct pci_id {
    uint16_t    vendor;
    uint16_t    device;
```

```

uint16_t    subven;
uint16_t    subdev;
const char  *desc;
int         rid;
int         rclk;
int         regshft;
};

```

The table entry is richer than Chapter 18's. The `subven` and `subdev` fields let the match discriminate among cards from different vendors that share a common chipset. The `rid` field carries the BAR's configuration-space offset (different boards use different BARs). The `rclk` carries the reference clock frequency in Hz, which varies among manufacturers. The `regshft` carries a register shift (some boards put their UART registers on 4-byte boundaries, some on 8-byte boundaries).

```

static const struct pci_id pci_ns8250_ids[] = {
    { 0x1028, 0x0008, 0xffff, 0, "Dell Remote Access Card III", 0x14,
      128 * DEFAULT_RCLK },
    { 0x1028, 0x0012, 0xffff, 0, "Dell RAC 4 Daughter Card Virtual UART",
      0x14, 128 * DEFAULT_RCLK },
    /* ... many more entries ... */
    { 0xffff, 0, 0xffff, 0, NULL, 0, 0 }
};

```

The table has dozens of entries. Each one is a board the `uart(4)` driver supports. A subvendor value of `0xffff` means “match any subvendor”. The last entry is the sentinel.

Chapter 18's driver has one entry because it targets one demo device. `uart_bus_pci.c` has dozens because the UART hardware ecosystem is large and drivers must enumerate every supported variant.

18.10.4 The Probe Routine

```

static int
uart_pci_probe(device_t dev)
{
    struct uart_softc *sc;
    const struct pci_id *id;
    struct pci_id cid = {
        .regshft = 0,
        .rclk = 0,
        .rid = 0x10 | PCI_NO_MSI,
        .desc = "Generic SimpleComm PCI device",
    };
    int result;

```

```

    sc = device_get_softc(dev);

    id = uart_pci_match(dev, pci_ns8250_ids);
    if (id != NULL) {
        sc->sc_class = &uart_ns8250_class;
        goto match;
    }
    if (pci_get_class(dev) == PCIC_SIMPLECOMM &&
        pci_get_subclass(dev) == PCIS_SIMPLECOMM_UART &&
        pci_get_progif(dev) < PCIP_SIMPLECOMM_UART_16550A) {
        id = &cid;
        sc->sc_class = &uart_ns8250_class;
        goto match;
    }
    return (ENXIO);

match:
    result = uart_bus_probe(dev, id->regshft, 0, id->rclk,
        id->rid & PCI_RID_MASK, 0, 0);
    if (result > 0)
        return (result);
    if (sc->sc_sysdev == NULL)
        uart_pci_unique_console_match(dev);
    if (id->desc)
        device_set_desc(dev, id->desc);
    return (result);
}

```

The probe is more complex than Chapter 18's. It first searches the vendor/device ID table. If that fails, it falls back to a class-based match: any device whose class is `PCIC_SIMPLECOMM` (Simple Communications) and subclass is `PCIS_SIMPLECOMM_UART` (UART controller) and interface is older than `PCIP_SIMPLECOMM_UART_16550A` (older than 16550A means "a classic UART without enhanced features"). This is the fallback probe that lets the driver handle generic UART controllers even when their vendor and device ID are not in the table.

The `match:` label is reached from either path. It calls `uart_bus_probe` (the core UART driver's probe helper) with the entry's register shift, reference clock, and BAR offset. The return value is either a `BUS_PROBE_*` priority or a positive error code. Chapter 18's driver returns `BUS_PROBE_DEFAULT` directly; `uart(4)` delegates to `uart_bus_probe` because the core driver has additional checks.

The `pci_get_class`, `pci_get_subclass`, and `pci_get_progif` accessors return the class-code fields Chapter 18 described. Their use here is a concrete example of class-based matching.

18.10.5 The Attach Routine

```
static int
uart_pci_attach(device_t dev)
{
    struct uart_softc *sc;
    const struct pci_id *id;
    int count;

    sc = device_get_softc(dev);

    id = uart_pci_match(dev, pci_ns8250_ids);
    if ((id == NULL || (id->rid & PCI_NO_MSI) == 0) &&
        pci_msi_count(dev) == 1) {
        count = 1;
        if (pci_alloc_msi(dev, &count) == 0) {
            sc->sc_irid = 1;
            device_printf(dev, "Using %d MSI message\n", count);
        }
    }

    return (uart_bus_attach(dev));
}
```

The attach is short. It re-matches the device (because the probe's match state is not preserved across probe/attach calls), checks whether the device supports MSI (single-vector), allocates one MSI vector if available, and then delegates to `uart_bus_attach` for the actual attach.

This is a pattern Chapter 18 did not use. `uart(4)` takes advantage of MSI when available, falling back to legacy IRQs otherwise. Chapter 20 in this book will introduce MSI and MSI-X; `uart(4)`'s attach is a preview.

The `PCI_NO_MSI` flag in some table entries marks boards where MSI is known to be buggy or unreliable; for those boards the attach skips MSI and relies on legacy IRQs.

18.10.6 The Detach Routine

```
static int
uart_pci_detach(device_t dev)
{
    struct uart_softc *sc;

    sc = device_get_softc(dev);
```

```
    if (sc->sc_iris != 0)
        pci_release_msi(dev);

    return (uart_bus_detach(dev));
}
```

Eight lines, every one meaningful. Release MSI if it was allocated. Delegate to `uart_bus_detach` for the rest of the teardown.

Chapter 18's detach is longer because the `myfirst` driver does not delegate to a core driver; everything is in the PCI file. `uart(4)` factors the common teardown into `uart_bus_detach`, called from every attach variant's detach.

18.10.7 The DRIVER_MODULE Line

```
DRIVER_MODULE(uart, pci, uart_pci_driver, NULL, NULL);
```

One line. The module name is `uart` (matching the `driver_t`). The bus is `pci`. The two `NULL`s are for module init and cleanup handlers that `uart(4)` does not need.

Chapter 18's driver has the same line with `myfirst` in place of `uart`.

18.10.8 What This Walkthrough Teaches

`uart_bus_pci.c` is 366 lines. About 60 lines are code; the rest is the ID table (250+ entries, many on multiple lines each) and helper functions specific to UART handling.

The code is almost indistinguishable from Chapter 18's driver in shape. A `pci_id` struct. An ID table. A probe that matches the table. An attach that claims the BAR (through `uart_bus_attach`). A detach that releases everything. `DRIVER_MODULE`. `MODULE_DEPEND`. The differences are all about UART-specific features: the subvendor match, the class-based fallback, the MSI allocation, the register-shift and reference-clock fields.

A reader who finds `uart_bus_pci.c` readable after Chapter 18 has made the chapter's point. The Chapter 18 driver is a real FreeBSD PCI driver, not a toy. It is missing a few features (MSI, resume, DMA) that later chapters will add, but its bones are the bones of every real driver in the tree.

Worth reading after `uart_bus_pci.c`, for comparison: `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c`, which is the modern (non-legacy) virtio PCI attach. It is richer than `uart_bus_pci.c` because it handles virtio's layered transport, but the shape is the same.

18.11 A Deeper Look at the PCI Capability List

Section 5 introduced `pci_find_cap(9)` and `pci_find_extcap(9)` as tools for discovering a device's optional features. This subsection goes a level deeper, showing how the capability list is structured in configuration space and how a driver might walk the whole list rather than looking up a specific capability.

18.11.1 Structure of the Legacy Capability List

The legacy capability list lives in the first 256 bytes of configuration space. It starts at an offset held in the device's `PCIR_CAP_PTR` byte (at offset `0x34`). The byte at that offset is the capability ID; the byte immediately after is the offset of the next capability (or zero if this is the last one); the remaining bytes of the capability are feature-specific.

The minimum capability header is two bytes:

```
offset 0: capability ID (one byte, values like PCIY_MSI = 0x05)
offset 1: next pointer (one byte, offset of next capability, 0 means end)
```

A driver walking the list reads the cap pointer from `PCIR_CAP_PTR`, then follows the chain by reading each capability's next byte until a zero is reached.

A concrete walk, in code:

```
static void
myfirst_dump_caps(device_t dev)
{
    uint8_t ptr, id;
    int safety = 64; /* protects against malformed lists */

    ptr = pci_read_config(dev, PCIR_CAP_PTR, 1);
    while (ptr != 0 && safety-- > 0) {
        id = pci_read_config(dev, ptr, 1);
        device_printf(dev,
            "legacy capability ID 0x%02x at offset 0x%02x\n", id, ptr);
        ptr = pci_read_config(dev, ptr + 1, 1);
    }
}
```

The safety counter guards against a malformed configuration space where the next pointer forms a cycle. A well-behaved device never produces this, but defensive code treats the configuration space as potentially adversarial.

The walk prints each capability's ID and offset. The driver can then match the IDs against the `PCIY_*` constants and handle those it supports.

18.11.2 Structure of the Extended Capability List

The PCIe extended capability list starts at offset `PCIR_EXTCAP` (`0x100`) and uses 4-byte headers. The layout, as encoded in `/usr/src/sys/dev/pci/pci.h`, is:

bits 15:0	capability ID	(PCIM_EXTCAP_ID,	mask 0x0000ffff)
bits 19:16	capability version	(PCIM_EXTCAP_VER,	mask 0x000f0000)
bits 31:20	next pointer	(PCIM_EXTCAP_NEXTPTR,	mask 0xffff00000)

FreeBSD exposes three helper macros on top of the raw masks:

- `PCI_EXTCAP_ID(header)` returns the capability ID.
- `PCI_EXTCAP_VER(header)` returns the version.
- `PCI_EXTCAP_NEXTPTR(header)` returns the next pointer (already shifted into its natural range).

The 12-bit next pointer is always 4-byte aligned; a next pointer of zero terminates the list.

A walk using the helpers:

```
static void
myfirst_dump_extcaps(device_t dev)
{
    uint32_t header;
    int off = PCIR_EXTCAP;
    int safety = 64;

    while (off != 0 && safety-- > 0) {
        header = pci_read_config(dev, off, 4);
        if (header == 0 || header == 0xffffffff)
            break;
        device_printf(dev,
            "extended capability ID 0x%04x ver %u at offset 0x%03x\n",
            PCI_EXTCAP_ID(header), PCI_EXTCAP_VER(header), off);
        off = PCI_EXTCAP_NEXTPTR(header);
    }
}
```

The walker reads the 4-byte header and unpacks it with the helpers. A zero or all-ones header means there are no extended capabilities (the latter is what a non-PCIe device returns for any extended-capability read).

18.11.3 Why the Walk Matters

A driver rarely needs the full walk. `pci_find_cap` and `pci_find_extcap` are the common interface: the driver asks for a specific capability and either gets the offset or gets `ENOENT`. A driver that wants to dump the full capability list for diagnostic purposes uses the walkers shown above.

The value of understanding the structure is in reading datasheets. A datasheet that says “the device implements the MSI capability starting at offset 0xa0” is saying: the byte at configuration-space offset 0xa0 is the capability ID (will equal 0x05 for MSI), the byte at 0xa1 is the next pointer, and the bytes from 0xa2 onward are the MSI capability structure. `pci_find_cap(dev, PCIY_MSI, &capreg)` returns `capreg = 0xa0` because that is where the capability lives.

A driver accessing the capability structure reads from `capreg + offset`, where `offset` is defined in the MSI capability's own structure. Specific fields have specific offsets; the `pcireg.h` header defines the offsets as `PCIR_MSI_*`.

18.11.4 Walking a Specific Capability's Fields

An example. The MSI capability has several fields the driver cares about, at specific offsets relative to the capability header:

```
PCIR_MSI_CTRL (0x02): message control (16 bits, enables, vector count)
PCIR_MSI_ADDR (0x04): message address low (32 bits)
PCIR_MSI_ADDR_HIGH (0x08): message address high (32 bits, 64-bit only)
PCIR_MSI_DATA (0x08 or 0x0c): message data (16 bits)
```

A driver that has `capreg` from `pci_find_cap(dev, PCIY_MSI, &capreg)` reads the message control register with:

```
uint16_t msi_ctrl = pci_read_config(dev, capreg + PCIR_MSI_CTRL, 2);
```

The macro `PCIR_MSI_CTRL` is `0x02`; the full offset is `capreg + 0x02`. Similar patterns apply to every capability.

For Chapter 18 this level of detail is not needed because the driver does not use MSI. Chapter 20 does, and uses helper functions (`pci_alloc_msi`, `pci_alloc_msix`, `pci_enable_msi`, `pci_enable_msix`) that hide the raw field access. The walker shown here is useful mostly for diagnostics and for reading datasheets.

18.12 A Deeper Look at Configuration Space

Section 1 and Section 5 introduced configuration space; this subsection adds a few practical details a driver author should know.

18.12.1 Configuration Space Layout

The first 64 bytes of every PCI configuration space are standardised. The layout is:

Offset	Width	Field
0x00	2	Vendor ID
0x02	2	Device ID
0x04	2	Command register
0x06	2	Status register
0x08	1	Revision ID

Offset	Width	Field
0x09	3	Class code (progIF, subclass, class)
0x0c	1	Cache line size
0x0d	1	Latency timer
0x0e	1	Header type
0x0f	1	BIST (built-in self test)
0x10	4	BAR 0
0x14	4	BAR 1
0x18	4	BAR 2
0x1c	4	BAR 3
0x20	4	BAR 4
0x24	4	BAR 5
0x28	4	CardBus CIS pointer
0x2c	2	Subsystem vendor ID
0x2e	2	Subsystem device ID
0x30	4	Expansion ROM base address
0x34	1	Capability list pointer
0x35	7	Reserved
0x3c	1	Interrupt line
0x3d	1	Interrupt pin
0x3e	1	Min grant
0x3f	1	Max latency

The bytes from 0x40 to 0xff are reserved for device-specific use and for the legacy capability list (starting at the offset stored in `PCIR_CAP_PTR`).

PCIe extends configuration space to 4096 bytes. The bytes from 0x100 to 0xffff hold the extended capability list, which starts at offset 0x100 and follows its own chain of 4-byte-aligned capabilities.

18.12.2 Header Type

The byte at `PCIR_HDRTYPE` (0x0e) distinguishes among three kinds of PCI configuration headers:

- 0x00: standard device (what Chapter 18 assumes).
- 0x01: PCI-to-PCI bridge (a bridge that connects a secondary bus to the primary bus).
- 0x02: CardBus bridge (a PC card bridge; increasingly obsolete).

The layout beyond offset 0x10 differs among header types. A driver for a standard device uses offsets 0x10

through 0x24 as BARs; a driver for a bridge uses the same offsets for secondary bus number, subordinate bus number, and bridge-specific registers.

The high bit of PCIR_HDRTYPE indicates a multi-function device: if set, the device has functions beyond function 0. The kernel's PCI enumerator uses this bit to decide whether to probe functions 1 through 7.

18.12.3 Commands and Status

The command register (PCIR_COMMAND, offset 0x04) holds enable bits that control the device's PCI-level behaviour:

- PCIM_CMD_PORTEN (0x0001): enable I/O BARs.
- PCIM_CMD_MEMEN (0x0002): enable memory BARs.
- PCIM_CMD_BUSMASTEREN (0x0004): allow the device to initiate DMA.
- PCIM_CMD_SERRESPEN (0x0100): report system errors.
- PCIM_CMD_INTxDIS (0x0400): disable legacy INTx assertion (used when the driver uses MSI or MSI-X instead).

The kernel sets MEMEN and PORTEN automatically during resource activation. The driver sets BUSMASTEREN through `pci_enable_busmaster` if it uses DMA. The driver sets INTxDIS when it has successfully allocated MSI or MSI-X vectors and wants to prevent the device from also raising legacy interrupts.

The status register (PCIR_STATUS, offset 0x06) holds sticky bits that the driver reads to find out about PCI-level events: the device has received a master abort, a target abort, a parity error, or a signalled system error. A driver that cares about PCI error recovery reads the status register periodically or in its error handler; a driver that does not care (most drivers, at the Chapter 18 level) ignores it.

18.12.4 Reading Wider Than Available Width

`pci_read_config(dev, offset, width)` takes a width of 1, 2, or 4. It never takes a width of 8, even though some 64-bit fields (64-bit BARs) exist in configuration space. A driver reading a 64-bit BAR does it as two 32-bit reads:

```
uint32_t bar_lo = pci_read_config(dev, PCIR_BAR(0), 4);
uint32_t bar_hi = pci_read_config(dev, PCIR_BAR(1), 4);
uint64_t bar_64 = ((uint64_t)bar_hi << 32) | bar_lo;
```

Note that this reads the *configuration-space* BAR, which the driver rarely needs after the kernel has allocated the resource. The kernel's allocation returns the same information as a `struct resource *` whose start address is available through `rman_get_start`.

18.12.5 Alignment in Configuration-Space Reads

Configuration-space accesses are aligned by design. A read of width 1 may start at any offset; a read of width 2 must start at an even offset; a read of width 4 must start at an offset divisible by 4. Unaligned accesses (for example, a width-4 read at offset 0x03) are not supported by the PCI bus's configuration transaction and will

return undefined values or an error on some implementations. Every standard field in the first 64 bytes of configuration space is laid out so that its natural width is naturally aligned, so a driver that reads each field at its documented offset and width never runs into alignment trouble.

A driver reading a vendor-specific field whose layout is unclear should read it in the width the datasheet specifies. Do not assume that a 32-bit-wide read of a 16-bit field returns well-defined values in the high bits. The PCI specification requires unused byte lanes to return zeros, but a cautious driver reads only the width it needs.

18.12.6 Writing Configuration Space: Caveats

Three caveats for configuration-space writes.

First, some fields are sticky: once set, they do not clear. The command register's `INTxDIS` bit is an example. Writing zero to the bit does not re-enable legacy interrupts in all cases; the device may latch the disabled state. A driver that needs to toggle such a bit must write the full register (read-modify-write) and may need to tolerate the device ignoring the clearing write.

Second, some fields are RW1C ("read-write-one-to-clear"). Writing a 1 to the bit clears it; writing 0 is a no-op. The status register's error bits are all RW1C. A driver that wants to clear a sticky error bit writes a 1 to that bit's position.

Third, some writes have timing requirements. The power-management capability's control register, for example, requires 10 milliseconds of settle time after a state transition. A driver that writes such a field must respect the timing, usually with a `DELAY(9)` or `pause_sbt(9)` call.

For Chapter 18's driver, only the probe's ID reads and the capability walker's reads touch configuration space. No writes are done. Chapter 19 onward will add writes (enabling interrupts, clearing status bits); each write will have the relevant caveats called out at the point it is introduced.

18.13 A Deeper Look at the `bus_space` Abstraction

Section 4 used the Chapter 16 accessor layer unchanged against a real BAR. This subsection describes, in more depth, what the `bus_space` layer does under the hood and why it matters.

18.13.1 What `bus_space_tag_t` Is

On x86, `bus_space_tag_t` is an integer that selects between two address spaces: memory (`X86_BUS_SPACE_MEM`) and I/O port (`X86_BUS_SPACE_IO`). The tag tells the accessor which CPU instructions to emit: memory accesses use normal load and store instructions; I/O port accesses use `in` and `out`.

On arm64, `bus_space_tag_t` is a pointer to a structure of function pointers (a `struct bus_space`). The tag encodes not only memory vs I/O but also properties like endianness and access granularity.

On every platform, the tag is opaque to the driver. The driver stores it, passes it to `bus_space_read_*` and `bus_space_write_*`, and never inspects its contents. The inclusion of `machine/bus.h` brings in the platform-specific definition.

18.13.2 What `bus_space_handle_t` Is

On x86 for memory space, `bus_space_handle_t` is a kernel virtual address. The accessor dereferences it as a `volatile` pointer of the appropriate width.

On x86 for I/O port space, `bus_space_handle_t` is an I/O port number (0 to 65535). The accessor uses the `in` or `out` instruction with the port number.

On arm64, `bus_space_handle_t` is a kernel virtual address, similar to x86 memory space. The platform's MMU is configured to map the physical BAR into the virtual range with device-memory attributes.

The handle is also opaque to the driver. Together with the tag, it uniquely identifies a range of addresses where a specific resource lives.

18.13.3 What Happens Inside `bus_space_read_4`

On x86 for memory space, `bus_space_read_4(tag, handle, offset)` expands to roughly:

```
static inline uint32_t
bus_space_read_4(bus_space_tag_t tag, bus_space_handle_t handle,
                 bus_size_t offset)
{
    return (*(volatile uint32_t *) (handle + offset));
}
```

A volatile pointer dereference. The `volatile` keyword prevents the compiler from caching the value or reordering the access past other volatile accesses.

On x86 for I/O port space, the implementation uses the `inl` instruction:

```
static inline uint32_t
bus_space_read_4(bus_space_tag_t tag, bus_space_handle_t handle,
                 bus_size_t offset)
{
    uint32_t value;
    __asm volatile ("inl %w1, %0" : "=a"(value) : "Nd"(handle + offset));
    return (value);
}
```

The tag selects between the two implementations. On arm64 and other platforms, the tag is richer and the implementation dispatches through a function-pointer table.

18.13.4 Why the Abstraction Matters

A driver that uses `bus_space_read_4` and `bus_space_write_4` compiles to the right CPU instructions on every supported platform. The driver author does not need to know whether the BAR is memory or I/O; does

not need to write platform-specific code; does not need to annotate pointers with the correct access attributes. The `bus_space` layer handles all of this.

A driver that bypasses `bus_space` and dereferences a raw pointer may work on x86 by accident (because the kernel's `pmap` layer happens to set up the mapping in a way that pointer accesses work). On arm64 it will fail: the device memory is mapped with attributes that prevent normal memory access patterns from working correctly.

The lesson is: always use `bus_space` or the Chapter 16 accessors that wrap it. Never dereference a raw pointer into device memory, even if you know the virtual address.

18.13.5 The `bus_read` vs `bus_space_read` Naming

FreeBSD has two families of accessor functions that do essentially the same thing. The older `bus_space_read_*` family takes a tag, a handle, and an offset. The newer `bus_read_*` family takes a `struct resource *` and an offset, and pulls the tag and handle out of the resource internally.

The newer family is more convenient; the driver stores only the resource and does not need to store the tag and handle separately. The older family is more flexible; the driver can build a tag and handle from scratch (which Chapter 16's simulation used).

Chapter 18's driver uses the older family because it inherits from Chapter 16. A rewrite could use the newer family with no semantic change. Both families produce the same output. The book's choice is to teach the tag-and-handle story because it makes the abstraction explicit; the newer family hides the abstraction, which is nicer for writing drivers but less pedagogical.

For reference, the newer family members are named like `bus_read_4(res, offset)` and `bus_write_4(res, offset, value)`. They are defined in `/usr/src/sys/sys/bus.h` as inline functions that extract the tag and handle and delegate to `bus_space_read_*` and `bus_space_write_*`.

18.14 Hands-On Labs

The labs in this chapter are structured as graduated checkpoints. Each lab builds on the previous one. A reader who works through all five labs will have a complete PCI driver, a bhyve test environment, a regression script, and a small library of diagnostic tools. Labs 1 and 2 can be done on any FreeBSD machine without a guest; labs 3, 4, and 5 require a bhyve or QEMU guest with a `virtio-rnd` device.

The time budget for each lab assumes the reader has already read the relevant sections and understood the concepts. A reader who is still learning should budget more time.

18.14.1 Lab 1: Explore Your PCI Topology

Time: thirty minutes to an hour, depending on how much time you want to spend on comprehension.

Objective: Build an intuition for PCI on your own system.

Steps:

1. Run `pciconf -lv` on your lab host and redirect the output to a file: `pciconf -lv > ~/pci-inventory.txt`.
2. Count the devices: `wc -l ~/pci-inventory.txt`. Divide by an estimate (typically 5 lines per device in the output) to get the approximate device count.
3. Identify the following classes of devices from the inventory:
 - Host bridges (class = bridge, subclass = HOST-PCI)
 - PCI-PCI bridges (class = bridge, subclass = PCI-PCI)
 - Network controllers (class = network)
 - Storage controllers (class = mass storage)
 - USB host controllers (class = serial bus, subclass = USB)
 - Graphics (class = display)
4. For each of the above, note:
 - The device's name@pciN:B:D:F string.
 - The vendor and device IDs.
 - The driver binding (look at the leading name, before the @).
5. Pick one PCI device (any unclaimed device, visible as none@. . ., works best). Note its B:D:F.
6. Run `devinfo -v | grep -B 1 -A 5 <B:D:F>` and note the resources.
7. Compare the resource list with the BAR information in the `pciconf -lv` entry.

Expected observations:

- Most devices on a modern system are on `pci0` (the primary bus) or on a bus behind a PCIe bridge. Your machine probably has three to ten visible buses.
- Every device has at least a vendor and device ID. Many have subvendor and subsystem IDs.
- Most devices are bound to a driver. Some (especially on laptops, where a manufacturer ships hardware that FreeBSD does not yet support) are unclaimed.
- The resource lists in `devinfo -v` match the BAR information you can see in `pciconf -lv`. The addresses are the ones the firmware assigned.

This lab is about building vocabulary. No code. No driver. Just reading.

18.14.2 Lab 2: Write the Probe Skeleton on Paper

Time: one to two hours.

Objective: Internalise the probe-attach-detach sequence by writing it out longhand.

Steps:

1. Open a blank file, `myfirst_pci_sketch.c`, in your editor.
2. Without looking at Section 2's finished code, write:
 - A `myfirst_pci_id` struct.
 - A `myfirst_pci_ids[]` table with one entry for a hypothetical vendor `0x1234` and device `0x5678`.
 - A `myfirst_pci_probe` function that matches against the table.
 - A `myfirst_pci_attach` function that prints `device_printf(dev, "attached\n")`.

- A `myfirst_pci_detach` function that prints `device_printf(dev, "detached\n")`.
- A `device_method_t` table with `probe`, `attach`, `detach`.
- A `driver_t` with the driver's name.
- A `DRIVER_MODULE` line.
- A `MODULE_DEPEND` line.
- A `MODULE_VERSION` line.

3. Compare your sketch to the Section 2 code. Note every difference.
4. For each difference, ask: is mine wrong, or does it work differently for a reason?
5. Update your sketch to match the Section 2 code where yours was wrong.

Expected outcomes:

- You will probably forget `MODULE_DEPEND` and `MODULE_VERSION` on first pass.
- You may use `0` instead of `BUS_PROBE_DEFAULT` in `probe` (a common beginner mistake).
- You may forget the `device_set_desc` call in `probe`.
- You may use `printf` instead of `device_printf` in `attach` and `detach`.
- You may forget `DEVMETHOD_END` at the end of the method table.

Each of these is a real mistake that produces a real bug. Finding them in your own sketch, rather than in a compiled driver at two in the morning, is the point of the lab.

18.14.3 Lab 3: Load the Stage 1 Driver in a bhyve Guest

Time: two to three hours, including setting up the guest if you do not already have one.

Objective: Observe the probe-attach-detach sequence in action.

Steps:

1. If you do not already have a bhyve guest running FreeBSD 14.3, set one up. The canonical recipe is in `/usr/share/examples/bhyve/` or in the FreeBSD Handbook. Include a `virtio-rnd` device in the guest's bhyve command line: `-s 4:0,virtio-rnd`.
2. Inside the guest, list the PCI devices: `pciconf -lv | grep -B 1 -A 2 0x1005`. Note whether the `virtio-rnd` entry is bound to `virtio_random` (a leading `virtio_random@...`), to `none` (unclaimed), or missing entirely (check your bhyve command line).
3. Copy the Chapter 18 Stage 1 source into the guest (`scp`, shared filesystem, or any method you prefer).
4. Inside the guest, in the driver's source directory: `make`. Verify that `myfirst.ko` is produced.
5. If `virtio_random` claimed the device at step 2, unload it: `sudo kldunload virtio_random`. If the device was already unclaimed (`none`), skip this step.
6. Load `myfirst`: `sudo kldload ./myfirst.ko`.
7. Check the attach: `dmesg | tail -10`. You should see the Stage 1 attach banner.
8. Check the device: `devinfo -v | grep -B 1 -A 3 myfirst`. You should see `myfirst0` as a child of `pci0`.
9. Check the binding: `pciconf -lv | grep myfirst`. You should see the entry with `myfirst0` as the device name.
10. Unload the driver: `sudo kldunload myfirst`.
11. Check the detach: `dmesg | tail -5`. You should see the Stage 1 detach banner.

12. If you unloaded `virtio_random` at step 5 and want to restore it: `sudo kldload virtio_random`.

Expected outcomes:

- Every step produces the expected output.
- If step 7's `dmesg` does not show the attach banner, the driver did not probe the device. Check that you unloaded any other driver that might have claimed it.
- If step 7 shows the attach banner but step 8 does not show `myfirst0`, there is an accounting bug in `newbus`; unlikely, but worth reporting if you see it.
- If step 10 fails with `Device busy`, the driver's detach returned `EBUSY`. At Stage 1 there is no open `cdev`; the failure is unexpected. Check the detach code.

This lab is the first time the reader's driver meets a real device. The emotional payoff is real: `myfirst0`: attaching in `dmesg` is the proof that the driver works.

18.14.4 Lab 4: Claim the BAR and Read a Register

Time: two to three hours.

Objective: Extend the Stage 1 driver to Stage 2 (BAR allocation) and Stage 3 (first real register read).

Steps:

1. Starting from the Stage 1 driver from Lab 3, edit `myfirst_pci.c` to add Stage 2's BAR allocation. Compile. Load. Verify the BAR allocation banner in `dmesg`.
2. Verify the resource is visible: `devinfo -v | grep -A 3 myfirst0` should show a memory resource.
3. Unload. Verify the detach cleanly releases the BAR.
4. Edit `myfirst_pci.c` again to add Stage 3's capability walk and first register read. Compile. Load. Verify the capability output in `dmesg`.
5. Verify that `CSR_READ_4` operates on the real BAR by reading the first four bytes of the BAR and comparing to the first four bytes of `pciconf -r myfirst0 0x00:4`. (These are different; one is configuration space, the other is the BAR. The point of comparison is that both produce plausible values without crashing.)
6. Run the full regression script from Section 7. Verify that it completes without errors.

Expected outcomes:

- The BAR allocation succeeds and the resource is visible in `devinfo -v`.
- The capability walk may show zero offsets for the `virtio-rnd` device (the legacy layout does not have PCI capabilities in the way modern devices do); this is normal.
- The first register read returns a non-zero value; the exact value depends on the device's current state.

If any step produces a crash or a page fault, consult Section 7's common mistakes and re-check each step against Section 3's allocation discipline and Section 4's tag-and-handle code.

18.14.5 Lab 5: Exercise the cdev and Verify Detach Cleanup

Time: two to three hours.

Objective: Prove that the full Chapter 18 driver works end-to-end.

Steps:

1. Starting from the Stage 3 driver from Lab 4, write a small user-space program (`myfirst_test.c`) that opens `/dev/myfirst0`, reads up to 64 bytes, writes 16 bytes, and closes the device.
2. Compile and run the program. Observe the output. Ensure that no kernel message reports an error.
3. In a second terminal, tail `dmesg` with `dmesg -w`.
4. Run the program several times, watching for any warnings or errors.
5. Run the detach-attach cycle ten times with `devctl detach myfirst0; devctl attach pci0:0:4:0`. Verify that `dmesg` shows clean attach and detach banners each cycle.
6. After the cycle, run `vmstat -m | grep myfirst` and verify that the `myfirst` malloc type has zero live allocations.
7. Unload the driver. Verify `kldstat -v | grep myfirst` returns nothing.
8. Reload the driver. Verify the attach fires again.

Expected outcomes:

- Every step succeeds.
- The `vmstat -m` check at step 6 is the most important. If it shows live allocations after the detach cycle, there is a leak that needs fixing.
- The attach-detach-reattach cycle is stable. The driver can be bound, unbound, rebound indefinitely.

This lab is the regression proof. A driver that passes Lab 5 ten times in a row without issue is a driver that Chapter 19 can extend safely.

18.14.6 Lab Summary

The five labs together take ten to fifteen hours. They produce a complete PCI driver, a working test environment, a regression script, and a small toolbox of diagnostic commands the reader can reuse in later chapters. A reader who has done all five labs has done the hands-on equivalent of reading the chapter twice: the concepts are grounded in code that ran, failures that were fixed, and outputs that were observed.

If any lab resists (the BAR allocation fails, the capability walk produces an error, the detach leaks a resource), stop and diagnose. The troubleshooting section at the end of this chapter covers the common failure modes. The labs are calibrated to work; if a lab does not work, either the lab has a subtle error (rare) or the reader's environment has a detail that differs from the author's (much more common). Either way, the diagnosis is where the real learning happens.

18.15 Challenge Exercises

The challenges build on the labs. Each challenge is optional: the chapter is complete without them. But a reader who works through them will consolidate what they learned and extend the driver in ways the chapter did not.

18.15.1 Challenge 1: Support a Second Vendor and Device ID

Extend `myfirst_pci_ids[]` with a second entry. Target a different bhyve-emulated device: `virtio-blk` (vendor `0x1af4`, device `0x1001`) or `virtio-net` (`0x1af4`, `0x1000`). Unload the corresponding base-system driver (`virtio_blk` or `virtio_net`), load `myfirst`, and verify that the attach picks up the new device.

This exercise is trivial in code (one table entry) but exercises the reader's understanding of how the probe decision is made. After the change, both virtio devices will be eligible for `myfirst` if their drivers are unloaded.

18.15.2 Challenge 2: Print the Full Capability Chain

Extend the capability-walking code in `myfirst_pci_attach` to print every capability in the list, not only the ones the driver knows about. Walk the legacy capability list starting at `PCIR_CAP_PTR` and following the next pointers; for each capability, print the ID and the offset. Do the same for the extended capability list starting at offset `0x100`.

This exercise goes beyond the chapter's treatment of `pci_find_cap`. It requires reading `/usr/src/sys/dev/pci/pcireg.h` to find the layout of capability and extended-capability headers. The output on a typical virtio-rnd device may be sparse; on a real-hardware PCIe device it is richer.

18.15.3 Challenge 3: Implement a Simple ioctl for Configuration-Space Access

Extend the `cdev`'s `ioctl` entry point to accept a request for reading configuration space. Define a new `ioctl` command `MYFIRST_IOCTL_PCI_READ_CFG` that takes a `{ offset, width }` input and returns a `uint32_t` value. Have the implementation call `pci_read_config` under `sc->mtx`.

Write a user-space program that uses the new `ioctl` to read the first 16 bytes of configuration space, byte by byte, and prints them.

This exercise introduces the reader to custom ioctls, which are a common pattern for exposing driver-specific behaviour to user space without adding new system calls.

18.15.4 Challenge 4: Refuse to Attach if the BAR Is Too Small

The Chapter 18 driver assumes BAR 0 is at least `MYFIRST_REG_SIZE` (64) bytes. A different device with the same vendor and device IDs might expose a smaller BAR. Extend the attach path to read `rman_get_size(sc->bar_res)`, compare it to `MYFIRST_REG_SIZE`, and refuse to attach (return `ENXIO` after cleanup) if the BAR is too small.

Verify the behaviour by artificially setting `MYFIRST_REG_SIZE` to a value larger than the actual BAR size. The driver should refuse to attach and `dmesg` should print an informative message.

18.15.5 Challenge 5: Split the Driver into Two Modules

Using the technique sketched in Section 5, split the driver into `myfirst_core.ko` (hardware layer, simulation, `cdev`, locks) and `myfirst_pci.ko` (PCI attach). Add a `MODULE_DEPEND(myfirst_pci, myfirst_core, 1, 1, 1)` declaration. Verify that `kldload myfirst_pci` automatically loads `myfirst_core` as a dependency.

This exercise is a moderate refactor. It introduces the reader to cross-module symbol visibility (which functions need to be exported from `myfirst_core` to `myfirst_pci`) and to the module loader's dependency resolution. The result is a clean separation between the driver's generic machinery and its PCI-specific attach.

18.15.6 Challenge 6: Reimplement probe Using Class and Subclass Matching

Instead of matching by vendor and device ID, extend the probe routine to also match by class and subclass. For example, match any device in class `PCIC_BASEPERIPH` (base peripheral) with subclass matching a chosen value. Return `BUS_PROBE_GENERIC` (a lower-priority match) when the class-based match succeeds but no vendor/device-specific entry matched.

This exercise teaches the reader how drivers coexist. The vendor-specific match wins over the class match (by returning `BUS_PROBE_DEFAULT` vs `BUS_PROBE_GENERIC`). A fallback driver can claim devices that no specific driver recognises.

18.15.7 Challenge 7: Add a Read-Only sysctl That Reports the Driver's PCI State

Add a sysctl `dev.myfirst.N.pci_info` that returns a short string describing the driver's PCI attachment: the vendor and device IDs, the subvendor and subsystem, the B:D:F, and the BAR size and address. Use `sbuf_printf` to format the string.

The result is a user-space-readable dump of the driver's view of its device. This is useful for diagnostics and becomes a pattern that drivers for more complex devices reuse.

18.15.8 Challenge 8: Simulate a Failed Attach

Introduce a sysctl `hw.myfirst.fail_attach` that, when set to 1, causes attach to fail after claiming the BAR. Verify that the goto cascade cleans up correctly and `vmstat -m | grep myfirst` shows zero leaks after the failed attach.

This exercise exercises the partial-failure path that Section 6 described but the lab sequence did not test explicitly. It is the best way to confirm that the unwind cascade is correct.

18.15.9 Challenge Summary

Eight challenges, covering a range of difficulty. A reader who completes four or five of them has deepened their understanding meaningfully. A reader who completes all eight has essentially written a second Chapter 18.

Save your solutions. Several of them (Challenge 1, Challenge 3, Challenge 7) are natural starting points for Chapter 19 extensions.

18.16 Troubleshooting and Common Mistakes

This section consolidates the common failure modes a reader may encounter in Chapter 18's labs. Each entry names the symptom, the likely cause, and the fix.

18.16.1 "Driver does not attach; no dmesg banner"

Symptom: `kldload ./myfirst.ko` returns success. `dmesg | tail` shows nothing from `myfirst`. `devinfo -v` does not list `myfirst0`.

Likely causes:

1. Another driver has claimed the target device. Check `pciconf -lv` for the device and see which driver (if any) is bound. If `virtio_random0` owns the `virtio-rnd` device, the probe priority tie goes to `virtio_random` and `myfirst` never attaches. Fix: `kldunload virtio_random` first.
2. The vendor or device ID in `myfirst_pci_ids[]` is wrong. Check against the guest's actual device. Fix: correct the IDs.
3. The probe routine has a bug that always returns `ENXIO`. Check that the comparison compares vendor and device against the table entries, not against themselves. Fix: re-read the probe code carefully.
4. The `DRIVER_MODULE` declaration is missing or wrong. Check that the third argument is the `driver_t` and the second is `"pci"`. Fix: correct the declaration.

18.16.2 “kldload panics the kernel”

Symptom: `kldload ./myfirst.ko` crashes the kernel before it returns.

Likely causes:

1. Missing `MODULE_DEPEND(myfirst, pci, ...)`. The driver tries to register against a bus that is not yet initialised. Fix: add the declaration.
2. The driver's initialisation calls a function that does not exist at module-load time. Rare, but possible if the driver defines a `MOD_LOAD` handler that accesses `device_*` functions before the bus is ready.
3. The `softc` size declared in the `driver_t` is wrong. If the attach code expects fields that are not in the declared structure, the kernel writes past the allocated block and crashes. Fix: ensure `sizeof(struct myfirst_softc)` matches the structure definition.

The debug kernel is good at catching all three; the backtrace in `ddb` will name the function where the crash occurred.

18.16.3 “BAR allocation fails with NULL”

Symptom: `bus_alloc_resource_any` returns `NULL`. `dmesg` says “cannot allocate BAR0”.

Likely causes:

1. Wrong `rid`. Use `PCIR_BAR(0)` for BAR 0, not 0. Fix: use the macro.
2. Wrong type. If the device's BAR 0 is an I/O port (bit 0 of the BAR is set in configuration space), passing `SYS_RES_MEMORY` fails. Read the BAR value with `pci_read_config(dev, PCIR_BAR(0), 4)` and check the low bit. Fix: use the correct type.
3. The BAR is already allocated by another driver or by the BIOS. Unlikely on a bhyve guest; possible on real hardware with a misconfigured BIOS. Fix: check `devinfo -v` for the claimed resources.
4. The `RF_ACTIVE` flag is missing. The resource is allocated but not activated. The handle is not usable for `bus_space` accesses. Fix: add `RF_ACTIVE`.

18.16.4 “CSR_READ_4 returns 0xffffffff”

Symptom: register reads return all ones. The reader expects non-zero values.

Likely causes:

1. The BAR is not activated. Check `RF_ACTIVE` in the `bus_alloc_resource_any` call.
2. The tag and handle are swapped. Read `rman_get_bustag` returns the tag; `rman_get_bushandle` returns the handle. Passing them to `bus_space_read_4` in the wrong order produces undefined behaviour.
3. The offset is wrong. The BAR is 32 bytes; reading at offset 64 reads past the end. The debug kernel's `KASSERT` in `myfirst_reg_read` catches this.
4. The device has been reset or powered off. Some devices return all ones when off. Read the command register with `pci_read_config(dev, PCIR_COMMAND, 2)`; if it returns `0xffff`, the device is unresponsive.

18.16.5 “kldunload returns Device busy”

Symptom: `kldunload myfirst` fails with `Device busy`.

Likely causes:

1. A user-space process has `/dev/myfirst0` open. Close the process. Check with `fstat /dev/myfirst0`.
2. The driver has an in-flight command (simulation callout, taskqueue work). Wait a few seconds and retry.
3. The detach function incorrectly returns `EBUSY` unconditionally. Check the detach code.
4. The driver's busy check has a stale reference to an uninitialised field. Check that `sc->open_count` is zero when no descriptors are open.

18.16.6 “dmesg says ‘cleanup failed in detach’”

Symptom: `dmesg` shows a warning from the detach path.

Likely causes:

1. A callout was still scheduled when detach ran. Check that `callout_drain` was called before the driver's softc cleanup.
2. A taskqueue work item was still pending. Check that `taskqueue_drain` was called.
3. The `cdev` was open at detach. The `destroy_dev` call should block until closed, but if the driver releases other resources first, the close will find stale state. Fix the order: destroy the `cdev` before releasing dependent resources.

18.16.7 “ioctl or read returns an unexpected error”

Symptom: a user-space system call returns an error that the reader did not expect (`EINVAL`, `ENODEV`, `ENXIO`, etc.).

Likely causes:

1. The cdev's entry point checks for state the driver did not set. Example: the Chapter 10 driver checks `sc->is_attached`; the Chapter 18 driver might have forgotten to set it.
2. The `ioctl` command number in user space does not match the one in the driver. Check the `_IOR/_IOW/_IOWR` macros and confirm that the types are the same.
3. The lock order is wrong. The cdev entry point takes a lock in an order that conflicts with some other code. `WITNESS` on a debug kernel reports this.

18.16.8 “vmstat -m shows leaked allocations”

Symptom: after a load-unload cycle, `vmstat -m | grep myfirst` shows non-zero “Allocations” or “InUse”.

Likely causes:

1. A `malloc` in `attach` that is not freed in `detach`. Usually the hardware-layer wrapper struct or a `sysctl` buffer.
2. A callout that was not drained. The callout allocates a small structure; if it runs after `detach`, the structure leaks.
3. The `M_MYFIRST` `malloc` type is used for the `softc`. Newbus frees the `softc` automatically; the driver should not `malloc(M_MYFIRST, sizeof(softc))` at `attach`. The `softc` is allocated by newbus.

18.16.9 “pci_find_cap returns ENOENT for a capability I know the device has”

Symptom: `pci_find_cap(dev, PCIY_EXPRESS, &capreg)` returns `ENOENT`, but the device is a PCIe device and should have the PCI Express capability.

Likely causes:

1. The device is a legacy PCI device in a PCIe slot (it works because PCIe is backward-compatible with PCI). Legacy devices do not have the PCI Express capability. Check by reading `pci_get_class(dev)` and comparing to what you expected.
2. The capability list is corrupt or empty. Read `PCIR_CAP_PTR` directly with `pci_read_config(dev, PCIR_CAP_PTR, 1)`; if it returns zero, the device does not implement capabilities.
3. Wrong capability ID. `PCIY_EXPRESS` is `0x10`, not `0x1f`. Check `pci.h` for the correct constant.
4. The status register's `PCIM_STATUS_CAPPRESENT` bit is zero. This bit tells the PCI subsystem that the device implements a capability list. Without it, the list is not present. The bit is in `PCIR_STATUS`.

18.16.10 “Module unloads, but dmesg shows a page fault during unload”

Symptom: `kldunload myfirst` appears to succeed, but `dmesg` shows a page fault that occurred during the unload.

Likely causes:

1. A callout fired after `myfirst_hw_detach` but before the driver returned. The callout accessed `sc->hw`, which had been set to `NULL`. Fix: ensure `callout_drain` is called before `myfirst_hw_detach`.

2. A taskqueue work item ran after resources were freed. Fix: ensure `taskqueue_drain` is called before freeing anything the task touches.
3. A user-space process still has `/dev/myfirst0` open. The `destroy_dev` call completes quickly, but any outstanding I/O against the `cdev` continues until the process closes the descriptor or exits. Fix: ensure all user-space consumers close the `cdev` before detach; in emergency situations, `devctl detach` followed by killing the process works.

18.16.11 “devinfo -v shows the driver attached but the cdev does not appear”

Symptom: `devinfo -v | grep myfirst` shows `myfirst0`, but `ls /dev/myfirst*` returns nothing.

Likely causes:

1. The `make_dev` call failed and the attach did not check the return value. Check `sc->cdev` after `make_dev`; if it is `NULL`, the call failed.
2. The `cdev` name is not `myfirst%d`. Check the `make_dev` call's format string. The device node path uses the exact string passed to `make_dev`.
3. The `cdevsw` structure has not been registered or has wrong methods. Check that `myfirst_cdevsw` is initialised correctly.
4. A stale `/dev` entry is hiding the new one. Try `sudo devfs rule -s 0 apply` or reboot. Unlikely on modern FreeBSD but possible in edge cases.

18.16.12 “Attach takes a long time to return”

Symptom: `kldload ./myfirst.ko` hangs for seconds or minutes.

Likely causes:

1. A `DELAY` or `pause_sbt` call in `attach` is too long. Check for hidden delays in capability walks or device bring-up.
2. A `bus_alloc_resource_any` call is blocked on a resource that another driver has allocated. Rare on PCI; more common on platforms with limited I/O port space.
3. An infinite loop in the capability walker. A malformed device could produce a loop; the safety counter in the walker protects against this.
4. A `callout_init_mtx` call is waiting on a lock that another code path holds. Deadlock; check `WITNESS` output in `dmesg`.

18.16.13 “Driver attaches on boot but never produces output for the first few seconds”

Symptom: after a guest reboot with `myfirst` loaded at boot time, the driver attaches but takes seconds to produce any log output.

Likely causes:

1. The module was loaded early in boot, before the console was fully initialised. The messages are in the kernel buffer but not yet written to the console. Check `dmesg` for the messages; they should be present.
2. A callout was scheduled but has not yet fired. Chapter 17's sensor callout runs every second; the first tick is one second after attach.
3. The driver is waiting for a condition that takes time. Not a Chapter 18 issue, but possible in drivers that wait for the device to complete a reset.

18.16.14 “A second attempt to attach after a failed first attempt succeeds”

Symptom: `kldload` on a misconfigured kernel fails; a second `kldload` after fixing the configuration succeeds. This is actually expected behaviour.

Likely cause: the kernel's module loader is stateless between load attempts. A failed load removes any partial state. A subsequent load tries again with the fresh state. The symptom is not a bug.

18.16.15 “`vmstat -m InUse` grows after each load-unload cycle”

Symptom: the `myfirst` malloc type shows a few bytes of `InUse` memory increasing every cycle.

Likely causes:

1. A leak in attach or detach that is too small to notice in a single cycle but accumulates. Run 100 cycles and watch the growth.
2. The `myfirst_hw` or `myfirst_sim` wrapper struct is allocated but not freed. Check that the detach path calls `myfirst_hw_detach` and `myfirst_sim_detach` (if the simulation is loaded).
3. A string or similar small allocation in a `sysctl` handler is leaking. Check the `sysctl` handlers for `sbuf` that are created but not deleted.

The `vmstat -m` output has columns for `Requests`, `InUse`, `MemUse`. `Requests` is the total number of allocations ever made. `InUse` is the number currently allocated. `MemUse` is the total bytes. A healthy driver's `InUse` returns to zero after detach and unload.

18.16.16 Troubleshooting Summary

Every one of these failures is recoverable. The debug kernel (with `INVARIANTS`, `WITNESS`, and `KDB`) catches most of them with a useful message. A reader who runs a debug kernel and reads the message carefully will fix most Chapter 18 bugs in under an hour.

If a bug resists, the next step is to read the relevant section of this chapter again. The troubleshooting list above is short because the chapter's teaching is deliberately designed to prevent these failures. When a failure occurs, the question is usually “which section's discipline did I break?” and the answer is usually obvious on a second reading.

18.16.17 A Debug Kernel Checklist

If you are serious about driver development and debugging, build a debug kernel. The configuration options that catch PCI-driver bugs reliably are:

```
options INVARIANTS
options INVARIANT_SUPPORT
options WITNESS
options WITNESS_SKIPSPIN
options DEBUG_VFS_LOCKS
options DEBUG_MEMGUARD
options DIAGNOSTIC
options DDB
options KDB
options KDB_UNATTENDED
options MALLOC_DEBUG_MAXZONES=8
```

A driver that passes its regression tests under a kernel with all of these enabled is a driver that will rarely produce production bugs. The runtime cost is significant (the kernel is slower, and `WITNESS` in particular adds measurable overhead to every lock operation), but the debugging value is enormous.

Build the debug kernel with:

```
cd /usr/src
sudo make buildkernel KERNCONF=GENERIC-DEBUG
sudo make installkernel KERNCONF=GENERIC-DEBUG
sudo shutdown -r now
```

Use the debug kernel for all driver development; switch back to `GENERIC` only for performance benchmarking.

18.17 Wrapping Up

Chapter 18 turned the simulated driver into a PCI driver. The starting point was `1.0-simulated`, a module with a `malloc(9)`-backed register block and a Chapter 17 simulation that made the registers breathe. The ending point is `1.1-pci`, the same module with one new file (`myfirst_pci.c`), one new header (`myfirst_pci.h`), and a handful of small extensions to the existing files. The accessor layer did not change. The command-response protocol did not change. The lock discipline did not change. What changed is the origin of the tag and handle that the accessors use.

The transition walked through eight sections. Section 1 introduced PCI as a concept, covering the topology, the B:D:F tuple, configuration space, BARs, vendor and device IDs, and the `pci(4)` subsystem. Section 2 wrote the probe-attach-detach skeleton, tied to the PCI bus with `DRIVER_MODULE(9)` and `MODULE_DEPEND(9)`. Section 3 explained what BARs are and claimed one through `bus_alloc_resource_any(9)`. Section 4 wired the claimed BAR to the Chapter 16 accessor layer, completing the transition from simulated to real register access. Section 5 added the attach-time plumbing: `pci_find_cap(9)` and `pci_find_extcap(9)` for capability

discovery, the cdev creation, and the discipline that keeps the Chapter 17 simulation inactive on the PCI path. Section 6 consolidated the detach path with strict reverse ordering, a busy check, callout and task draining, and partial-failure recovery. Section 7 tested the driver in a bhyve or QEMU guest, exercising every path the driver exposes. Section 8 refactored the code into its final shape and documented the result.

What Chapter 18 did not do is interrupt handling. The `virtio-rnd` device under bhyve has an interrupt line; our driver does not register a handler for it; the device's internal state changes do not reach the driver. The cdev is still reachable, but the data path has no active producer on the PCI build (the Chapter 17 simulation callouts are not running). Chapter 19 introduces the real handler that will give the data path a producer.

What Chapter 18 did accomplish is the crossing of a threshold. Up to the end of Chapter 17, the `myfirst` driver was a teaching module: it existed because we loaded it, not because any device required it. From Chapter 18 onward, the driver is a PCI driver: it exists because the kernel enumerated a device and our probe said yes. The newbus machinery carries the driver now. Every later Part 4 chapter extends it without changing this fundamental relationship.

The file layout has grown: `myfirst.c`, `myfirst_hw.c`, `myfirst_hw.h`, `myfirst_sim.c`, `myfirst_sim.h`, `myfirst_pci.c`, `myfirst_pci.h`, `myfirst_sync.h`, `cbuf.c`, `cbuf.h`, `myfirst.h`. The documentation has grown: `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`. The test suite has grown: the bhyve or QEMU setup scripts, the regression script, the small user-space test programs. Each of these is a layer; each of them was introduced in a specific chapter and is now a permanent part of the driver's story.

18.17.1 A Reflection Before Chapter 19

A pause before the next chapter. Chapter 18 taught the PCI subsystem and the newbus attach dance. The patterns you practised here (probe-attach-detach, resource claim-release, tag-and-handle extraction, capability discovery) are patterns you will use throughout your driver-writing life. They apply as much to the USB attach dance in Chapter 21 as to the PCI dance you just wrote, as much to the NIC driver you might write for a real card as to the demo driver you just extended. The PCI skill is permanent.

Chapter 18 also taught the discipline of strict reverse ordering in detach. The goto cascade in attach, the mirror detach, the busy check, the quiesce step: these are the patterns that keep a driver from leaking resources across its lifecycle. They apply to every kind of driver, not only PCI. A reader who has internalised Chapter 18's detach discipline will write cleaner Chapter 19, Chapter 20, and Chapter 21 code.

One more observation. The payoff of Chapter 16's accessor layer is now visible. A reader who wrote the Chapter 16 accessors and wondered "is this worth the effort?" can look at Chapter 18's Stage 3 attach and see the answer. The upper-layer code of the driver (every call site that uses `CSR_READ_4`, `CSR_WRITE_4`, or `CSR_UPDATE_4`) did not change at all when the backend switched from simulated to real PCI. That is what a good abstraction buys: a major change in the lower layer costs zero changes in the upper layer. The Chapter 16 accessors were the abstraction. Chapter 18 was the proof.

18.17.2 What to Do If You Are Stuck

Two suggestions.

First, focus on the regression script from Section 7. If the script runs end-to-end without error, the driver is working; every confusion about internal details is decorative. If the script fails, the first failing step is the starting point for debugging.

Second, open `/usr/src/sys/dev/uart/uart_bus_pci.c` and read it slowly. The file is 366 lines. Every line is a pattern that Chapter 18 taught or referenced. Reading it after Chapter 18 should feel familiar: probe, attach, detach, ID table, `DRIVER_MODULE`, `MODULE_DEPEND`. A reader who finds the file readable after Chapter 18 has made the chapter's real progress.

Third, skip the challenges on first pass. The labs are calibrated for Chapter 18; the challenges assume the chapter's material is already solid. Come back to them after Chapter 19 if they feel out of reach now.

Chapter 18's goal was to let the driver meet real hardware. If it has, the rest of Part 4 will feel like a natural progression: Chapter 19 adds interrupts, Chapter 20 adds MSI and MSI-X, Chapters 20 and 21 add DMA. Each chapter extends what Chapter 18 established.

18.18 Bridge to Chapter 19

Chapter 19 is titled *Handling Interrupts*. Its scope is the topic Chapter 18 deliberately did not take: the path that lets a device tell the driver, asynchronously, that something happened. Chapter 17's simulation used callouts to produce autonomous state changes. Chapter 18's real-PCI driver ignores the device's interrupt line entirely. Chapter 19 registers a handler through `bus_setup_intr(9)`, attaches it to an IRQ resource allocated through `bus_alloc_resource_any(9)` with `SYS_RES_IRQ`, and teaches the driver to react to the device's own signals.

Chapter 18 prepared the ground in four specific ways.

First, **you have a PCI-attached driver**. The Chapter 18 driver at `1.1-pci` allocates a BAR, claims a memory resource, and has every newbus hook in place. Chapter 19 adds one more resource (an IRQ) and one more pair of calls (`bus_setup_intr` and `bus_teardown_intr`). The rest of the attach and detach flow stays put.

Second, **you have an accessor layer that can be called from an interrupt context**. The Chapter 16 accessors take `sc->mtx`; an interrupt handler that needs to read or write a register acquires `sc->mtx` and calls `CSR_READ_4` or `CSR_WRITE_4`. The Chapter 19 handler will compose with the accessors without any new plumbing.

Third, **you have a detach order that accommodates IRQ teardown**. Chapter 18's detach releases the BAR at a specific point in the sequence; Chapter 19's detach will release the IRQ resource before releasing the BAR. The goto cascade expands by one label; the pattern does not change.

Fourth, **you have a test environment that produces interrupts**. The bhyve or QEMU guest with a `virtio-rnd` device is the same environment Chapter 19 uses; the `virtio-rnd` device's interrupt line is what Chapter 19's handler receives. No new lab setup is required.

Specific topics Chapter 19 will cover:

- What an interrupt is, in contrast to a polled callout.
- The two-stage model of FreeBSD interrupt handlers: filter (fast, in interrupt context) and `ithread` (slow, in a kernel thread context).
- `bus_alloc_resource_any(9)` with `SYS_RES_IRQ`.
- `bus_setup_intr(9)` and `bus_teardown_intr(9)`.
- `INTR_TYPE_*` and `INTR_MPSAFE` flags.
- What an interrupt handler may and may not do (no sleeping, no blocking locks, no `malloc(M_WAITOK)`).
- Reading a status register at interrupt time to decide what happened.

- Clearing interrupt flags to prevent re-entry.
- Logging interrupts safely.
- Interaction between interrupts and the Chapter 16 access log.
- A minimal interrupt handler that increments a counter and logs.

You do not need to read ahead. Chapter 18 is sufficient preparation. Bring your `myfirst` driver at `1.1-pci`, your `LOCKING.md`, your `HARDWARE.md`, your `SIMULATION.md`, your new `PCI.md`, your WITNESS-enabled kernel, and your regression script. Chapter 19 starts where Chapter 18 ended.

Chapter 20 is two chapters further along; it is worth a brief forward pointer. MSI and MSI-X will replace the single legacy interrupt line with a richer routing mechanism: separate vectors for separate tasks, interrupt coalescing, per-queue affinity. The `pci_alloc_msi(9)` and `pci_alloc_msix(9)` functions are part of the PCI subsystem Chapter 18 introduced; we saved them for Chapter 20 because MSI-X in particular requires a deeper understanding of interrupt handling than Chapter 18 was ready to introduce. If the reader has glanced at the `PCIY_MSI` and `PCIY_MSIX` offsets in the capability walk and wondered what they were for, Chapter 20 is the answer.

The hardware conversation is deepening. The vocabulary is yours; the protocol is yours; the discipline is yours. Chapter 19 adds the next missing piece.

18.19 Reference: PCI Header Offsets the Chapter Used

A compact reference of the configuration-space offsets Chapter 18 references, sourced from `/usr/src/sys/dev/pci/pci.h`. Keep this at hand while writing PCI code.

Offset	Macro	Width	Meaning
0x00	PCIR_VENDOR	2	Vendor ID
0x02	PCIR_DEVICE	2	Device ID
0x04	PCIR_COMMAND	2	Command register
0x06	PCIR_STATUS	2	Status register
0x08	PCIR_REVID	1	Revision ID
0x09	PCIR_PROGIF	1	Programming interface
0x0a	PCIR_SUBCLASS	1	Subclass
0x0b	PCIR_CLASS	1	Class
0x0c	PCIR_CACHELNSZ	1	Cache line size
0x0d	PCIR_LATTIMER	1	Latency timer
0x0e	PCIR_HDRTYPE	1	Header type
0x0f	PCIR_BIST	1	Built-in self test
0x10	PCIR_BAR(0)	4	BAR 0
0x14	PCIR_BAR(1)	4	BAR 1

Offset	Macro	Width	Meaning
0x18	PCIR_BAR(2)	4	BAR 2
0x1c	PCIR_BAR(3)	4	BAR 3
0x20	PCIR_BAR(4)	4	BAR 4
0x24	PCIR_BAR(5)	4	BAR 5
0x2c	PCIR_SUBVEND_0	2	Subsystem vendor
0x2e	PCIR_SUBDEV_0	2	Subsystem device
0x34	PCIR_CAP_PTR	1	Capability list start
0x3c	PCIR_INTLINE	1	Interrupt line
0x3d	PCIR_INTPIN	1	Interrupt pin

18.19.1 Command Register Bits

Bit	Macro	Meaning
0x0001	PCIM_CMD_PORTEN	Enable I/O space
0x0002	PCIM_CMD_MEMEN	Enable memory space
0x0004	PCIM_CMD_BUSMASTEREN	Enable bus master
0x0008	PCIM_CMD_SPECIALEN	Enable special cycles
0x0010	PCIM_CMD_MWRICEN	Memory write and invalidate
0x0020	PCIM_CMD_PERRESPEN	Parity error response
0x0040	PCIM_CMD_SERRESPEN	SERR# enable
0x0400	PCIM_CMD_INTxDIS	Disable INTx generation

18.19.2 Capability IDs (legacy)

Value	Macro	Meaning
0x01	PCIY_PMG	Power Management
0x05	PCIY_MSI	Message Signaled Interrupts
0x09	PCIY_VENDOR	Vendor-specific
0x10	PCIY_EXPRESS	PCI Express
0x11	PCIY_MSIX	MSI-X

18.19.3 Extended Capability IDs (PCIe)

Value	Macro	Meaning
0x0001	PCIZ_AER	Advanced Error Reporting
0x0002	PCIZ_VC	Virtual Channel
0x0003	PCIZ_SERNUM	Device Serial Number
0x0004	PCIZ_PWRBDGT	Power Budgeting
0x000d	PCIZ_ACS	Access Control Services
0x0010	PCIZ_SRIOV	Single Root I/O Virtualisation

A reader who needs other PCI constants should open `/usr/src/sys/dev/pci/pci.h` directly. The file is well commented; finding a specific offset or bit takes less than a minute.

18.20 Reference: A Comparison with Chapter 16 and Chapter 17 Patterns

A side-by-side comparison of where Chapter 18 extends Chapters 16 and 17 and where it introduces genuinely new material.

Pattern	Chapter 16	Chapter 17	Chapter 18
Register access	CSR_READ_4, etc.	Same API, unchanged	Same API, unchanged
Access log	Introduced	Extended with fault-injection entries	Unchanged
Lock discipline	sc->mtx around each access	Same, plus callouts	Same
File layout	myfirst_hw.c added	myfirst_sim.c added	myfirst_pci.c added
Register map	10 registers, 40 bytes	16 registers, 60 bytes	Same
Attach routine	Simple (malloc block)	Simple (malloc block plus sim setup)	Real PCI BAR claim
Detach routine	Simple	Same plus callout drain	Same plus BAR release
Module loading	kldload triggers load	Same	kldload plus PCI probe
Device instance	Global (implicit)	Global	Per-PCI-device, numbered
BAR	N/A	N/A	BAR 0, SYS_RES_MEMORY, RF_ACTIVE
Capability walk	N/A	N/A	pci_find_cap / pci_find_extcap
cdev	Created at module load	Same	Created per attach

Pattern	Chapter 16	Chapter 17	Chapter 18
Version	0.9-mmio	1.0-simulated	1.1-pci
Documentation	HARDWARE.md introduced	SIMULATION.md introduced	PCI.md introduced

Chapter 18 builds on Chapters 16 and 17 without breaking anything. Every earlier-chapter capability is preserved; the real-PCI attach is added as a new backend that composes with the existing structure. The driver at 1.1-pci is a strict superset of the driver at 1.0-simulated.

18.21 Reference: Patterns From Real FreeBSD PCI Drivers

A short tour of patterns that appear repeatedly in the `/usr/src/sys/dev/` tree. Each pattern is a concrete snippet from a real driver, rewritten slightly for readability, with a pointer to the file and a short note on why the pattern matters. Reading these patterns after Chapter 18 consolidates the vocabulary.

18.21.1 Pattern: Walking BARs by Type

From `/usr/src/sys/dev/e1000/if_em.c`:

```
for (rid = PCIR_BAR(0); rid < PCIR_CIS;) {
    val = pci_read_config(dev, rid, 4);
    if (EM_BAR_TYPE(val) == EM_BAR_TYPE_IO) {
        break;
    }
    rid += 4;
    if (EM_BAR_MEM_TYPE(val) == EM_BAR_MEM_TYPE_64BIT)
        rid += 4;
}
```

This loop walks the BAR table looking for the I/O port BAR. It reads each BAR's configuration-space value, checks its type bit, and advances by 4 bytes (one BAR slot) or 8 bytes (two slots, for a 64-bit memory BAR). The loop terminates either at `PCIR_CIS` (the CardBus pointer, which is just beyond the BAR table) or when it finds an I/O BAR.

Why it matters: on drivers that support a mix of memory and I/O BARs across a range of hardware revisions, the BAR layout is not fixed. Walking dynamically is the right approach. Chapter 18's driver targets one device with a known BAR layout and does not need this walker; a driver like `em(4)` that covers a family of chips does.

18.21.2 Pattern: Matching on Class, Subclass, and progIF

From `/usr/src/sys/dev/uart/uart_bus_pci.c`:

```

if (pci_get_class(dev) == PCIC_SIMPLECOMM &&
    pci_get_subclass(dev) == PCIS_SIMPLECOMM_UART &&
    pci_get_progif(dev) < PCIP_SIMPLECOMM_UART_16550A) {
    id = &cid;
    sc->sc_class = &uart_ns8250_class;
    goto match;
}

```

This snippet is a class-based fallback. If the vendor-and-device match failed, the probe falls back to matching any device advertising “simple communications / UART / pre-16550A” in its class code. The progIF field distinguishes 16450, 16550A, and later variants; the snippet specifically targets the older ones.

Why it matters: class codes let a driver attach to families of devices the specific match table does not enumerate. A UART chip from a vendor not in the `uart(4)` table is still handled as long as the class code is standard. The pattern works well for standardised device types (AHCI, xHCI, UART, NVMe, HD Audio) where the programming interface is class-defined.

18.21.3 Pattern: Conditional MSI Allocation

From `/usr/src/sys/dev/uart/uart_bus_pci.c`:

```

id = uart_pci_match(dev, pci_ns8250_ids);
if ((id == NULL || (id->rid & PCI_NO_MSI) == 0) &&
    pci_msi_count(dev) == 1) {
    count = 1;
    if (pci_alloc_msi(dev, &count) == 0) {
        sc->sc_irid = 1;
        device_printf(dev, "Using %d MSI message\n", count);
    }
}

```

This snippet allocates MSI if the device supports it and the driver has not marked the entry with `PCI_NO_MSI`. The `pci_msi_count(dev)` call returns the number of MSI vectors the device advertises; `pci_alloc_msi` allocates them. The `sc->sc_irid = 1` line reflects the rid assigned to the MSI resource (MSI resources start at rid 1; legacy IRQs use rid 0).

Why it matters: MSI is preferred over legacy IRQs on modern systems because it avoids the IRQ-sharing problems of the `INTx` pin. A driver that supports MSI and falls back to legacy IRQs when MSI is unavailable is the right pattern. Chapter 20 returns to MSI in detail; the snippet here is a preview.

18.21.4 Pattern: Detach-Time IRQ Release

From `/usr/src/sys/dev/uart/uart_bus_pci.c`:

```
static int
uart_pci_detach(device_t dev)
{
    struct uart_softc *sc;

    sc = device_get_softc(dev);

    if (sc->sc_irid != 0)
        pci_release_msi(dev);

    return (uart_bus_detach(dev));
}
```

Detach releases MSI (if allocated) and delegates the rest to `uart_bus_detach`. The `sc->sc_irid != 0` check guards against calling `pci_release_msi` on a driver that used legacy IRQs; releasing MSI when it was not allocated is an error.

Why it matters: every resource allocated at attach must be released at detach. The driver tracks what it allocated through state (here, `sc_irid != 0` means MSI was used) and releases accordingly. Chapter 19 and Chapter 20 will extend Chapter 18's detach in a similar pattern.

18.21.5 Pattern: Reading Vendor-Specific Configuration Fields

From `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c` (simplified):

```
cap_offset = 0;
while (pci_find_next_cap(dev, PCIY_VENDOR, cap_offset, &cap_offset) == 0) {
    uint8_t cap_type = pci_read_config(dev,
        cap_offset + VIRTIO_PCI_CAP_TYPE, 1);
    if (cap_type == VIRTIO_PCI_CAP_COMMON_CFG) {
        /* This is the capability we're looking for. */
        break;
    }
}
```

This walks every vendor-specific capability in the list (`ID = PCIY_VENDOR = 0x09`), checking each one's vendor-defined type byte until it finds the one the driver wants. The `pci_find_next_cap` function is the iterating version of `pci_find_cap`, picking up where the last call left off.

Why it matters: when multiple capabilities share the same ID (as with virtio's vendor-specific capabilities), the driver must walk and disambiguate by reading the capability's own type field. The `pci_find_next_cap` function exists specifically for this case.

18.21.6 Pattern: A Power-Aware Resume Handler

From various drivers:

```
static int
myfirst_pci_resume(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Restore the device to its pre-suspend state. */
    MYFIRST_LOCK(sc);
    CSR_WRITE_4(sc, MYFIRST_REG_CTRL, sc->saved_ctrl);
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, sc->saved_intr_mask);
    MYFIRST_UNLOCK(sc);

    /* Re-enable the user-space interface. */
    return (0);
}
```

A suspend handler saves the device state; the resume handler restores it. The pattern matters for systems that support suspend-to-RAM (S3) or suspend-to-disk (S4); a driver that does not implement suspend and resume prevents the system from entering those states.

Chapter 18's driver does not implement suspend and resume. Chapter 22 adds them.

18.21.7 Pattern: Responding to a Device-Specific Error State

From `/usr/src/sys/dev/e1000/if_em.c`:

```
if (reg_icr & E1000_ICR_RX0)
    sc->rx_overruns++;
if (reg_icr & E1000_ICR_LSC)
    em_handle_link(ctx);
if (reg_icr & E1000_ICR_INT_ASSERTED) {
    /* ... */
}
```

After an interrupt, the driver reads the interrupt cause register (`reg_icr`) and dispatches based on which bits are set. Each bit corresponds to a different event: receive overrun, link state change, general interrupt. The driver takes a different action for each.

Why it matters: a real driver handles many event types. The dispatching pattern is familiar from Chapter 17's fault injection, where the simulation could inject different fault types. Chapter 19 will introduce the interrupt-handling version of this pattern.

18.21.8 Pattern: Using sysctl to Expose Driver Configuration

From any number of drivers:

```
SYSCALL_ADD_U32(&sc->sysctl_ctx,  
    SYSCALL_CHILDREN(sc->sysctl_tree), OID_AUTO,  
    "max_retries", CTLFLAG_RW,  
    &sc->max_retries, 0,  
    "Maximum retry attempts");
```

Drivers expose tunable parameters through sysctl. The parameter can be read or written from user space with `sysctl dev.myfirst.0.max_retries`. A driver that exposes a handful of such tunables gives its operators a way to adjust behaviour without rebuilding the driver.

Why it matters: sysctl is the right place for per-driver tunables. Kernel command-line options (tunables set at boot time) are for early-boot parameters only; runtime adjustment goes through sysctl.

18.21.9 Pattern: Recording Supported Features in a Capabilities Structure

From `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c`:

```
sc->vtpci_modern_res.vtprm_common_cfg_cap_off = common_cfg_off;  
sc->vtpci_modern_res.vtprm_notify_cap_off = notify_off;  
sc->vtpci_modern_res.vtprm_isr_cfg_cap_off = isr_cfg_off;  
sc->vtpci_modern_res.vtprm_device_cfg_cap_off = device_cfg_off;
```

The driver stores the offsets of each capability in a per-device state structure. Later code that needs to access a capability's registers reaches it through the stored offset.

Why it matters: after attach, the driver should not need to re-walk the capability list. Storing the offsets at attach time saves a walk on every access. Chapter 18's driver walks the capabilities for informational purposes but does not store the offsets because it does not use them. A real driver that cares about a capability stores its offset.

18.21.10 Pattern Summary

The patterns above are the common currency of FreeBSD PCI drivers. A reader who recognises them in unfamiliar code is a reader who can learn from any driver in the tree. Chapter 18 taught the base patterns; the real drivers layer specific variations on top. The specific variations are always small (a class-based match here, an MSI allocation there); the base patterns are what recur.

After finishing Chapter 18 and the labs, pick a driver in `/usr/src/sys/dev/` you find interesting (perhaps for a device you own, or perhaps just one whose name you recognise) and read its PCI attach. Use this section as a checklist: which patterns does the driver use? Which ones does it skip? Why? A driver author who has done this exercise three or four times across different drivers has built an enormous fund of pattern recognition.

18.22 Reference: A Closing Note on PCI Driver Philosophy

A paragraph to close the chapter with, worth returning to after the labs.

A PCI driver's job is not to understand the device. A PCI driver's job is to present the device to the kernel in a form the kernel can use. The understanding of the device (what its registers mean, what protocol it speaks, what invariants it maintains) belongs to the driver's upper layers: the hardware abstraction, the protocol implementation, the user-space interface. The PCI layer is a narrow thing. It matches a vendor and device ID. It claims a BAR. It hands the BAR to the upper layers. It registers an interrupt handler. It hands control to the upper layers. It exists to connect two halves of the driver's identity: the device half, which belongs to the hardware, and the software half, which belongs to the kernel.

A reader who has written the Chapter 18 driver has written one PCI layer. It is small. The rest of the driver is what makes it useful. In Chapter 19 the driver's PCI layer will gain one more responsibility (interrupt registration). In Chapter 20 it will gain MSI and MSI-X. In Chapters 20 and 21 it will manage DMA tags. Each of these is a narrow extension of the PCI layer's existing role. None of them changes the PCI layer's fundamental character.

For this reader and for this book's future readers, the Chapter 18 PCI layer is a permanent piece of the `myfirst` driver's architecture. Every later chapter assumes it. Every later chapter extends it. The driver's overall complexity will grow, but the PCI layer will remain what Chapter 18 made it: a connector between the device and the rest of the driver, small and predictable.

The skill Chapter 18 teaches is not "how to write a driver for `virtio-rnd`". It is "how to connect a driver to a PCI device, regardless of what the device is". That skill is transferable, and it is the skill that will serve you across every PCI driver you write.

18.23 Reference: Chapter 18 Quick-Reference Card

A compact summary of the vocabulary, APIs, macros, and procedures Chapter 18 introduced. Useful as a single-page refresher while working through Chapter 19 and later chapters.

18.23.1 Vocabulary

- **PCI**: Peripheral Component Interconnect, the shared parallel bus introduced by Intel in the early 1990s.
- **PCIe**: PCI Express, the modern serial successor. Same software-visible model as PCI.
- **B:D:F**: Bus, Device, Function. The address of a PCI device. Written `pciN:B:D:F` in FreeBSD output.
- **Configuration space**: the small metadata area each PCI device exposes. 256 bytes on PCI, 4096 bytes on PCIe.
- **BAR**: Base Address Register. A configuration-space field where a device advertises a range of addresses it needs.
- **Vendor ID**: 16-bit identifier assigned by the PCI-SIG to a manufacturer.
- **Device ID**: 16-bit identifier assigned by the vendor to a specific product.
- **Subvendor/subsystem ID**: secondary 16+16-bit tuple identifying the board.
- **Capability list**: a linked list of optional feature blocks in configuration space.
- **Extended capability list**: the PCIe-specific list, starting at offset `0x100`.

18.23.2 Essential APIs

- `pci_get_vendor(dev)` / `pci_get_device(dev)`: read cached ID fields.
- `pci_get_class(dev)` / `pci_get_subclass(dev)` / `pci_get_progif(dev)` / `pci_get_revid(dev)`: read cached classification fields.
- `pci_get_subvendor(dev)` / `pci_get_subdevice(dev)`: read cached subsystem identification.
- `pci_read_config(dev, offset, width)` / `pci_write_config(dev, offset, val, width)`: raw configuration-space access (width 1, 2, or 4).
- `pci_find_cap(dev, cap, &offset)` / `pci_find_next_cap(dev, cap, start, &offset)`: walk the legacy capability list.
- `pci_find_extcap(dev, cap, &offset)` / `pci_find_next_extcap(dev, cap, start, &offset)`: walk the PCIe extended capability list.
- `pci_enable_busmaster(dev)` / `pci_disable_busmaster(dev)`: toggle the bus-master enable bit.
- `pci_msi_count(dev)` / `pci_msix_count(dev)`: report MSI and MSI-X vector counts.
- `pci_alloc_msi(dev, &count)` / `pci_alloc_msix(dev, &count)`: allocate MSI or MSI-X vectors (Chapter 20).
- `pci_release_msi(dev)`: release MSI or MSI-X.
- `bus_alloc_resource_any(dev, type, &rid, flags)`: claim a resource (BAR, IRQ, etc.).
- `bus_release_resource(dev, type, rid, res)`: release a claimed resource.
- `rman_get_bustag(res)` / `rman_get_bushandle(res)`: extract the bus_space tag and handle.
- `rman_get_start(res)` / `rman_get_size(res)` / `rman_get_end(res)`: inspect a resource's range.
- `bus_space_read_4(tag, handle, off)` / `bus_space_write_4(tag, handle, off, val)`: the low-level accessors.
- `bus_read_4(res, off)` / `bus_write_4(res, off, val)`: resource-based shorthand.

18.23.3 Essential Macros

- `DEVMETHOD(device_probe, probe_fn)` and similar: populate a method table.
- `DEVMETHOD_END`: terminate a method table.
- `DRIVER_MODULE(name, bus, driver, modev_fn, modev_arg)`: register a driver against a bus.
- `MODULE_DEPEND(name, dep, minver, prefver, maxver)`: declare a module dependency.
- `MODULE_VERSION(name, version)`: declare the driver's version.
- `PCIR_BAR(n)`: compute the configuration-space offset of BAR n.
- `BUS_PROBE_DEFAULT`, `BUS_PROBE_GENERIC`, `BUS_PROBE_VENDOR`, `BUS_PROBE_SPECIFIC`: probe priority values.
- `SYS_RES_MEMORY`, `SYS_RES_IOPORT`, `SYS_RES_IRQ`: resource types.
- `RF_ACTIVE`, `RF_SHAREABLE`: resource allocation flags.

18.23.4 Common Procedures

Attach a PCI driver to a specific device ID:

1. Write a probe that reads `pci_get_vendor(dev)` and `pci_get_device(dev)`, compares against a table, returns `BUS_PROBE_DEFAULT` on match and `ENXIO` otherwise.

2. Write an attach that calls `bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE)` with `rid = PCIR_BAR(0)`.
3. Extract the tag and handle with `rman_get_bustag` and `rman_get_bushandle`.
4. Store them where the accessor layer can reach them.

Release a PCI resource at detach:

1. Drain any callouts or tasks that might access the resource.
2. Release the resource with `bus_release_resource(dev, type, rid, res)`.
3. Set the stored resource pointer to NULL.

Unload a conflicting base-system driver before loading your own:

```
sudo kldunload virtio_random    # or whatever driver owns the device
sudo kldload ./myfirst.ko
```

Force a device to rebind from one driver to another:

```
sudo devctl detach <driver0_name>
sudo devctl set driver -f <pci_selector> <new_driver_name>
```

18.23.5 Useful Commands

- `pciconf -lv`: list every PCI device with its IDs, class, and driver binding.
- `pciconf -r <selector> <offset>:<length>`: dump configuration-space bytes.
- `pciconf -w <selector> <offset> <value>`: write a configuration-space value.
- `devinfo -v`: dump the newbus tree with resources and bindings.
- `devctl detach, attach, disable, enable, rescan`: control bus bindings at runtime.
- `dmesg, dmesg -w`: view (and follow) the kernel message buffer.
- `kldstat -v`: list loaded modules with verbose info.
- `kldload, kldunload`: load and unload kernel modules.
- `vmstat -m`: report memory allocations by malloc type.

18.23.6 Files to Keep Bookmarked

- `/usr/src/sys/dev/pci/pci.h`: PCI register definitions (`PCIR_*`, `PCIM_*`, `PCIY_*`, `PCIZ_*`).
- `/usr/src/sys/dev/pci/pciivar.h`: PCI accessor function declarations.
- `/usr/src/sys/sys/bus.h`: newbus method and resource macros.
- `/usr/src/sys/sys/rman.h`: resource manager accessors.
- `/usr/src/sys/sys/module.h`: module registration macros.
- `/usr/src/sys/dev/uart/uart_bus_pci.c`: a clean, readable example PCI driver.
- `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c`: a modern transport example.

18.24 Reference: Glossary of Chapter 18 Terms

A short glossary for readers who want a compact reminder of Chapter 18's vocabulary.

AER (Advanced Error Reporting): a PCIe extended capability that reports transaction-layer errors to the OS.

Attach: the newbus method a driver implements to take ownership of a specific device instance. Called once per device, after probe succeeds.

Bar (Base Address Register): a configuration-space field where a device advertises one range of addresses it needs mapped.

Bus Master: a device that initiates its own transactions on the PCI bus. Necessary for DMA. Enabled through the BUSMASTEREN bit of the command register.

Capability: an optional feature block in configuration space. Discovered by walking the capability list.

Class code: a three-byte classification (class, subclass, programming interface) that categorises the device's function.

cdev: a character device node in /dev/, created by `make_dev(9)`.

Configuration space: the per-device metadata area. 256 bytes on PCI, 4096 bytes on PCIe.

Detach: the newbus method that undoes everything attach did. Called once per device, when the driver is being unbound.

device_t: the opaque handle the newbus layer passes to driver methods.

DRIVER_MODULE: a macro that registers a driver against a bus and wraps it as a kernel module.

ENXIO: the errno a probe returns to say "I do not match this device".

EBUSY: the errno a detach returns to say "I refuse to detach; the driver is in use".

IRQ: an interrupt request. In PCI, the PCIR_INTLINE configuration-space field holds the legacy IRQ number.

Legacy interrupt (INTx): the pin-based interrupt mechanism inherited from PCI. Superseded by MSI and MSI-X on modern systems.

MMIO (Memory-Mapped I/O): the pattern of accessing device registers through memory-like load and store instructions.

MSI / MSI-X: Message Signaled Interrupts; interrupt mechanisms that use writes to specific memory addresses rather than pin assertions. Chapter 20.

Newbus: FreeBSD's device tree abstraction. Every device has a parent bus and a driver.

PCI: the older parallel bus standard.

PCIe: the modern serial successor to PCI. Software-compatible with PCI.

PIO (Port-Mapped I/O): the pattern of accessing device registers through x86 in and out instructions. Largely obsolete.

Probe: the newbus method that tests whether the driver can handle a specific device. Must be idempotent.

Resource: a generic name for a kernel-managed device resource (memory range, I/O port range, IRQ). Allocated through `bus_alloc_resource_any(9)`.

Softc (software context): the per-device state structure a driver maintains. Sized through the `driver_t` and allocated by `newbus`.

Subclass: the middle byte of the class code; refines the class.

Subvendor / subsystem ID: a second-level identification tuple that refines the primary vendor/device pair for distinct board designs.

Vendor ID: the 16-bit manufacturer identifier assigned by the PCI-SIG.

19 Handling Interrupts

19.1 Reader Guidance & Outcomes

Chapter 18 ended with a driver that had finally met real PCI hardware. The `myfirst` module at version `1.1-pci` probes a PCI device by vendor and device ID, attaches as a proper newbus child of `pci0`, claims the device's BAR through `bus_alloc_resource_any(9)` with `SYS_RES_MEMORY` and `RF_ACTIVE`, hands the BAR to the Chapter 16 accessor layer so `CSR_READ_4` and `CSR_WRITE_4` read and write real silicon, creates a per-instance `cdev`, and tears everything down in strict reverse order on detach. The Chapter 17 simulation is still in the tree but does not run on the PCI path; its callouts stay silent so they cannot write into the real device's registers.

What the driver does not yet do is react to the device. Every register access so far has been initiated by the driver: a user-space read or write hits the `cdev`, the `cdev` handler acquires `sc->mtx`, the accessor reads or writes the BAR, and control returns to user space. If the device itself has something to say, such as “my receive queue has a packet” or “a command completed” or “a temperature threshold was crossed”, the driver has no way of hearing it. The driver polls; it does not listen.

That is what Chapter 19 fixes. Real devices talk by **interrupting** the CPU. The bus fabric carries a signal from the device to the interrupt controller, the interrupt controller dispatches the signal to a CPU, the CPU takes a short detour from whatever it was doing, and a handler the driver registered runs for a few microseconds. The handler's job is small: figure out what the device wants, acknowledge the interrupt at the device, do the little bit of work that is safe to do here, and hand the rest off to a thread that has the freedom to block, sleep, or take slow locks. The “hand off” is the second half of modern interrupt discipline; the first half is getting into the handler at all.

Chapter 19's scope is precisely the core interrupt path: what interrupts are at the hardware level, how FreeBSD models them in the kernel, how a driver allocates an IRQ resource and registers a handler through `bus_setup_intr(9)`, how the split between a fast filter handler and a deferred ithread handler works, what the `INTR_MPSAFE` flag commits the driver to, how to simulate interrupts for testing when real events are not easy to produce, how to behave correctly on a shared IRQ line that other drivers also listen to, and how to tear every one of these things down in detach without leaking resources or executing stale handlers. The chapter stops short of MSI and MSI-X, which belong to Chapter 20; those mechanisms build on the core handler the reader writes here, and teaching both at once would dilute both.

Chapter 19 holds back on territory that interrupt work naturally touches. MSI and MSI-X, per-vector handlers, interrupt coalescing, and per-queue interrupt routing are Chapter 20. DMA and the interaction between interrupts and DMA descriptor rings are Chapters 20 and 21. Advanced interrupt affinity strategies on NUMA platforms are discussed briefly but the deep treatment belongs to Chapter 20 and beyond. Platform-specific interrupt routing (GICv3 on arm64, APIC on x86, NVIC on embedded targets) is mentioned only for vocabulary; the book's focus is the driver-visible API that hides those differences. Chapter 19 stays inside the ground it can cover well and hands off explicitly where a topic deserves its own chapter.

The filter-plus-ithread model Chapter 19 teaches does not stand alone. Chapter 16 gave the driver a vocabulary of register access. Chapter 17 taught it to think like a device. Chapter 18 introduced it to a real PCI device. Chapter 19 gives it ears. Chapters 20 and 21 will give it legs: direct memory access so the device can reach into RAM without the driver in the loop. Each chapter adds one layer. Each layer depends on the ones before it. Chapter 19 is where the driver stops polling and starts listening, and the disciplines Part 3 built are what keep the listening honest.

19.1.1 Why Interrupt Handling Earns a Chapter of Its Own

One concern that surfaces here is whether `bus_setup_intr(9)` and the filter-plus-ithread model really justify a full chapter. The Chapter 17 simulation used callouts to produce autonomous state changes; the Chapter 18 driver runs on real PCI but ignores the interrupt line entirely. Could we not just keep polling through callouts and avoid the topic?

Two reasons.

The first is performance. A callout that polls the device ten times a second wastes CPU time when there is nothing to do and misses events that happen between polls. A real device may produce many events per millisecond; a poll interval of 100 milliseconds misses nearly all of them. Interrupts invert the cost: no CPU is spent when nothing is happening, and the handler runs within microseconds of the event. Every serious driver in FreeBSD uses interrupts for the same reason; a driver that polls is a driver with a special excuse.

The second is correctness. Some devices require the driver to respond within a tight time window. A network card's receive FIFO fills in a handful of microseconds; if the driver does not drain it, the card drops packets. A serial port's transmit FIFO empties at the wire's rate; if the driver does not refill it, the transmitter starves. Polling at any interval long enough to be cheap is an interval short enough to miss deadlines. Interrupts are the only mechanism that lets a driver meet real-time device requirements without burning a CPU full time.

The chapter also earns its place by teaching a discipline that applies far beyond PCI. The FreeBSD interrupt model (filter plus ithread, `INTR_MPSAFE`, `bus_setup_intr(9)`, clean teardown in detach) is the same model USB drivers use, the same model SDIO drivers use, the same model virtio drivers use, and the same model arm64 SoC drivers use. A reader who understands Chapter 19's model can read any FreeBSD driver's interrupt handler with comprehension. That generality is what makes the chapter worth reading carefully even for readers who will not work on PCI.

19.1.2 Where Chapter 18 Left the Driver

A short checkpoint before we go further. Chapter 19 extends the driver produced at the end of Chapter 18 Stage 4, tagged as version `1.1-pci`. If any of the items below feels uncertain, return to Chapter 18 before starting this chapter.

- Your driver compiles cleanly and identifies itself as `1.1-pci` in `kldstat -v`.
- On a bhyve or QEMU guest that exposes a virtio-rnd device (vendor `0x1af4`, device `0x1005`), the driver attaches through `myfirst_pci_probe` and `myfirst_pci_attach`, prints its banner, claims BAR 0 as `SYS_RES_MEMORY` with `RF_ACTIVE`, walks the PCI capability list, and creates `/dev/myfirst0`.
- The softc holds the BAR resource pointer (`sc->bar_res`), the resource ID (`sc->bar_rid`), and the `pci_attached` flag.

- The detach path destroys the cdev, quiesces any active callouts and tasks, detaches the hardware layer, releases the BAR, and deinit the softc.
- The full regression script from Chapter 18 passes: attach, exercise cdev, detach, unload, no leaks.
- `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, and `PCI.md` are current.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel.

That driver is what Chapter 19 extends. The additions are again modest in volume: one new file (`myfirst_intr.c`), one new header (`myfirst_intr.h`), a small set of new softc fields (`irq_res`, `irq_rid`, `intr_cookie`, a counter or two), three new functions in the interrupt file (`setup`, `teardown`, the filter handler), one `sysctl` for simulated interrupts, a version bump to `1.2-intr`, and a short `INTERRUPTS.md` document. The mental-model change is again larger than the line count suggests: the driver finally has two threads of control instead of one, and the discipline that keeps them from stepping on each other is new.

19.1.3 What You Will Learn

By the end of this chapter you will be able to:

- Explain what an interrupt is at the hardware level, the difference between edge-triggered and level-triggered signalling, and how a CPU's interrupt-handling flow gets from the device to a driver's handler.
- Describe how FreeBSD represents interrupt events: what an interrupt event (`intr_event`) is, what an interrupt thread (`ithread`) is, what a filter handler is, and why the split between filters and ithreads matters.
- Read the output of `vmstat -i` and `devinfo -v` and locate the interrupts your system is handling, their counts, and the drivers bound to each.
- Allocate an IRQ resource through `bus_alloc_resource_any(9)` with `SYS_RES_IRQ`, using `rid = 0` on a legacy PCI line and (in Chapter 20) non-zero RIDs for MSI and MSI-X vectors.
- Register an interrupt handler through `bus_setup_intr(9)`, choosing between a filter handler (`driver_filter_t`), an ithread handler (`driver_intr_t`), or the filter-plus-ithread combination, and picking the right `INTR_TYPE_*` flag for the device's class of work.
- Write a minimal filter handler that reads the device's status register, acknowledges the interrupt at the device, returns `FILTER_HANDLED` or `FILTER_STRAY` appropriately, and cooperates with the kernel's interrupt machinery.
- Know what is safe inside a filter (spin locks only, no `malloc`, no sleeping, no blocking locks) and what the ithread relaxes (sleep mutexes, condition variables, `malloc(M_WAITOK)`), and why the constraints exist.
- Set `INTR_MPSAFE` only when you mean it, and understand what the flag commits the driver to (own synchronisation, no implicit Giant acquisition, the right to run on any CPU concurrently).
- Hand deferred work from a filter handler to a taskqueue task or to the ithread, and preserve the discipline that small urgent work happens in the filter while bulk work happens in thread context.
- Simulate interrupts through a `sysctl` that invokes the handler directly under the normal locking rules, so the reader can exercise the handler's state machine without needing a real IRQ to fire.
- Handle shared interrupt lines correctly: read the device's `INTR_STATUS` register first, decide whether this interrupt belongs to our device, return `FILTER_STRAY` if it does not, and avoid stealing another driver's work.
- Tear down the interrupt handler in detach with `bus_teardown_intr(9)` before releasing the IRQ with `bus_release_resource(9)`, and structure the detach path so no interrupt can fire against freed state.

- Recognise what an interrupt storm is, know how FreeBSD's `hw.intr_storm_threshold` machinery detects one, and understand the common device-side causes (failing to clear `INTR_STATUS`, edge-triggered lines mis-configured as level).
- Bind an interrupt to a specific CPU through `bus_bind_intr(9)` when affinity matters, and describe the interrupt to `devinfo -v` through `bus_describe_intr(9)` so operators can see which handler is on which CPU.
- Split the interrupt-related code into its own file, update the module's `SRCS` line, tag the driver as `1.2-intr`, and produce a short `INTERRUPTS.md` document that describes the handler's behaviour and the deferred-work discipline.

The list is long; each item is narrow. The point of the chapter is the composition.

19.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 19 stays focused.

- **MSI and MSI-X.** `pci_alloc_msi(9)`, `pci_alloc_msix(9)`, vector allocation, per-vector handlers, and the MSI-X table layout are Chapter 20. Chapter 19 targets the legacy PCI INTx line allocated with `rid = 0`; the vocabulary transfers, but the per-vector mechanics do not.
- **DMA.** `bus_dma(9)` tags, scatter-gather lists, bounce buffers, cache coherence around DMA descriptors, and the way interrupts signal the completion of descriptor-ring transfers are Chapters 20 and 21. Chapter 19's handler reads a BAR register and decides what to do; it does not touch DMA.
- **Per-queue multi-queue networking.** Modern NICs have separate receive and transmit queues with separate MSI-X vectors and separate interrupt handlers. The `iflib(9)` framework builds on this; `em(4)`, `ix(4)`, and `ixl(4)` use it. Chapter 19's driver has one interrupt; Chapter 20 onwards develops the multi-queue story.
- **Deep interrupt affinity on NUMA hardware.** `bus_bind_intr` is introduced; elaborate strategies for pinning interrupts to CPUs near the device's PCIe root port are left for later chapters on scalability.
- **Driver suspend and resume around interrupts.** `bus_suspend_intr(9)` and `bus_resume_intr(9)` exist; they are mentioned for completeness but are not exercised in Chapter 19's driver.
- **Real-time interrupt-priority manipulation.** FreeBSD's `intr_priority(9)` and the `INTR_TYPE_*` flags influence ithread priority, but the book treats the priority system as a black box outside advanced-topics chapters.
- **Software-only interrupts (SWI).** `swi_add(9)` creates a pure software interrupt that a driver can schedule from arbitrary context. The chapter mentions SWIs when discussing deferred work, but the preferred modern pattern (a taskqueue) covers the same use cases with fewer footguns.

Staying inside those lines keeps Chapter 19 a chapter about core interrupt handling. The vocabulary is what transfers; the specific chapters that follow apply the vocabulary to MSI/MSI-X, DMA, and multi-queue designs.

19.1.5 Estimated Time Investment

- **Reading only:** four to five hours. The interrupt model is conceptually small but requires careful reading, particularly around filter vs ithread and the safety rules inside a filter.

- **Reading plus typing the worked examples:** ten to twelve hours over two or three sessions. The driver evolves in four stages; each stage is a small but real extension on top of the Chapter 18 codebase.
- **Reading plus all labs and challenges:** sixteen to twenty hours over four or five sessions, including standing up the bhyve lab (if Chapter 18's setup is not already in place), reading `if_em.c`'s interrupt path and `if_mgb.c`'s filter handler, and running the Chapter 19 regression against both the simulated-interrupt path and (where possible) a real-interrupt path.

Sections 3, 4, and 6 are the densest. If the filter-versus-ithread split feels unfamiliar on first pass, that is normal. Stop, re-read Section 3's decision tree, and continue when the shape has settled.

19.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 18 Stage 4 (1.1-pci). The starting point assumes the Chapter 16 hardware layer, the Chapter 17 simulation backend, the Chapter 18 PCI attach, the complete `CSR_*` accessor family, the sync header, and every primitive introduced in Part 3.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- `bhyve(8)` or `qemu-system-x86_64` is available, and Chapter 18's lab environment (a FreeBSD guest with a `virtio-rnd` device at `-s 4:0,virtio-rnd`) is reproducible on demand.
- The `devinfo(8)`, `vmstat(8)`, and `pciconf(8)` tools are in your path. All three live in the base system.

If any item above is shaky, fix it now rather than pushing through Chapter 19 and trying to reason from a moving foundation. Interrupt bugs often manifest as kernel panics or subtle corruption under load; the debug kernel's `WITNESS` in particular catches the common classes of lock mistakes early.

19.1.7 How to Get the Most Out of This Chapter

Four habits will pay off quickly.

First, keep `/usr/src/sys/sys/bus.h` and `/usr/src/sys/kern/kern_intr.c` bookmarked. The first file defines `driver_filter_t`, `driver_intr_t`, `INTR_TYPE_*`, `INTR_MPSAFE`, and the `FILTER_*` return values you will use in every handler. The second file is the kernel's interrupt-event machinery: the code that receives the low-level IRQ, dispatches to filters, wakes ithreads, and detects interrupt storms. You do not need to read `kern_intr.c` in depth, but skimming the top thousand lines once gives you a picture of what happens between “the device asserts IRQ 19” and “your filter gets called”.

Second, run `vmstat -i` on your lab host and your guest, and keep the output open in a terminal as you read. Every concept Section 2 and Section 3 introduce (per-handler counts, per-CPU affinity, interrupt naming conventions) is visible in that output. A reader who has stared at `vmstat -i` for their own machine finds interrupt routing much less abstract.

Third, type the changes by hand and run each stage. Interrupt code is where small mistakes become silent bugs. Forgetting `FILTER_HANDLED` makes your handler technically illegal; forgetting `INTR_MPSAFE` silently acquires Giant around your handler; forgetting to clear `INTR_STATUS` produces an interrupt storm five milliseconds

later. Typing each line, checking the `dmesg` output after each `kldload`, and watching `vmstat -i` between iterations is how you catch these mistakes at the point where they are cheap.

Fourth, read `/usr/src/sys/dev/mgb/if_mgb.c` (look for `mgb_legacy_intr` and `mgb_admin_intr`) after Section 4. `mgb(4)` is the driver for Microchip's LAN743x gigabit Ethernet controllers. Its interrupt path is a clean, readable example of filter-plus-ithread design, and it sits at about the level of complexity Chapter 19 teaches. Seven hundred lines of careful reading pays off across the rest of Part 4.

19.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Are Interrupts?** The hardware picture: what an interrupt is, edge versus level triggering, the CPU's dispatch flow, and the minimum a driver must do when one arrives. The conceptual foundation.
2. **Interrupts in FreeBSD.** How the kernel represents interrupt events, what an ithread is, how interrupts are counted and displayed through `vmstat -i` and `devinfo -v`, and what happens from the IRQ line to the driver's handler.
3. **Registering an Interrupt Handler.** The code the driver writes: `bus_alloc_resource_any(9)` with `SYS_RES_IRQ`, `bus_setup_intr(9)`, `INTR_TYPE_*` flags, `INTR_MPSAFE`, `bus_describe_intr(9)`. The first stage of the Chapter 19 driver (`1.2-intr-stage1`).
4. **Writing a Real Interrupt Handler.** The filter handler's shape: read `INTR_STATUS`, decide ownership, acknowledge the device, return the right `FILTER_*` value. The ithread handler's shape: take sleep locks, defer to a taskqueue, do the slow work. Stage 2 (`1.2-intr-stage2`).
5. **Using Simulated Interrupts for Testing.** A `sysctl` that invokes the handler synchronously with the real lock discipline, so the reader can exercise the handler without a real IRQ. Stage 3 (`1.2-intr-stage3`).
6. **Handling Shared Interrupts.** Why `RF_SHAREABLE` matters on a legacy PCI line, how a filter handler must decide ownership against other handlers on the same IRQ, and how to avoid starvation. No stage bump; this is a discipline, not a new code artefact.
7. **Cleaning Up Interrupt Resources.** `bus_teardown_intr(9)` first, then `bus_release_resource(9)`. The detach ordering now has two more steps, and the partial-failure cascade gets one more label.
8. **Refactoring and Versioning Your Interrupt-Ready Driver.** The final split into `myfirst_intr.c`, a new `INTERRUPTS.md`, the version bump to `1.2-intr`, and the regression pass. Stage 4.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 19's story and opens Chapter 20's, and a bridge to Chapter 20. The reference-and-cheat-sheet material at the end of the chapter is meant to be re-read as you work through Chapter 20 and 21; Chapter 19's vocabulary is the foundation both of them build on.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3 and 4 stand alone and make good single-sitting reads.

19.2 Section 1: What Are Interrupts?

Before the driver code, the hardware picture. Section 1 teaches what an interrupt is at the level of the CPU and the bus, without any FreeBSD-specific vocabulary. A reader who understands Section 1 can read the rest of the

chapter with the kernel's interrupt path as a concrete object rather than a vague abstraction. The payoff is that every later section is easier.

The one-sentence summary, which you can keep with you through the rest of the chapter: an interrupt is a way for a device to interrupt the CPU's current work, run a driver's handler for a short time, and then let the CPU go back to what it was doing. Everything else is mechanism around that sentence.

19.2.1 The Problem Interrupts Solve

A CPU runs a stream of instructions in order. Each instruction completes, the program counter advances, the next instruction runs, and so on. Left alone, the CPU would execute one program until that program finished, then another, and so on, never paying attention to anything happening outside its own instruction stream.

That is not how computers work. A keyboard pressed for half a second generates four or five separate events; a network packet arrives within a few microseconds of the previous one; a disk finishes a read, the fan controller crosses a temperature threshold, a sensor value updates, a timer expires. Each of these events happens outside the CPU's direct control, at a time the CPU did not choose. The CPU has to notice.

One way to notice is to poll. The CPU can look at the device's status register periodically. If the status register says "I have data", the CPU reads the data. If the status register says "I have nothing", the CPU moves on. Polling works for devices whose events are rare, predictable, and not time-sensitive. It works badly for everything else. A keyboard polled every hundred milliseconds feels sluggish. A network card polled every millisecond still misses most of its packets. And polling consumes CPU time proportional to the poll rate, even when nothing is happening.

The other way to notice is to let the device tell the CPU. That is an interrupt. The device raises a signal on a wire or sends a message over the bus. The CPU interrupts its current work, remembers where it was, runs a small piece of code that asks the device what happened, responds appropriately, and then resumes the work it was doing. The discipline for writing that "small piece of code" is what the rest of Chapter 19 teaches.

19.2.2 What a Hardware Interrupt Actually Is

Physically, a hardware interrupt starts as a signal on a wire (or, more commonly on modern systems, as a message on a bus). A device asserts the signal when something has happened that the OS needs to know about. Examples include:

- A network card asserts its IRQ line when a packet has arrived and is sitting in its receive FIFO.
- A serial UART asserts its IRQ line when a byte has arrived at the receiver, or when the transmit FIFO has fallen below a threshold.
- A SATA controller asserts its IRQ line when a command queue entry has completed.
- A timer chip asserts its IRQ line when a programmed interval has elapsed.
- A temperature sensor asserts its IRQ line when a programmed threshold is crossed.

The assertion is the device's way of saying "something I need you to know about". The CPU and the OS must be prepared to respond. The path from "signal asserted" to "handler called" passes through the interrupt controller, the CPU's interrupt dispatch mechanism, and the kernel's interrupt-event machinery. Section 2 walks the whole path; this subsection stays at the hardware level.

Several useful facts about the signalling itself.

First, **interrupt lines are usually shared**. A CPU has a small number of interrupt inputs, often sixteen to twenty-four on legacy PCs and more on modern platforms through APICs and GICs. A system typically has more devices than interrupt inputs, so multiple devices share a single line. When an interrupt fires on a shared line, each driver whose device might be the source has to check: is this my interrupt? If no, return a “stray” indication; if yes, handle it. Section 6 covers the shared-interrupt protocol.

Second, **interrupt signalling comes in two flavours**. Edge-triggered signalling means the interrupt is signalled by a transition on the wire (low to high, or high to low). Level-triggered signalling means the interrupt is signalled by holding the wire at a specific level (high or low) for as long as the interrupt is pending. The two flavours have different operational consequences, which the next subsection explores.

Third, **the interrupt is asynchronous with respect to the CPU**. The CPU does not know when the device will raise the signal. The driver’s handler must tolerate being called at any point in the driver’s own work, and must synchronise with its own non-interrupt code appropriately. Chapter 11’s locking discipline is what the driver uses to do that.

Fourth, **the interrupt carries essentially no information on its own**. The wire says “something happened”; it does not say what. The driver discovers what happened by reading the device’s status register. A single IRQ line can report many different events (receive data ready, transmit FIFO empty, link state change, error, and so on), and it is the driver’s job to decode the status bits and decide what to do.

19.2.3 Edge-Triggered vs Level-Triggered

The difference is worth understanding because it explains why certain bugs produce interrupt storms, certain bugs produce silently-dropped interrupts, and certain bugs produce stuck systems.

An **edge-triggered** interrupt fires once when the signal transitions. The device pulls the wire low (for an active-low line); the interrupt controller notices the transition; an interrupt is queued for the CPU. If the device continues to hold the wire low, no additional interrupts fire, because the signal is not transitioning, only continuing to be asserted. For a new interrupt to fire, the device must release the wire and then assert it again.

Edge-triggered interrupts are efficient. The interrupt controller only needs to track transitions, not ongoing signals. The downside is fragility: if an interrupt fires while the controller is not watching (because another interrupt is being handled, for example), the transition may be missed. Modern interrupt controllers queue edge-triggered interrupts to avoid most of this, but the risk is real, and some drivers (or some device bugs) produce edge-triggered setups that occasionally drop an event.

A **level-triggered** interrupt fires continuously while the signal is asserted. As long as the device holds the wire at the asserted level, the interrupt controller reports an interrupt. When the device releases the wire, the interrupt controller stops reporting. The CPU sees an interrupt, the driver’s handler runs, the handler reads the device’s status and clears the pending condition, the device stops asserting the signal, and the interrupt controller stops reporting. If the handler fails to clear the pending condition, the signal stays asserted, the interrupt controller keeps reporting, and the driver’s handler gets called again immediately, in a loop that consumes the CPU. This is the classic **interrupt storm**.

Level-triggered interrupts are robust. As long as the device has something to report, the OS will know; there is no window where an event can be missed. The cost is that a buggy driver can produce a storm. FreeBSD has storm detection to mitigate this (the appendix *A Deeper Look at Interrupt Storm Detection* later in the chapter

covers it); other operating systems have similar protections. The common rule of thumb: level-triggered is the safer default, and PCI's legacy INTx lines are level-triggered for that reason.

The distinction matters for driver authors in a few specific places:

- A driver that fails to clear the device's INTR_STATUS register before returning from the handler will produce an interrupt storm on a level-triggered line. On an edge-triggered line the same bug produces a lost interrupt instead.
- A driver that reads and writes INTR_STATUS correctly works on both types without special knowledge.
- A driver that manipulates the interrupt controller's trigger mode directly (rare; mostly legacy) must understand the distinction.

For Chapter 19's PCI driver the signalling is level-triggered INTx on the legacy path. On MSI and MSI-X (Chapter 20) the signalling is message-based and does not correspond directly to either edge or level, but the driver pattern is the same: read status, acknowledge the device, return.

19.2.4 The CPU's Interrupt Handling Flow, Simplified

What happens, step by step, when a device's IRQ line is asserted? A simplified trace on a modern x86 system:

1. The device asserts its IRQ on the bus (or sends an MSI packet, for PCIe with MSI enabled).
2. The system's interrupt controller (APIC on x86, GIC on arm64) receives the signal and determines which CPU should handle it, based on the configured affinity. On multi-CPU systems this is a steerable decision.
3. The chosen CPU's interrupt hardware detects the pending interrupt. Before completing the current instruction, the CPU saves enough state (the program counter, the flags register, and a few other fields) to return to the interrupted work later.
4. The CPU jumps to a vector in its interrupt descriptor table. The entry for this vector is a small piece of kernel code called a **trap stub** that transitions to supervisor mode, saves the interrupted thread's register set, and calls into the kernel's interrupt dispatch code.
5. The kernel's interrupt dispatch code finds the `intr_event` associated with the IRQ (this is the FreeBSD structure Section 2 covers) and calls the driver handlers attached to it.
6. The driver's filter handler runs. It reads the device's status register, decides what kind of event has occurred, writes the device's INTR_STATUS register to acknowledge the event (so the device stops asserting the line, for level-triggered), and returns a value that tells the kernel what to do next.
7. If the filter returned `FILTER_SCHEDULE_THREAD`, the kernel schedules the `ithread` associated with this interrupt. The `ithread` is a kernel thread that wakes up, runs the driver's secondary handler, and goes back to sleep.
8. After all handlers have run, the kernel sends an End-of-Interrupt (EOI) signal to the interrupt controller, which re-arms the IRQ line.
9. The CPU returns from the interrupt. The interrupted thread's register set is restored and the thread resumes at the instruction that was about to execute when the interrupt arrived.

Steps 3 through 9 take a few microseconds on modern hardware for a simple handler. The whole flow is invisible to the interrupted thread: code that was not designed to be interrupt-safe (say, a floating-point computation in user space) runs correctly on either side of the interrupt, because the CPU saves and restores its state around the whole sequence.

From the driver author's perspective, steps 1 through 5 are the kernel's concern; steps 6 and 7 are where the driver code runs. The driver's handler must be fast (step 8's EOI waits for it), must not sleep (the interrupted thread holds CPU resources), and must not take locks that could block indirectly on the interrupted thread. Section 2 will make these constraints precise in FreeBSD terms; Section 1 has now set up the mental model.

19.2.5 What a Driver Must Do When an Interrupt Arrives

The driver's obligations on an interrupt are small in number but not small in detail:

1. **Identify the cause.** Read the device's interrupt status register. If no bit is set (the device has no pending interrupt), this is a shared-IRQ spurious call; return `FILTER_STRAY` and let the kernel try the next handler on the line.
2. **Acknowledge the interrupt at the device.** Write the status bits back (typically by writing a 1 to each bit, since most `INTR_STATUS` registers are RW1C) so the device deasserts the line and the interrupt controller can re-enable the IRQ. Not every device requires the acknowledgment to be inside the filter, but doing it here is the safe default; the level-triggered storm story depends on timely acknowledgment.
3. **Decide what work to do.** Read enough of the device to decide. Was this a receive event? A transmit completion? An error? A link change? The status bits tell you.
4. **Do the urgent small work.** Update a counter. Copy a byte from a FIFO into a queue. Toggle a control bit. Whatever can be done in microseconds without taking a sleep lock is fair game here.
5. **Defer the bulk work.** If the event triggers a long operation (processing a received packet, decoding a data stream, sending a command to user space), schedule an ithread or a taskqueue task and return. The deferred work runs in thread context, where it can take sleep locks, allocate memory, and take its time.
6. **Return the appropriate `FILTER_*` value.** `FILTER_HANDLED` means the interrupt is entirely handled; no ithread is needed. `FILTER_SCHEDULE_THREAD` means the ithread should run. `FILTER_STRAY` means the interrupt was not for this driver. These three values are the vocabulary the kernel uses to dispatch further work.

A driver that does these six things correctly on every interrupt has the shape the rest of Chapter 19 teaches. A driver that skips any one of them has a bug.

19.2.6 Real-World Examples

A short tour of the events Chapter 19's vocabulary will cover.

Keypresses. A PS/2 keyboard controller fires an interrupt when a scancode arrives. The driver reads the scan-code, passes it to the keyboard subsystem, and acknowledges. The whole handler runs in a few microseconds; a taskqueue is usually unnecessary.

Network packets. A NIC fires an interrupt when packets accumulate in the receive queue. The driver's filter reads a status register to confirm receive events, schedules the ithread, and returns. The ithread walks the descriptor ring, constructs mbuf packets, and passes them up the network stack. The split between filter and ithread matters here because stack processing is slow enough that running it in the filter would extend the interrupt window too far.

Sensor readings. An I2C-attached temperature sensor fires an interrupt when a new measurement is ready. The driver reads the value, updates a sysctl cache, optionally wakes up any pending user-space readers, and acknowledges. Simple and fast.

Serial port. A UART fires an interrupt on receive or transmit-FIFO-empty conditions. The driver drains or refills the FIFO, updates a circular buffer, and acknowledges. At high baud rates this can happen tens of thousands of times per second, so the handler must be tight.

Disk completion. A SATA or NVMe controller fires an interrupt when a queued command completes. The driver walks the completion queue, matches each completion to a pending I/O request, wakes the waiting thread, and acknowledges. The matching and waking is sometimes split between filter and itthread.

Each of these devices reaches Chapter 19's vocabulary in the same way: the filter reads status, the filter decides what happened, the filter acknowledges, and the filter either handles or defers. The specific register layout differs; the pattern does not.

19.2.7 A Quick Exercise: Find Interrupt-Driven Devices on Your Lab Host

Before moving to Section 2, a short exercise to make the hardware picture concrete.

On your lab host, run:

```
vmstat -i
```

The output is a list of interrupt sources with their counts since boot. Each line looks roughly like this:

interrupt	total	rate
cpu0:timer	1234567	123
cpu1:timer	1234568	123
irq9: acpi0	42	0
irq19: uhci0+	12345	12
irq21: ahci0	98765	99
irq23: em0	123456	123

Pick three lines from your own output. For each, identify:

- The interrupt name (a mix of the IRQ number and the driver-set description).
- The total count (how many times the interrupt has fired since boot).
- The rate (interrupts per second; a high rate means the device is busy).

Run `vmstat -i` a second time ten seconds later. Compare the counts. Which interrupts are actively counting? Which ones are essentially idle?

Now match interrupts to devices with `devinfo -v`:

```
devinfo -v | grep -B 2 irq
```

Each match shows a device that claims an IRQ. Cross-check against `vmstat -i`'s output to see which driver is served by each line.

Keep this output open while you read Section 2. The `em0` entry in the example is the Intel Ethernet controller; if you are using an Intel-based system with FreeBSD, `em0` or `igc0` or `ix0` is probably running a version of the same pattern Chapter 19 teaches. A modern NUC running FreeBSD 14.3 shows one or two dozen interrupt sources; a server shows many more. The system you actually have is more interesting to stare at than any diagram.

19.2.8 A Brief History of Interrupts

Interrupts are one of the oldest ideas in computer architecture. The original PDP-1 supported them in 1961 as a way for I/O devices to signal the CPU without the CPU polling. The IBM 704 had them at around the same time. Early timesharing systems used interrupts for the clock tick that drove scheduling, and for every I/O completion.

Through the 1970s and 1980s, personal computers inherited the pattern. The original IBM PC used the 8259 Programmable Interrupt Controller (PIC), which supported eight IRQ lines; the PC/AT extended this to fifteen usable lines by cascading two PICs. The x86 instruction set added specific interrupt-handling instructions (`CLI`, `STI`, `INT`, `IRET`) that persist today in extended forms.

PCI introduced the concept of a device advertising its interrupt through configuration space (the `INTLINE` and `INTPIN` fields Chapter 18 discussed). PCIe added MSI and MSI-X, which replace the physical IRQ line with a memory-write message. All three coexist in modern systems; Chapter 19's legacy `INTx` is the oldest of the three and the only one that shares lines.

Operating systems have evolved alongside. Early Unix was monolithic and single-threaded in the kernel; interrupts preempted whatever was running. Modern kernels (FreeBSD included) have fine-grained locking, per-CPU data structures, and ithread-based deferred dispatch. The handler discipline Chapter 19 teaches is the distillation of that evolution: fast in the filter, slow in the task, MP-safe by default, shareable, debuggable.

Knowing the history is not required for writing a driver. But the vocabulary (IRQ, PIC, EOI, `INTx`) comes from specific points in the history, and a driver author who knows where the words come from finds less of the field mysterious.

19.2.9 Wrapping Up Section 1

An interrupt is a way for a device to interrupt the CPU's current work, run a small piece of driver code, and let the CPU resume. The mechanism runs through the interrupt controller, the CPU's interrupt dispatch, the kernel's interrupt-event machinery, and finally the driver's handler. Edge-triggered and level-triggered signalling have different operational consequences, most visibly in the form of interrupt storms when a level-triggered line is not properly acknowledged.

A driver's handler has six obligations: identify the cause, acknowledge the device, decide the work, do the urgent part, defer the bulk part, and return the right `FILTER_*` value. Each of these is small in isolation and demanding in aggregate; the rest of Chapter 19 is about doing each one correctly in FreeBSD terms.

Section 2 now walks the FreeBSD kernel's interrupt model: what an `intr_event` is, what an ithread is, how `vmstat -i` and `devinfo -v` expose the kernel's view of interrupts, and what constraints the model places on driver handlers.

19.3 Section 2: Interrupts in FreeBSD

Section 1 established the hardware model. Section 2 introduces the software model. The kernel's interrupt machinery is the layer between the interrupt controller and the driver's handler; understanding it clearly is what turns the hardware model into a driver-writable concept. A reader who finishes Section 2 should be able to

answer three questions in plain English: what runs when an interrupt fires, what runs later as deferred work, and what the driver has to promise so both can happen safely.

19.3.1 The FreeBSD Interrupt Model in One Picture

A driver's handler does not run in isolation. It runs inside a small ecosystem of kernel objects that together make interrupt handling orderly and debuggable. The ecosystem has three pieces worth naming up front.

The first is the **interrupt event**, represented by struct `intr_event` in `/usr/src/sys/sys/interrupt.h` (with the dispatch code in `/usr/src/sys/kern/kern_intr.c`). One `intr_event` exists per IRQ line (or per MSI vector, in Chapter 20's world). It is the central coordinator: it holds a list of handlers (the driver's filter functions and `ithread` functions), a human-readable name, flags, a loop counter used for storm detection (`ie_count`), a rate-limiter for warning messages (`ie_warntm`), and a CPU binding. When the interrupt controller reports an IRQ to the kernel, the kernel looks up the corresponding `intr_event` and walks its list of handlers. Stray interrupts are counted globally, not per-event; they surface through `vmstat -i`'s separate accounting and through kernel log messages rather than through a field on the event.

The second is the **interrupt handler**, represented by struct `intr_handler`. One `intr_handler` exists per registered handler on an `intr_event`. A single IRQ line can have many handlers (one per driver that shares the line). The handler carries the driver-provided filter function (if any), the driver-provided `ithread` function (if any), the `INTR_*` flags (most importantly `INTR_MPSAFE`), and a cookie pointer the kernel keeps for the driver's reference.

The third is the **interrupt thread**, usually called an **ithread**, represented by struct `intr_thread`. Unlike the event and the handler, the `ithread` is a real kernel thread with its own stack, its own scheduling priority, and its own `proc` structure. When a filter returns `FILTER_SCHEDULE_THREAD` (or when a driver registered an `ithread`-only handler with no filter), the `ithread` is scheduled to run. The `ithread` then calls the driver's handler function in thread context, where regular sleep mutexes and sleeping are permitted.

The three together produce the classic two-phase interrupt pattern FreeBSD has used for more than a decade: a fast filter runs in primary interrupt context to do the urgent work, and a thread-context handler runs later to do the slow work. Chapter 19's driver will use both phases.

19.3.2 IRQ Assignment and Routing

A modern x86 system has more than one interrupt controller. The legacy 8259 PIC has been superseded by the Local APIC (one per CPU, handling per-CPU interrupts like the local timer) and the I/O APIC (a shared unit that receives IRQs from the I/O fabric and routes them to CPUs). On arm64, the equivalent is the Generic Interrupt Controller (GIC), with per-CPU redistributors and a shared distributor. On embedded targets there are a handful of other controllers. FreeBSD abstracts these behind the `intr_pic(9)` interface; a driver author rarely interacts with the interrupt controller directly.

What the driver sees is an IRQ number (on legacy PCI paths, the number a BIOS assigned in configuration space) or a vector index (on MSI and MSI-X paths). The driver asks for an IRQ resource by that number, the kernel allocates a struct `resource *`, and the driver hands the resource to `bus_setup_intr(9)` to attach a handler. The kernel does the work of wiring the handler to the right `intr_event`, configuring the interrupt controller to route the IRQ to a CPU, and arming the line.

From a driver author's perspective, IRQ routing is usually a black box. The kernel handles it; the driver sees a handle and a handler. One exception: on platforms with many CPUs and multiple devices, **affinity** matters. An interrupt that fires on a CPU far from the device produces cache misses and cross-socket traffic; an interrupt that fires on a CPU close to the device is cheaper. `bus_bind_intr(9)` lets the driver ask for a specific CPU; operators use `cpuset -x <irq> -l <cpu>` to override the affinity at runtime, and `cpuset -g -x <irq>` to query it. The appendix *A Deeper Look at CPU Affinity for Interrupts* later in the chapter covers both paths in more detail.

19.3.3 SYS_RES_IRQ: The Interrupt Resource

Chapter 18 introduced three resource types: `SYS_RES_MEMORY` for memory-mapped BARs, `SYS_RES_IOPORT` for I/O port BARs, and (mentioned in passing) `SYS_RES_IRQ` for interrupts. Section 3 will use the third one for the first time. The vocabulary is the same as for BARs:

```
int rid = 0;                /* legacy PCI INTx */
struct resource *irq_res;

irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ, &rid,
    RF_SHAREABLE | RF_ACTIVE);
```

Three things are worth calling out about this allocation.

First, `rid = 0` is the convention for a legacy PCI INTx line. The PCI bus driver treats the zeroth IRQ resource as the device's legacy interrupt, set up from the `PCIR_INTLINE` field in configuration space. For MSI and MSI-X (Chapter 20), the rid is 1, 2, 3, and so on, corresponding to allocated vectors.

Second, `RF_SHAREABLE` asks the kernel to allow the IRQ line to be shared with other drivers. On legacy PCI this is the common case: one physical line can serve multiple devices. Without `RF_SHAREABLE`, the allocation fails if another driver already holds a handler on the same line. Passing `RF_SHAREABLE` does not mean your driver must handle stray interrupts; it means it must tolerate them. Section 6 is about exactly that tolerance.

Third, `RF_ACTIVE` activates the resource in one step, as with BAR allocation. Without it, the driver would need to call `bus_activate_resource(9)` separately. Chapter 19 always uses `RF_ACTIVE`.

On success, the returned `struct resource *` is a handle to the IRQ. It is not the IRQ number; the kernel does not expose that. The driver passes the handle to `bus_setup_intr(9)` and `bus_tearardown_intr(9)` and `bus_release_resource(9)`.

19.3.4 Filter Handlers vs ithread Handlers

This is the conceptual heart of Section 2 and of the chapter. A reader who internalises the filter-versus-ithread distinction reads every FreeBSD driver's interrupt code with comprehension.

A **filter handler** is a C function registered by the driver that runs in primary interrupt context. Primary interrupt context means: the CPU jumped directly from whatever it was doing, minimal state was saved, and the filter is running with the interrupted thread's context still partially in place. Specifically:

- The filter cannot sleep. There is no thread to block; the kernel is in the middle of dispatching an interrupt.

- The filter cannot acquire a sleep mutex (`mtx(9)` by default is a sleep-ish adaptive mutex, which can spin briefly but will eventually sleep). Spin mutexes (`mtx_init` with `MTX_SPIN`) are safe.
- The filter cannot allocate memory with `M_WAITOK`; it can use `M_NOWAIT`, which may fail.
- The filter cannot call into code that uses any of the above.

The filter is supposed to be fast (microseconds), do the urgent work (read status, acknowledge, update a counter), and return. The kernel's return value convention is:

- `FILTER_HANDLED`: the interrupt is mine, it is fully handled, no `ithread` is needed.
- `FILTER_SCHEDULE_THREAD`: the interrupt is mine, some of the work is done, schedule the `ithread` for the rest.
- `FILTER_STRAY`: the interrupt is not mine; try the next handler on this line.

A driver can also specify `FILTER_HANDLED | FILTER_SCHEDULE_THREAD` to say both “I handled part of it” and “schedule the thread for more”.

An **ithread handler** is a different C function that runs in thread context. The thread is scheduled by the kernel after a filter returns `FILTER_SCHEDULE_THREAD`, or if the handler is registered as `ithread-only` (with no filter), the `ithread` is scheduled automatically when the kernel dispatches the interrupt.

In `ithread` context, the constraints loosen considerably:

- The `ithread` can sleep briefly on a mutex or condition variable.
- The `ithread` can use `malloc(M_WAITOK)`.
- The `ithread` can call into most kernel APIs that use sleepable locks.
- The `ithread` cannot still sleep arbitrarily long (it is a real-time-ish thread), but it can do normal driver work.

The split lets a driver separate urgent, short work (in the filter) from slower, bulk work (in the `ithread`). A network driver's filter might read the status register and acknowledge; its `ithread` walks the receive descriptor ring and passes packets up the stack. A disk driver's filter might record which completions happened and acknowledge; its `ithread` matches completions to pending requests and wakes waiting threads.

19.3.5 When to Use Filter Only

A driver uses filter-only when every piece of work it does on an interrupt can run in primary interrupt context. Examples:

- A **minimal test driver** that increments a counter on each interrupt and nothing more.
- A **simple sensor driver** that reads one register, caches the value, and wakes a `sysctl` reader. (If `se_lwakeup` or a condition-variable broadcast requires a sleep mutex, this moves to filter-plus-`ithread`.)
- A **timer driver** whose job is to tick some kernel-internal counter.

The Chapter 19 driver at Stage 1 is filter-only: it reads `INTR_STATUS`, acknowledges, updates a counter, and returns `FILTER_HANDLED`. That is enough to prove the handler is wired up.

19.3.6 When to Use Filter Plus `ithread`

A driver uses filter-plus-`ithread` when the interrupt requires urgent small work followed by slower bulk work. Examples:

- **A NIC driver.** The filter acknowledges and marks which queues have events. The ithread walks the descriptor rings, builds mbufs, and passes packets up.
- **A disk controller.** The filter reads the completion status and acknowledges. The ithread matches completions to I/O requests and wakes waiters.
- **A USB host controller.** The filter reads the status and acknowledges. The ithread walks the transfer descriptor list and completes any pending URBs.

The Chapter 19 driver at Stage 2 moves to filter-plus-ithread when simulated “work-requested” events are added; the filter records the event, and a deferred worker (via a taskqueue; Chapter 14’s primitive) handles the work.

19.3.7 When to Use ithread Only

A driver uses ithread-only when every piece of work must run in thread context. This is less common; the usual reason is that the driver needs to take a sleep mutex on every interrupt and cannot usefully do anything in primary context.

Registering an ithread-only handler is simple: pass `NULL` for the filter argument of `bus_setup_intr(9)`. The kernel schedules the ithread whenever the interrupt fires.

The Chapter 19 driver does not use ithread-only; the filter is always cheap to run.

19.3.8 INTR_MPSAFE: What the Flag Promises

`INTR_MPSAFE` is a bit in the flags argument of `bus_setup_intr(9)`. Setting it promises the kernel two things:

1. Your handler does its own synchronisation. The kernel will not acquire the Giant lock around it.
2. Your handler is safe to run concurrently on multiple CPUs (for a handler shared by multiple CPUs, which happens in MSI-X scenarios and in some PIC configurations).

If you do **not** set `INTR_MPSAFE`, the kernel acquires Giant before calling your handler. This is the old BSD default, preserved for backward compatibility with pre-SMP drivers that relied on Giant’s implicit protection. Modern drivers always set `INTR_MPSAFE`.

Failing to set `INTR_MPSAFE` has a visible symptom: the `dmesg` banner on `kldload` includes a line like `myfirst0: [GIANT-LOCKED]`. This is the kernel telling you that Giant is being acquired around your handler. On production systems it serialises every interrupt through a single lock, which is disastrous for scalability. The line is a deliberate nag from `bus_setup_intr` to help you notice.

Setting `INTR_MPSAFE` when you actually still rely on Giant is also a bug, but a quieter one. The kernel will not acquire Giant, so any code path that used to be serialised by Giant will no longer be. Race conditions appear where none existed before. The fix is not to remove `INTR_MPSAFE` (that masks the bug); the fix is to add the right locking to the handler and the code it touches.

Chapter 19’s driver always sets `INTR_MPSAFE` and relies on the existing `sc->mtx` for synchronisation. The Chapter 11 discipline carries through.

19.3.9 INTR_TYPE_* Flags

In addition to `INTR_MPSAFE`, `bus_setup_intr` takes a category flag that hints at the interrupt’s class:

- `INTR_TYPE_TTY`: tty and serial devices.
- `INTR_TYPE_BIO`: block I/O (disk, CD-ROM).
- `INTR_TYPE_NET`: network.
- `INTR_TYPE_CAM`: SCSI (CAM framework).
- `INTR_TYPE_MISC`: miscellaneous.
- `INTR_TYPE_CLK`: clock and timer interrupts.
- `INTR_TYPE_AV`: audio and video.

The category influences the ithread's scheduling priority. Historically, each category had a distinct priority; in modern FreeBSD, only `INTR_TYPE_CLK` gets an elevated priority, and the rest are approximately equal. The category is still worth setting correctly because it flows through `devinfo -v` and `vmstat -i` output, making the interrupt self-identifying.

For the Chapter 19 driver, `INTR_TYPE_MISC` is appropriate because the demo target does not fit any of the more specific categories. Chapter 20 will use `INTR_TYPE_NET` once the driver starts targeting NICs in labs.

19.3.10 Shared vs Exclusive Interrupts

On legacy PCI, multiple devices can share a single INTx line. The kernel tracks this with two resource flags:

- `RF_SHAREABLE`: this driver is willing to share the line with other drivers.
- `RF_SHAREABLE` absent: this driver wants the line for itself; allocation fails if another driver already holds it.

A driver that wants shareable interrupts uses `RF_SHAREABLE | RF_ACTIVE` in its `bus_alloc_resource_any` call. A driver that wants exclusive access (perhaps for latency reasons) uses `RF_ACTIVE` alone, but the request may fail on crowded systems.

The kernel never stops the driver from sharing; it stops another driver from joining if this one asks for exclusivity. On modern PCIe with MSI-X, sharing is much less common because each device has its own message-signalled vector.

Chapter 19's driver sets `RF_SHAREABLE` because `virtio-rnd` in `bhyve` may or may not share its line with other `bhyve`-emulated devices, depending on the slot topology. Being shareable is the safe default.

The `INTR_EXCL` flag passed through `bus_setup_intr`'s `flags` field (not to be confused with the resource-allocation flag) is a related but distinct concept: it asks the bus to give the handler exclusive access at the interrupt-event level. Legacy PCI drivers rarely need it. Some bus drivers use it internally. For Chapter 19's driver, we do not set `INTR_EXCL`.

19.3.11 What `vmstat -i` Shows

`vmstat -i` prints the kernel's interrupt counters. Each line corresponds to one `intr_event`. The columns are:

- **interrupt**: a human-readable identifier. For hardware interrupts, the name is derived from the IRQ number and the driver description. `devinfo -v`-style names (such as `em0:rx 0`) appear when MSI-X vectors are in use.
- **total**: the number of times this interrupt has fired since boot.

- **rate**: the interrupt rate in interrupts per second, averaged over a recent window.

A few interpretation notes. A total column that grows quickly for an idle device is a red flag (interrupt storm). A rate column at zero for a device that should be handling traffic suggests the handler is not wired up correctly. When several devices share a legacy INTx line, `vmstat -i` shows one line per `intr_event` (per IRQ source), and the driver name on that line is the description of the first registered handler; the other drivers sharing the line do not get their own lines. When a device has its own MSI or MSI-X vectors, each vector is its own `intr_event`, and each gets its own line. Per-CPU interrupts such as the local timer appear as distinct per-CPU lines (`cpu0:timer`, `cpu1:timer`) because the kernel creates one event per CPU for them.

The kernel exposes the same counters through `sysctl hw.intrcnt` and `sysctl hw.intrnames`, which are the raw data `vmstat -i` formats. A driver author rarely reads these directly; `vmstat -i` is the friendly view.

19.3.12 What devinfo -v Shows About Interrupts

`devinfo -v` walks the newbus tree and prints each device with its resources. For a PCI driver with an interrupt, the resources list includes an `irq:` entry next to the `memory:` entry:

```
myfirst0
  pnpinfo vendor=0x1af4 device=0x1005 ...
  resources:
    memory: 0xc1000000-0xc100001f
    irq: 19
```

The number after `irq:` is the kernel’s IRQ identifier. On x86 it is often a pin number from the I/O APIC; on arm64 it is a GIC vector; the exact meaning is platform-specific but the number is stable across reboots of the same system.

Matching the `irq: 19` to `vmstat -i`’s `irq19:` entry confirms the driver is attached to the expected interrupt line.

For MSI-X interrupts (Chapter 20), each vector has its own `irq:` entry, and `devinfo -v` lists them individually.

19.3.13 A Simple Interrupt Path Diagram

Putting it all together, here is what happens from device to driver:

The diagram elides several details (interrupt coalescing, the swapping of the interrupted thread's stack for the ithread's stack, the ithread's own scheduling), but it captures the shape. A filter runs in interrupt context, an ithread (if scheduled) runs later in thread context, the EOI happens after filters are done, and the interrupted thread resumes once the CPU is free.

19.3.14 Constraints on What Handlers May Do

A short consolidated list of what a filter handler may and may not do. This is the most-referenced list in Chapter 19; mark it for return visits.

Filter handlers MAY:

- Read and write device registers through the accessor layer.
- Acquire spin mutexes (`struct mtx` initialised with `MTX_SPIN`).
- Read softc fields that are protected only by spin locks.
- Call the kernel's atomic operations (`atomic_add_int`, etc.).
- Call `taskqueue_enqueue(9)` to schedule thread-context work.

- Call `wakeup_one(9)` to wake a thread sleeping on a channel, if the context permits (most do).
- Return `FILTER_HANDLED`, `FILTER_SCHEDULE_THREAD`, `FILTER_STRAY`, or combinations.

Filter handlers MAY NOT:

- Acquire a sleep mutex (`struct mtx` initialised default, `struct sx`, `struct rwlock`).
- Call any function that may sleep: `malloc(M_WAITOK)`, `tsleep`, `pause`, `cv_wait`, and so on.
- Acquire Giant.
- Call code that may indirectly do any of the above.
- Take a long time (microseconds are fine; milliseconds are a bug).

Ithread handlers MAY:

- Everything a filter handler may do, plus:
- Acquire sleep mutexes, `sx` locks, `rwlocks`.
- Call `malloc(M_WAITOK)`.
- Call `cv_wait`, `tsleep`, `pause`, and other blocking primitives.
- Take longer (tens or hundreds of microseconds are normal).
- Do bounded work with unpredictable completion time.

Ithread handlers SHOULD NOT:

- Sleep for arbitrarily long times. The `ithread` has a scheduling priority that assumes responsiveness; a handler that sleeps for seconds starves other work on the same `ithread`.
- Block the `ithread` waiting for external events that have no bound.

Chapter 19's filter respects the first list rigorously; any violation is a bug the debug kernel will often catch.

19.3.15 A Note on Per-CPU vs Shared `ithreads`

For legacy PCI INTx lines, the kernel usually assigns one `ithread` per `intr_event`, shared among any handlers on that event. For MSI-X (Chapter 20), each vector has its own `ithread`. The difference matters when multiple handlers need to run concurrently on the same IRQ: on the shared `ithread`, they serialise; on separate MSI-X vectors, they can run in parallel.

Chapter 19's driver uses legacy PCI. One IRQ, one `ithread` (if any `ithread` at all), one queue of deferred work. The serialisation is usually what you want for a single-device driver.

19.3.16 Wrapping Up Section 2

FreeBSD's interrupt model centres on three objects: the `intr_event` (one per IRQ line or MSI vector), the `intr_handler` (one per registered driver on that event), and the `ithread` (one per event, shared among handlers). A driver registers a filter function, an `ithread` function, or both, through `bus_setup_intr(9)`, and promises `INTR_MPSAFE` compliance via the `flags` argument. The kernel dispatches filter handlers in primary interrupt context and schedules `ithreads` after the filter returns.

The constraints on filter handlers are strict (no sleeping, no sleep locks, no slow calls); the constraints on `ithread` handlers are loose by comparison. Shared PCI INTx lines allow many drivers on one IRQ, so filters must

identify whether the interrupt belongs to their device and return `FILTER_STRAY` when it does not. `vmstat -i` and `devinfo -v` expose the kernel's view so operators and driver authors can see what is happening.

Section 3 is where the driver finally writes code against this model. It allocates an IRQ resource with `SYS_RES_IRQ`, registers a filter handler through `bus_setup_intr(9)`, sets `INTR_MPSAFE`, and logs a short message on every call. Stage 1 is the first time the driver gets interrupted in anger.

19.4 Section 3: Registering an Interrupt Handler

Sections 1 and 2 established the hardware and kernel models. Section 3 puts the driver to work. The task is narrow: extend Chapter 18's attach path so that after allocating the BAR and walking the capability list, it also allocates an IRQ resource, registers a filter handler, and sets `INTR_MPSAFE`. The detach path grows in the mirror direction: tear down the handler first, then release the IRQ. At the end of Section 3 the driver is at version `1.2-intr-stage1` and fires a small counter-bumping filter handler every time its IRQ line is asserted.

19.4.1 What Stage 1 Produces

Stage 1's handler is deliberately minimal. The driver needs a filter that is correct in every formal sense (returns the right `FILTER_*` value, respects the “no sleeping” rule, is `INTR_MPSAFE`) but does not yet do any real work. The goal is to prove the handler is wired correctly before introducing the complications of status decoding and deferred work.

The handler's behaviour at Stage 1:

1. Acquire a spin-safe counter lock (in our case a simple atomic operation).
2. Increment a counter in the softc.
3. Return `FILTER_HANDLED`.

That is it. No status register read, no acknowledgment, no deferred work. The counter lets the reader observe whether the handler fires, and if so how often. The `dmesg` output is silent by default; the count is visible through a `sysctl` the stage exposes.

Section 4 adds the real work (status decoding, acknowledgment, `ithread` scheduling). Section 5 adds simulated interrupts for testing. Section 6 extends the filter to be shared-IRQ-safe by checking whether the interrupt is actually for our device. But the scaffolding is this stage's contribution, and it needs to be right before anything else lands on top.

19.4.2 The IRQ Resource Allocation

The first new line of attach, right after the BAR allocation:

```
sc->irq_rid = 0; /* legacy PCI INTx */
sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ, &sc->irq_rid,
    RF_SHAREABLE | RF_ACTIVE);
if (sc->irq_res == NULL) {
    device_printf(dev, "cannot allocate IRQ\n");
```

```

    error = ENXIO;
    goto fail_hw;
}

```

A few things worth noticing.

First, `rid = 0` is the legacy PCI INTx convention. Every PCI device has a single legacy IRQ line advertised through the `PCIR_INTLINE` and `PCIR_INTPIN` fields of configuration space; the PCI bus driver exposes this as resource `rid 0`. Chapter 20 will use non-zero `rids` for MSI and MSI-X vectors, but Chapter 19's driver uses the legacy path.

Second, the `rid` variable is updated by `bus_alloc_resource_any` if the kernel chose a different `rid` than requested. For `rid = 0` the kernel always returns `rid = 0`, so the update is a no-op, but the pattern is consistent with BAR allocation from Chapter 18.

Third, `RF_SHAREABLE | RF_ACTIVE` is the standard flag set. `RF_SHAREABLE` allows the kernel to put our handler on a shared `intr_event` with other drivers. `RF_ACTIVE` activates the resource in one step.

Fourth, the allocation can fail. The most common reason on a real system is that the device's PCI configuration-space interrupt fields are zero (the firmware did not route an interrupt to the device). On bhyve with a `virtio-rnd` device, the allocation normally succeeds; on some older QEMU configurations with `intx=off`, it can fail. If the allocation fails, the attach path unwinds through the `goto` cascade.

19.4.3 Storing the Resource in the Softc

The `softc` gains three new fields:

```

struct myfirst_softc {
    /* ... existing fields ... */

    /* Chapter 19 interrupt fields. */
    struct resource *irq_res;
    int          irq_rid;
    void         *intr_cookie;    /* for bus_teardown_intr */
    uint64_t     intr_count;      /* handler invocation count */
};

```

`irq_res` is the handle to the claimed IRQ resource. `irq_rid` is the resource ID (for the matching release call). `intr_cookie` is the opaque cookie that `bus_setup_intr(9)` returns and `bus_teardown_intr(9)` consumes; it identifies the specific handler so the kernel can remove it cleanly later. `intr_count` is a diagnostic counter the Stage 1 handler increments on every call.

The three fields parallel the three BAR fields (`bar_res`, `bar_rid`, `pci_attached`) added in Chapter 18. The parallelism is not accidental: every resource class gets a handle, an ID, and whatever bookkeeping the driver needs.

19.4.4 The Filter Handler's Signature

The driver's filter is a function with signature:

```
static int myfirst_intr_filter(void *arg);
```

The argument is whatever pointer the driver passes to `bus_setup_intr`'s `arg` parameter; by convention, a pointer to the driver's `softc`. The return value is a bitwise OR of `FILTER_STRAY`, `FILTER_HANDLED`, and `FILTER_SCHEDULE_THREAD`, as Section 2 described.

The Stage 1 implementation:

```
static int
myfirst_intr_filter(void *arg)
{
    struct myfirst_softc *sc = arg;

    atomic_add_64(&sc->intr_count, 1);
    return (FILTER_HANDLED);
}
```

One line of real work. The counter is incremented atomically because the handler may run concurrently on multiple CPUs (MSI-X scenarios) or in parallel with non-interrupt code that reads the counter through the `sysctl`. A sleep lock would be wrong in a filter; an atomic operation is the lightweight primitive that is safe here.

The return value is `FILTER_HANDLED` because we have no `ithread` work to do and no reason to return `FILTER_STRAY` (Section 6 adds the stray check; Stage 1 assumes the IRQ is ours).

19.4.5 Registering the Handler With `bus_setup_intr`

After the IRQ allocation, the driver calls `bus_setup_intr(9)`:

```
error = bus_setup_intr(dev, sc->irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->intr_cookie);
if (error != 0) {
    device_printf(dev, "bus_setup_intr failed (%d)\n", error);
    goto fail_release_irq;
}
```

The seven arguments:

1. **dev**: the device handle.
2. **sc->irq_res**: the IRQ resource we just allocated.

3. **INTR_TYPE_MISC | INTR_MPSAFE**: the flags. `INTR_TYPE_MISC` categorises the interrupt (Section 2). `INTR_MPSAFE` promises the handler does its own synchronisation.
4. **myfirst_intr_filter**: our filter handler. Non-NULL.
5. **NULL**: the ithread handler. NULL because Stage 1 is filter-only.
6. **sc**: the argument passed to both handlers.
7. **&sc->intr_cookie**: out-parameter where the kernel stores the cookie for later teardown.

The return value is 0 on success, or an `errno` on failure. A failure at this point is rare; the most common cause is an interrupt controller or platform-specific restriction.

A successful `bus_setup_intr` combined with the `device_printf` below produces a short banner in `dmesg` when the driver is loaded:

```
myfirst0: attached filter handler on IRQ resource
```

The IRQ number itself is not in this line; `devinfo -v` and `vmstat -i` show it (the IRQ number depends on the guest's configuration). If you see an additional `myfirst0: [GIANT-LOCKED]` line, your flags argument is missing `INTR_MPSAFE` and the kernel is warning that Giant is being acquired around the handler; fix it.

19.4.6 Describing the Handler to devinfo

An optional but recommended step. `bus_describe_intr(9)` lets the driver attach a human-readable name to the handler, which `devinfo -v` and the kernel's diagnostics will use:

```
bus_describe_intr(dev, sc->irq_res, sc->intr_cookie, "legacy");
```

After this call, `vmstat -i` shows the handler's line as `irq19: myfirst0:legacy` rather than plain `irq19: myfirst0`. The suffix is the name the driver provided. For Chapter 19's single-interrupt driver the suffix is mostly decorative; for Chapter 20's MSI-X driver with multiple vectors it becomes essential for distinguishing `rx0`, `rx1`, `tx0`, `admin`, and so on.

19.4.7 The Extended Attach Cascade

Putting the new pieces into the Stage 3 attach from Chapter 18:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error, capreg;

    sc->dev = dev;
    sc->unit = device_get_unit(dev);
    error = myfirst_init_softc(sc);
}
```

```
if (error != 0)
    return (error);

/* Step 1: allocate BAR0. */
sc->bar_rid = PCIR_BAR(0);
sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
    &sc->bar_rid, RF_ACTIVE);
if (sc->bar_res == NULL) {
    device_printf(dev, "cannot allocate BAR0\n");
    error = ENXIO;
    goto fail_softc;
}

/* Step 2: walk PCI capabilities (informational). */
if (pci_find_cap(dev, PCIY_EXPRESS, &capreg) == 0)
    device_printf(dev, "PCIe capability at 0x%x\n", capreg);
if (pci_find_cap(dev, PCIY_MSI, &capreg) == 0)
    device_printf(dev, "MSI capability at 0x%x\n", capreg);
if (pci_find_cap(dev, PCIY_MSIX, &capreg) == 0)
    device_printf(dev, "MSI-X capability at 0x%x\n", capreg);

/* Step 3: attach the hardware layer against the BAR. */
error = myfirst_hw_attach_pci(sc, sc->bar_res,
    rman_get_size(sc->bar_res));
if (error != 0)
    goto fail_release_bar;

/* Step 4: allocate the IRQ. */
sc->irq_rid = 0;
sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ,
    &sc->irq_rid, RF_SHAREABLE | RF_ACTIVE);
if (sc->irq_res == NULL) {
    device_printf(dev, "cannot allocate IRQ\n");
    error = ENXIO;
    goto fail_hw;
}

/* Step 5: register the filter handler. */
error = bus_setup_intr(dev, sc->irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->intr_cookie);
if (error != 0) {
    device_printf(dev, "bus_setup_intr failed (%d)\n", error);
}
```

```

        goto fail_release_irq;
    }
    bus_describe_intr(dev, sc->irq_res, sc->intr_cookie, "legacy");
    device_printf(dev, "attached filter handler on IRQ resource\n");

    /* Step 6: create the cdev. */
    sc->cdev = make_dev(&myfirst_cdevsw, sc->unit, UID_ROOT,
        GID_WHEEL, 0600, "myfirst%d", sc->unit);
    if (sc->cdev == NULL) {
        error = ENXIO;
        goto fail_teardown_intr;
    }
    sc->cdev->si_drv1 = sc;

    /* Step 7: read a diagnostic word from the BAR. */
    MYFIRST_LOCK(sc);
    sc->bar_first_word = CSR_READ_4(sc, 0x00);
    MYFIRST_UNLOCK(sc);
    device_printf(dev, "BAR[0x00] = 0x%08x\n", sc->bar_first_word);

    sc->pci_attached = true;
    return (0);

fail_teardown_intr:
    bus_teardown_intr(dev, sc->irq_res, sc->intr_cookie);
    sc->intr_cookie = NULL;
fail_release_irq:
    bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid, sc->irq_res);
    sc->irq_res = NULL;
fail_hw:
    myfirst_hw_detach(sc);
fail_release_bar:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail_softc:
    myfirst_deinit_softc(sc);
    return (error);
}

```

The attach sequence now has seven steps instead of five. Two new goto labels (`fail_teardown_intr`, `fail_release_irq`) extend the cascade. The pattern is the same as Chapter 18's: each step undoes the one before it, chaining down to the softc init.

19.4.8 The Extended Detach

The detach path mirrors the attach, with the interrupt teardown fitting between the cdev teardown and the hardware-layer detach:

```
static int
myfirst_pci_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    if (myfirst_is_busy(sc))
        return (EBUSY);

    sc->pci_attached = false;

    /* Destroy the cdev so no new user-space access starts. */
    if (sc->cdev != NULL) {
        destroy_dev(sc->cdev);
        sc->cdev = NULL;
    }

    /* Tear down the interrupt handler before anything it depends on. */
    if (sc->intr_cookie != NULL) {
        bus_teardown_intr(dev, sc->irq_res, sc->intr_cookie);
        sc->intr_cookie = NULL;
    }

    /* Quiesce callouts and tasks (includes Chapter 17 simulation if
     * attached; includes any deferred taskqueue work). */
    myfirst_quiesce(sc);

    /* Release the Chapter 17 simulation if attached. */
    if (sc->sim != NULL)
        myfirst_sim_detach(sc);

    /* Detach the hardware layer. */
    myfirst_hw_detach(sc);

    /* Release the IRQ resource. */
    if (sc->irq_res != NULL) {
        bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid,
            sc->irq_res);
        sc->irq_res = NULL;
    }
}
```

```

/* Release the BAR. */
if (sc->bar_res != NULL) {
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,
        sc->bar_res);
    sc->bar_res = NULL;
}

myfirst_deinit_softc(sc);

device_printf(dev, "detached\n");
return (0);
}

```

Two changes from Chapter 18: the `bus_tearardown_intr` call, and the `bus_release_resource(..., SYS_RES_IRQ, ...)` call. The ordering is important. `bus_tearardown_intr` must happen before anything the handler reads or writes is freed; in particular, before `myfirst_hw_detach` (which frees `sc->hw`). After `bus_tearardown_intr` returns, the kernel guarantees the handler is not running and will not be called again; the driver can then free anything the handler touched.

Releasing the IRQ resource happens after the teardown and after the hardware layer is detached. The exact position between the hardware detach and the BAR release is a judgment call: the BAR and the IRQ do not depend on each other, so either order works. The Chapter 19 driver releases the IRQ first because that is the reverse of the attach order (attach allocated the IRQ after the BAR; detach releases it before the BAR).

Section 7 has more to say about ordering.

19.4.9 The sysctl for the Interrupt Counter

A small diagnostic: a sysctl exposing the `intr_count` field so the reader can watch the counter grow:

```

SYSCTL_ADD_U64(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "intr_count",
    CTLFLAG_RD, &sc->intr_count, 0,
    "Number of times the interrupt filter has run");

```

After load, `sysctl dev.myfirst.0.intr_count` returns the current count. For the `virtio-rnd` device with no interrupts firing (the device has nothing to signal yet), the count stays at zero. Section 5's simulated interrupts will drive the count up without needing real IRQ events.

The `sysctl` is readable by any user (the `CTLFLAG_RD` makes it world-readable at the sysctl level; file permissions on the sysctl MIB are set elsewhere). Access is through:

```
sysctl dev.myfirst.0.intr_count
```

19.4.10 What Stage 1 Proves

Loading the Stage 1 driver on a bhyve guest with a virtio-rnd device produces:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0: BAR0 allocated: 0x20 bytes at 0xc1000000
myfirst0: hardware layer attached to BAR: 32 bytes
myfirst0: attached filter handler on IRQ resource
myfirst0: BAR[0x00] = 0x10010000
```

`vmstat -i | grep myfirst` shows the interrupt event the kernel created:

```
irq19: myfirst0:legacy          0          0
```

(The IRQ number and the rate depend on the environment.)

The initial count is zero because the virtio-rnd device is not generating interrupts yet (we have not programmed it to). The driver is correctly wired up, the handler is registered, and the filter is ready to fire. Stage 1's job is done.

19.4.11 What Stage 1 Does Not Do

Several things are deliberately absent from Stage 1 and appear in later stages:

- **Status register reading.** The filter does not read the device's `INTR_STATUS`; it just increments a counter. Section 4 adds the status read.
- **Acknowledgment.** The filter does not write `INTR_STATUS` to acknowledge. On a level-triggered line with a device that is actually firing, this is a bug. On our virtio-rnd target in bhyve, the device is not firing, so the absence is invisible. Section 4 adds the acknowledgment and explains why it matters.
- **Ithread handler.** No deferred work yet. Section 4 introduces a taskqueue-based deferred path and wires the filter to schedule it.
- **Simulated interrupts.** There is no way to make the handler fire without a real IRQ from the device. Section 5 adds a `sysctl` that invokes the filter directly under the driver's normal lock rules.
- **Shared-IRQ discipline.** The filter assumes every interrupt belongs to our device. Section 6 adds the `FILTER_STRAY` check for devices that share a line.

These are the topics of Sections 4, 5, and 6. Stage 1 is deliberately incomplete; each later section adds a specific thing that Stage 1 left out.

19.4.12 Common Mistakes at This Stage

A short list of traps beginners hit at Stage 1.

Forgetting `INTR_MPSAFE`. The handler gets wrapped in Giant. Scalability disappears. `dmesg` prints `[GIANT-LOCKED]`. Fix: add `INTR_MPSAFE` to the flags argument.

Passing the wrong argument to the filter. A C function pointer is fussy; passing `&sc` instead of `sc` produces a double pointer that the filter then dereferences incorrectly. The result is usually a kernel panic. Fix: the arg in `bus_setup_intr` is `sc`; the filter receives the same value as a void `*`.

Returning 0 from the filter. The return value is a bitwise OR of `FILTER_*` values. Zero is “no flags”, which is illegal (the kernel requires at least one of `FILTER_STRAY`, `FILTER_HANDLED`, or `FILTER_SCHEDULE_THREAD`). The debug kernel asserts on this. Fix: return `FILTER_HANDLED`.

Using a sleep lock in the filter. The filter takes `sc->mtx` (a regular sleep mutex). `WITNESS` complains; the debug kernel panics. Fix: use atomic operations, or move the work to an `ithread`.

Tearing down the IRQ before the cookie is consumed. Calling `bus_release_resource` on the IRQ before `bus_teardown_intr` is a bug: the resource is gone, but the handler is still registered against it. The next interrupt fires and the kernel dereferences freed state. Fix: always `bus_teardown_intr` first.

Mismatched rid. The rid passed to `bus_release_resource` must match the rid that `bus_alloc_resource_any` returned (or the rid passed in initially, for `rid = 0`). Mismatch usually surfaces as “Resource not found” or a kernel message. Fix: store the rid in the `softc` alongside the resource handle.

Forgetting to drain pending deferred work before teardown. This applies more in Stage 2, but worth flagging here: if the filter has scheduled a taskqueue item, the item must complete before the `softc` goes away. A teardown that releases the IRQ but leaves a taskqueue item pending produces a use-after-free when the item runs.

19.4.13 Checkpoint: Stage 1 Working

Before Section 4, confirm Stage 1 is in place:

- `kldstat -v | grep myfirst` shows the driver at version `1.2-intr-stage1`.
- `dmesg | grep myfirst` shows the attach banner including attached filter handler on IRQ resource.
- No `[GIANT-LOCKED]` warning.
- `devinfo -v | grep -A 5 myfirst` shows both the BAR and the IRQ resource.
- `vmstat -i | grep myfirst` shows the handler’s row.
- `sysctl dev.myfirst.0.intr_count` returns 0 (or a small number, depending on whether the device happens to interrupt).
- `kldunload myfirst` runs cleanly; no panic, no warning.

If any step fails, return to the relevant subsection. The failures are diagnosed the same way Chapter 18’s failures were: check `dmesg` for banners, check `devinfo -v` for resources, check `WITNESS` output for lock-order issues.

19.4.14 Wrapping Up Section 3

Registering an interrupt handler is three new calls (`bus_alloc_resource_any` with `SYS_RES_IRQ`, `bus_setup_intr`, `bus_describe_intr`), three new `softc` fields (`irq_res`, `irq_rid`, `intr_cookie`), and one new counter (`intr_count`). The attach cascade grows by two labels; the detach path grows by the `bus_teardown_intr` call. The handler itself is a one-line atomic increment returning `FILTER_HANDLED`.

The point of Stage 1 is not the work the handler does. The point is that the handler is correctly registered, `INTR_MPSAFE` is set, the counter increments when an interrupt fires, and the teardown runs cleanly on unload.

Every later stage builds on top of this scaffolding; getting it right now is the investment that pays off through the rest of the chapter.

Section 4 makes the handler do real work: read `INTR_STATUS`, decide what to do, acknowledge the device, and defer bulk work to a taskqueue. This is the heart of a real interrupt handler, and the content that matters most for the rest of Part 4.

19.5 Section 4: Writing a Real Interrupt Handler

Stage 1 proved the handler wiring is correct. Stage 2 makes the handler do the work a real driver's filter does. The structure of Section 4 is a close walk through the Chapter 17 simulation's hardware model, with the filter now reading and acknowledging the device's `INTR_STATUS` register, making decisions based on which bits are set, handling the urgent small work inline, and deferring the bulk work to a taskqueue. By the end of Section 4 the driver is at version `1.2-intr-stage2` and has a filter-plus-task pipeline that behaves like a small real driver.

19.5.1 The Register Picture

A quick recap of the Chapter 17 simulation's interrupt register layout (see `HARDWARE.md` for the full details). Offset `0x14` holds `INTR_STATUS`, a 32-bit register with these bits defined:

- `MYFIRST_INTR_DATA_AV` (`0x00000001`): a data-available event has occurred.
- `MYFIRST_INTR_ERROR` (`0x00000002`): an error condition has been detected.
- `MYFIRST_INTR_COMPLETE` (`0x00000004`): a command has completed.

The register is “write-one-to-clear” (RW1C) semantics: writing a 1 to a bit clears that bit; writing a 0 leaves it unchanged. This is the standard PCI interrupt-status convention and is what Chapter 19's handler expects.

Offset `0x10` holds `INTR_MASK`, a parallel register that controls which bits of `INTR_STATUS` actually assert the IRQ line. Setting a bit in `INTR_MASK` enables that interrupt class; clearing it disables it. The driver sets `INTR_MASK` at attach time to enable the interrupts it wants to receive.

Chapter 17's simulation can drive these bits autonomously. Chapter 18's PCI driver runs against a real `virtio-rnd` BAR, where the offsets mean something different (`virtio` legacy configuration, not the Chapter 17 register map). Section 4 writes the handler against the Chapter 17 semantics; Section 5 shows how to exercise the handler without real IRQ events; the `virtio-rnd` device does not implement this register layout, so in the bhyve lab the handler is primarily exercised through the simulated-interrupt path.

This is an honest limitation of the teaching target. A reader adapting the driver to a real device that implements Chapter 17-style registers would see the handler fire on real interrupts directly. For the bhyve `virtio-rnd` target, Section 5's `sysctl`-triggered handler is the way to exercise the Stage 2 filter in practice.

19.5.2 The Filter Handler at Stage 2

The Stage 2 filter reads `INTR_STATUS`, decides what happened, acknowledges the bits it is handling, and either does the urgent work inline or schedules a task for bulk work.

```
int
myfirst_intr_filter(void *arg)
{
    struct myfirst_softc *sc = arg;
    uint32_t status;
    int rv = 0;

    /*
     * Read the raw status. The filter runs in primary interrupt
     * context and cannot take sc->mtx (a sleep mutex), so the access
     * goes through the specialised accessor that asserts the correct
     * context. We use a local, spin-safe helper for the BAR access;
     * Stage 2 uses a small inline instead of the lock-asserting
     * CSR_READ_4 macro.
     */
    status = bus_read_4(sc->bar_res, MYFIRST_REG_INTR_STATUS);
    if (status == 0)
        return (FILTER_STRAY);

    atomic_add_64(&sc->intr_count, 1);

    /* Handle the DATA_AV bit: small urgent work only. */
    if (status & MYFIRST_INTR_DATA_AV) {
        atomic_add_64(&sc->intr_data_av_count, 1);
        bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS,
            MYFIRST_INTR_DATA_AV);
        taskqueue_enqueue(sc->intr_tq, &sc->intr_data_task);
        rv |= FILTER_HANDLED;
    }

    /* Handle the ERROR bit: log and acknowledge. */
    if (status & MYFIRST_INTR_ERROR) {
        atomic_add_64(&sc->intr_error_count, 1);
        bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS,
            MYFIRST_INTR_ERROR);
        rv |= FILTER_HANDLED;
    }

    /* Handle the COMPLETE bit: wake any pending waiters. */
    if (status & MYFIRST_INTR_COMPLETE) {
        atomic_add_64(&sc->intr_complete_count, 1);
        bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS,
            MYFIRST_INTR_COMPLETE);
        rv |= FILTER_HANDLED;
    }
}
```

```

    }

    /* If we didn't recognise any bit, this wasn't our interrupt. */
    if (rv == 0)
        return (FILTER_STRAY);

    return (rv);
}

```

Several things worth reading carefully.

The raw access. The filter uses `bus_read_4` and `bus_write_4` (the newer resource-based accessors) directly, not the `CSR_READ_4` and `CSR_WRITE_4` macros from Chapter 16. The reason is subtle. The Chapter 16 macros take `sc->mtx` via `MYFIRST_ASSERT`, which is a sleep mutex. A filter must not take a sleep mutex. The right approach is either to use the raw `bus_space` accessors directly (as shown) or to introduce a parallel family of CSR macros that assert no lock requirement. Section 8's refactor introduces `ICSR_READ_4` and `ICSR_WRITE_4` ("I" for interrupt-context) to make the distinction explicit; Stage 2 uses the raw accessors.

The early stray check. A status of zero means no bit is set; this is a shared-IRQ call from another driver. Returning `FILTER_STRAY` lets the kernel try the next handler. The check is also a defence against a real hardware race: if the interrupt controller asserts the line but the device has already cleared the status (by the time we read it), we should not claim the interrupt.

The per-bit handling. Each bit of interest is checked, counted, and acknowledged. The order does not matter (the bits are independent), but the structure is conventional: one `if` per bit.

The acknowledgment. Writing the bit back to `INTR_STATUS` clears it (RW1C). This is what makes the interrupt line deassert. Failing to acknowledge on a level-triggered line produces an interrupt storm.

The taskqueue enqueue. The `DATA_AV` bit triggers deferred work. The filter enqueues a task; the taskqueue's worker thread runs the task later in thread context, where it can take sleep locks and do slow work. The enqueue is safe to call from a filter (taskqueues use spin locks internally for this path).

The final return value. A bitwise OR of `FILTER_HANDLED` for each bit we recognised, or `FILTER_STRAY` if nothing matched. If we had work for an ithread, we would OR in `FILTER_SCHEDULE_THREAD`; but Stage 2 uses a taskqueue rather than the ithread, so the return value is just `FILTER_HANDLED`.

19.5.3 Why a Taskqueue, Not an ithread?

FreeBSD lets a driver register an ithread handler through the fifth argument of `bus_setup_intr(9)`. Why does Stage 2 use a taskqueue instead?

Two reasons.

First, the taskqueue is more flexible. An ithread is tied to the specific `intr_event`; it runs the driver's ithread function after the filter. A taskqueue lets the driver schedule a task from any context (filter, ithread, other tasks, user-space ioctl paths) and have it run on a shared worker thread. For the Chapter 19 driver, which exercises the handler through simulated interrupts as well as real ones, the taskqueue is a more uniform deferred-work primitive.

Second, the taskqueue separates priority from the interrupt type. The ithread's priority is derived from `INTR_TYPE_*`; the taskqueue's priority is controlled by `taskqueue_start_threads(9)`. For drivers that want their deferred work at a different priority than the interrupt category implies, the taskqueue gives that control.

Real FreeBSD drivers use both patterns. Simple drivers with fire-and-forget interrupts often use the ithread (less code). Drivers with richer deferred-work patterns use taskqueues. The `iflib(9)` framework uses a kind of hybrid.

Chapter 19 teaches the taskqueue pattern because it composes better with the rest of the book. Chapter 17 already has a taskqueue; Chapter 14 introduced the pattern; the deferred-work discipline is a book-wide theme.

19.5.4 The Deferred-Work Task

The filter enqueued `sc->intr_data_task` when it saw `DATA_AV`. That task is:

```
static void
myfirst_intr_data_task_fn(void *arg, int npending)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_LOCK(sc);

    /*
     * The data-available event has fired. Read the device's data
     * register through the Chapter 16 accessor (which takes sc->mtx
     * implicitly), update the driver's state, and wake any waiting
     * readers.
     */
    uint32_t data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
    sc->intr_last_data = data;
    sc->intr_task_invocations++;

    /* Wake any thread sleeping on the data-ready condition. */
    cv_broadcast(&sc->data_cv);

    MYFIRST_UNLOCK(sc);
}
```

Several notable properties.

The task runs in thread context. It can take `sc->mtx`, use `cv_broadcast`, call `malloc(M_WAITOK)`, and do slow work.

The task respects the Chapter 11 locking discipline. The mutex is acquired; the CSR access uses the standard Chapter 16 macro; the condition-variable broadcast uses the Chapter 12 primitive.

The task's argument is the softc. Same as the filter. One subtle implication: the task cannot assume the driver has not been detached. If detach fires after the filter has enqueued the task but before the task runs, the task could execute against a freed softc. Section 7 covers the discipline that prevents this (drain before release).

The npending argument is the number of times the task was enqueued since its last run. For most drivers this is useful as a coalescing hint: if npending is 5, the device signalled five data-ready events that all coalesce into one run. Stage 2's task ignores it; larger drivers use it to size batch operations.

19.5.5 Declaring and Initialising the Task

The softc gains task-related fields:

```
struct myfirst_softc {
    /* ... existing fields ... */

    /* Chapter 19 interrupt-related fields. */
    struct resource      *irq_res;
    int                  irq_rid;
    void                 *intr_cookie;
    uint64_t             intr_count;
    uint64_t             intr_data_av_count;
    uint64_t             intr_error_count;
    uint64_t             intr_complete_count;
    uint64_t             intr_task_invocations;
    uint32_t             intr_last_data;

    struct taskqueue     *intr_tq;
    struct task          intr_data_task;
};
```

In myfirst_init_softc (or the init path):

```
TASK_INIT(&sc->intr_data_task, 0, myfirst_intr_data_task_fn, sc);
sc->intr_tq = taskqueue_create("myfirst_intr", M_WAITOK,
    taskqueue_thread_enqueue, &sc->intr_tq);
taskqueue_start_threads(&sc->intr_tq, 1, PI_NET,
    "myfirst intr taskq");
```

The taskqueue is created with one worker thread at priority PI_NET (an interrupt priority; see /usr/src/sys/sys/priority.h). The name "myfirst intr taskq" appears in top -H for diagnosis. The M_WAITOK during create is fine because myfirst_init_softc runs in attach context, before any interrupts fire.

19.5.6 Enabling the Interrupts at the Device

A detail often forgotten: the device itself must be told to deliver interrupts. For the Chapter 17 simulation's register layout, this is done by setting bits in the INTR_MASK register:

```
/* After attaching the hardware layer, enable the interrupts we care
   * about. */
MYFIRST_LOCK(sc);
CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
    MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR |
    MYFIRST_INTR_COMPLETE);
MYFIRST_UNLOCK(sc);
```

The INTR_MASK register controls which bits of INTR_STATUS actually assert the IRQ line. Without it the device may set INTR_STATUS bits internally but never raise the line, so the handler never fires. Setting all three bits enables all three interrupt classes.

This is another honest limitation of the teaching target. Offset 0x10 on the virtio-rnd legacy BAR is not an interrupt-mask register at all. In the legacy virtio layout (see /usr/src/sys/dev/virtio/pci/virtio_pci_legacy_var.h), the dword starting at 0x10 is shared by three small fields: queue_notify at offset 0x10 (16-bit), device_status at offset 0x12 (8-bit), and isr_status at offset 0x13 (8-bit). A 32-bit write of our DATA_AV | ERROR | COMPLETE pattern (0x00000007) at that offset writes 0x0007 to queue_notify (notifying a virtqueue index the device does not have) and 0x00 to device_status (which the virtio specification defines as a **device reset**). Writing zero to device_status is how the virtio driver is supposed to reset the device before reinitialisation.

For that reason, the CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, ...) call as written is **safe but pointless** on the bhyve virtio-rnd target: it resets the device's virtio state machine (which our driver was not using anyway), and it never enables any real interrupt because the Chapter 17 INTR_MASK register does not exist on that device. If you plan to drive a reader through this on bhyve, keep the write in the code for continuity with a real Chapter-17-compatible device, and rely on Section 5's simulated-interrupt sysctl for testing instead of expecting real IRQ events. A reader who adapts the driver to a real device that matches the Chapter 17 register map would see the mask write do its job.

19.5.7 Disabling the Interrupts at Detach

The symmetric step at detach:

```
/* Disable all interrupts at the device before tearing down. */
MYFIRST_LOCK(sc);
if (sc->hw != NULL)
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
MYFIRST_UNLOCK(sc);
```

This write happens before bus_tearardown_intr so the device stops asserting the line before the handler is removed. The guard against sc->hw == NULL protects against partial-attach cases where the hardware layer failed; the disable is skipped if the hardware is not attached.

19.5.8 A Worked Flow

A concrete trace of what happens when a `DATA_AV` event fires (on a device that actually implements the Chapter 17 semantics):

1. The device sets `INTR_STATUS.DATA_AV`. Because `INTR_MASK.DATA_AV` is set, the device asserts its IRQ line.
2. The interrupt controller routes the IRQ to a CPU.
3. The CPU takes the interrupt and jumps to the kernel's dispatch code.
4. The kernel finds the `intr_event` for our IRQ and calls `myfirst_intr_filter`.
5. The filter reads `INTR_STATUS`, sees `DATA_AV`, increments counters, writes `DATA_AV` back to `INTR_STATUS` (clearing it), enqueues `intr_data_task`, returns `FILTER_HANDLED`.
6. The device deasserts its IRQ line (because `INTR_STATUS.DATA_AV` is now clear).
7. The kernel sends EOI, returns to the interrupted thread.
8. Some milliseconds later, the taskqueue's worker thread wakes up, runs `myfirst_intr_data_task_fn`, reads `DATA_OUT`, updates the softc, broadcasts the condition variable.
9. Any thread that was waiting on the condition variable wakes up and proceeds.

Steps 1 through 7 take a few microseconds. Step 8 can take hundreds of microseconds or more, which is why it is in thread context. The split is what lets the interrupt path stay fast.

For the bhyve virtio-rnd target, steps 1 through 6 do not happen (the device does not match the Chapter 17 register layout). Steps 4 through 9 can still be exercised through the Section 5 simulated-interrupt path.

19.5.9 Urgent Work Inline vs Deferred

A useful way to decide what goes in the filter versus in the task: the filter handles what must be done **per interrupt**, the task handles what must be done **per event**.

Per-interrupt (filter): - Read `INTR_STATUS` to identify the event. - Acknowledge the event at the device (write back to `INTR_STATUS`). - Update counters. - Make a single scheduling decision (enqueue the task).

Per-event (task): - Read data from device registers or DMA buffers. - Update the driver's internal state machine. - Wake waiting threads. - Pass data up to the network stack, the storage stack, or the cdev queue. - Handle errors that require slow recovery.

The rule of thumb: if the filter takes more than a hundred CPU cycles of real work (not counting the register accesses, which are cheap in themselves), it is probably doing too much.

19.5.10 FILTER_SCHEDULE_THREAD vs Taskqueue

A reader might ask: when would I use `FILTER_SCHEDULE_THREAD` instead of a taskqueue?

Use `FILTER_SCHEDULE_THREAD` when: - You want the kernel's per-event ithread (one per `intr_event`) to run the slow work. - You do not need to schedule the work from anywhere except the filter. - You want the scheduling priority to follow the interrupt's `INTR_TYPE_*`.

Use a taskqueue when: - You want to schedule the same work from multiple paths (filter, `ioctl`, `sysctl`, sleep-based timeout). - You want to share the worker thread across multiple devices. - You want explicit control over priority via `taskqueue_start_threads`.

For the Chapter 19 driver the taskqueue is the cleaner choice because Section 5 will schedule the same task from a simulated-interrupt path. An ithread would not be reachable from there.

19.5.11 When the Taskqueue Itself Is the Wrong Answer

A caveat. The taskqueue is great for short deferred work. It is not great for long-running operations. If the driver needs to run a state machine for seconds, or block waiting on a USB transfer, or process a large buffer chain, a dedicated worker thread is better. The taskqueue's worker thread is shared across tasks; a single task that blocks for a long time delays every other task behind it.

Chapter 19's task runs for microseconds. The taskqueue is fine. Chapter 20's MSI-X driver with per-queue receive processing may want per-queue worker threads. Chapter 21's DMA-driven bulk transfer may want a dedicated thread. Each chapter picks the right primitive for its workload; Chapter 19 uses the simplest one that fits.

19.5.12 Common Mistakes at This Stage

A short list.

Reading INTR_STATUS without acknowledging. The handler reads, decides, and returns without writing back. On a level-triggered line, the device keeps asserting; the handler fires again immediately; storm. Fix: acknowledge every bit you handled.

Acknowledging too many bits. A sloppy handler writes 0xffffffff to INTR_STATUS on every call to “clear all bits”. This also clears events the handler has not processed, dropping data or confusing the state machine. Fix: acknowledge only the bits you actually handled.

Taking sleep locks in the filter. MYFIRST_LOCK(sc) takes sc->mtx, which is a sleep mutex. In the filter this is a bug; WITNESS panics. Fix: use atomic operations in the filter, and take the sleep mutex only in the task (which runs in thread context).

Scheduling a task after the softc is torn down. If the task is scheduled from the filter but the filter runs after detach has partially torn down, the task runs against stale state. Fix: Section 7 covers the ordering. Briefly: bus_tearardown_intr must happen before the hardware layer is freed, and taskqueue_drain must happen before the taskqueue is freed.

Using CSR_READ_4/CSR_WRITE_4 directly in the filter. If the Chapter 16 accessor asserts sc->mtx held (which it does on debug kernels), the filter panics. Fix: use raw bus_read_4/bus_write_4 or introduce a parallel set of interrupt-safe CSR macros. Section 8 handles this with ICSR_READ_4.

Enqueueing the task without TASK_INIT. A task enqueued before TASK_INIT has a corrupt function pointer. The first run of the task jumps to garbage. Fix: initialise the task in the attach path before enabling interrupts.

Forgetting to enable interrupts at the device. The handler is registered and bus_setup_intr succeeded; vmstat -i still shows zero firings. The problem is the device's INTR_MASK register is still zero (or whatever post-reset value it has), so the device never asserts the line. Fix: write the INTR_MASK during attach.

Forgetting to disable interrupts at detach. The handler has been torn down but the device is still asserting the line. The kernel will eventually complain about a stray interrupt, or (worse) another driver that shares the line will see mysterious activity. Fix: clear INTR_MASK before bus_tearardown_intr.

19.5.13 Stage 2 Output: What Success Looks Like

After loading Stage 2 on a real device that produces interrupts, `dmesg` shows:

```
myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: attaching: vendor=0x1af4 device=0x1005 revid=0x00
myfirst0: BAR0 allocated: 0x20 bytes at 0xc1000000
myfirst0: hardware layer attached to BAR: 32 bytes
myfirst0: attached filter handler on IRQ resource
myfirst0: interrupts enabled (mask=0x7)
myfirst0: BAR[0x00] = 0x10010000
```

The `interrupts enabled` line is new. It confirms the driver has written to `INTR_MASK`.

On a real device generating interrupts, `sysctl dev.myfirst.0.intr_count` will tick up. On the bhyve `virtio-rnd` target, the count stays at zero because the device does not fire our expected interrupts. Section 5's simulated-interrupt path is the way to exercise the handler from there.

19.5.14 Wrapping Up Section 4

A real interrupt handler reads `INTR_STATUS` to identify the cause, handles each bit of interest, acknowledges the bits it handled by writing back to `INTR_STATUS`, and returns the right combination of `FILTER_*` values. Urgent work (register access, counter updates, acknowledgments) happens in the filter. Slow work (data reads through Chapter 16 accessors that take `sc->mtx`, condition-variable broadcasts, user-space notifications) happens in a taskqueue task that the filter enqueues.

The filter is short (twenty to forty lines of real code for a typical device). The task is short too (ten to thirty lines). The composition is what makes the driver functional: the filter handles interrupts at interrupt rate; the task handles events at thread-rate; the split keeps the interrupt window tight and the deferred work free to block.

Section 5 is the section that lets a reader exercise this machinery on a bhyve target where the real IRQ path does not match the Chapter 17 register semantics. It adds a `sysctl` that invokes the filter under the driver's normal lock rules, lets the reader trigger simulated interrupts at will, and confirms that the counters, the task, and the condition-variable broadcast all behave as designed.

19.6 Section 5: Using Simulated Interrupts for Testing

Section 4's filter and task are real driver code. They are ready to handle real interrupts on a device that matches the Chapter 17 register layout. The problem Chapter 19's lab target presents is that the device we have (`virtio-rnd` under bhyve) does not match that layout; writing the Chapter 17 interrupt-mask bits to the `virtio-rnd` BAR has defined but unrelated effects, and reading Chapter 17 interrupt-status bits from the `virtio-rnd` BAR returns `virtio`-specific values that have nothing to do with our simulated semantics. On this target the filter, if it fires at all, will see garbage.

Section 5 solves this by teaching the reader to simulate interrupts. The core idea is simple: expose a `sysctl` that, when written, invokes the filter handler directly under the driver's normal lock rules, exactly as the kernel would

invoke it from a real interrupt. The filter reads the `INTR_STATUS` register (which the reader has also written to through another `sysctl`, or through the Chapter 17 simulation backend on a simulation-only build), makes the same decisions it would on a real interrupt, and drives the full pipeline end-to-end.

19.6.1 Why Simulation Deserves a Section

A reader who finished Chapter 17 might reasonably ask: was the whole Chapter 17 simulation not already a way to simulate interrupts? Yes and no.

Chapter 17 simulated an **autonomous device**. Its callouts changed register values on their own schedule, its command callout fired when the driver wrote `CTRL.GO`, its fault-injection framework made the simulated device misbehave. The driver at Chapter 17 was a simulation-only driver; there was no `bus_setup_intr` because there was no real bus.

Chapter 19 is different. The driver now has a real `bus_setup_intr` handler registered on a real IRQ line. Chapter 17's callouts are not involved; on the PCI build the Chapter 17 simulation does not run. What we want is a way to trigger the **filter handler** directly, with the exact lock semantics a real interrupt would produce, so we can validate Section 4's filter and task pipeline without depending on a device that actually produces the right interrupts.

The cleanest way to do this, and the way many FreeBSD drivers have for similar purposes, is a `sysctl` write that invokes the filter function directly. The filter runs in the caller's context (thread context, where the `sysctl` write originates), but the filter's code does not care about the outer context as long as the lock discipline inside is right. An atomic increment, a BAR read, a BAR write, a `taskqueue_enqueue`: all of these work from thread context too. The simulated call exercises the same code paths the kernel would exercise on a real interrupt.

There is one subtle distinction. On a real interrupt, the kernel arranges for filters on the same `intr_event` to run serially on one CPU. A `sysctl`-triggered simulated call does not have that guarantee; another thread could be invoking the filter at the same moment. For the Chapter 19 driver this is fine because the filter's state is protected by atomic operations (not by the kernel's single-CPU-per-IRQ guarantee). For a driver that relies on implicit single-CPU serialisation, simulation through a `sysctl` would not be a faithful test. The lesson is: `INTR_MPSAFE` drivers that use atomics and spin locks translate cleanly to simulation.

19.6.2 The Simulated-Interrupt `sysctl`

The mechanism is a write-only `sysctl` that invokes the filter:

```
static int
myfirst_intr_simulate_sysctl(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    uint32_t mask;
    int error;

    mask = 0;
    error = sysctl_handle_int(oidp, &mask, 0, req);
    if (error != 0 || req->newptr == NULL)
```

```

        return (error);

    /*
     * "mask" is the INTR_STATUS bits the caller wants to pretend
     * the device has set. Set them in the real register, then call
     * the filter directly.
     */
    MYFIRST_LOCK(sc);
    if (sc->hw == NULL) {
        MYFIRST_UNLOCK(sc);
        return (ENODEV);
    }
    bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS, mask);
    MYFIRST_UNLOCK(sc);

    /* Invoke the filter directly. */
    (void)myfirst_intr_filter(sc);

    return (0);
}

```

And the sysctl declaration in `myfirst_intr_add_sysctls`:

```

SYSCTL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "intr_simulate",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE,
    sc, 0, myfirst_intr_simulate_sysctl, "IU",
    "Simulate an interrupt by setting INTR_STATUS bits and "
    "invoking the filter");

```

Writing to `dev.myfirst.0.intr_simulate` causes the handler to run with the specified `INTR_STATUS` bits set.

19.6.3 Exercising the Simulation

Once the sysctl is in place, the reader can drive the full pipeline from user space:

```

# Simulate a DATA_AV event.
sudo sysctl dev.myfirst.0.intr_simulate=1

# Check counters.
sysctl dev.myfirst.0.intr_count
sysctl dev.myfirst.0.intr_data_av_count

```

```
sysctl dev.myfirst.0.intr_task_invocations

# Simulate an ERROR event.
sudo sysctl dev.myfirst.0.intr_simulate=2

# Simulate a COMPLETE event.
sudo sysctl dev.myfirst.0.intr_simulate=4

# Simulate all three at once.
sudo sysctl dev.myfirst.0.intr_simulate=7
```

The first call increments `intr_count` (filter fired), `intr_data_av_count` (DATA_AV bit recognised), and eventually `intr_task_invocations` (the taskqueue task ran). The second increments `intr_count` and `intr_error_count`. The third increments `intr_count` and `intr_complete_count`. The fourth hits all three.

A reader can verify the full pipeline:

```
# Watch counters in a loop.
while true; do
    sudo sysctl dev.myfirst.0.intr_simulate=1
    sleep 0.5
    sysctl dev.myfirst.0 | grep intr_
done
```

The counters tick forward at the expected rate. The driver behaves as if real interrupts were arriving.

19.6.4 Why This Is Not a Toy

One might think this simulated path is a teaching artifact. It is not. Many real drivers keep a similar path for diagnostic purposes. The reasons are worth naming:

Regression testing. A simulated-interrupt path lets a CI pipeline exercise the handler without needing real hardware. Chapter 17 made the same argument for simulating device behaviour; Section 5 makes it for simulating the interrupt path.

Fault injection. A simulated-interrupt `sysctl` lets a test inject specific `INTR_STATUS` patterns to exercise error-handling code. The driver's response to `INTR_STATUS = ERROR | COMPLETE` (both bits set simultaneously) is hard to trigger through real hardware; a `sysctl` that sets both bits and calls the handler makes it easy.

Developer productivity. When a driver author is debugging the handler logic, having a `sysctl` that triggers the handler on demand is enormously useful. `dtrace -n 'fbt::myfirst_intr_filter:entry'` combined with `sudo sysctl dev.myfirst.0.intr_simulate=1` gives a single-step view of the handler on demand.

Bringing up new hardware. A driver author often has a prototype device that does not yet produce interrupts correctly. A simulated-interrupt path lets the driver's upper layers be tested before the hardware works, which means the driver and the hardware can be brought up in parallel rather than serially.

Teaching. For this book’s purpose, the simulated path makes the filter and task observable on a lab target that does not naturally produce the expected interrupts. The reader can see the pipeline work even though the hardware does not cooperate.

19.6.5 Locking in the Simulated Path

A detail worth thinking through. The sysctl writes `INTR_STATUS` while holding `sc->mtx`. The filter handler, when invoked through the kernel’s real interrupt path, runs without `sc->mtx` held (the filter uses `bus_read_4` / `bus_write_4` directly, not the lock-asserting CSR macros). When invoked through the sysctl, what is the calling context?

The sysctl handler runs in thread context. The `MYFIRST_LOCK(sc)` acquires the sleep mutex. Between the lock acquisition and the release, the thread holds the mutex. Then the lock is released, and `myfirst_intr_filter(sc)` is called. The filter takes no locks, uses only atomics and `bus_read_4/bus_write_4`, enqueues a task, and returns. The whole sequence is safe.

Would it be safe to call the filter with `sc->mtx` held? Yes, actually: the filter does not try to acquire the same mutex, and the filter runs in a context where holding the lock is not itself illegal (thread context). But the filter was designed to be context-agnostic; calling it with a sleep lock held would obscure that contract. The sysctl releases the lock before invoking the filter for clarity.

19.6.6 Using the Chapter 17 Simulation to Produce Interrupts

A complementary technique worth mentioning. Chapter 17’s simulation backend, if attached, produces autonomous state changes on its own schedule. In particular, its `DATA_AV`-producing callout sets `INTR_STATUS.DATA_AV`. On a simulation-only build (`MYFIRST_SIMULATION_ONLY` defined at compile time), the simulation is live, the callout fires, and the Chapter 17 driver can even call the filter from the callout itself.

Chapter 19 does not change Chapter 17’s behaviour on simulation-only builds. A reader who wants to see the filter driven by the Chapter 17 simulation can build with `-DMYFIRST_SIMULATION_ONLY`, load the module, and watch the callouts set `INTR_STATUS` bits. The sysctl-triggered path from Section 5 remains available on both builds.

On the PCI build, the Chapter 17 simulation is not attached (Chapter 18’s discipline), so the Chapter 17 callouts do not run. The simulated-interrupt path is the only way to drive the filter on the PCI build.

19.6.7 Extending the sysctl to Schedule at a Rate

A useful extension for load testing: a sysctl that schedules simulated interrupts periodically through a callout. The callout fires every `N` milliseconds, sets a bit in `INTR_STATUS`, and invokes the filter. A reader can tune the rate and observe the pipeline under load.

```
static void
myfirst_intr_sim_callout_fn(void *arg)
{
```

```
struct myfirst_softc *sc = arg;

MYFIRST_LOCK(sc);
if (sc->intr_sim_period_ms > 0 && sc->hw != NULL) {
    bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS,
        MYFIRST_INTR_DATA_AV);
    MYFIRST_UNLOCK(sc);
    (void)myfirst_intr_filter(sc);
    MYFIRST_LOCK(sc);
    callout_reset_sbt(&sc->intr_sim_callout,
        SBT_1MS * sc->intr_sim_period_ms, 0,
        myfirst_intr_sim_callout_fn, sc, 0);
}
MYFIRST_UNLOCK(sc);
}
```

The callout reschedules itself as long as `intr_sim_period_ms` is non-zero. A `sysctl` exposes the period:

```
# Fire a simulated interrupt every 100 ms.
sudo sysctl hw.myfirst.intr_sim_period_ms=100

# Stop simulating.
sudo sysctl hw.myfirst.intr_sim_period_ms=0
```

Watch the counters grow at the expected rate:

```
sleep 10
sysctl dev.myfirst.0.intr_count
```

After ten seconds of 100 ms period, the counter should read about 100. If it reads much less, the filter or the task is the bottleneck (unlikely at this scale; more of a concern for high-rate tests). If it reads much more, something is firing the filter from elsewhere.

19.6.8 What the Simulation Does Not Capture

Honest limits of the technique.

Concurrent firings. The `sysctl` serialises simulated interrupts at one per write. A real interrupt path can see two interrupts back-to-back on different CPUs, which a `sysctl` test would not produce. For stress-testing concurrency, a separate test that spawns multiple threads each writing the `sysctl` is more effective.

Interrupt-controller behaviour. The simulation bypasses the interrupt controller entirely. Tests that depend on EOI timing, masking, or storm detection cannot be driven this way.

CPU affinity. The simulated filter runs on whichever CPU the sysctl-writing thread is on. A real interrupt fires on whichever CPU the affinity configuration selects. Tests of per-CPU behaviour need real interrupts or another mechanism.

Contention with the real interrupt path. If real interrupts are also firing (perhaps because the device actually does generate some), the simulated path can race with the real path. The atomic counters handle it correctly; more complex shared state might not.

These are limits, not deal-breakers. For most Chapter 19 testing, the simulated path is sufficient. For advanced stress testing, additional techniques (rt-threads, multi-CPU invocations, real hardware) apply.

19.6.9 Observing the Task Running

A diagnostic worth exposing. The task’s `intr_task_invocations` counter ticks every time the task runs. A reader can compare it to `intr_data_av_count` to check whether the taskqueue is keeping up:

```
sudo sysctl dev.myfirst.0.intr_simulate=1    # fire DATA_AV
sleep 0.1
sysctl dev.myfirst.0.intr_data_av_count      # should be 1
sysctl dev.myfirst.0.intr_task_invocations   # should also be 1
```

If the task counter lags the `DATA_AV` counter, the taskqueue worker is backlogged. At this scale it should not be; at higher rates (thousands per second) it might be.

A more sensitive probe: add a `cv_signal` path that a user-space program waits on. The sysctl fires the simulated interrupt; the filter enqueues the task; the task updates `sc->intr_last_data` and broadcasts; the user-space thread that was waiting on the condition variable (via the `cdev`’s `read`) wakes up. Round-trip latency from sysctl write to wake-up is the driver’s interrupt-to-user-space latency, roughly, a useful number to know.

19.6.10 Integration With Chapter 17’s Fault Framework

A thought worth noting. Chapter 17’s fault-injection framework (the `FAULT_MASK` and `FAULT_PROB` registers) applies to commands, not to interrupts. Chapter 19 can extend the framework by adding a “fault on next interrupt” option: a sysctl that makes the next filter call skip the acknowledgment, causing a storm on a level-triggered line.

This is an optional extension. The challenge exercises mention it; the chapter’s main body does not require it.

19.6.11 Wrapping Up Section 5

Simulating interrupts is a simple but effective technique. A sysctl writes `INTR_STATUS`, invokes the filter directly, and the filter drives the full pipeline: counter updates, acknowledgment, task enqueue, task execution. The technique lets a driver be exercised end-to-end on a lab target that does not naturally produce the expected interrupts, and it is cheap to keep in production drivers for regression testing and diagnostic access.

Section 6 is the last conceptual piece of core interrupt handling. It covers shared interrupts: what happens when multiple drivers listen on the same IRQ line, how a filter handler must identify whether the interrupt belongs to its device, and what `FILTER_STRAY` means in practice.

19.7 Section 6: Handling Shared Interrupts

Section 4's Stage 2 filter already has the right return-value shape for shared IRQs: it returns `FILTER_STRAY` when `INTR_STATUS` is zero. Section 6 explores why that check is the entire discipline, what goes wrong when a handler gets it wrong, and when the `RF_SHAREABLE` flag is worth setting.

19.7.1 Why Share an IRQ at All?

Two reasons.

First, **hardware constraints**. The classic PC architecture had 16 hardware IRQ lines; the I/O APIC expanded this to 24 on many chipsets. A system with 30 devices necessarily has some of them sharing lines. On modern x86 systems the shortage is less acute (hundreds of vectors), but on legacy PCI and on many arm64 SoCs sharing is normal.

Second, **driver portability**. A driver that handles shared interrupts correctly also handles exclusive interrupts correctly (the shared path is a superset). A driver that assumes exclusive interrupts breaks when the hardware changes or when another driver arrives on the same line. Writing for the shared case costs essentially nothing and future-proofs the driver.

On PCIe with MSI or MSI-X enabled (Chapter 20), each device has its own vectors and sharing is rarely needed. But even there, a driver that correctly handles a stray interrupt (by returning `FILTER_STRAY`) is a better driver than one that does not. The discipline transfers.

19.7.2 The Flow on a Shared IRQ

When a shared IRQ fires, the kernel walks the list of filter handlers attached to the `intr_event` in registration order. Each filter runs, checks whether the interrupt belongs to its device, and returns accordingly:

- If the filter claims the interrupt (returns `FILTER_HANDLED` or `FILTER_SCHEDULE_THREAD`), the kernel continues with the next filter if any and aggregates the results. On modern kernels a filter that returns `FILTER_HANDLED` does not stop later filters from running; the kernel always walks the whole list.
- If the filter returns `FILTER_STRAY`, the kernel tries the next filter.

After all filters have run, if any filter claimed the interrupt, the kernel acknowledges at the interrupt controller and returns. If all filters returned `FILTER_STRAY`, the kernel increments a stray-interrupt counter; if the stray count exceeds a threshold, the kernel disables the IRQ (the drastic last resort).

A filter that returns `FILTER_STRAY` when the interrupt actually was for its device is a bug: the line stays asserted (level-triggered), the storm machinery kicks in, and the device does not get serviced. A filter that returns `FILTER_HANDLED` when the interrupt was not for its device is also a bug: another driver's interrupt is marked as serviced, its handler never runs, its data sits in its FIFO, and the user's network or disk stops working.

The discipline is to decide ownership precisely, based on the device's state, and return the right value.

19.7.3 The `INTR_STATUS` Test

The standard way to decide ownership is to read a device register that tells you whether the interrupt is pending. On a device with a per-device `INTR_STATUS` register, the question is "is any bit in `INTR_STATUS` set?" If

yes, the interrupt is mine. If no, it is not.

The Chapter 17 register layout makes this easy:

```
status = bus_read_4(sc->bar_res, MYFIRST_REG_INTR_STATUS);  
if (status == 0)  
    return (FILTER_STRAY);
```

This is exactly what the Stage 2 filter already does. The pattern is robust: if the status register reads as zero, there is no pending event from this device, so the interrupt is not ours.

A subtle detail: the read of `INTR_STATUS` must happen before any state changes that could mask or reset the bits. Reading `INTR_STATUS` with the device in a mid-state is fine (the register reflects the device's current view); writing to other registers first and then reading `INTR_STATUS` could miss bits that the writes inadvertently cleared.

19.7.4 What “Is It Mine?” Looks Like on Real Hardware

The `INTR_STATUS` test is textbook because the Chapter 17 register layout is textbook. Real devices come in flavours.

Devices with a clean `INTR_STATUS`. Most modern devices have a register that, when read as zero, definitively says “not mine”. The Chapter 19 driver's filter shape applies directly.

Devices with bits that are always set. Some devices have pending-interrupt bits that stay set across interrupts (waiting for the driver to reset them). The filter must mask these out or check against a per-interrupt-class mask. The Chapter 17 register layout avoids this complication; real drivers occasionally face it.

Devices with no `INTR_STATUS` at all. A few older devices require the driver to read a separate register sequence (or to infer from state registers) whether the interrupt is pending. These drivers are more complex; the filter may need to acquire a spin lock and read several registers. The FreeBSD source has examples in a few embedded drivers.

Devices with a global `INTR_STATUS` and per-source registers. A common pattern on NICs: a top-level register reports which queue has a pending event, and per-queue registers contain the event details. The filter reads the top-level register to decide ownership; the ithread or task reads the per-queue registers to process events.

Chapter 19's driver uses the first flavour. The discipline for the other flavours is the same: read a register, decide.

19.7.5 Returning `FILTER_STRAY` Correctly

The rule is simple: if the filter does not recognise any bit as belonging to a class it handles, return `FILTER_STRAY`.

```
if (rv == 0)  
    return (FILTER_STRAY);
```

The variable `rv` accumulates `FILTER_HANDLED` from each recognised bit. If no bit was recognised, `rv` is zero, and the filter has nothing to return but `FILTER_STRAY`.

A subtle corollary: a filter that recognises some bits but not others returns `FILTER_HANDLED` for the bits it recognised, and does not return `FILTER_STRAY` for the bits it did not. Setting a bit in `INTR_MASK` that the driver will not handle is a driver bug; the kernel cannot help.

An interesting edge case: a bit is set in `INTR_STATUS` but the driver does not recognise it (perhaps a new device revision added a bit the driver's code predates). The driver has two options:

1. Ignore the bit. Do not acknowledge it. Let it stay set. On a level-triggered line this produces a storm because the bit asserts the line forever. Bad.
2. Acknowledge the bit without doing any work. Write it back to `INTR_STATUS`. The device stops asserting for that bit, no storm, but the event is lost. On an essential event this is a functional bug; on a diagnostic event it may be acceptable.

The recommended pattern is option 2 with a log message: acknowledge unrecognised bits, log them at a reduced rate (to avoid log flooding if the bit is asserted continuously), and move on. This makes the driver robust against new hardware revisions at the cost of potentially losing information about unknown events.

```
uint32_t unknown = status & ~(MYFIRST_INTR_DATA_AV |
    MYFIRST_INTR_ERROR | MYFIRST_INTR_COMPLETE);
if (unknown != 0) {
    atomic_add_64(&sc->intr_unknown_count, 1);
    bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS, unknown);
    rv |= FILTER_HANDLED;
}
```

This snippet is not in Stage 2's filter; it is a useful extension for Stage 3 or beyond.

19.7.6 What Happens If Multiple Drivers Share an IRQ

A concrete scenario. Suppose the `virtio-rnd` device in a bhyve guest shares IRQ 19 with the AHCI controller. Both drivers have registered handlers. An interrupt arrives on IRQ 19.

The kernel walks the handler list in registration order. Suppose AHCI registered first, so its filter runs first:

1. AHCI filter: reads its `INTR_STATUS`, sees bits set (AHCI has pending I/O), acknowledges, returns `FILTER_HANDLED`.
2. `myfirst` filter: reads its `INTR_STATUS`, reads zero, returns `FILTER_STRAY`.

The kernel sees “at least one `FILTER_HANDLED`” and does not mark the interrupt as stray.

Now the reverse case. The `virtio-rnd` device has an event:

1. AHCI filter: reads its `INTR_STATUS`, sees zero, returns `FILTER_STRAY`.
2. `myfirst` filter: reads its `INTR_STATUS`, sees `DATA_AV`, acknowledges, returns `FILTER_HANDLED`.

The kernel sees one `FILTER_HANDLED` and is happy.

The key property is that each filter checks only its own device. No filter assumes the interrupt is its own; each decides from its device's state.

19.7.7 What Happens If a Driver Gets It Wrong

A broken AHCI filter that returns `FILTER_HANDLED` whenever it fires (without checking status) would claim our `myfirst` interrupt. The `myfirst` filter would never run, `DATA_AV` would never be acknowledged, and the line would storm.

The fix is not on the `myfirst` side; it is on the AHCI side. In reality, all major FreeBSD drivers get the check right because the code has been audited and tested for years. The lesson is that the shared-IRQ protocol requires cooperation: every driver on the line must check its own state correctly.

The protection against a single broken driver is `hw.intr_storm_threshold`. When the kernel detects a run of interrupts all marked as stray (or all returning `FILTER_HANDLED` without any device actually having work), it will eventually mask the line. The machinery is detection, not prevention.

19.7.8 Coexisting With Non-Sharing Drivers

A driver that allocates its IRQ with `RF_SHAREABLE` can coexist with drivers that allocate without sharing, provided the kernel can satisfy both requests. If our `myfirst` driver allocates first with `RF_SHAREABLE`, then AHCI tries to allocate exclusively, AHCI's allocation will fail (the line is already held by a driver that might not be exclusive). If AHCI allocates first without sharing, our `myfirst` allocation (with `RF_SHAREABLE`) will fail.

In practice, modern drivers almost always use `RF_SHAREABLE`. Legacy drivers occasionally omit it; if a reader's driver cannot be loaded because of an interrupt-allocation conflict, the fix is often to add `RF_SHAREABLE` to the allocation.

Exclusive allocation is appropriate for:

- Drivers with strict latency requirements that cannot tolerate other handlers on the line.
- Drivers that use `INTR_EXCL` for a specific kernel reason.
- Some legacy drivers that were written before shared-IRQ support matured.

For Chapter 19's driver, `RF_SHAREABLE` is the default and never wrong.

19.7.9 The bhyve Virtio IRQ Topology

A practical detail about the Chapter 19 lab environment. The bhyve emulator maps each emulated PCI device to an IRQ line based on the slot's `INTx` pin. Multiple devices on the same slot's different functions share a line; different slots usually have different lines. The `virtio-rnd` device at slot 4 function 0 has its own pin.

In practice, on a bhyve guest with just a handful of emulated devices, each device often has its own IRQ line (no sharing). The `myfirst` driver with `RF_SHAREABLE` allocated on a non-shared line behaves identically to a non-shareable allocation; the flag is harmless.

To deliberately test shared-IRQ behaviour in bhyve, a reader can stack multiple virtio devices onto the same slot (different functions), forcing them to share a line. This is advanced and not necessary for basic Chapter 19 labs.

19.7.10 The Starvation Concern

A shared-IRQ line has a potential starvation problem: a single driver that takes too long in its filter can delay every other driver on the line. Every filter sees its device's state as "unchanging" for the duration of the slow filter, and events can accumulate undetected.

The discipline is the same one Section 4 covered: filters must be fast. Tens or hundreds of microseconds of real work is usually the maximum a well-behaved filter does; anything slower moves to the task. A filter that does long work starves not only its own driver's upper layers but also every other driver on the line.

On MSI-X (Chapter 20), each vector has its own `intr_event`, so the starvation concern disappears for the specific driver pairs that use MSI-X. But the discipline still applies: a filter that takes a millisecond is hurting latency for every subsequent interrupt.

19.7.11 False Positives and Defensive Handling

A useful property of the status-register check is that it is naturally tolerant of false positives from the kernel side. Occasionally, interrupt controllers report a spurious interrupt when no device is actually asserting (noise on the line, a race between edge-trigger and masking, a platform-specific quirk). The kernel dispatches, the filter reads `INTR_STATUS`, it is zero, the filter returns `FILTER_STRAY`, the kernel moves on.

This is a no-op for the driver. The count of stray interrupts goes up; nothing else changes.

Some drivers add a rate-limited log message to make spurious interrupts visible. A reasonable default is to log only if the rate exceeds a threshold:

```
static struct timeval last_stray_log;
static int stray_rate_limit = 5; /* messages per second */
if (rv == 0) {
    if (ppsratecheck(&last_stray_log, &stray_rate_limit, 1))
        device_printf(sc->dev, "spurious interrupt\n");
    return (FILTER_STRAY);
}
```

The `ppsratecheck(9)` utility limits the message rate. Without it, a line that is storming would flood `dmesg` with identical messages.

Chapter 19's driver does not include the rate-limited log in its Stage 2 filter; it is added in a challenge exercise.

19.7.12 When the Filter Should Handle and the Task Should Not Run

A thought experiment. Imagine the filter recognises `ERROR` but not `DATA_AV`. The filter handles `ERROR` (acknowledges, increments counter) and returns `FILTER_HANDLED`. No task is queued. The device is satisfied; the line deasserts.

But `INTR_STATUS.DATA_AV` might still be set, because the filter did not acknowledge it (the filter did not recognise the bit as belonging to a class the driver handles). On a level-triggered line, the device keeps asserting for `DATA_AV`, a new interrupt fires, and the loop repeats.

This is a version of the “unknown bit storm” problem. The fix is to acknowledge every bit the driver is willing to see, even if the driver does not do anything with some of them. Setting `INTR_MASK` to only the bits the driver handles is the preventive measure; acknowledging unrecognised bits in the filter is the defensive measure.

19.7.13 Wrapping Up Section 6

Shared interrupts are the common case on legacy PCI and still the right assumption to write for on modern hardware. A filter on a shared line must check whether the interrupt belongs to its device (usually by reading the device’s `INTR_STATUS` register), handle the bits it recognises, acknowledge those bits, and return `FILTER_STRAY` if it recognised nothing. The discipline is small in code and large in reliability: a driver that gets it right coexists with every other well-behaved driver on its line, and `RF_SHAREABLE` in the allocation is the only additional line of code it needs.

Section 7 is the teardown section. It is short: `bus_tearardown_intr` before `bus_release_resource`, drain the taskqueue before anything the task touches is freed, clear `INTR_MASK` so the device stops asserting, and verify the counters make sense. But the ordering is strict, and Chapter 19’s detach path extends by exactly these steps.

19.8 Section 7: Cleaning Up Interrupt Resources

The attach path gained three new operations (allocate IRQ, register handler, enable interrupts at the device); the detach path must undo each of them in strict reverse order. Section 7 is short because the pattern is now familiar; but the order matters in specific ways the previous sections did not touch on, and a mistake here produces kernel panics that the debug kernel is very good at catching and very good at making confusing to diagnose.

19.8.1 The Required Order

From most-specific-to-most-general, the detach sequence at Chapter 19 Stage 2 is:

1. **Refuse if busy.** `myfirst_is_busy(sc)` returns true if the cdev is open or a command is in flight.
2. **Mark as no longer attached** so user-space paths refuse to start.
3. **Destroy the cdev** so no new user-space access begins.
4. **Disable interrupts at the device.** Clear `INTR_MASK` so the device stops asserting.
5. **Tear down the interrupt handler.** `bus_tearardown_intr(9)` on `irq_res` with the saved cookie. After this returns, the kernel guarantees the filter will not run again.
6. **Drain the taskqueue.** `taskqueue_drain(9)` waits for any pending task to complete and prevents new ones from starting.
7. **Destroy the taskqueue.** `taskqueue_free(9)` shuts down the worker threads.
8. **Quiesce Chapter 17 simulation callouts** if `sc->sim` is non-NULL.
9. **Detach the Chapter 17 simulation** if attached.
10. **Detach the hardware layer** so `sc->hw` is freed.
11. **Release the IRQ resource** with `bus_release_resource(9)`.

12. **Release the BAR** with `bus_release_resource(9)`.

13. **Deinit the softc.**

Thirteen steps. Each does one thing. The hazards are in the ordering.

19.8.2 Why Disable at the Device Before `bus_tearardown_intr`

Clearing `INTR_MASK` before tearing down the handler is defensive. If we tore down the handler first, a pending interrupt at the device might fire and have no handler; the kernel would mark it as stray and eventually disable the line. Clearing `INTR_MASK` first stops the device from asserting, then the teardown removes the handler, and no interrupts can fire in between.

For MSI-X (Chapter 20), the logic is slightly different because each vector is independent. But the principle transfers: stop the source before removing the handler.

On real hardware this window is microseconds; a stray interrupt during it is rare. On bhyve, where the event rate is low, it essentially never happens. But careful drivers close the window anyway because careful drivers are the ones you want to read in production.

19.8.3 Why `bus_tearardown_intr` Before Releasing the Resource

`bus_tearardown_intr` removes the driver's handler from the `intr_event`. After it returns, the kernel guarantees the filter will not run again. But the IRQ resource (the `struct resource *`) is still valid; the kernel has not freed it. `bus_release_resource` is what frees it.

If we released the resource first, the kernel's internal bookkeeping around the `intr_event` would see a handler registered against a resource that no longer exists. Depending on timing, this produces either an immediate failure during `bus_release_resource` (the kernel detects the handler is still attached) or a delayed problem later when the line tries to fire.

The safe ordering is always `bus_tearardown_intr` first. The man page for `bus_setup_intr(9)` makes this explicit.

19.8.4 Why Drain the Taskqueue Before Freeing the Softc

The filter may have enqueued a task that has not yet run. The task's function pointer is stored in the `struct task`, and the argument pointer is the `softc`. If we freed the `softc` before the task ran, the task would dereference a freed pointer and panic.

`taskqueue_drain(9)` on a specific task waits for that task to complete and prevents future enqueues of that task from running. Calling `taskqueue_drain` on `&sc->intr_data_task` is the exact right thing: it waits for the data-available task to finish.

After `taskqueue_drain` returns, no task run is in progress. The `softc` can be freed safely.

A common mistake: draining a single task with `taskqueue_drain(tq, &task)` is different from draining the whole taskqueue with `taskqueue_drain_all(tq)`. For a driver with multiple tasks on the same taskqueue, each task needs its own drain, or `taskqueue_drain_all` handles them as a group.

For Chapter 19's driver, there is one task, so a single `taskqueue_drain` suffices.

19.8.5 Why bus_tearardown_intr Before taskqueue_drain

The filter may still enqueue a task between the time INTR_MASK was cleared and the time bus_tearardown_intr returns. If we drained the taskqueue before tearing down the handler, a still-running filter could enqueue a task after the drain, and the drain's guarantee would be violated.

The correct order is: clear INTR_MASK (stops new interrupts), tear down the handler (stops the filter from running again), drain the taskqueue (stops any previously enqueued task from running). Each step narrows the set of code paths that can touch the state.

19.8.6 The Cleanup Code

Putting the order into the Chapter 19 Stage 2 detach:

```
static int
myfirst_pci_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    if (myfirst_is_busy(sc))
        return (EBUSY);

    sc->pci_attached = false;

    /* Destroy the cdev so no new user-space access starts. */
    if (sc->cdev != NULL) {
        destroy_dev(sc->cdev);
        sc->cdev = NULL;
    }

    /* Disable interrupts at the device. */
    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        bus_write_4(sc->bar_res, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);

    /* Tear down the interrupt handler. */
    if (sc->intr_cookie != NULL) {
        bus_tearardown_intr(dev, sc->irq_res, sc->intr_cookie);
        sc->intr_cookie = NULL;
    }

    /* Drain and destroy the interrupt taskqueue. */
    if (sc->intr_tq != NULL) {
        taskqueue_drain(sc->intr_tq, &sc->intr_data_task);
    }
}
```

```
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
}

/* Quiesce Chapter 17 callouts (if sim attached). */
myfirst_quiesce(sc);

/* Detach Chapter 17 simulation if attached. */
if (sc->sim != NULL)
    myfirst_sim_detach(sc);

/* Detach the hardware layer. */
myfirst_hw_detach(sc);

/* Release the IRQ resource. */
if (sc->irq_res != NULL) {
    bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid,
        sc->irq_res);
    sc->irq_res = NULL;
}

/* Release the BAR. */
if (sc->bar_res != NULL) {
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,
        sc->bar_res);
    sc->bar_res = NULL;
}

myfirst_deinit_softc(sc);

device_printf(dev, "detached\n");
return (0);
}
```

Thirteen distinct actions, each simple. The code is longer than earlier stages only because each new capability adds its own teardown step.

19.8.7 Handling Partial-Attach Failure

The attach path's goto cascade in Section 3 had labels for each allocation step. With the interrupt handler registered at Stage 2, the cascade grows one more:

```
fail_teardown_intr:
    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        bus_write_4(sc->bar_res, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);
    bus_teardown_intr(dev, sc->irq_res, sc->intr_cookie);
    sc->intr_cookie = NULL;
fail_release_irq:
    bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid, sc->irq_res);
    sc->irq_res = NULL;
fail_hw:
    myfirst_hw_detach(sc);
fail_release_bar:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail_softc:
    myfirst_deinit_softc(sc);
    return (error);
```

Each cascade label undoes the step that succeeded before it. A failed `bus_setup_intr` jumps to `fail_release_irq` (skips teardown because the handler was not registered). A failed `make_dev` (cdev creation) jumps to `fail_teardown_intr` (tears down the handler before releasing the IRQ).

The taskqueue is initialised in `myfirst_init_softc` and destroyed in `myfirst_deinit_softc`, so the cascade does not need to handle it explicitly; whichever label reaches `fail_softc` gets the taskqueue cleaned up via `deinit`.

19.8.8 Verifying the Teardown

After `kldunload myfirst` the kernel should be in a clean state. Specific checks:

- `kldstat -v | grep myfirst` returns nothing (module unloaded).
- `devinfo -v | grep myfirst` returns nothing (device detached).
- `vmstat -i | grep myfirst` returns nothing (interrupt event cleaned up).
- `vmstat -m | grep myfirst` returns nothing or shows zero InUse (malloc type drained).
- `dmesg | tail` shows the detach banner and no warnings or panics.

Failing any of these is a bug. The most common failure is `vmstat -i` showing a stale entry; this usually means `bus_teardown_intr` was not called. The second most common is `vmstat -m` showing live allocations; this usually means a task was enqueued and not drained, or the simulation was attached and not detached.

19.8.9 Handling the “Handler Fired During Detach” Case

A subtle case worth thinking through. Suppose a real interrupt fires on a shared IRQ line between the cdev destruction and the `INTR_MASK` write. Another driver’s device is asserting, our filter runs (because the line is

shared), our filter reads `INTR_STATUS` (which is zero on our device), and returns `FILTER_STRAY`. No state is touched, no task is enqueued.

Suppose instead that the interrupt is from our device. Our `INTR_STATUS` has a bit set. The filter recognises it, acknowledges, enqueues a task, returns. The task enqueue happens against a taskqueue that has not yet been drained. The task runs later, acquires `sc->mtx`, reads `DATA_OUT` through the hardware layer (which is still attached because we haven't called `myfirst_hw_detach` yet). All safe.

Suppose the interrupt arrives after `INTR_MASK = 0` but before `bus_tear_down_intr`. The device has stopped asserting for the bits we cleared, but an already-in-flight interrupt (queued in the interrupt controller) can still run the filter. The filter reads `INTR_STATUS`, sees zero (because the mask write was ahead of the device's internal state), returns `FILTER_STRAY`. The interrupt is counted as stray; the kernel ignores it.

Suppose the interrupt arrives after `bus_tear_down_intr`. The handler is gone. The kernel's stray-interrupt accounting notices. After enough strays, the kernel disables the line. This is the scenario the `INTR_MASK = 0` step is designed to prevent; if the mask is cleared first, no strays can accumulate.

The code paths are all defensive. The debug kernel's assertions catch the common mistakes. A driver that follows the Chapter 19 order reliably tears down cleanly.

19.8.10 What Goes Wrong When Teardown Is Skipped

A few scenarios that produce concrete symptoms.

Handler not torn down, resource released. `kldunload` calls `bus_release_resource` on the IRQ without `bus_tear_down_intr`. The kernel detects an active handler on a resource being released and panics with a message like “releasing allocated IRQ with active handler”. The debug kernel is reliable here.

Handler torn down, taskqueue not drained. The task is enqueued in the filter, the filter's last call happens just before teardown, the task has not yet run. The driver frees `sc` (via `softc_deinit`) and unloads. The task's worker thread wakes up, runs the task function, dereferences the freed `softc`, panics with a null-pointer or use-after-free fault. The debug kernel's `WITNESS` or `MEMGUARD` may catch it; if not, the crash is at the task function's first memory access.

Taskqueue drained, not freed. `taskqueue_drain` succeeds, but `taskqueue_free` is skipped. The taskqueue's worker thread keeps running (idle). A `vmstat -m` shows the allocation. Not a functional bug, but a leak that accumulates across load-unload cycles.

Simulation callouts not quiesced. If the Chapter 17 simulation is attached (on a simulation-only build), its callouts are running. Without quiescing, they fire after detach has freed the register block, and access garbage. The `WITNESS` or `MEMGUARD` catch varies by hit; sometimes a plain null dereference is the symptom.

INTR_MASK not cleared. Real interrupts fire after detach starts. The filter (briefly, until teardown) handles them; after teardown, they are strays that the kernel eventually disables the line for. The line's disabled state is visible in `vmstat -i` (growing stray count) and in `dmesg` (kernel warnings).

Each of these is recoverable by fixing the teardown order. The Chapter 19 code is set up correctly; the hazards are for a reader who modifies the order.

19.8.11 Sanity Testing the Teardown

A simple sanity test the reader can run after writing the detach code:

```
# Load.
sudo kldload ./myfirst.ko

# Fire a few simulated interrupts, make sure tasks run.
for i in 1 2 3 4 5; do
    sudo sysctl dev.myfirst.0.intr_simulate=1
done
sleep 1
sysctl dev.myfirst.0.intr_task_invocations # should be 5

# Unload.
sudo kldunload myfirst

# Check nothing leaked.
vmstat -m | grep myfirst # should be empty
devinfo -v | grep myfirst # should be empty
vmstat -i | grep myfirst # should be empty
```

Running this sequence in a loop (twenty iterations in a shell loop) is a reasonable regression test: any leak accumulates, any crash manifests, any failure pattern becomes visible.

19.8.12 Wrapping Up Section 7

Cleaning up interrupt resources is six small operations in the detach path: disable `INTR_MASK`, tear down the handler, drain and free the taskqueue, detach the hardware layer, release the IRQ, release the BAR. Each operation undoes exactly one attach-path operation. The order is the inverse of attach. The taskqueue drain is an important new concern specific to filter-plus-task drivers; a driver that skips it has a use-after-free bug waiting for the next load-unload cycle.

Section 8 is the housekeeping section: split the interrupt code into its own file, bump the version to `1.2-intr`, write `INTERRUPTS.md`, and run the regression pass. The driver is functionally complete after Section 7; Section 8 makes it maintainable.

19.9 Section 8: Refactoring and Versioning Your Interrupt-Ready Driver

The interrupt handler is working. Section 8 is the housekeeping section. It splits the interrupt code into its own file, updates the module metadata, adds a new `INTERRUPTS.md` document, introduces a small set of interrupt-context CSR macros so the filter can access registers without the lock-asserting macros, bumps the version to `1.2-intr`, and runs the regression pass.

A reader who has made it this far may again be tempted to skip this section. It is the same temptation Chapter 18's Section 8 warned against, and the same refusal: a driver whose interrupt code is mixed into the PCI file, whose filter uses `raw_bus_read_4` ad hoc, whose taskqueue setup is split across three files, becomes painful to extend. Chapter 20 adds MSI and MSI-X; Chapter 21 adds DMA. Both of them build on Chapter 19's interrupt code. A clean structure now saves effort across both.

19.9.1 The Final File Layout

At the end of Chapter 19, the driver consists of these files:

<code>myfirst.c</code>	- Main driver: <code>softc</code> , <code>cdev</code> , module events, data path.
<code>myfirst.h</code>	- Shared declarations: <code>softc</code> , lock macros, prototypes.
<code>myfirst_hw.c</code>	- Ch16 hardware access layer: <code>CSR_*</code> accessors, access log, <code>sysctl</code> handlers.
<code>myfirst_hw_pci.c</code>	- Ch18 hardware layer extension: <code>myfirst_hw_attach_pci</code> .
<code>myfirst_hw.h</code>	- Register map and accessor declarations.
<code>myfirst_sim.c</code>	- Ch17 simulation backend.
<code>myfirst_sim.h</code>	- Ch17 simulation interface.
<code>myfirst_pci.c</code>	- Ch18 PCI attach: <code>probe</code> , <code>attach</code> , <code>detach</code> , <code>DRIVER_MODULE</code> , <code>MODULE_DEPEND</code> , ID table.
<code>myfirst_pci.h</code>	- Ch18 PCI declarations.
<code>myfirst_intr.c</code>	- Ch19 interrupt handler: <code>filter</code> , <code>task</code> , <code>setup</code> , <code>teardown</code> .
<code>myfirst_intr.h</code>	- Ch19 interrupt interface.
<code>myfirst_sync.h</code>	- Part 3 synchronisation primitives.
<code>cbuf.c</code> / <code>cbuf.h</code>	- Ch10 circular buffer.
<code>Makefile</code>	- <code>kmod</code> build.
<code>HARDWARE.md</code>	- Ch16/17 register map.
<code>LOCKING.md</code>	- Ch15 onward lock discipline.
<code>SIMULATION.md</code>	- Ch17 simulation.
<code>PCI.md</code>	- Ch18 PCI support.
<code>INTERRUPTS.md</code>	- Ch19 interrupt handling.

`myfirst_intr.c` and `myfirst_intr.h` are new. `INTERRUPTS.md` is new. Every other file either existed before or was extended slightly (the `softc` gained fields; the PCI attach calls into `myfirst_intr.c`).

The rule of thumb remains: each file has one responsibility. `myfirst_intr.c` owns the interrupt handler, the deferred task, and the simulated-interrupt `sysctl`. `myfirst_pci.c` owns the PCI attach but delegates interrupt setup and teardown to functions exported by `myfirst_intr.c`.

19.9.2 The Final Makefile

```
# Makefile for the Chapter 19 myfirst driver.
```

```

KMOD=  myfirst
SRCS=  myfirst.c \
      myfirst_hw.c myfirst_hw_pci.c \
      myfirst_sim.c \
      myfirst_pci.c \
      myfirst_intr.c \
      cbuf.c

CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.2-intr\"

# CFLAGS+= -DMYFIRST_SIMULATION_ONLY
# CFLAGS+= -DMYFIRST_PCI_ONLY

#include <bsd.kmod.mk>

```

One additional source file in the SRCS list; the version string bumped; the rest unchanged.

19.9.3 The Version String

1.1-pci to 1.2-intr. The bump reflects that the driver has acquired a significant new capability (interrupt handling) without changing any user-visible interface (the cdev still does what it did). A minor-version bump is appropriate.

Later chapters continue: 1.3-msi after Chapter 20's MSI and MSI-X work; 1.4-dma after Chapters 20 and 21 add DMA. Each minor version reflects one significant capability addition.

19.9.4 The myfirst_intr.h Header

The header exports the interrupt layer's public interface to the rest of the driver:

```

#ifndef _MYFIRST_INTR_H_
#define _MYFIRST_INTR_H_

#include <sys/types.h>
#include <sys/taskqueue.h>

struct myfirst_softc;

/* Interrupt setup and teardown, called from the PCI attach path. */
int myfirst_intr_setup(struct myfirst_softc *sc);
void myfirst_intr_teardown(struct myfirst_softc *sc);

/* Register sysctl nodes specific to the interrupt layer. */
void myfirst_intr_add_sysctls(struct myfirst_softc *sc);

```

```

/* Interrupt-context accessor macros. These do not acquire sc->mtx
 * and therefore are safe in the filter. They are NOT a replacement
 * for CSR_READ_4 / CSR_WRITE_4 in other contexts. */
#define ICSR_READ_4(sc, off) \
    bus_read_4((sc)->bar_res, (off))
#define ICSR_WRITE_4(sc, off, val) \
    bus_write_4((sc)->bar_res, (off), (val))

#endif /* _MYFIRST_INTR_H_ */

```

The public API is three functions (`myfirst_intr_setup`, `myfirst_intr_teardown`, `myfirst_intr_add_sysctls`) and two accessor macros (`ICSR_READ_4`, `ICSR_WRITE_4`). The “I” prefix is for “interrupt-context”; these macros do not take `sc->mtx`, so they are safe in the filter.

19.9.5 The `myfirst_intr.c` File

The full file is in the companion examples tree; here is the core structure:

```

#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/bus.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/sysctl.h>
#include <sys/taskqueue.h>
#include <sys/rman.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include "myfirst.h"
#include "myfirst_hw.h"
#include "myfirst_intr.h"

/* Deferred task for data-available events. */
static void myfirst_intr_data_task_fn(void *arg, int npending);

/* The filter handler. Exported so the simulated-interrupt sysctl can
 * call it directly. */
int myfirst_intr_filter(void *arg);

int

```

```

myfirst_intr_setup(struct myfirst_softc *sc)
{
    int error;

    TASK_INIT(&sc->intr_data_task, 0, myfirst_intr_data_task_fn, sc);
    sc->intr_tq = taskqueue_create("myfirst_intr", M_WAITOK,
        taskqueue_thread_enqueue, &sc->intr_tq);
    taskqueue_start_threads(&sc->intr_tq, 1, PI_NET,
        "myfirst intr taskq");

    sc->irq_rid = 0;
    sc->irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ,
        &sc->irq_rid, RF_SHAREABLE | RF_ACTIVE);
    if (sc->irq_res == NULL)
        return (ENXIO);

    error = bus_setup_intr(sc->dev, sc->irq_res,
        INTR_TYPE_MISC | INTR_MPSAFE,
        myfirst_intr_filter, NULL, sc,
        &sc->intr_cookie);
    if (error != 0) {
        bus_release_resource(sc->dev, SYS_RES_IRQ, sc->irq_rid,
            sc->irq_res);
        sc->irq_res = NULL;
        return (error);
    }

    bus_describe_intr(sc->dev, sc->irq_res, sc->intr_cookie, "legacy");

    /* Enable the interrupts we care about at the device. */
    MYFIRST_LOCK(sc);
    if (sc->hw != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
            MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR |
            MYFIRST_INTR_COMPLETE);
    MYFIRST_UNLOCK(sc);

    return (0);
}

void
myfirst_intr_teardown(struct myfirst_softc *sc)
{
    /* Disable interrupts at the device. */

```

```
MYFIRST_LOCK(sc);
if (sc->hw != NULL && sc->bar_res != NULL)
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
MYFIRST_UNLOCK(sc);

/* Tear down the handler. */
if (sc->intr_cookie != NULL) {
    bus_teardown_intr(sc->dev, sc->irq_res, sc->intr_cookie);
    sc->intr_cookie = NULL;
}

/* Drain and destroy the taskqueue. */
if (sc->intr_tq != NULL) {
    taskqueue_drain(sc->intr_tq, &sc->intr_data_task);
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
}

/* Release the IRQ resource. */
if (sc->irq_res != NULL) {
    bus_release_resource(sc->dev, SYS_RES_IRQ, sc->irq_rid,
        sc->irq_res);
    sc->irq_res = NULL;
}
}

int
myfirst_intr_filter(void *arg)
{
    /* ... as in Section 4 ... */
}

static void
myfirst_intr_data_task_fn(void *arg, int npending)
{
    /* ... as in Section 4 ... */
}

void
myfirst_intr_add_sysctls(struct myfirst_softc *sc)
{
    /* ... counters and intr_simulate sysctl ... */
}
```

The file is about 250 lines at Stage 4. `myfirst_pci.c` shrinks correspondingly: the interrupt allocation and setup move out.

19.9.6 The Refactored PCI Attach

After moving interrupt code into `myfirst_intr.c`, `myfirst_pci_attach` becomes:

```
static int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error;

    sc->dev = dev;
    sc->unit = device_get_unit(dev);
    error = myfirst_init_softc(sc);
    if (error != 0)
        return (error);

    /* Step 1: allocate BAR 0. */
    sc->bar_rid = PCIR_BAR(0);
    sc->bar_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
        &sc->bar_rid, RF_ACTIVE);
    if (sc->bar_res == NULL) {
        device_printf(dev, "cannot allocate BAR0\n");
        error = ENXIO;
        goto fail_softc;
    }

    /* Step 2: attach the hardware layer. */
    error = myfirst_hw_attach_pci(sc, sc->bar_res,
        rman_get_size(sc->bar_res));
    if (error != 0)
        goto fail_release_bar;

    /* Step 3: set up interrupts. */
    error = myfirst_intr_setup(sc);
    if (error != 0) {
        device_printf(dev, "interrupt setup failed (%d)\n", error);
        goto fail_hw;
    }

    /* Step 4: create cdev. */
    sc->cdev = make_dev(&myfirst_cdevsw, sc->unit, UID_ROOT,
        GID_WHEEL, 0600, "myfirst%d", sc->unit);
}
```

```

    if (sc->cdev == NULL) {
        error = ENXIO;
        goto fail_intr;
    }
    sc->cdev->si_drv1 = sc;

    /* Step 5: register sysctls. */
    myfirst_intr_add_sysctls(sc);

    sc->pci_attached = true;
    return (0);

fail_intr:
    myfirst_intr_tear_down(sc);
fail_hw:
    myfirst_hw_detach(sc);
fail_release_bar:
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid, sc->bar_res);
    sc->bar_res = NULL;
fail_softc:
    myfirst_deinit_softc(sc);
    return (error);
}

```

The PCI attach is shorter; the interrupt details are hidden behind `myfirst_intr_setup`. The goto cascade is four labels instead of six (the interrupt-specific labels moved into `myfirst_intr.c`).

19.9.7 The Refactored Detach

```

static int
myfirst_pci_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    if (myfirst_is_busy(sc))
        return (EBUSY);

    sc->pci_attached = false;

    if (sc->cdev != NULL) {
        destroy_dev(sc->cdev);
        sc->cdev = NULL;
    }
}

```

```

myfirst_intr_teardown(sc);

if (sc->sim != NULL)
    myfirst_sim_detach(sc);

myfirst_hw_detach(sc);

if (sc->bar_res != NULL) {
    bus_release_resource(dev, SYS_RES_MEMORY, sc->bar_rid,
        sc->bar_res);
    sc->bar_res = NULL;
}

myfirst_deinit_softc(sc);

device_printf(dev, "detached\n");
return (0);
}

```

The interrupt-specific teardown is one call to `myfirst_intr_teardown`, which encapsulates the mask-clear, teardown, drain, and resource-release steps.

19.9.8 The INTERRUPTS.md Document

The new document lives next to the driver source. Its role is to describe the driver's interrupt handling to a future reader without requiring them to read `myfirst_intr.c`:

Interrupt Handling in the myfirst Driver

Allocation and Setup

The driver allocates a single legacy PCI IRQ through ``bus_alloc_resource_any(9)`` with ``SYS_RES_IRQ``, ``rid = 0``, ``RF_SHAREABLE | RF_ACTIVE``. The filter handler is registered through ``bus_setup_intr(9)`` with ``INTR_TYPE_MISC | INTR_MPSAFE``. A taskqueue named "myfirst_intr" is created with one worker thread at ``PI_NET`` priority.

On successful setup, ``INTR_MASK`` is written with ``DATA_AV | ERROR | COMPLETE`` so the device will assert the line for those three event classes.

Filter Handler

``myfirst_intr_filter(sc)`` reads ``INTR_STATUS``. If zero, it returns ``FILTER_STRAY`` (shared-IRQ defence). Otherwise it inspects each of the three recognised bits, increments a per-bit counter atomically, writes the bit back to ``INTR_STATUS`` to acknowledge the device, and (for ``DATA_AV``) enqueues ``intr_data_task`` on the taskqueue.

The filter returns ``FILTER_HANDLED`` if any bit was recognised, or ``FILTER_STRAY`` otherwise.

Deferred Task

``myfirst_intr_data_task_fn(sc, npending)`` runs in thread context on the taskqueue's worker thread. It acquires ``sc->mtx``, reads ``DATA_OUT``, stores the value in ``sc->intr_last_data``, broadcasts ``sc->data_cv`` to wake pending readers, and releases the lock.

Simulated Interrupt sysctl

``dev.myfirst.N.intr_simulate`` is write-only; writing a bitmask to it sets the corresponding bits in ``INTR_STATUS`` and invokes ``myfirst_intr_filter`` directly. This exercises the full pipeline without needing real IRQ events.

Teardown

``myfirst_intr_teardown(sc)`` runs during detach. It clears ``INTR_MASK``, calls ``bus_teardown_intr``, drains and destroys the taskqueue, and releases the IRQ resource. The order is strict: mask-clear before teardown (so strays do not accumulate), teardown before drain (so no new task enqueues happen), drain before free (so no task runs against freed state).

Interrupt-Context Accessor Macros

Since the filter runs in primary interrupt context, it cannot take ``sc->mtx``. Two macros in ``myfirst_intr.h`` hide the raw ``bus_read_4``/``bus_write_4`` calls without asserting any lock: ``ICSR_READ_4`` and ``ICSR_WRITE_4``. Use them only in contexts where a sleep lock would be illegal.

Known Limitations

- Only the legacy PCI INTx line is handled. MSI and MSI-X are

Chapter 20.

- The filter coalesces per-bit counters via atomic ops; the task runs at a single priority. Per-queue or per-priority designs are later-chapter topics.
- Interrupt storm detection is managed by the kernel (``hw.intr_storm_threshold``); the driver does not implement its own storm mitigation.
- Chapter 17 simulation callouts are not active on the PCI build; the simulated-interrupt sysctl is the way to drive the pipeline on a bhyve lab target.

Five minutes to read; a clear picture of the interrupt layer's shape.

19.9.9 The Regression Pass

The Chapter 19 regression is a superset of Chapter 18's:

1. Compile cleanly. `make` succeeds; no warnings.
2. Load. `kldload ./myfirst.ko` succeeds; `dmesg` shows the attach sequence.
3. Attach to a real PCI device. `devinfo -v` shows the BAR and the IRQ.
4. No `[GIANT-LOCKED]` warning.
5. `vmstat -i | grep myfirst` shows the `intr_event`.
6. `sysctl dev.myfirst.0.intr_count` starts at zero.
7. Simulated interrupt. `sudo sysctl dev.myfirst.0.intr_simulate=1`; counters increment; task runs.
8. Rate test. Set `intr_sim_period_ms` to 100; check counters after 10 seconds.
9. Detach. `devctl detach myfirst0`; `dmesg` shows clean detach.
10. Reattach. `devctl attach pci0:0:4:0`; full attach cycle runs.
11. Unload. `kldunload myfirst`; `vmstat -m | grep myfirst` shows zero live allocations; `vmstat -i | grep myfirst` returns nothing.

Running the full regression takes a minute or two per iteration. A CI job that runs it twenty times in a loop is the kind of guard that catches regressions introduced by Chapter 20's and Chapter 21's extensions.

19.9.10 What the Refactor Accomplished

The Chapter 19 code is one file smaller than it would have been without the refactor; one new document exists; the version number has moved forward by one. The driver is recognisably FreeBSD, structurally parallel to a production driver in `/usr/src/sys/dev/`, and ready to accept Chapter 20's MSI-X machinery and Chapter 21's DMA machinery without another reorganisation.

19.9.11 Wrapping Up Section 8

The refactor follows the same shape Chapters 16 through 18 established. A new file owns the new responsibility. A new header exports the public interface. A new document explains the behaviour. The version bumps; the

regression passes; the driver stays maintainable. Nothing dramatic; a little housekeeping; a clean codebase to build on.

The instructional body of Chapter 19 is complete. Labs, challenges, troubleshooting, a wrap-up, and the bridge to Chapter 20 follow.

19.10 Reading a Real Driver Together: mgb(4)'s Interrupt Path

Before the labs, a short walk through a real driver that uses the same filter-plus-task pattern Chapter 19 teaches. `/usr/src/sys/dev/mgb/if_mgb.c` is the FreeBSD driver for Microchip's LAN743x gigabit Ethernet controllers. It is readable, it is production-quality, and its interrupt handling is about the level of complexity Chapter 19's vocabulary covers.

This section walks through the interrupt-relevant parts of `mgb_legacy_intr` and the setup code, and flags where each piece corresponds to a Chapter 19 concept.

19.10.1 The Legacy Filter

The filter handler for `mgb(4)`'s legacy-IRQ path:

```
int
mgb_legacy_intr(void *xsc)
{
    struct mgb_softc *sc;
    if_softc_ctx_t scctx;
    uint32_t intr_sts, intr_en;
    int qidx;

    sc = xsc;
    scctx = iflib_get_softc_ctx(sc->ctx);

    intr_sts = CSR_READ_REG(sc, MGB_INTR_STS);
    intr_en = CSR_READ_REG(sc, MGB_INTR_ENBL_SET);
    intr_sts &= intr_en;

    /* TODO: shouldn't continue if suspended */
    if ((intr_sts & MGB_INTR_STS_ANY) == 0)
        return (FILTER_STRAY);

    if ((intr_sts & MGB_INTR_STS_TEST) != 0) {
        sc->isr_test_flag = true;
        CSR_WRITE_REG(sc, MGB_INTR_STS, MGB_INTR_STS_TEST);
        return (FILTER_HANDLED);
    }
    if ((intr_sts & MGB_INTR_STS_RX_ANY) != 0) {
```

```

    for (qidx = 0; qidx < scctx->isc_nrxqsets; qidx++) {
        if ((intr_sts & MGB_INTR_STS_RX(qidx))) {
            iflib_rx_intr_deferred(sc->ctx, qidx);
        }
    }
    return (FILTER_HANDLED);
}

if ((intr_sts & MGB_INTR_STS_TX_ANY) != 0) {
    for (qidx = 0; qidx < scctx->isc_ntxqsets; qidx++) {
        if ((intr_sts & MGB_INTR_STS_RX(qidx))) {
            CSR_WRITE_REG(sc, MGB_INTR_ENBL_CLR,
                MGB_INTR_STS_TX(qidx));
            CSR_WRITE_REG(sc, MGB_INTR_STS,
                MGB_INTR_STS_TX(qidx));
            iflib_tx_intr_deferred(sc->ctx, qidx);
        }
    }
    return (FILTER_HANDLED);
}

return (FILTER_SCHEDULE_THREAD);
}

```

Walk through it. The filter reads two registers (INTR_STS and INTR_ENBL_SET), ANDs them to get the subset of pending interrupts that are enabled, and checks whether any bit is set. If none, it returns FILTER_STRAY, the Chapter 19 discipline for shared IRQs.

For each class of interrupt (test, receive, transmit), the filter acknowledges the relevant bits in INTR_STS (by writing them back) and schedules deferred processing. `iflib_rx_intr_deferred` is the `iflib` framework's way of scheduling receive-queue work; conceptually it is the same as Chapter 19's `taskqueue_enqueue`.

A line worth noting: the test-interrupt handler writes INTR_STS but also sets a flag (`sc->isr_test_flag = true`). This is the driver's way of signalling user-space code (via a `sysctl` or `ioctl`) that a test interrupt fired. Chapter 19's equivalent is the `intr_count` counter.

The last return is `FILTER_SCHEDULE_THREAD`. This fires if none of the specific bit classes matched but `MGB_INTR_STS_ANY` did. The `ithread` handles the residual case. Chapter 19's driver does not have this particular fall-through because it does not have a registered `ithread`; `mgb(4)` does.

19.10.2 What the `mgb` Filter Teaches

Three lessons transfer directly to Chapter 19's filter:

1. **Read-AND-mask.** `intr_sts & intr_en` ensures the filter only reports interrupts that were actually enabled. A device may internally report events the driver has masked out; the AND filters them.
2. **Acknowledge per-bit.** Each bit class is acknowledged individually (by writing the specific bits back). The filter does not write `0xffffffff`; it writes only the bits it handled.

3. **Defer per-queue work.** Each receive queue and transmit queue has its own deferred path. Chapter 19's simpler driver has one task; `mgb(4)`'s multi-queue driver has many.

19.10.3 Interrupt Setup in `mgb`

Searching for `bus_setup_intr` in `if_mgb.c` shows several call sites, one for the legacy IRQ path and one for each MSI-X vector:

```
if (bus_setup_intr(sc->dev, sc->irq[0], INTR_TYPE_NET | INTR_MPSAFE,
    mgb_legacy_intr, NULL, sc, &sc->irq_tag[0]) != 0) {
    /* ... */
}
```

The pattern is exactly Chapter 19's: filter handler, no `ithread`, `INTR_MPSAFE`, `softc` as argument, cookie returned. The only difference is `INTR_TYPE_NET` instead of `INTR_TYPE_MISC` (the driver targets networking).

19.10.4 Interrupt Teardown in `mgb`

The teardown pattern is distributed across `iflib(9)`'s helpers, which handle the drain and release for the driver. A bespoke driver outside the `iflib` framework does the teardown explicitly; Chapter 19's driver does it explicitly.

19.10.5 What the Walkthrough Teaches

`mgb(4)`'s interrupt path is not a toy. It is a production-quality implementation of the same pattern Chapter 19's driver follows. A reader who can read `mgb_legacy_intr` with comprehension has internalised the Chapter 19 vocabulary. The file is freely available; reading the surrounding code (the attach path, the `ithread`, the `iflib` integration) deepens the understanding further.

Worth reading after `mgb(4)`: `/usr/src/sys/dev/e1000/em_txrx.c` for MSI-X multi-vector patterns (Chapter 20 material), `/usr/src/sys/dev/usb/controller/xhci_pci.c` for a USB host controller's interrupt path (Chapter 21+), and `/usr/src/sys/dev/ahci/ahci_pci.c` for a storage controller's interrupt path.

19.11 A Deeper Look at Interrupt Context

Section 2 listed what may and may not happen in a filter. This section goes one level deeper and explains why each rule exists. A reader who understands the why can reason about unfamiliar constraints (new locks, new kernel APIs) and predict whether they are filter-safe.

19.11.1 The Stack Situation

When the CPU takes an interrupt, it saves the interrupted thread's registers and switches to a kernel interrupt stack. The interrupt stack is small (a few KB, platform-dependent), is per-CPU, and is shared among all interrupts on that CPU. The filter runs on this stack.

Two implications:

First, the filter has limited stack space. A filter that allocates a large array on the stack (hundreds of bytes or more) can overflow the interrupt stack. The symptom is usually a panic, sometimes a silent corruption of whatever sits next to the stack in memory. The rule is: filters have small stack budgets. Big arrays belong to the task.

Second, the stack is shared among interrupts. A filter that sleeps (hypothetically, though it cannot) would leave the stack occupied; other interrupts on the same CPU could not reuse it. Even if sleep were allowed, it would not be free. The small-stack constraint is one reason the filter must be short.

19.11.2 Why No Sleep Locks

A sleep mutex (default `mtx(9)`) may block: if another thread holds the mutex, `mtx_lock` puts the calling thread to sleep on the mutex. In the filter's context:

- There is no calling "thread" in the usual sense. The interrupted thread was suspended mid-instruction; the filter is a kernel-side excursion on the CPU.
- Sleeping from the interrupt would stall the CPU: the interrupt stack is occupied, no other interrupts can run on this CPU, and the scheduler cannot easily schedule a different thread without a working kernel state.

The kernel could, in principle, handle this (some kernels do). FreeBSD's design is to prohibit it. The prohibition is enforced by `WITNESS` on debug kernels: any attempt to acquire a sleepable lock in interrupt context produces an immediate panic.

Spin mutexes (`MTX_SPIN` mutexes) are safe because they do not sleep; they just spin. A filter acquiring a spin mutex is fine.

19.11.3 Why No Sleeping malloc

`malloc(M_WAITOK)` calls the VM page allocator and may sleep if the system is low on memory. Same problem as with locks: the caller cannot be suspended. `malloc(M_NOWAIT)` is the alternative; it may fail, but it never sleeps.

In the filter, the only safe options are `M_NOWAIT`, UMA zones (which have their own bounded allocators), or pre-allocated buffers. Chapter 19's driver does not allocate in the filter at all; all the memory the filter needs is in the `softc`, pre-allocated during attach.

19.11.4 Why No Condition Variables

`cv_wait` and `cv_timedwait` sleep. The filter cannot sleep. `cv_signal` and `cv_broadcast` do not sleep, but they acquire a sleep mutex internally in most usages; a filter using them must be careful. The Chapter 19 task handles the `cv_broadcast`; the filter only enqueues the task.

19.11.5 Why the Filter Cannot Re-enter Itself

The kernel's interrupt dispatch disables further interrupts on the CPU while the filter is running (on most platforms; some architectures use priority levels instead). This means the filter cannot recursively fire itself, even if its device asserts the line during execution. Any such assertion is queued and fires after the filter returns.

A consequence: the filter does not need internal re-entry protection. A single `sc->intr_count++` is safe from the filter's perspective against simultaneous filter calls on the same CPU. It may still race with other code (the task, user-space reads), which is why the atomic operation is used, but the filter does not race with itself.

19.11.6 Why Atomic Operations Are Safe

Atomic operations in FreeBSD are implemented as CPU instructions that are, by definition, atomic. They do not take a lock; they do not sleep; they do not block. They are safe in every context, including the filter.

Chapter 19 uses `atomic_add_64` extensively: for the interrupt counter, for each per-bit counter, and for task-invocation counts. The operations are cheap (a few cycles) and predictable (no scheduling involved).

19.11.7 Why the ithread Gets More Rope

The ithread runs in thread context. It has:

- Its own stack (normal kernel thread stack, much larger than the interrupt stack).
- Its own scheduling priority (elevated, but still a normal thread).
- The ability to sleep if the scheduler decides to.

Its constraints are the usual thread-context rules: hold sleepable locks in order (to prevent deadlocks), avoid holding a lock while calling unbounded code, use `M_WAITOK` if the allocation might fail otherwise, and so on. The Chapter 13 and 15 disciplines apply.

The ithread's elevated priority means it should not block for arbitrary lengths of time. Blocking for microseconds (a short mutex contention) is fine; blocking for seconds starves every other ithread on the system.

19.11.8 Why taskqueue Threads Have Still More Rope

A taskqueue's worker thread is a regular kernel thread, usually at normal priority (or at the priority the driver specified in `taskqueue_start_threads`). It can sleep, it can block on any sleepable lock, it can allocate arbitrarily. It is the most flexible of the three contexts.

The trade-off is that taskqueue work is less timely than ithread work. The taskqueue's worker may not run immediately; the scheduler decides. For latency-critical work, the ithread is better; for bulk work, the taskqueue is simpler.

Chapter 19's driver uses the taskqueue because the bulk work it does (reading `DATA_OUT`, updating the `softc`, broadcasting a condition variable) is not latency-critical. Chapter 20's and Chapter 21's drivers may choose ithreads or taskqueues differently depending on their workload.

19.11.9 How Interrupt Context Interacts With Locking

The locking discipline introduced in Part 3 still applies, with one addition: know which locks you can take in each context.

Filter context. Only spin locks, atomics, lock-free algorithms. No sleepable mutexes, sx locks, rwlocks, or mtx initialised without MTX_SPIN.

ithread context. All lock types. Obeys the project's lock ordering as defined in `LOCKING.md`.

Taskqueue worker context. All lock types. Obeys the project's lock ordering. May sleep arbitrarily if needed (though the driver author should not).

Thread context in general (cdev open/read/write/ioctl, sysctl handlers). All lock types. Obeys the project's lock ordering.

For Chapter 19's driver, the filter takes no locks (uses atomics), the task takes `sc->mtx` (a sleep mutex) via `MYFIRST_LOCK`, and the sysctl handlers take `sc->mtx` too. The discipline is preserved.

19.11.10 The “Giant” Footnote

Older BSDs used a single global lock called Giant to serialise the whole kernel. When FreeBSD introduced SMPng (fine-grained locking) in the late 1990s and early 2000s, most of the kernel was converted, but some legacy paths still hold Giant. Drivers that do not set `INTR_MPSAFE` are automatically wrapped with Giant acquisition around their handlers; `WITNESS` may complain about lock-ordering issues involving Giant.

Chapter 19's driver sets `INTR_MPSAFE` and does not touch Giant. Modern FreeBSD driver conventions deprecate Giant in driver code. The footnote is here because a reader who searches for “Giant” in `kern_intr.c` will find references; they are backward-compatibility artefacts.

19.12 A Deeper Look at CPU Affinity for Interrupts

A short appendix on interrupt affinity, which Section 2 introduced briefly. The deep treatment belongs to Chapter 20 (when multiple MSI-X vectors are available) and to later scalability chapters; Chapter 19's coverage is a starting point.

19.12.1 What Affinity Means

Interrupt affinity is the set of CPUs on which an interrupt is allowed to fire. For a single-CPU system, affinity is trivial (one CPU). For multi-CPU systems, affinity becomes interesting: routing an interrupt to a specific CPU (rather than letting the interrupt controller pick) can improve cache locality, reduce cross-socket traffic, and align interrupt handling with thread placement.

On x86, the I/O APIC has a programmable destination field per IRQ; the kernel uses this to route IRQs. On arm64, the GIC has similar facilities. FreeBSD's `bus_bind_intr(9)` is the portable API that configures the affinity for a specific IRQ resource.

19.12.2 Default Behaviour

Without explicit binding, FreeBSD spreads interrupts across CPUs using a round-robin or platform-specific algorithm. For a single-interrupt driver like Chapter 19's, this usually means the interrupt fires on whichever CPU the kernel decided at boot. The current affinity is visible through `cpuset -g -x <irq>`; the per-CPU breakdown of firings for a given IRQ is not part of `vmstat -i`'s default output (which aggregates all firings for the `intr_event` into one count) but can be reconstructed from kernel tooling when the platform supports it.

For many drivers the default is fine. The interrupt rate is low enough that affinity does not matter, or the work is brief enough that cross-CPU costs are negligible. Chapter 19's driver is in this category.

19.12.3 When Affinity Matters

Three scenarios where a driver author wants explicit affinity:

1. **High interrupt rate.** A NIC handling ten gigabits of traffic fires tens of thousands of interrupts per second. The overhead of moving interrupt work between CPUs becomes a real cost. Binding each receive queue's MSI-X vector to a specific CPU keeps its cache lines warm.
2. **NUMA locality.** On multi-socket systems, the device's PCIe root complex is physically attached to one socket. Interrupts from that device are cheaper to handle on CPUs in the same NUMA node as the root complex. Placement matters for both latency and throughput.
3. **Real-time constraints.** A system that needs low-latency response on specific CPUs (for real-time applications) may pin housekeeping interrupts away from those CPUs. `bus_bind_intr` lets the driver participate in this partitioning.

19.12.4 The `bus_bind_intr` API

The function signature:

```
int bus_bind_intr(device_t dev, struct resource *r, int cpu);
```

`cpu` is an integer CPU ID in the range 0 to `mp_ncpus - 1`. On success, the interrupt is routed to that CPU. On failure, the function returns an `errno` (most commonly `EINVAL` if the platform does not support rebinding or the CPU is invalid).

The call goes after `bus_setup_intr`:

```
error = bus_setup_intr(dev, irq_res, flags, filter, ihand, arg,
    &cookie);
if (error == 0)
    bus_bind_intr(dev, irq_res, preferred_cpu);
```

Chapter 19's driver does not bind its interrupt. A challenge exercise adds a `sysctl` that lets the operator set the preferred CPU.

19.12.5 The Kernel's CPU-Set Abstraction

A more sophisticated API: `bus_get_cpus(9)` lets the driver query which CPUs are considered “local” for a device, useful for multi-queue drivers that want to spread interrupts across a NUMA-local subset of CPUs. The `LOCAL_CPUS` and `INTR_CPUS` cpusets from `/usr/src/sys/sys/bus.h` expose this information.

Chapter 20's MSI-X work will use `bus_get_cpus(9)` to place per-queue interrupts on different CPUs in the device's local NUMA node. Chapter 19's single-interrupt driver does not need the complexity.

19.12.6 Observing Affinity

The `cpuset -g -x <irq>` command shows the current CPU mask for an IRQ. For the `myfirst` driver on a multi-CPU system, obtain the IRQ number from `devinfo -v | grep -A 5 myfirst0`, bind the interrupt to (say) CPU 1 with `cpuset -l 1 -x <irq>`, and confirm with `cpuset -g -x <irq>`.

The details are platform-specific. On x86 the I/O APIC (or MSI routing) implements the request; on arm64 the GIC redistributor does. Some architectures refuse rebinding and return an error; a cooperative driver's `bus_bind_intr` call treats that as a non-fatal hint.

19.13 A Deeper Look at Interrupt Storm Detection

The FreeBSD kernel has built-in protection against a specific failure mode: a level-triggered IRQ that fires continuously because the driver fails to acknowledge. The protection is called interrupt storm detection, is implemented in `/usr/src/sys/kern/kern_intr.c`, and is controlled by a single sysctl.

19.13.1 The `hw.intr_storm_threshold` Sysctl

```
static int intr_storm_threshold = 0;
SYSCTL_INT(_hw, OID_AUTO, intr_storm_threshold, CTLFLAG_RWTUN,
    &intr_storm_threshold, 0,
    "Number of consecutive interrupts before storm protection is enabled");
```

The default is zero (storm detection disabled). Setting the sysctl to a positive value enables detection: if an `intr_event` delivers more than N interrupts in a row without any other interrupt happening on the same CPU, the kernel assumes a storm and throttles the event.

Throttling means the kernel pauses (via `pause("istorm", 1)`) before running the handlers again. The pause is a single clock tick, which on most systems is a millisecond or so. The effect is to cap the rate at which a storming source can consume CPU.

19.13.2 When to Enable Detection

Default off is the production setting. Enabling storm detection means the kernel pauses interrupts when it thinks a storm is happening; if the detection is wrong (a high-rate legitimate interrupt, say a 10-gigabit NIC), the pause is a performance bug.

For driver development, enabling storm detection is useful: a forgotten acknowledgment in the filter produces an interrupt storm, which the kernel detects and throttles (and logs to `dmesg`). Without detection, the storm consumes a CPU forever; with detection, the storm is visible and throttled.

A reasonable development-time setting is `hw.intr_storm_threshold=1000`. A thousand consecutive interrupts on the same event without interleaving is unusual for legitimate traffic and reliably flags a storm.

19.13.3 What a Storm Looks Like

In `dmesg`:

```
interrupt storm detected on "irq19: myfirst0:legacy"; throttling interrupt source
```

Repeated at rate-limited intervals (once per second by default, governed by the `ppsratecheck` inside the kernel's storm code). The interrupt source is named; the driver can be identified from the name.

The kernel does not disable the line permanently; it paces the handler. After the storm ends (perhaps because the driver was unloaded, or the device stopped asserting), the handler resumes at full rate.

19.13.4 Driver-Side Storm Mitigation

A driver can implement its own storm mitigation. The classic technique is:

1. Count interrupts in a rolling window.
2. If the rate exceeds a threshold, mask the device's interrupts (via `INTR_MASK`) and schedule a task to re-enable them later.
3. In the task, inspect the device, clear whatever is causing the storm, and re-enable.

This is more invasive than the kernel's default. Most drivers do not implement it. The Chapter 19 driver does not; the kernel's threshold is sufficient for the scenarios the chapter exercises.

19.13.5 The Relationship to Shared IRQs

On a shared IRQ line, one driver's storm can interfere with another driver's legitimate interrupts. The kernel's storm detection is per-event, not per-handler, so if one driver's handler is slow or incorrect, the whole event throttles. This is a strong argument for writing correct filters: the storm impact is not confined to the buggy driver.

19.14 A Mental Model for Filter vs `ithread` Selection

Beginners often struggle with the decision between filter-only, filter-plus-`ithread`, filter-plus-taskqueue, and `ithread`-only. This section provides a decision framework that helps in most situations, grounded in questions a driver author can answer about their specific device.

19.14.1 Four Questions

Ask these about the interrupt's work:

1. **Can every piece of the work be done in primary context?** If yes (all state access through spin locks or atomics; all acknowledgments through BAR writes; no sleeping), filter-only is the cleanest choice.
2. **Does any piece of the work require a sleep lock or a condition-variable broadcast?** If yes, the bulk work must go in thread context. The choice is between ithread and taskqueue.
3. **Is the deferred work scheduled from anywhere besides the interrupt?** If yes (sysctl handlers, ioctl, timer callouts, other tasks), a taskqueue is better. The same work can be scheduled from any context.
4. **Is the deferred work sensitive to the interrupt's priority class?** If yes (you want `INTR_TYPE_NET` ithread priority for network work), register an ithread handler. The ithread inherits the interrupt's priority; a taskqueue runs at whatever priority its worker thread got at creation.

19.14.2 Applying the Framework

Filter-only fits: - A counter-incrementing demo driver. - A driver that only reads a device register and passes the value through an atomic. - A very simple sensor whose data is produced rarely and read directly.

Filter-plus-ithread fits: - A simple driver where the deferred work only matters on interrupt. - A driver that benefits from the interrupt's priority class. - A driver that wants the kernel-managed ithread without the taskqueue's extra machinery.

Filter-plus-taskqueue fits: - A driver where the same deferred work can be triggered by multiple sources (interrupt, sysctl, ioctl). - A driver that needs to coalesce interrupts (the taskqueue's npending count tells you how many enqueues happened since the last run). - A driver that wants a specific worker-thread count or priority independent of the interrupt category. - Chapter 19's target case: the `myfirst` driver schedules the same task from the filter and from the simulated-interrupt sysctl.

ithread-only fits: - A driver where there is no urgent work and every action needs a sleep lock. - A driver where the filter would be trivial (just "schedule the thread"); registering no filter and letting the kernel schedule the ithread saves a function call.

19.14.3 Worked Example: A Hypothetical Storage Driver

Suppose you are writing a driver for a small storage controller. The device has one IRQ line. When an I/O completes, it sets `INTR_STATUS.COMPLETION` and lists the completed command IDs in a completion queue register.

The decisions:

- **Can every piece be done in primary context?** No. Waking up the thread that issued the I/O requires a condition-variable broadcast, which requires the thread's lock. The filter cannot take that lock.
- **Which deferred mechanism?** The completion-handling work is scheduled only by the interrupt, so filter-plus-ithread is clean. The priority class is `INTR_TYPE_BIO`, which the ithread inherits.
- **Final design.** Filter reads `INTR_STATUS`, extracts the completed command IDs into a per-interrupt-context queue, acknowledges, returns `FILTER_SCHEDULE_THREAD`. ithread walks the per-context queue, matches command IDs to pending requests, wakes each request's thread.

19.14.4 Worked Example: A Hypothetical Network Driver

A NIC with four MSI-X vectors (two receive queues, two transmit queues). Each vector has its own filter.

The decisions:

- **Filter work?** Per-queue: acknowledge, note that the queue has events.
- **Deferred work?** Per-queue: walk the descriptor ring, build mbufs, pass to the stack.
- **Multiple sources?** Just the interrupt for normal operation; polling mode (for high-load offload) is a second source. Taskqueue is better: both the filter and the poll-mode timer can enqueue.
- **Priority?** `INTR_TYPE_NET`, which the taskqueue worker's `PI_NET` priority matches.
- **Final design.** Per-vector filter returns `FILTER_HANDLED` after enqueueing the per-queue task. Taskqueue per receive queue, one worker each. Taskqueues configured at priority `PI_NET`.

19.14.5 Worked Example: The Chapter 19 Driver

One IRQ line, simple event types, taskqueue-based deferred work.

- **Filter work:** Read `INTR_STATUS`, per-bit counters, acknowledge, enqueue task for `DATA_AV`.
- **Deferred work:** Read `DATA_OUT`, update softc, broadcast `data_cv`.
- **Multiple sources?** Filter and simulated-interrupt `sysctl` both need the task. Taskqueue is right.
- **Priority?** `PI_NET` is a sensible default even though the driver isn't a NIC; the simulation framework expects responsiveness.

19.14.6 When to Revisit the Decision

The decision is not permanent. A driver that starts as filter-only may grow a task when it gains a new capability; a driver that starts as taskqueue may move to `ithread` when the extra flexibility of taskqueue is not needed. The refactor is usually small (half an hour of code movement).

The framework helps you avoid an obviously-wrong initial choice. The details are a judgment call that the driver author makes based on the specific device.

19.15 Lock Ordering and the Interrupt Path

Part 3's lock discipline introduced the idea that the driver has a fixed lock order: `sc->mtx` -> `sc->cfg_sx` -> `sc->stats_cache_sx`. Chapter 19 does not add new locks but does add new contexts where existing locks are touched. This subsection examines whether the Chapter 19 additions respect the existing order.

19.15.1 The Filter Takes No Locks

The filter reads `INTR_STATUS`, updates atomic counters, and enqueues a task. No sleep lock is acquired. The filter's access to `INTR_STATUS` uses `ICSR_READ_4` and `ICSR_WRITE_4`, which do not assert any lock. Therefore the filter does not participate in the lock order; it is lock-free.

This is the simplest possible choice. A more sophisticated filter might use a spin lock (to protect a small shared data structure); Chapter 19's filter is simpler than that.

19.15.2 The Task Acquires `sc->mtx`

The task's function `myfirst_intr_data_task_fn` acquires `sc->mtx` (via `MYFIRST_LOCK`), does its work, and releases. It does not acquire any other lock. Therefore the task respects the existing lock order by not introducing any new lock acquisition pattern.

19.15.3 The Simulated-Interrupt `sysctl` Acquires and Releases `sc->mtx`

The `sysctl` handler acquires `sc->mtx` to set `INTR_STATUS`, releases the lock, and then invokes the filter. This is not a lock-order violation because the filter takes no locks; no new edge is added to the lock graph.

19.15.4 The Attach and Detach Paths

The attach path acquires `sc->mtx` briefly to set `INTR_MASK` and to perform the initial diagnostic read. It does not hold the lock across `bus_setup_intr` (which could, in principle, call into other parts of the kernel that take their own locks; `bus_setup_intr` is documented as lockable, meaning the caller can hold nothing of its own). The detach path similarly brief-holds `sc->mtx` around the `INTR_MASK` clear, then releases before calling `bus_teardown_intr`.

19.15.5 A Subtle Ordering Concern: `bus_teardown_intr` Can Block

A detail worth calling out. `bus_teardown_intr` waits for any in-progress filter or `ithread` invocation to complete before returning. If the driver holds a lock that the filter needs (say, a spin lock that the filter acquires briefly), `bus_teardown_intr` may block forever because the filter cannot run to completion.

Chapter 19's filter takes no spin locks, so this concern is academic. But a driver that uses spin locks in the filter must be careful: never hold the filter's spin lock while calling `bus_teardown_intr`.

19.15.6 WITNESS and the Interrupt Path

The debug kernel's `WITNESS` tracks lock ordering across every context, including the filter. A filter that takes a spin lock creates an ordering edge in `WITNESS`'s graph. If any thread-context code takes the same spin lock while holding a different spin lock, `WITNESS` flags a potential deadlock.

For the Chapter 19 driver, no edges are added. `WITNESS` is silent.

19.15.7 What to Document in `LOCKING.md`

A good driver's `LOCKING.md` documents the lock order clearly. Chapter 19's additions are minor:

- The filter takes no locks (atomic operations only).
- The task takes `sc->mtx` (leaf of the existing order).
- The simulated-interrupt `sysctl` takes `sc->mtx` briefly to set state, releases, then invokes the filter (outside any lock).

A short paragraph in `LOCKING.md` notes these facts. The order itself does not change.

19.16 Observability: What Chapter 19 Exposes to Operators

A chapter about interrupts is also, indirectly, about observability. The user of a driver (a system operator or a driver author debugging an issue) wants to see what the driver is doing. Chapter 19 exposes a modest amount of observability through counters and the simulated-interrupt `sysctl`; this subsection consolidates what is visible and how.

19.16.1 The Counter Suite

After Stage 4, the driver exposes these read-only `sysctls`:

- `dev.myfirst.N.intr_count`: total filter invocations.
- `dev.myfirst.N.intr_data_av_count`: `DATA_AV` events.
- `dev.myfirst.N.intr_error_count`: `ERROR` events.
- `dev.myfirst.N.intr_complete_count`: `COMPLETE` events.
- `dev.myfirst.N.intr_task_invocations`: task runs.
- `dev.myfirst.N.intr_last_data`: most recent `DATA_OUT` read by the task.

The counters give a concise view of the interrupt activity. Watching them over time (through `watch sysctl dev.myfirst.0` or a shell loop) shows the driver's activity live.

19.16.2 The Writable `Sysctls`

- `dev.myfirst.N.intr_simulate`: write a bitmask to simulate an interrupt.

(Chapter 19's driver only exposes this one writable `sysctl` for interrupts. Challenge exercises add `intr_sim_period_ms` for rate-based simulation and `intr_cpu` for affinity.)

19.16.3 The Kernel-Level View

`vmstat -i` and `devinfo -v` already show the kernel's view:

- `vmstat -i` shows the `intr_event`'s total count and rate.
- `devinfo -v` shows the device's IRQ resource.

These are not specific to `myfirst`; they are available for every driver. Learning to read them is part of general FreeBSD operator skill.

19.16.4 Correlating the Views

An operator trying to diagnose an issue might cross-check counters:

```
# The kernel's count of interrupts delivered to our handler.  
vmstat -i | grep myfirst
```

```
# The driver's count of times the filter was invoked.
sysctl dev.myfirst.0.intr_count
```

If these numbers match, the kernel's path and the driver's filter are in agreement. If the kernel count exceeds the driver count, some interrupts are being handled but not recognised (perhaps by another handler on a shared line). If the driver count exceeds the kernel count, something is wrong (the driver is counting invocations the kernel did not deliver; the simulated-interrupt sysctl is the most likely culprit if it was fired recently).

A disparity of one or two across a load-unload cycle is normal (timing around the unload). A consistent growing disparity indicates a bug.

19.16.5 DTrace

The kernel's fbt provider lets you trace the entry and exit of any kernel function, including `myfirst_intr_filter`:

```
sudo dtrace -n 'fbt::myfirst_intr_filter:entry { @[probefunc] = count(); }'
```

This prints the count of filter invocations seen by DTrace. Cross-check against `intr_count`.

More interestingly, a DTrace script can aggregate per-call timing:

```
sudo dtrace -n '
fbt::myfirst_intr_filter:entry { self->t = timestamp; }
fbt::myfirst_intr_filter:return /self->t/ {
    @["filter_ns"] = quantize(timestamp - self->t);
    self->t = 0;
}'
```

The output is a histogram of filter execution times in nanoseconds. A healthy filter spends between a few hundred nanoseconds and a few microseconds; anything higher is a bug or an extremely slow device.

19.16.6 ktrace and kgdb

For deep debugging, `ktrace` can trace system-call activity; `kgdb` can inspect a panic's kernel core dump. Chapter 19 does not use these directly, but a reader whose driver panics in the interrupt path would need them.

Each lab builds on the previous one and corresponds to one of the chapter's stages. A reader who works through all five has a complete interrupt-aware driver, a simulated-interrupt pipeline, and a regression script that validates the whole thing.

Time budgets assume the reader has already read the relevant sections.

19.16.7 Lab 1: Explore Interrupt Sources on Your System

Time: thirty minutes.

Objective: Build an intuition for what interrupts your system is handling and at what rate.

Steps:

1. Run `vmstat -i > /tmp/intr_before.txt`.
2. Do something that exercises the system for thirty seconds: run `dd if=/dev/urandom of=/dev/null bs=1m count=1000`, or open a browser page (on a system with a graphical session), or scp a file from another host.
3. Run `vmstat -i > /tmp/intr_after.txt`.
4. Compute the difference with `diff`:

```
paste /tmp/intr_before.txt /tmp/intr_after.txt
```

5. For each source that changed, note:
 - The interrupt name.
 - The count before and after.
 - The inferred rate during the thirty seconds.
6. Pick one source and identify its driver with `devinfo -v` or `pciconf -lv`.

Expected observations:

- The timer interrupts (`cpu0:timer` and so on) are high and steady, one per CPU.
- Network interrupts (`em0`, `igc0`, etc.) are high during `dd` or `scp` activity, near-zero otherwise.
- Storage interrupts (`ahci0`, `nvme0`, etc.) are high during disk activity, low otherwise.
- Some interrupts never change; those are devices that are quiet during your test.

This lab is about reading reality. No code. The payoff is that every later lab's `vmstat -i` output is familiar territory.

19.16.8 Lab 2: Stage 1, Register and Fire the Handler

Time: two to three hours.

Objective: Add the interrupt allocation, filter registration, and cleanup to Chapter 18's driver. Version target: `1.2-intr-stage1`.

Steps:

1. Starting from Chapter 18 Stage 4, copy the driver source to a new working directory.
2. Edit `myfirst.h` and add the four softc fields (`irq_res`, `irq_rid`, `intr_cookie`, `intr_count`).
3. In `myfirst_pci.c`, add the minimal filter handler (`atomic_add_64`; return `FILTER_HANDLED`).
4. Extend the attach path with the IRQ allocation, `bus_setup_intr`, and `bus_describe_intr` calls. Add the corresponding goto labels.
5. Extend the detach path with `bus_teardown_intr` and `bus_release_resource` for the IRQ.

6. Add a read-only sysctl `dev.myfirst.N.intr_count`.
7. Bump the version string to `1.2-intr-stage1`.
8. Compile: `make clean && make`.
9. Load on a bhyve guest. Check:
 - No `[GIANT-LOCKED]` warning in `dmesg`.
 - `devinfo -v | grep -A 5 myfirst0` shows both `memory:` and `irq:`.
 - `vmstat -i | grep myfirst` shows the handler.
 - `sysctl dev.myfirst.0.intr_count` returns a sensible value (zero if the device is quiet).
10. Unload. Check `vmstat -m | grep myfirst` shows zero live allocations.

Common failures:

- Missing `INTR_MPSAFE`: check for `[GIANT-LOCKED]` in `dmesg`.
- Wrong `rid` value: `bus_alloc_resource_any` returns `NULL`. Confirm `sc->irq_rid = 0`.
- Sleep lock in the filter: `WITNESS` panics.
- Missing teardown: `kldunload` panics or the debug kernel complains about active handlers.

19.16.9 Lab 3: Stage 2, Real Filter and Deferred Task

Time: three to four hours.

Objective: Extend the filter to read `INTR_STATUS`, acknowledge, and enqueue a deferred task. Version target: `1.2-intr-stage2`.

Steps:

1. Starting from Lab 2, add the per-bit counters (`intr_data_av_count`, `intr_error_count`, `intr_complete_count`, `intr_task_invocations`, `intr_last_data`) to the softc.
2. Add the taskqueue (`intr_tq`) and task (`intr_data_task`) fields.
3. In `myfirst_init_softc`, initialise the task and create the taskqueue.
4. In `myfirst_deinit_softc`, drain the task, free the taskqueue.
5. Rewrite the filter to read `INTR_STATUS`, check each bit, acknowledge, enqueue the task for `DATA_AV`, and return the right `FILTER_*` value.
6. Write the task function (`myfirst_intr_data_task_fn`) that reads `DATA_OUT`, updates the softc, and broadcasts the condition variable.
7. In the attach path, after the filter registration, enable `INTR_MASK` at the device.
8. In the detach path, disable `INTR_MASK` before `bus_teardown_intr`.
9. Add read-only sysctls for the new counters.
10. Bump the version to `1.2-intr-stage2`.
11. Compile, load, verify basic wiring (same as Lab 2).

For observation, wait a few seconds after load: if the device is producing real interrupts that match our bit layout, counters tick up. On the bhyve virtio-rnd target, no real interrupts of the right kind arrive; verify counters by proceeding to Lab 4.

19.16.10 Lab 4: Stage 3, Simulated Interrupts via sysctl

Time: two to three hours.

Objective: Add the `intr_simulate` sysctl, use it to drive the pipeline. Version target: 1.2-intr-stage3.

Steps:

1. Starting from Lab 3, add the `intr_simulate` sysctl handler (the one in Section 5).
2. Register it in `myfirst_init_softc` or the sysctl setup.
3. Compile, load.
4. Simulate a single `DATA_AV` event:

```
sudo sysctl dev.myfirst.0.intr_simulate=1
sleep 0.1
sysctl dev.myfirst.0.intr_count
sysctl dev.myfirst.0.intr_data_av_count
sysctl dev.myfirst.0.intr_task_invocations
```

All three counters should show 1.

5. Simulate ten `DATA_AV` events in a loop:

```
for i in 1 2 3 4 5 6 7 8 9 10; do
    sudo sysctl dev.myfirst.0.intr_simulate=1
done
sleep 0.5
sysctl dev.myfirst.0.intr_task_invocations
```

The task count should be close to 10 (may be less if the taskqueue coalesced multiple enqueues into a single run; each run records only one invocation but `npending` would be larger).

6. Simulate all three bits together:

```
sudo sysctl dev.myfirst.0.intr_simulate=7
```

All three per-bit counters increment.

7. Check the `intr_error_count` and `intr_complete_count` increment correctly:

```
sudo sysctl dev.myfirst.0.intr_simulate=2 # ERROR
sudo sysctl dev.myfirst.0.intr_simulate=4 # COMPLETE
sysctl dev.myfirst.0 | grep intr_
```

8. Implement the optional rate-based callout (`intr_sim_period_ms`), verify rate:

```
sudo sysctl hw.myfirst.intr_sim_period_ms=100
sleep 10
sysctl dev.myfirst.0.intr_count # around 100
sudo sysctl hw.myfirst.intr_sim_period_ms=0
```

19.16.11 Lab 5: Stage 4, Refactor, Regression, Version

Time: three to four hours.

Objective: Move interrupt code into `myfirst_intr.c/.h`, introduce `ICSR_*` macros, write `INTERRUPTS.md`, run the regression. Version target: `1.2-intr`.

Steps:

1. Starting from Lab 4, create `myfirst_intr.c` and `myfirst_intr.h`.
2. Move the filter, the task, the setup, the teardown, and the sysctl registration into `myfirst_intr.c`.
3. Add `ICSR_READ_4` and `ICSR_WRITE_4` macros to `myfirst_intr.h`.
4. Update the filter to use `ICSR_READ_4/ICSR_WRITE_4` instead of `raw bus_read_4/bus_write_4`.
5. In `myfirst_pci.c`, replace the inline interrupt code with calls to `myfirst_intr_setup` and `myfirst_intr_teardown`.
6. Update the Makefile to add `myfirst_intr.c` to SRCS. Bump the version to `1.2-intr`.
7. Write `INTERRUPTS.md` documenting the interrupt handler's design.
8. Compile.
9. Run the full regression script (ten cycles of attach/detach/unload with counter checks; see the companion example).
10. Confirm: no warnings, no leaks, counters match expectations.

Expected outcomes:

- The driver at `1.2-intr` has the same behaviour as Stage 3 but a cleaner file structure.
- `myfirst_pci.c` is shorter by 50-80 lines.
- `myfirst_intr.c` is roughly 200-300 lines.
- The regression script passes ten times in a row.

19.17 Challenge Exercises

The challenges are optional. Each builds on one of the labs and extends the driver in a direction the chapter did not take. They consolidate the chapter's material and are good preparation for Chapter 20.

19.17.1 Challenge 1: Add a Filter-Plus-ithread Handler

Rewrite Stage 2's filter so that it returns `FILTER_SCHEDULE_THREAD` instead of enqueueing a taskqueue task. Register an ithread handler through the fifth argument of `bus_setup_intr(9)` that does the work the task did. Compare the two approaches.

This exercise is the way to internalise the difference between ithread-based deferred work and taskqueue-based deferred work. After completing it, the reader should be able to say when each is appropriate.

19.17.2 Challenge 2: Implement Driver-Side Storm Mitigation

Add a counter that tracks the number of interrupts handled in the current millisecond. If the count exceeds a threshold (say, 10000), mask the device's interrupts and schedule a task to re-enable them 10 ms later.

This exercise demonstrates that driver-side mitigation is possible, and it shows why the kernel's default (do-nothing) is usually fine.

19.17.3 Challenge 3: Bind the Interrupt to a Specific CPU

Add a `sysctl dev.myfirst.N.intr_cpu` that accepts a CPU ID. When written, call `bus_bind_intr(9)` to route the interrupt to that CPU. Verify with `cpuset -g` or the per-CPU counts in `vmstat -i`.

This exercise introduces the CPU-affinity API and shows how the choice is visible in system-level tools.

19.17.4 Challenge 4: Extend the Simulated Interrupts With Per-Type Rates

Modify the `intr_sim_period_ms` callout to accept a bitmask of which event classes to simulate, not just `DATA_AV`. A reader should be able to simulate alternating `ERROR` and `COMPLETE` events at different rates.

The exercise exercises the reader's understanding of the Stage 2 filter's per-bit handling.

19.17.5 Challenge 5: Add a Rate-Limited Stray Log

Implement the `ppsratecheck(9)`-based stray-interrupt log mentioned in Section 6. Verify that the log appears at the expected rate when the driver receives strays (you can induce strays by disabling `INTR_MASK` while the device is generating events, or by manually calling the filter with a zero status).

19.17.6 Challenge 6: Implement MSI Allocation (Preview of Chapter 20)

Add code to the attach path that attempts `pci_alloc_msi(9)` first and falls back to legacy IRX if MSI is not available. The filter remains the same. This is a preview of Chapter 20; doing it now gets the reader comfortable with the MSI allocation API.

Note that on the bhyve virtio-rnd target, MSI is typically not available (bhyve's legacy virtio transport uses INTx). QEMU's `virtio-rng-pci` exposes MSI-X; you may want to switch labs to QEMU for this challenge.

19.17.7 Challenge 7: Write a Latency Test

Use the simulated-interrupt path to measure the driver's interrupt-to-user-space latency. A user-space program opens `/dev/myfirst0`, issues a `read(2)` that sleeps waiting on the condition variable; a second program writes the `intr_simulate` sysctl, starting a wall-clock timer; the first program's read returns, stopping the timer. Plot the distribution over many iterations.

This exercise exposes the reader to performance measurement on the driver's deferred path. Typical latencies are tens of microseconds on a well-tuned system.

19.17.8 Challenge 8: Share the IRQ Deliberately

If you have a bhyve guest configured with multiple devices on the same slot's functions, deliberately force them to share an IRQ. Load both drivers (the base-system driver for the other device; our `myfirst` for `virtio-rnd`). Verify with `vmstat -i` that they share the line. Observe the behaviour when either fires.

This exercise is the clearest demonstration of shared-IRQ correctness. A driver that gets Section 6's discipline wrong will misbehave here.

19.18 Troubleshooting and Common Mistakes

A consolidated list of interrupt-specific failure modes, symptoms, and fixes. Kept as a reference you can return to.

19.18.1 “Driver loads but no interrupts are counted”

Symptom: `kldload` succeeds, `dmesg` shows the attach banner, but `sysctl dev.myfirst.0.intr_count` stays at zero indefinitely.

Likely causes:

1. The device is not producing interrupts. On the bhyve `virtio-rnd` target this is normal because the device does not generate Chapter 17-style events. Use the simulated-interrupt `sysctl` to drive the pipeline.
2. `INTR_MASK` was not set. The handler is registered, but the device is not asserting the line because the mask is zero. Check the attach path for the `CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, ...)` call.
3. The device is masked by other means. Check the command register for `PCIM_CMD_INTxDIS` (interrupt disable bit); if set, clear it.
4. The wrong IRQ was allocated. `rid = 0` should produce the device's legacy `INTx`. Check `devinfo -v | grep -A 5 myfirst0` shows an `irq:` entry.

19.18.2 “GIANT-LOCKED warning in dmesg”

Symptom: `dmesg` after `kldload` shows `myfirst0: [GIANT-LOCKED]`.

Cause: `INTR_MPSAFE` was not passed to `bus_setup_intr`'s flags argument.

Fix: Add `INTR_MPSAFE` to the flags. Verify the filter uses spin-safe operations only (atomics, spin mutexes). Verify the lock discipline in the softc allows MP-safe operation.

19.18.3 “Kernel panic in the filter”

Symptom: A kernel panic whose backtrace shows `myfirst_intr_filter`.

Likely causes:

1. `sc` is `NULL` or stale. Check the argument to `bus_setup_intr`; it should be `sc`, not `&sc`.
2. A sleep lock is being acquired. `WITNESS` panics on this. The fix is to remove the sleep lock or move the work to a taskqueue.

3. The filter is called against a freed softc. This usually means detach did not tear down the handler before freeing state. Check the detach order.
4. `sc->bar_res` is NULL. A race between attach partial-failure unwinding and the filter running. Guard the filter's first access with a check.

19.18.4 “Task runs but accesses freed state”

Symptom: Kernel panic in the task function, backtrace shows `myfirst_intr_data_task_fn`.

Cause: The task was enqueued during or just before detach, and detach freed the softc before the task ran.

Fix: Add `taskqueue_drain` to the detach path, before freeing anything the task touches. See Section 7.

19.18.5 “INTR_STATUS bits keep firing; storm detected”

Symptom: `dmesg` shows `interrupt storm detected`.

Cause: The filter is not acknowledging `INTR_STATUS` correctly. Possibilities:

1. Filter does not write `INTR_STATUS` at all. Add the write.
2. Filter writes the wrong value. Write the specific bits you handled, not 0 and not `0xffffffff`.
3. Filter handles only some bits; unrecognised bits stay set and keep asserting. Either recognise all bits, or acknowledge unrecognised ones explicitly, or unset them in `INTR_MASK`.

19.18.6 “Simulated interrupt does not run the task”

Symptom: `sudo sysctl dev.myfirst.0.intr_simulate=1` increments `intr_count` but not `intr_task_invocations`.

Likely causes:

1. The simulated bit does not match what the filter looks for. The Stage 2 filter enqueues the task for `DATA_AV` (bit 0x1). Writing 2 or 4 sets `ERROR` or `COMPLETE`; those do not enqueue. Write 1 or 7.
2. The task function is not registered. Check `TASK_INIT` is called in `myfirst_init_softc`.
3. The taskqueue is not created. Check `taskqueue_create` and `taskqueue_start_threads` in `myfirst_init_softc`.

19.18.7 “kldunload fails with Device busy”

Symptom: `kldunload myfirst` fails with `Device busy`.

Causes: Same as Chapter 18. A user-space process has the `cdev` open; an in-flight command is not complete; the driver's busy check has a bug. Add `fstat /dev/myfirst0` to see who has it open.

19.18.8 “vmstat -m shows live allocations after unload”

Symptom: `vmstat -m | grep myfirst` returns non-zero `InUse` after `kldunload`.

Likely causes:

1. The taskqueue was not drained. Check `taskqueue_drain` in the detach path.
2. The simulation backend was attached (simulation-only build) and not detached. Check for `my-first_sim_detach` in the detach path.
3. A leak in `myfirst_init_softc / myfirst_deinit_softc`. Check that every allocation has a matching free.

19.18.9 “Handler fires on the wrong CPU”

Symptom: `cpuset -g` shows the interrupt fired on CPU X; the reader wanted it on CPU Y.

Cause: `bus_bind_intr` was not called, or was called with the wrong CPU argument.

Fix: Add a `sysctl` that lets the operator set the desired CPU and call `bus_bind_intr`. See Challenge 3.

19.18.10 “INTR_MASK write has unintended side effects”

Symptom: On the bhyve virtio-rnd target, writing to offset 0x10 (the Chapter 17 `INTR_MASK` offset) changes the device’s state in unexpected ways.

Cause: The Chapter 17 register layout does not match virtio-rnd’s. The offset 0x10 on virtio-rnd is `queue_notify`, not `INTR_MASK`.

Fix: This is a target mismatch, not a driver bug. The chapter acknowledges the issue. For correctness on a real device with the Chapter 17 layout, the write is right. For the bhyve teaching target, the write is harmless (it notifies an idle virtqueue) but not meaningful.

19.18.11 “Stray interrupt messages in dmesg”

Symptom: `dmesg` periodically shows messages about stray interrupts on the IRQ line.

Likely causes:

1. The handler is not masking `INTR_MASK` at the device properly during detach (level-triggered stray).
2. The device is producing interrupts the driver has not enabled. Check `INTR_MASK` setting.
3. Another driver sharing the line is returning the wrong `FILTER_*` value. This is that driver’s bug, not ours.

19.18.12 “Handler is called concurrently on multiple CPUs”

Symptom: Atomic counters increment non-monotonically, suggesting concurrent filter invocations.

Cause: On MSI-X (Chapter 20) the same handler can run concurrently on different CPUs. This is by design. For legacy IRQs this is rare but possible in some configurations.

Fix: Ensure all filter state access is atomic or spin-lock-protected. The Chapter 19 driver uses `atomic_add_64` throughout; no changes needed.

19.18.13 “bus_setup_intr returns EINVAL”

Symptom: The return value of `bus_setup_intr` is `EINVAL` and the driver fails to load.

Likely causes:

1. Both `filter` and `ihand` arguments are `NULL`. At least one must be non-`NULL`; the kernel has nothing to call otherwise.
2. The `INTR_TYPE_*` flag was omitted from the `flags` argument. Exactly one category must be set.
3. The IRQ resource was not allocated with `RF_ACTIVE`. An unactivated resource cannot have a handler attached.
4. The `flags` argument contains mutually-exclusive bits (rare; a driver author would have to invent this).

Fix: read the `bus_setup_intr(9)` manual page; the common case is that the `filter` or `ithread` argument is missing or the category flag is missing.

19.18.14 “bus_setup_intr returns EEXIST”

Symptom: `bus_setup_intr` returns `EEXIST` on a subsequent load.

Cause: The IRQ line already has an exclusive handler attached. Either this driver was loaded before and did not tear down properly, or another driver has claimed the line exclusively.

Fix: First, try unloading any previous instance (`kldunload myfirst`). If the problem persists, check `devinfo -v` for any driver currently using the IRQ.

19.18.15 “Debug kernel panics on taskqueue_drain”

Symptom: `taskqueue_drain` panics in the debug kernel.

Likely causes:

1. The taskqueue was never created. `sc->intr_tq` is `NULL`. Check `myfirst_init_softc`.
2. The taskqueue was already freed. Check for double-free in the teardown path.
3. `TASK_INIT` was never called. The task function pointer is garbage.

Fix: Ensure `TASK_INIT` runs before `taskqueue_enqueue` ever runs; ensure `taskqueue_free` runs at most once.

19.18.16 “Filter is called but INTR_STATUS reads as 0xffffffff”

Symptom: The filter runs, reads `INTR_STATUS`, sees `0xffffffff`.

Likely causes:

1. The device is unresponsive (perhaps the bhyve guest died or the device was hot-unplugged).
2. The BAR mapping is wrong. Check the attach path.
3. A PCI error has put the device into a limp state.

Fix: If the device is alive, the read returns real status bits. If `0xffffffff`, something else is wrong. The filter should still return `FILTER_STRAY` (because `0xffffffff` is unlikely to be a legitimate status value; cross-check with the device's datasheet for valid bit combinations).

19.18.17 “Interrupts are counted but the device makes no progress”

Symptom: `intr_count` ticks up, but the device's operation (data transfer, task completion, etc.) does not advance.

Likely causes:

1. The filter acknowledges every bit but the task does not run. Check `intr_task_invocations`; if zero, the `taskqueue_enqueue` path is broken.
2. The task runs but does not wake waiters. Check `cv_broadcast` in the task.
3. The device is signalling an unusual condition. Check `INTR_STATUS` contents (read via the `sysctl` path, or in DDB).

Fix: Add logging in the task (via `device_printf`); check whether the task's logic matches the device's actual behaviour.

19.18.18 “kldunload hangs”

Symptom: `kldunload myfirst` does not return. No panic, no output.

Likely causes:

1. `bus_tear_down_intr` is blocked waiting for an in-progress handler (filter or `ithread`). The handler is stuck.
2. `taskqueue_drain` is blocked waiting for a task that is stuck.
3. The detach function is waiting on a condition variable that is never broadcast.

Fix: If the system is responsive otherwise, switch to DDB (press the NMI key or type `sysctl debug.kdb.enter=1`) and `ps` to find the stuck threads. The backtrace usually pinpoints the stuck function.

19.18.19 “Unaligned memory access in the filter”

Symptom: A kernel panic on an architecture sensitive to alignment (arm64, MIPS, SPARC), with a backtrace pointing to the filter.

Cause: The filter is reading or writing a register at an unaligned offset. PCI BAR reads and writes require natural alignment (4-byte for 32-bit reads, 2-byte for 16-bit reads).

Fix: Use `bus_read_4` / `bus_write_4` at 4-byte-aligned offsets. Chapter 17's register map is 4-byte aligned throughout.

19.18.20 “device_printf from the filter slows the system”

Symptom: Adding `device_printf` calls to the filter makes the system noticeably laggy at high interrupt rates.

Cause: `device_printf` acquires a lock and does a formatted print. At ten thousand interrupts per second, the overhead is measurable.

Fix: Remove debug prints from the filter before production testing. Use counters and DTrace for observability instead.

19.18.21 “Driver passes all tests but misbehaves under load”

Symptom: The single-threaded tests pass, but load testing with many concurrent processes triggers occasional errors or state corruption.

Likely causes:

1. A race condition between the filter and the task. The filter sets a flag the task reads; the task updates state the filter reads. Without proper synchronisation, one can miss the other’s update.
2. A race between the task and another thread-context path (cdev handler, `sysctl`). The task takes `sc->mtx`; the other path should too.
3. An atomic variable used in a compound operation without a lock. `atomic_add_64` on its own is atomic; `atomic_load_64` followed by a computation followed by `atomic_store_64` is not atomic as a sequence.

Fix: Review the locking discipline. WITNESS does not catch pure atomic-variable races; careful code review does. Run under heavy load with INVARIANTS enabled and watch for assertion failures.

19.18.22 “vmstat -i shows many strays on a line I don’t own”

Symptom: A driver on a shared line sees the line’s stray counter growing steadily.

Likely causes:

1. Another driver on the line returns `FILTER_STRAY` incorrectly (the interrupt is for it but it claims otherwise).
2. A device on the line is signalling events the drivers do not acknowledge, producing phantom strays.
3. Hardware noise or a misconfigured trigger mode.

Fix: The fix is usually in whichever driver is returning `FILTER_STRAY` wrongly. Your own driver’s behaviour is correct as long as its status-register check is right.

19.19 Advanced Observability: Integrating With DTrace

FreeBSD’s DTrace can observe the interrupt path at many levels. This subsection shows some useful DTrace one-liners and scripts a driver author can use during development.

19.19.1 Counting Filter Invocations

```
sudo dtrace -n '  
fbt::myfirst_intr_filter:entry { @invocations = count(); }'
```

Shows the total number of times the filter has been called since DTrace started. Compare with `sysctl dev.myfirst.0.intr_count`; they should agree.

19.19.2 Measuring Filter Latency

```
sudo dtrace -n '  
fbt::myfirst_intr_filter:entry { self->ts = vtimestamp; }  
fbt::myfirst_intr_filter:return /self->ts/ {  
    @["filter_ns"] = quantize(vtimestamp - self->ts);  
    self->ts = 0;  
}'
```

`vtimestamp` measures CPU-time (not wall-clock), so the histogram is truly the filter's CPU time. A healthy filter is in the hundreds of nanoseconds to single-digit microseconds range.

19.19.3 Observing the Task Queue

```
sudo dtrace -n '  
fbt::myfirst_intr_data_task_fn:entry {  
    @["task_runs"] = count();  
    self->ts = vtimestamp;  
}  
fbt::myfirst_intr_data_task_fn:return /self->ts/ {  
    @["task_ns"] = quantize(vtimestamp - self->ts);  
    self->ts = 0;  
}'
```

Shows the task's invocation count and per-invocation execution time. The task is typically an order of magnitude slower than the filter (because it takes a sleep lock and does more work).

19.19.4 Correlating the Filter and Task

```
sudo dtrace -n '  
fbt::myfirst_intr_filter:entry /!self->in_filter/ {  
    self->in_filter = 1;  
    self->filter_start = vtimestamp;  
    @["filter_enters"] = count();  
}  
fbt::myfirst_intr_filter:return /self->in_filter/ {  
    self->in_filter = 0;  
}  
fbt::myfirst_intr_data_task_fn:entry {  
    @["task_starts"] = count();  
}'
```

If `filter_enters` is 100 and `task_starts` is 80, some filter invocations did not schedule a task (because the event was `ERROR` or `COMPLETE`, not `DATA_AV`).

19.19.5 Tracing Taskqueue Scheduling Decisions

The taskqueue infrastructure has DTrace probes too; one can observe how the task is enqueued and when the worker thread runs:

```
sudo dtrace -n '  
fbt::taskqueue_enqueue:entry /arg0 == ${tq_addr}/ {  
    @["enqueues"] = count();  
}'
```

where `${tq_addr}` is the numeric address of `sc->intr_tq`, obtainable through `kldstat` / `kgdb` combinations. This level of detail is usually overkill for Chapter 19's driver.

19.19.6 DTrace and the Simulated-Interrupt Path

Simulated interrupts are distinguishable from real interrupts because the simulated path goes through the `sysctl` handler:

```
sudo dtrace -n '  
fbt::myfirst_intr_simulate_sysctl:entry { @["simulate"] = count(); }  
fbt::myfirst_intr_filter:entry { @["filter"] = count(); }'
```

The difference between the two counts is the number of real interrupts (filter calls not preceded by a `sysctl` call).

19.20 Detailed Walkthrough: Stage 2 End to End

To make the Chapter 19 driver concrete, here is a complete walkthrough of what happens when a `DATA_AV` event is simulated through the `sysctl`, traced step by step.

19.20.1 The Sequence

1. User runs `sudo sysctl dev.myfirst.0.intr_simulate=1`.
2. The kernel's `sysctl` machinery routes the write to `myfirst_intr_simulate_sysctl`.
3. The handler parses the value (1), acquires `sc->mtx` via `MYFIRST_LOCK`.
4. The handler writes 1 to `INTR_STATUS` in the BAR.
5. The handler releases `sc->mtx`.
6. The handler calls `myfirst_intr_filter(sc)` directly.
7. The filter reads `INTR_STATUS` through `ICSR_READ_4`. Value is 1 (`DATA_AV`).
8. The filter increments `intr_count` atomically.
9. The filter sees `DATA_AV` bit set, increments `intr_data_av_count`.
10. The filter acknowledges by writing 1 back to `INTR_STATUS` via `ICSR_WRITE_4`.
11. The filter enqueues `intr_data_task` on `intr_tq` via `taskqueue_enqueue`.
12. The filter returns `FILTER_HANDLED`.
13. The `sysctl` handler returns 0 to the kernel's `sysctl` layer.
14. The user's `sysctl` command returns success.

Meanwhile, in the taskqueue:

15. The taskqueue's worker thread (woken by `taskqueue_enqueue`) schedules.
16. The worker thread calls `myfirst_intr_data_task_fn(sc, 1)`.
17. The task acquires `sc->mtx`.
18. The task reads `DATA_OUT` through `CSR_READ_4`.
19. The task stores the value in `sc->intr_last_data`.
20. The task increments `intr_task_invocations`.
21. The task broadcasts `sc->data_cv` (no waiters in this example).
22. The task releases `sc->mtx`.
23. The worker thread goes back to waiting for more work.

Steps 1-14 take microseconds; steps 15-23 take tens to hundreds of microseconds depending on scheduling.

19.20.2 What the Counters Show

After one simulated interrupt:

```
dev.myfirst.0.intr_count: 1
dev.myfirst.0.intr_data_av_count: 1
dev.myfirst.0.intr_error_count: 0
dev.myfirst.0.intr_complete_count: 0
dev.myfirst.0.intr_task_invocations: 1
```

If `intr_task_invocations` is still 0, the task has not run yet (usually because the `sysctl` returned before the worker thread was scheduled). A short `sleep 0.01` is enough.

19.20.3 What `dmesg` Shows

By default, nothing. The Stage 4 driver is not verbose. A reader who wants to see the filter fire can add `device_printf` calls for debugging, but production-quality drivers typically do not print on every interrupt.

19.20.4 What `vmstat -i` Shows

`vmstat -i | grep myfirst` shows the `intr_event`'s total count. This counts only real interrupts delivered by the kernel to our filter. Simulated interrupts invoked through the `sysctl` do not pass through the kernel's interrupt dispatcher, so they do not appear in the `vmstat -i` count.

This is a useful distinction: the `sysctl`-delivered simulation is a complementary mechanism, not a replacement. Real interrupts still count; simulated ones do not.

19.20.5 Tracing With Print Statements

For quick debugging, adding `device_printf` calls to the filter and task gives a live picture:

```
/* In the filter, temporarily for debugging: */
device_printf(sc->dev, "filter: status=0x%x\n", status);

/* In the task: */
device_printf(sc->dev, "task: data=0x%x npending=%d\n",
    data, npending);
```

This produces `dmesg` output like:

```
myfirst0: filter: status=0x1
myfirst0: task: data=0xdeadbeef npending=1
```

Remove these prints before production; the chatter at high interrupt rates is expensive.

19.21 Patterns From Real FreeBSD Drivers

A compact tour of interrupt patterns that appear repeatedly in `/usr/src/sys/dev/`. Each pattern is a concrete snippet from a real driver (rewritten slightly for readability) with a note on why it matters. Reading these after Chapter 19 consolidates the vocabulary.

19.21.1 Pattern: Fast-Filter-With-Slow-Task

From `/usr/src/sys/dev/mgb/if_mgb.c`:

```
int
mgb_legacy_intr(void *xsc)
{
    struct mgb_softc *sc = xsc;
    uint32_t intr_sts = CSR_READ_REG(sc, MGB_INTR_STS);
    uint32_t intr_en = CSR_READ_REG(sc, MGB_INTR_ENBL_SET);

    intr_sts &= intr_en;
    if ((intr_sts & MGB_INTR_STS_ANY) == 0)
        return (FILTER_STRAY);

    /* Acknowledge and defer per-queue work. */
    if ((intr_sts & MGB_INTR_STS_RX_ANY) != 0) {
        for (int qidx = 0; qidx < scctx->isc_nrxqsets; qidx++) {
            if (intr_sts & MGB_INTR_STS_RX(qidx))
                iflib_rx_intr_deferred(sc->ctx, qidx);
        }
        return (FILTER_HANDLED);
    }
    return (FILTER_SCHEDULE_THREAD);
}
```

Why it matters: the filter is short, the deferred work is per-queue, the shared-IRQ discipline is maintained. Chapter 19's filter follows the same shape.

19.21.2 Pattern: ithread-Only Handler

From `/usr/src/sys/dev/ath/if_ath_pci.c`:

```
bus_setup_intr(dev, psc->sc_irq,
    INTR_TYPE_NET | INTR_MPSAFE,
    NULL, ath_intr, sc, &psc->sc_ih);
```

The filter argument is `NULL`; `ath_intr` is the ithread handler. The kernel schedules `ath_intr` on every interrupt without a filter in the middle.

Why it matters: sometimes all the work needs thread context. Registering `NULL` for the filter is simpler than writing a trivial filter that just returns `FILTER_SCHEDULE_THREAD`.

19.21.3 Pattern: INTR_EXCL for Exclusive Access

Some drivers need exclusive access to an interrupt line:

```
bus_setup_intr(dev, irq,
    INTR_TYPE_BIO | INTR_MPSAFE | INTR_EXCL,
    NULL, driver_intr, sc, &cookie);
```

Why it matters: in rare cases, a driver needs the line to itself (the handler's assumption of being the only listener is baked in). INTR_EXCL asks the kernel to refuse other drivers on the same event.

19.21.4 Pattern: Short Debug Log

Some drivers have an optional verbose mode that logs every filter call:

```
if (sc->sc_debug > 0)
    device_printf(sc->sc_dev, "interrupt: status=0x%x\n", status);
```

Why it matters: a driver under development benefits from logging; a production driver wants the log suppressed. A sysctl (dev.driver.N.debug) toggles the mode.

19.21.5 Pattern: Bind to a Specific CPU

Drivers that know their topology bind the interrupt to a local CPU:

```
/* After bus_setup_intr: */
error = bus_bind_intr(dev, irq, local_cpu);
if (error != 0)
    device_printf(dev, "bus_bind_intr: %d\n", error);
/* Non-fatal: some platforms do not support binding. */
```

Why it matters: NUMA-local handlers are faster. A driver that bothers to bind produces a better scalability story on multi-socket systems.

19.21.6 Pattern: Describe the Handler for Diagnostics

Every driver should call bus_describe_intr:

```
bus_describe_intr(dev, irq, cookie, "rx-%d", queue_id);
```

Why it matters: `vmstat -i` and `devinfo -v` use the description to distinguish handlers on shared events. A driver with N queues and N MSI-X vectors has N bus_describe_intr calls.

19.21.7 Pattern: Quiesce Before Detach

```
mtx_lock(&sc->mtx);
sc->shutting_down = true;
mtx_unlock(&sc->mtx);

/* Let the interrupt handler drain. */
bus_teardown_intr(dev, sc->irq_res, sc->intr_cookie);
```

Why it matters: the `shutting_down` flag gives the handler a quick-exit path (the handler checks the flag before doing its normal work). The `bus_teardown_intr` is the definitive drain, but the flag makes the drain faster.

Chapter 19's driver uses `sc->pci_attached` for a similar purpose.

19.22 Reference: Common Mistakes Cheat Sheet

A compact list of interrupt-specific mistakes and their one-line fixes. Useful as a checklist when reviewing your own driver.

1. **No INTR_MPSAFE.** Fix: `flags = INTR_TYPE_MISC | INTR_MPSAFE.`
2. **Sleep lock in filter.** Fix: use atomic operations or a spin mutex.
3. **Missing acknowledgment.** Fix: `bus_write_4(res, INTR_STATUS, bits_handled);`.
4. **Acknowledging too many bits.** Fix: write back only the bits you handled.
5. **Missing FILTER_STRAY return.** Fix: if status is zero or unrecognised, return `FILTER_STRAY`.
6. **Missing FILTER_HANDLED return.** Fix: `rv |= FILTER_HANDLED;` for each recognised bit.
7. **Task using stale softc.** Fix: add `taskqueue_drain` to detach.
8. **Missing bus_teardown_intr.** Fix: before `bus_release_resource(SYS_RES_IRQ, ...)`.
9. **Missing INTR_MASK = 0 at detach.** Fix: clear the mask before teardown.
10. **Missing taskqueue_drain.** Fix: drain before freeing softc state.
11. **Wrong filter return value.** Fix: must be `FILTER_HANDLED`, `FILTER_STRAY`, `FILTER_SCHEDULE_THREAD`, or a bitwise OR.
12. **Enqueueing a task before TASK_INIT.** Fix: initialise the task in attach.
13. **Not setting INTR_MASK at attach.** Fix: write the bits you want enabled.
14. **Wrong rid for legacy IRQ.** Fix: use `rid = 0`.
15. **Wrong resource type.** Fix: use `SYS_RES_IRQ` for interrupts.
16. **Missing RF_SHAREABLE on shared line.** Fix: include the flag in allocation.
17. **Holding sc->mtx across bus_setup_intr.** Fix: release the lock before the call.
18. **Holding a spin lock across bus_teardown_intr.** Fix: never hold a filter's spin lock when tearing down.
19. **Taskqueue destroyed while task is still enqueued.** Fix: `taskqueue_drain` before `taskqueue_free`.
20. **Missing bus_describe_intr call.** Fix: add it after `bus_setup_intr` for diagnostic clarity.

19.23 Reference: ithread and Taskqueue Priorities

The Chapter 19 code uses `PI_NET` for the taskqueue. FreeBSD defines several priority constants in `/usr/src/sys/sys/priority.h`. A simplified view:

```

PI_REALTIME = PRI_MIN_ITHD + 0    (highest ithread priority)
PI_INTR     = PRI_MIN_ITHD + 4    (the common "hardware interrupt" level)
PI_AV       = PI_INTR             (audio/video)
PI_NET      = PI_INTR             (network)
PI_DISK     = PI_INTR             (block storage)
PI_TTY      = PI_INTR             (terminal/serial)
PI_DULL     = PI_INTR             (low-priority hardware ithreads)
PI_SOFT     = PRI_MIN_ITHD + 8    (soft interrupts)
PI_SOFTCLOCK = PI_SOFT            (soft clock)
PI_SWI(c)   = PI_SOFT            (per-category SWI)

```

A reader looking at this list will notice that most of the “hardware interrupt” aliases (`PI_AV`, `PI_NET`, `PI_DISK`, `PI_TTY`, `PI_DULL`) resolve to the same numeric value (`PI_INTR`). The comment at the top of that block in `priority.h` makes the reason explicit: “Most hardware interrupt threads run at the same priority, but can decay to lower priorities if they run for full time slices”. The category names exist because each one reads naturally at the call site, not because the numeric priorities differ.

Only `PI_REALTIME` (slightly above `PI_INTR`) and `PI_SOFT` (below `PI_INTR`) are actually distinct from the common hardware-interrupt level.

The `ithread`’s priority comes from the `INTR_TYPE_*` flag; the taskqueue’s priority is set explicitly. Passing `PI_NET` to `taskqueue_start_threads` puts the worker at the same nominal level as a network `ithread`, which is the right choice for work that cooperates with network-rate interrupt handling. A storage driver would pass `PI_DISK`; a low-priority background driver would pass `PI_DULL`. Because the constants all map to the same numeric value, the names are pragmatically interchangeable for correctness. They still matter for readability and for any future kernel where the distinction becomes real.

19.24 Reference: A Short Tour of /usr/src/sys/kern/kern_intr.c

A reader curious about what happens behind `bus_setup_intr(9)` and `bus_teardown_intr(9)` can open `/usr/src/sys/kern/kern_intr.c`. The file is about 1800 lines and has distinct sections:

- **intr_event management** (`intr_event_create`, `intr_event_destroy`): top-level creation and cleanup of the `intr_event` structure.
- **Handler management** (`intr_event_add_handler`, `intr_event_remove_handler`): the underlying operations that `bus_setup_intr` and `bus_teardown_intr` call.
- **Dispatch** (`intr_event_handle`, `intr_event_schedule_thread`): the code that actually runs when an interrupt fires.
- **Storm detection** (`intr_event_handle`): the `intr_storm_threshold` logic.
- **ithread creation and scheduling** (`ithread_create`, `ithread_loop`, `ithread_update`): the per-event `ithread` machinery.

- **SWI (software interrupt) management** (`swi_add`, `swi_sched`, `swi_remove`): soft interrupts.

A reader does not need to understand the whole file to write a driver. Browsing the top-level function list and reading the comments on `intr_event_handle` (the dispatch function) is a worthwhile half-hour.

19.24.1 Key Functions in `kern_intr.c`

Function	Purpose
<code>intr_event_create</code>	Allocate a new <code>intr_event</code> .
<code>intr_event_destroy</code>	Free an <code>intr_event</code> .
<code>intr_event_add_handler</code>	Attach a filter/ithread handler.
<code>intr_event_remove_handler</code>	Detach a handler.
<code>intr_event_handle</code>	Dispatch: called on each interrupt.
<code>intr_event_schedule_thread</code>	Wake the ithread.
<code>ithread_loop</code>	The body of an ithread.
<code>swi_add</code>	Register a software interrupt.
<code>swi_sched</code>	Schedule a software interrupt.

The `BUS_*` functions exposed to drivers (`bus_setup_intr`, `bus_teardown_intr`, `bus_bind_intr`, `bus_describe_intr`) call into these kernel-internal functions after platform-specific bus-driver hooks.

19.25 Wrapping Up

Chapter 19 gave the driver ears. At the start, `myfirst` at version `1.1-pci` was attached to a real PCI device but did not listen to it: every action the driver took was initiated by user space, and the device's own asynchronous events (if any) went unnoticed. At the end, `myfirst` at version `1.2-intr` has a filter handler wired to the device's IRQ line, a deferred-task pipeline that handles the bulk work in thread context, a simulated-interrupt path for testing on lab targets, a shared-IRQ discipline that coexists with other drivers on the same line, a clean teardown that releases every resource in the correct order, and a new `myfirst_intr.c` file plus `INTERRUPTS.md` document.

The transition walked through eight sections. Section 1 introduced interrupts at the hardware level, covering edge-triggered and level-triggered signalling, the CPU's dispatch flow, and the six obligations a driver's handler has. Section 2 introduced FreeBSD's kernel model: `intr_event`, `intr_handler`, `ithread`, the filter-plus-ithread split, `INTR_MPSAFE`, and the constraints on filter context. Section 3 wrote the minimal filter and the attach/detach wiring. Section 4 extended the filter with status decoding, per-bit acknowledgment, and taskqueue-based deferred work. Section 5 added the simulated-interrupt `sysctl` that lets the reader exercise the pipeline without real IRQ events. Section 6 codified the shared-IRQ discipline: check ownership, return `FILTER_STRAY` correctly, handle unrecognised bits defensively. Section 7 consolidated the teardown: mask at the device, tear down the handler, drain the taskqueue, release resources. Section 8 refactored the whole thing into a maintainable layout.

What Chapter 19 did not do is MSI, MSI-X, or DMA. The driver's interrupt path is a single legacy IRQ; the data path does not use DMA; the deferred work is a single taskqueue task. Chapter 20 introduces MSI and MSI-X (multiple vectors, per-vector filters, richer interrupt routing). Chapters 20 and 21 introduce DMA and the interaction between interrupts and DMA descriptor rings.

What Chapter 19 accomplished is the split between two threads of control. The driver's filter is short, runs in primary interrupt context, and handles the urgent per-interrupt work. The driver's deferred task is longer, runs in thread context, and handles the bulk per-event work. The discipline that keeps them cooperating (atomics for filter state, sleep locks for task state, strict ordering for teardown) is the discipline every later chapter's interrupt code assumes.

The file layout has grown: `myfirst.c`, `myfirst_hw.c`, `myfirst_hw_pci.c`, `myfirst_hw.h`, `myfirst_sim.c`, `myfirst_sim.h`, `myfirst_pci.c`, `myfirst_pci.h`, `myfirst_intr.c`, `myfirst_intr.h`, `myfirst_sync.h`, `cbuf.c`, `cbuf.h`, `myfirst.h`. The documentation has grown: `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`. The test suite has grown: the simulated-interrupt pipeline, the Stage 4 regression script, a handful of challenge exercises to keep the reader practising.

19.25.1 A Reflection Before Chapter 20

A pause before the next chapter. Chapter 19 taught the filter-plus-task pattern, the `INTR_MPSAFE` promise, the constraints of interrupt context, and the shared-IRQ discipline. The patterns you practised here (read status, acknowledge, defer work, return the right `FILTER_*`, tear down cleanly) are patterns every FreeBSD interrupt handler uses. Chapter 20 will layer MSI-X on top; Chapter 21 will layer DMA on top. Neither chapter replaces the Chapter 19 patterns; both build on them.

A second observation worth making. The composition of Chapter 17's simulation, Chapter 18's real PCI attach, and Chapter 19's interrupt handling is now a complete driver in the architectural sense. A reader who understands the three layers can open any FreeBSD PCI driver and recognise the parts: the register map, the PCI attach, the interrupt filter. The specifics differ; the structure is constant. That recognition is what makes the book's investment pay off across the whole FreeBSD source tree.

Third observation: the payoff of Chapter 16's accessor layer continues. The `CSR_*` macros did not change in Chapter 19; the `ICSR_*` macros were added for filter-context use, but they call the same underlying `bus_read_4` and `bus_write_4`. The abstraction has now paid off three times: against the Chapter 17 simulation backend, against the Chapter 18 real PCI BAR, and against the Chapter 19 filter context. A reader who builds similar accessor layers in their own drivers will find the same dividend.

19.25.2 What to Do If You Are Stuck

Three suggestions.

First, focus on the simulated-interrupt path. If `sudo sysctl dev.myfirst.0.intr_simulate=1` makes counters tick and the task run, the pipeline is working. Every other piece of the chapter is optional in the sense that it decorates the pipeline, but if the pipeline fails, the whole chapter is not working and Section 5 is the right place to diagnose.

Second, open `/usr/src/sys/dev/mgb/if_mgb.c` and re-read the `mgb_legacy_intr` function slowly. It is about sixty lines of filter code. Every line maps to a Chapter 19 concept. Reading it once after completing the chapter should feel like familiar territory.

Third, skip the challenges on first pass. The labs are calibrated for Chapter 19's pace; the challenges assume the chapter's material is solid. Come back to them after Chapter 20 if they feel out of reach now.

Chapter 19's goal was to give the driver a way to listen to its device. If it has, Chapter 20's MSI-X machinery becomes a specialisation rather than an entirely new topic, and Chapter 21's DMA becomes a matter of wiring descriptor completions to the interrupt path you already have.

19.26 Bridge to Chapter 20

Chapter 20 is titled *Advanced Interrupt Handling*. Its scope is the specialisation that Chapter 19 deliberately did not take: MSI (Message Signaled Interrupts) and MSI-X, the modern PCIe interrupt mechanisms that replace the legacy INTx line with per-device (or per-queue) vectors delivered as memory writes.

Chapter 19 prepared the ground in four specific ways.

First, **you have a functioning filter handler**. The Chapter 19 filter reads status, handles bits, acknowledges, and defers. Chapter 20's filter looks similar, but is replicated per vector: each MSI-X vector has its own filter, and each handles a specific subset of the device's events.

Second, **you understand the attach/detach cascade**. Chapter 19 grew the cascade by two labels (`fail_release_irq`, `fail_teardown_intr`). Chapter 20 grows it further: one pair of labels per vector. The pattern does not change; the count does.

Third, **you have an interrupt teardown discipline**. Chapter 20 reuses Chapter 19's order: clear interrupts at the device, `bus_teardown_intr` for each vector, `bus_release_resource` for each IRQ resource. The per-vector nature adds a small loop; the order is the same.

Fourth, **you have a lab environment that exposes MSI-X**. On QEMU with `virtio-rng-pci`, MSI-X is available; on bhyve with `virtio-rnd`, only legacy INTx is exposed. Chapter 20's labs may require switching to QEMU or to a more richly-emulated bhyve device to exercise the MSI-X path.

Specific topics Chapter 20 will cover:

- Why MSI and MSI-X are an improvement over legacy INTx.
- How MSI differs from MSI-X (single vector vs table of vectors).
- `pci_alloc_msi(9)`, `pci_alloc_msix(9)`: allocating vectors.
- `pci_msi_count(9)`, `pci_msix_count(9)`: querying capability.
- `pci_release_msi(9)`: the teardown counterpart.
- Multi-vector interrupt handlers: per-queue filters.
- The MSI-X table layout and how to reach specific entries.
- CPU affinity across vectors for NUMA awareness.
- Interrupt coalescing: reducing the rate of interrupts when the device supports it.
- Interaction between MSI-X and iflib (the modern network driver framework).
- Migrating the `myfirst` driver from Chapter 19's legacy path to an MSI-X path, with a fallback to legacy for devices that do not support MSI-X.

You do not need to read ahead. Chapter 19 is sufficient preparation. Bring your `myfirst` driver at `1.2-intr`, your `LOCKING.md`, your `INTERRUPTS.md`, your WITNESS-enabled kernel, and your regression script. Chapter 20 starts where Chapter 19 ended.

Chapter 21 is one chapter further along; it is worth a brief forward pointer. DMA will introduce yet another interaction with interrupts: completion interrupts that signal “descriptor ring entry N is done”. The filter-plus-task discipline Chapter 19 taught carries through; the task’s work now involves walking a descriptor ring rather than reading a single register.

The vocabulary is yours; the structure is yours; the discipline is yours. Chapter 20 adds precision to all three.

19.27 Reference: Chapter 19 Quick-Reference Card

A compact summary of the vocabulary, APIs, macros, and procedures Chapter 19 introduced.

19.27.1 Vocabulary

- **Interrupt**: an asynchronous hardware-signalled event.
- **IRQ (Interrupt Request)**: the identifier of an interrupt line.
- **Edge-triggered**: signalled by a transition; one interrupt per transition.
- **Level-triggered**: signalled by a level held; an interrupt fires while the level is held.
- **intr_event**: FreeBSD’s kernel structure for one interrupt source.
- **ithread**: FreeBSD’s kernel thread that runs deferred interrupt handlers.
- **filter handler**: a function that runs in primary interrupt context.
- **ithread handler**: a function that runs in thread context after the filter.
- **FILTER_HANDLED**: the filter handled the interrupt; no ithread needed.
- **FILTER_SCHEDULE_THREAD**: the filter partially handled; run the ithread.
- **FILTER_STRAY**: the interrupt was not for this driver.
- **INTR_MPSAFE**: a flag promising the handler does its own synchronisation.
- **INTR_TYPE_*** (TTY, BIO, NET, CAM, MISC, CLK, AV): handler-category hints.
- **INTR_EXCL**: exclusive interrupt.

19.27.2 Essential APIs

- `bus_alloc_resource_any(dev, SYS_RES_IRQ, &rid, flags)`: claim an IRQ.
- `bus_release_resource(dev, SYS_RES_IRQ, rid, res)`: release the IRQ.
- `bus_setup_intr(dev, res, flags, filter, ihand, arg, &cookie)`: register a handler.
- `bus_teardown_intr(dev, res, cookie)`: unregister the handler.
- `bus_describe_intr(dev, res, cookie, "name")`: name the handler for tools.
- `bus_bind_intr(dev, res, cpu)`: route the interrupt to a CPU.
- `pci_msi_count(dev), pci_msix_count(dev)` (Chapter 20).
- `pci_alloc_msi(dev, &count), pci_alloc_msix(dev, &count)` (Chapter 20).
- `pci_release_msi(dev)` (Chapter 20).
- `taskqueue_create("name", M_WAITOK, taskqueue_thread_enqueue, &tq)`: create a taskqueue.
- `taskqueue_start_threads(&tq, n, PI_pri, "thread name")`: start workers.
- `taskqueue_enqueue(tq, &task)`: enqueue a task.
- `taskqueue_drain(tq, &task)`: wait for a task to finish, prevent new enqueues.
- `taskqueue_free(tq)`: free the taskqueue.
- `TASK_INIT(&task, pri, fn, arg)`: initialise a task.

19.27.3 Essential Macros

- `FILTER_HANDLED`, `FILTER_STRAY`, `FILTER_SCHEDULE_THREAD`.
- `INTR_TYPE_TTY`, `INTR_TYPE_BIO`, `INTR_TYPE_NET`, `INTR_TYPE_CAM`, `INTR_TYPE_MISC`, `INTR_TYPE_CLK`, `INTR_TYPE_AV`.
- `INTR_MPSAFE`, `INTR_EXCL`.
- `RF_SHAREABLE`, `RF_ACTIVE`.
- `SYS_RES_IRQ`.

19.27.4 Common Procedures

Allocate a legacy PCI interrupt and register a filter handler:

1. `sc->irq_rid = 0;`
2. `sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ, &sc->irq_rid, RF_SHAREABLE | RF_ACTIVE);`
3. `bus_setup_intr(dev, sc->irq_res, INTR_TYPE_MISC | INTR_MPSAFE, filter, NULL, sc, &sc->intr_cookie);`
4. `bus_describe_intr(dev, sc->irq_res, sc->intr_cookie, "name");`

Tear down an interrupt handler:

1. Disable interrupts at the device (clear `INTR_MASK`).
2. `bus_tear_down_intr(dev, sc->irq_res, sc->intr_cookie);`
3. `taskqueue_drain(sc->intr_tq, &sc->intr_data_task);`
4. `taskqueue_free(sc->intr_tq);`
5. `bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid, sc->irq_res);`

Write a filter handler:

1. Read `INTR_STATUS`; if zero, return `FILTER_STRAY`.
2. For each recognised bit, increment a counter, acknowledge by writing back, and optionally enqueue a task.
3. Return `FILTER_HANDLED` (or `FILTER_SCHEDULE_THREAD`), or `FILTER_STRAY` if nothing was recognised.

19.27.5 Useful Commands

- `vmstat -i`: list interrupt sources with counts.
- `devinfo -v`: list devices with their IRQ resources.
- `sysctl hw.intrcnt` and `sysctl hw.intrnames`: raw counters.
- `sysctl hw.intr_storm_threshold`: enable kernel storm detection.
- `cpuset -g`: query interrupt CPU affinity (platform-specific).
- `sudo sysctl dev.myfirst.0.intr_simulate=1`: fire a simulated interrupt.

19.27.6 Files to Keep Bookmarked

- `/usr/src/sys/sys/bus.h`: `driver_filter_t`, `driver_intr_t`, `FILTER_*`, `INTR_*`.

- `/usr/src/sys/kern/kern_intr.c`: the kernel's interrupt-event machinery.
- `/usr/src/sys/sys/taskqueue.h`: taskqueue API.
- `/usr/src/sys/dev/mgb/if_mgb.c`: a readable filter-plus-task example.
- `/usr/src/sys/dev/ath/if_ath_pci.c`: a minimal ithread-only interrupt setup.

19.28 Reference: A Comparison Table Across Part 4

A compact summary of where each chapter of Part 4 fits, what it adds, and what it assumes. Useful for readers jumping in or back through the part.

Topic	Ch 16	Ch 17	Ch 18	Ch 19	Ch 20 (preview)	Ch 21 (preview)
BAR access	Simulated with malloc	Extended with sim layer	Real PCI BAR	Same	Same	Same
Chapter 17 simulation	N/A	Introduced	Inactive on PCI	Inactive on PCI	Inactive on PCI	Inactive on PCI
PCI attach	N/A	N/A	Introduced	Same + IRQ	MSI-X option	DMA init added
Interrupt handling	N/A	N/A	N/A	Introduced	MSI-X per-vector	Completion-driven
DMA	N/A	N/A	N/A	N/A	Preview	Introduced
Version	0.9-mmio	1.0-simulated	1.1-pci	1.2-intr	1.3-msi	1.4-dma
New file	<code>myfirst_hw.c</code>	<code>myfirst_sim.c</code>	<code>myfirst_pci.c</code>	<code>myfirst_intr.c</code>	<code>myfirst_msix.c</code>	<code>myfirst_dma.c</code>
Key discipline	Accessor abstraction	Fake device	Newbus attach	Filter/task split	Per-vector handlers	DMA maps

The table makes the book's cumulative structure visible at a glance. A reader who understands the row for a given topic can predict how Chapter 19's work fits into the bigger picture.

19.29 Reference: FreeBSD Manual Pages for Chapter 19

A list of the manual pages most useful for Chapter 19's material. Open each with `man 9 <name>` (for kernel APIs) or `man 4 <name>` (for subsystem overviews) on a FreeBSD system.

19.29.1 Kernel API Manual Pages

- **`bus_setup_intr(9)`**: registering an interrupt handler.

- **bus_teardown_intr(9)**: tearing down a handler.
- **bus_bind_intr(9)**: binding to a CPU.
- **bus_describe_intr(9)**: labelling a handler.
- **bus_alloc_resource(9)**: resource allocation (generic).
- **bus_release_resource(9)**: resource release.
- **atomic(9)**: atomic operations including `atomic_add_64`.
- **taskqueue(9)**: taskqueue primitives.
- **ppsratecheck(9)**: rate-limited logging helper.
- **swi_add(9)**: software interrupts (mentioned as alternative).
- **intr_event(9)**: interrupt event machinery (if present; some APIs are internal).

19.29.2 Device Subsystem Manual Pages

- **pci(4)**: PCI subsystem.
- **vmstat(8)**: `vmstat -i` for observing interrupts.
- **devinfo(8)**: device tree and resources.
- **devctl(8)**: runtime device control.
- **sysctl(8)**: reading and writing sysctls.
- **dtrace(1)**: dynamic tracing.

Most of these have been referenced in the chapter body. This consolidated list is for readers who want a single place to find them.

19.30 Reference: Driver Memorable Phrases

A few aphorisms that summarise Chapter 19's discipline. Useful for reading and for code review.

- **"Read, acknowledge, defer, return."** The four things a filter does.
- **"FILTER_STRAY if you didn't recognise anything."** The shared-IRQ protocol.
- **"Mask before teardown; teardown before release."** The detach ordering.
- **"Filter context is spin-lock-only."** The no-sleep-locks rule.
- **"Every enqueue needs a drain before free."** The taskqueue lifecycle.
- **"One filter, one device, one state."** The isolation that keeps per-device code sane.
- **"If WITNESS panics, believe it."** The debug kernel catches subtle mistakes.
- **"PROD first, interrupt second."** Program the device (`INTR_MASK`) before enabling the handler.
- **"Small in the filter; large in the task."** The work-size discipline.
- **"Storm detection is a safety net, not a design tool."** Do not rely on the kernel's throttling.

None of these are complete specifications. Each is a compact reminder that unpacks into the chapter's detailed treatment.

19.31 Reference: Glossary of Chapter 19 Terms

ack (acknowledge): the operation of writing back to `INTR_STATUS` to clear the pending bit and deassert the IRQ line.

driver_filter_t: the C typedef for a filter-handler function: `int f(void *)`.

driver_intr_t: the C typedef for an ithread handler function: `void f(void *)`.

edge-triggered: an interrupt signalling mode where the interrupt is signalled by a level transition.

FILTER_HANDLED: return value from a filter meaning “this interrupt is handled; no ithread needed”.

FILTER_SCHEDULE_THREAD: return value meaning “schedule the ithread to run”.

FILTER_STRAY: return value meaning “this interrupt is not for this driver”.

filter handler: a C function running in primary interrupt context.

Giant: the legacy single global kernel lock; modern drivers avoid it by setting `INTR_MPSAFE`.

IE (interrupt event): short for `intr_event`.

INTR_MPSAFE: a flag promising the handler does its own synchronisation and is safe without Giant.

INTR_STATUS: the device register that tracks pending interrupt causes (RW1C).

INTR_MASK: the device register that enables specific interrupt classes.

intr_event: kernel structure representing one interrupt source.

ithread: kernel interrupt thread; runs deferred handlers in thread context.

level-triggered: an interrupt signalling mode where the interrupt fires while the level is held.

MSI: Message Signaled Interrupts; a PCIe mechanism (Chapter 20).

MSI-X: the richer variant of MSI with a table of vectors (Chapter 20).

primary interrupt context: the context of a filter handler; no sleeping, no sleep locks.

PCIR_INTLINE / PCIR_INTPIN: PCI configuration-space fields specifying the legacy IRQ line and pin.

RF_ACTIVE: resource allocation flag; activate the resource in one step.

RF_SHAREABLE: resource allocation flag; allow sharing the resource with other drivers.

stray interrupt: an interrupt for which no filter returned a claim; counted separately by the kernel.

storm: a situation in which a level-triggered interrupt fires continuously because the driver does not acknowledge.

SYS_RES_IRQ: resource type for interrupts.

taskqueue: a kernel primitive for running deferred work in thread context.

trap stub: the small piece of kernel code that runs when the CPU takes an interrupt vector.

EOI (End of Interrupt): the signal sent to the interrupt controller to re-arm the IRQ line.

19.32 Reference: A Closing Note on Interrupt-Handling Philosophy

A paragraph to close the chapter with, worth returning to after the labs.

An interrupt handler’s job is not to do the device’s work. The device’s work (processing a packet, finishing an I/O, reading a sensor) is done by the rest of the driver, in thread context, under the driver’s full set of locks.

The handler's job is narrower: to notice that the device has something to say, to acknowledge the device so the conversation can continue, to schedule the real work that will happen later, and to return quickly enough that the CPU is free for the interrupted thread or for the next interrupt.

A reader who has written the Chapter 19 driver has written one interrupt handler. It is small. The rest of the driver is what makes it useful. Chapter 20 will specialise the handler to per-vector work on MSI-X. Chapter 21 will specialise the task to walking a DMA descriptor ring. Each of those is an extension, not a replacement. The Chapter 19 handler is the skeleton that both build on.

The skill Chapter 19 teaches is not “how to handle interrupts for the virtio-rnd device”. It is “how to split work between primary context and thread context, how to respect the filter's constraints, how to tear down cleanly, and how to cooperate with other drivers on a shared line”. Each of those is a transferable skill. Every driver in the FreeBSD tree exercises some of them; most drivers exercise all of them.

For this reader and for this book's future readers, the Chapter 19 filter and task are a permanent part of the `myfirst` driver's architecture. Every later chapter assumes them. Every later chapter extends them. The driver's overall complexity will grow, but the interrupt path will remain what Chapter 19 made it: a narrow, fast, correctly-ordered piece of code that gets out of the way so the rest of the driver can do its job.

20 Advanced Interrupt Handling

20.1 Reader Guidance & Outcomes

Chapter 19 ended with a driver that could listen to its device. The `myfirst` module at version `1.2-intr` has one filter handler registered on the legacy PCI INTx line, one deferred-work task on a taskqueue, a simulated-interrupt `sysctl` for testing on the bhyve lab target, a strict teardown order, and a new `myfirst_intr.c` file that keeps the interrupt code tidy. The Chapter 11 locking discipline carries through: atomics in the filter, sleep locks in the task, `INTR_MPSAFE` on the handler, shared-IRQ safety via `FILTER_STRAY`. The driver behaves like a small real driver that happens to have a single source of interrupts.

What the driver does not yet do is take advantage of everything PCIe offers. A modern PCIe device does not need to share a single line with its neighbours. It can request a dedicated interrupt through the message-signalled mechanism PCI 2.2 introduced (MSI) or the richer per-function table MSI-X added in PCIe. A device with several queues (a NIC with receive and transmit queues, an NVMe controller with admin and I/O submission queues, a modern USB3 host controller with event queues) usually wants an interrupt per queue rather than one shared interrupt for the whole device. Chapter 20 teaches the driver how to ask.

The chapter's scope is precisely this transition: what MSI and MSI-X are at the hardware level, how FreeBSD represents them in terms of additional IRQ resources, how a driver queries capability counts and allocates vectors, how the fallback ladder from MSI-X down to MSI down to legacy INTx works in practice, how to register several different filter functions on the same device, how to design per-vector data structures so each vector's handler touches its own state, how to give each vector a CPU affinity that matches the device's NUMA placement, how to label each vector with `bus_describe_intr(9)` so `vmstat -i` tells the operator which vector does what, and how to tear every one of these things down in the correct order. The chapter stops short of DMA, which is Chapter 21; per-queue receive and transmit vectors become especially valuable once a descriptor ring is in the picture, but teaching both at once would dilute both.

Chapter 20 keeps several neighbouring topics at arm's length. Full DMA (`bus_dma(9)` tags, descriptor rings, bounce buffers, cache coherence) is Chapter 21. `iflib`'s multi-queue framework, which wraps MSI-X with a layer of per-queue `iflib` machinery, is a Part 6 topic (Chapter 28) for readers who want the `iflib`-style networking path. The richer per-function MSI-X mask table operations (steering specific message addresses to specific CPUs through the MSI-X table directly) are discussed but not implemented end to end. Platform-specific interrupt remapping through the IOMMU, SR-IOV vector sharing, and PCIe AER-driven interrupt recovery are left for later chapters. Chapter 20 stays inside the ground it can cover well and hands off explicitly when a topic deserves its own chapter.

Multi-vector work rests on every earlier Part 4 layer. Chapter 16 gave the driver a vocabulary of register access. Chapter 17 taught it to think like a device. Chapter 18 introduced it to a real PCI device. Chapter 19 gave it ears on a single IRQ. Chapter 20 gives it a set of ears, one per conversation the device wants to have. Chapter 21 will teach those ears to cooperate with the device's own ability to reach into RAM. Each chapter adds one

layer. Each layer depends on the ones before it. Chapter 20 is where the driver stops pretending the device has only one thing to say and starts treating it as the multi-queue machine it really is.

20.1.1 Why MSI-X Earns a Chapter of Its Own

At this point you may be asking why MSI and MSI-X need a chapter of their own. The Chapter 19 driver has a working interrupt handler on the legacy IRQ line. If the filter-plus-task pipeline is already right, why not keep using it? Does MSI-X really justify a full chapter of new material?

Three reasons.

The first is scale. A single IRQ line on a shared system forces every driver on that line to serialise through one `intr_event`. On a host with dozens of PCIe devices, the legacy INTx mechanism would bottleneck the whole system if it were the only option. MSI-X lets each device (and each queue within a device) have its own dedicated `intr_event`, served by its own ithread or filter handler, pinned to its own CPU. The difference between a modern server handling ten million packets per second with MSI-X and the same workload on legacy INTx is the difference between “possible” and “impossible”; MSI-X is what makes the former a reality.

The second is locality. With a single interrupt line, the kernel has one choice of CPU to route the interrupt to, and that choice is global for the device. With MSI-X, each vector can be pinned to a different CPU, and good drivers pin each vector to a CPU that is NUMA-local to the queue it serves. The cache-line advantages of doing this are real: a receive queue whose interrupt fires on the same CPU that eventually consumes the packet avoids cross-socket cache traffic that dominates on legacy setups.

The third is cleanliness. Even for a driver that does not need high throughput, MSI or MSI-X can simplify the handler. With a dedicated line, the filter does not need to handle the shared-IRQ case. With a dedicated vector per event class (admin, receive, transmit, error), each handler is smaller and more specialised, and the whole driver becomes easier to read. Good drivers use MSI-X even when performance does not require it, because the code becomes better.

Chapter 20 earns its place by teaching all three of these benefits concretely. A reader finishes the chapter able to allocate vectors, route them, describe them, and tear them down, with a working driver that demonstrates the pattern end to end.

20.1.2 Where Chapter 19 Left the Driver

A brief recap of where you should stand. Chapter 20 extends the driver produced at the end of Chapter 19 Stage 4, tagged as version `1.2-intr`. If any of the items below feels uncertain, return to Chapter 19 before starting this chapter.

- Your driver compiles cleanly and identifies itself as `1.2-intr` in `kldstat -v`.
- On a bhyve or QEMU guest that exposes a `virtio-rnd` device, the driver attaches, allocates BAR 0 as `SYS_RES_MEMORY`, allocates the legacy IRQ as `SYS_RES_IRQ` with `rid = 0`, registers a filter handler through `bus_setup_intr(9)` with `INTR_TYPE_MISC | INTR_MPSAFE`, creates `/dev/myfirst0`, and supports the `dev.myfirst.N.intr_simulate` sysctl.
- The filter reads `INTR_STATUS`, increments per-bit counters, acknowledges, enqueues the deferred task for `DATA_AV`, and returns the right `FILTER_*` value.

- The task (`myfirst_intr_data_task_fn`) runs in thread context on a taskqueue named `myfirst_intr` at `PI_NET` priority, reads `DATA_OUT`, updates the `softc`, and broadcasts `sc->data_cv`.
- The detach path clears `INTR_MASK`, calls `bus_tearardown_intr`, drains and frees the taskqueue, releases the IRQ resource, detaches the hardware layer, and releases the BAR.
- `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, and `INTERRUPTS.md` are current.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel.

That driver is what Chapter 20 extends. The additions are noticeable in scope: one new file (`myfirst_msix.c`), one new header (`myfirst_msix.h`), several new `softc` fields to track per-vector state, a new family of per-vector filter functions, a new fallback ladder in the setup helper, per-vector `bus_describe_intr` calls, optional CPU binding, a version bump to 1.3-`msi`, a new `MSIX.md` document, and updates to the regression test. The mental model grows too: the driver starts thinking of interrupts as a vector of sources rather than a single event stream.

20.1.3 What You Will Learn

By the time you move on to the next chapter, you will be able to:

- Describe what an MSI and an MSI-X interrupt is at the hardware level, how each is signalled over PCIe (as a memory write rather than an electrical level change), and why the two mechanisms coexist with legacy INTx.
- Explain the key differences between MSI and MSI-X: the MSI vector count (1 to 32 from a contiguous block), the MSI-X vector count (up to 2048 independently-addressable vectors), and the per-vector address and mask capabilities MSI-X offers that MSI does not.
- Query a device's MSI and MSI-X capabilities through `pci_msi_count(9)` and `pci_msix_count(9)`, and know what the returned count means.
- Allocate MSI or MSI-X vectors through `pci_alloc_msi(9)` and `pci_alloc_msix(9)`, handle the case where the kernel allocates fewer vectors than requested, and recover from allocation failures.
- Build a three-tier fallback ladder: MSI-X first (if available), then MSI (if MSI-X is unavailable or allocation failed), then legacy INTx. Each tier uses the same `bus_setup_intr` pattern at its core, but the `rid` and handler-per-vector structure differ.
- Allocate per-vector IRQ resources with the correct `rid` (`rid=0` for legacy INTx; `rid=1, 2, 3, ...` for MSI and MSI-X vectors).
- Register a distinct filter handler per vector so that each vector has its own purpose (admin, receive-queue-N, transmit-queue-N, error).
- Design per-vector state (per-queue counters, per-queue task, per-queue lock) so that handlers running concurrently on different CPUs do not contend on shared data.
- Describe each vector with `bus_describe_intr(9)` so that `vmstat -i` and `devinfo -v` show each vector with a meaningful name.
- Bind each vector to a specific CPU with `bus_bind_intr(9)`, and query the device's NUMA-local CPU set with `bus_get_cpus(9)` using `LOCAL_CPUS` or `INTR_CPUS`.
- Handle partial-allocation failures: the device has eight vectors, the kernel gave us three; adjust the driver to use the three and do the remaining work through polling or scheduled tasks.
- Tear down a multi-vector driver correctly: per-vector `bus_tearardown_intr`, per-vector `bus_release_resource`, then a single `pci_release_msi(9)` at the end.

- Log a single clear dmesg summary line at attach time stating the interrupt mode (MSI-X / N vectors, MSI / K vectors, or legacy INTx), so the operator instantly sees which tier the driver ended up using.
- Split the multi-vector code into `myfirst_msix.c`, update the module's SRCS line, tag the driver as 1.3-`msi`, and produce `MSIX.md` documenting per-vector purposes and observed counter patterns.

The list is long; each item is narrow. The point of the chapter is the composition.

20.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 20 stays focused.

- **DMA.** `bus_dma(9)` tags, `bus_dmamap_load(9)`, scatter-gather lists, bounce buffers, cache coherence around DMA descriptors, and the way the device writes completions to RAM are Chapter 21. Chapter 20 gives the driver multiple vectors; Chapter 21 gives the device the ability to move data. Each half is independently valuable; together they are the backbone of every modern performance driver.
- **iflib(9) and the multi-queue networking framework.** `iflib` is a thick, opinionated framework that wraps MSI-X with per-queue ithreads, per-queue DMA pools, and a lot of machinery a generic driver does not need. Chapter 20 teaches the raw pattern; Part 6's networking chapter (Chapter 28) revisits it in `iflib`'s vocabulary.
- **PCIe AER recovery through MSI-X vectors.** Advanced Error Reporting can signal through its own MSI-X vector on some devices. Chapter 20 mentions the possibility; the full recovery path is a later-chapter topic.
- **SR-IOV and per-VF interrupts.** A Single-Root IO Virtualization virtual function has its own MSI-X capability and its own per-VF vectors. Chapter 20's driver is a physical function; the VF story is a later-chapter specialisation.
- **Thread priority tuning per vector.** A driver can pass a different priority to each vector's `bus_setup_intr` flags, or use `taskqueue_start_threads` at different priorities per vector. Chapter 20 uses `INTR_TYPE_MISC | INTR_MPSAFE` for each vector and does not tune priorities; Part 7's performance chapters (Chapter 33) cover the tuning story.
- **Modern-virtio-PCI transport using PCIe capabilities.** The `virtio_pci_modern(4)` driver puts the virtqueue notifications inside capability structures and uses MSI-X vectors for virtqueue completions. Chapter 20's driver still targets a legacy `virtio-rnd` BAR; a reader adapting it to a real production device would follow the Chapter 20 pattern but read from the modern virtio PCI layout.

Staying inside those lines keeps Chapter 20 a chapter about multi-vector interrupt handling. The vocabulary is what transfers; the specific chapters that follow apply the vocabulary to DMA, `iflib`, AER, and SR-IOV.

20.1.5 Estimated Time Investment

- **Reading only:** four to five hours. The MSI/MSI-X conceptual model is not complex, but the per-vector discipline, the fallback ladder, and the CPU-affinity story benefit from a careful read.
- **Reading plus typing the worked examples:** ten to twelve hours over two or three sessions. The driver evolves in four stages: fallback ladder, multiple vectors, per-vector handlers, refactor. Each stage is small but requires careful attention to per-vector state.

- **Reading plus all labs and challenges:** sixteen to twenty hours over four or five sessions, including reading real drivers (`virtio_pci.c`, `if_em.c`'s MSI-X code, `nvme.c`'s admin+IO vector split), setting up a bhyve or QEMU guest with MSI-X exposed, and running the chapter's regression test.

Sections 3, 5, and 6 are the densest. If the per-vector handler pattern feels unfamiliar on first pass, that is normal. Stop, re-read Section 3's diagram, and continue when the shape has settled.

20.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 19 Stage 4 (1.2-intr). The starting point assumes every Chapter 19 primitive: the filter plus task pipeline, the simulated-interrupt `sysctl`, the `ICSR_*` accessor macros, the clean teardown.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- `bhyve(8)` or `qemu-system-x86_64` is available. For MSI-X labs the guest must expose a device whose MSI-X capability is enabled. QEMU's `virtio-rng-pci` has MSI-X; bhyve's `virtio-rnd` uses legacy `virtio` and does not expose MSI-X on the host driver as a matter of default configuration. The chapter calls out which labs require which environment.
- The `devinfo(8)`, `vmstat(8)`, `pciconf(8)`, and `cpuset(1)` tools are in your path.

If any item above is shaky, fix it now. MSI-X tends to expose any latent weakness in the driver's interrupt-context discipline because multiple handlers can run on multiple CPUs at the same time; the debug kernel's `WITNESS` is especially valuable during Chapter 20 development.

20.1.7 How to Get the Most Out of This Chapter

Four habits will pay off quickly.

First, keep `/usr/src/sys/dev/pci/pci.h` and `/usr/src/sys/dev/pci/pcivar.h` bookmarked along with the new files `/usr/src/sys/dev/pci/pci.c` and `/usr/src/sys/dev/virtio/pci/virtio_pci.c`. The first two are from Chapter 18 and define the capability constants (`PCIY_MSI`, `PCIY_MSIX`, `PCIM_MSIXCTRL_*`) and the accessor wrappers. The third is the kernel's implementation of `pci_msi_count_method`, `pci_alloc_msi_method`, `pci_alloc_msix_method`, and `pci_release_msi_method`. The fourth is a clean real-driver example of the full MSI-X allocation ladder with fallback. Each file rewards half an hour of reading.

Second, run `pciconf -lvc` on your lab host and a guest. The `-c` flag tells `pciconf` to print each device's capability list, and you will see which devices expose MSI, MSI-X, or both. Looking at your own machine is the quickest way to understand why MSI-X is the default everywhere in modern PCIe.

Third, type the changes by hand and run each stage. MSI-X code is where subtle per-vector mistakes produce bugs that only appear under concurrent load. Typing carefully, watching `dmesg` for attach banners, and running the regression test after each stage catches these mistakes at the point where they are cheap to fix.

Fourth, read `/usr/src/sys/dev/nvme/nvme_ctrlr.c`'s MSI-X setup (look for `nvme_ctrlr_allocate_bar` and `nvme_ctrlr_construct_admin_qpair`) after Section 5. `nvme(4)` is a clean real-driver example of the

admin-plus-N-queues pattern that Chapter 20 teaches. The file is long but the MSI-X code is a small fraction of it; the rest of the reading is optional but educational.

20.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Are MSI and MSI-X?** The hardware picture: how message-signalled interrupts work over PCIe, the difference between MSI and MSI-X, and why modern devices prefer them.
2. **Enabling MSI in Your Driver.** The simpler of the two modes. Query count, allocate, register a handler. Stage 1 of the Chapter 20 driver (`1.3-msi-stage1`).
3. **Managing Multiple Interrupt Vectors.** The core of the chapter. Per-vector rid, per-vector filter function, per-vector softc state, per-vector `bus_describe_intr`. Stage 2 (`1.3-msi-stage2`).
4. **Designing Interrupt-Safe Data Structures.** Why multi-vector means multi-CPU, what locks each vector's handler may and may not touch, how to structure per-queue state. A discipline, not a stage bump.
5. **Using MSI-X for High Flexibility.** The fuller mechanism. Table layout, per-vector binding, NUMA-aware placement with `bus_get_cpus`. Stage 3 (`1.3-msi-stage3`).
6. **Handling Vector-Specific Events.** Per-vector handler functions, per-vector deferred work, a pattern the `nvme(4)` driver uses at scale.
7. **Teardown and Cleanup With MSI/MSI-X.** Per-vector teardown, then a single `pci_release_msi` call. The ordering rules that keep everything safe.
8. **Refactoring and Versioning Your Multi-Vector Driver.** The final split into `myfirst_msix.c`, the new `MSIX.md`, the version bump to `1.3-msi`, and the regression pass. Stage 4.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 20's story and opens Chapter 21's, and a bridge to Chapter 21. The reference-and-cheat-sheet material at the end of the chapter is meant to be re-read as you work through Chapter 21; Chapter 20's vocabulary (vector, rid, per-vector softc, affinity, teardown ordering) is the foundation Chapter 21's DMA work assumes.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3 and 5 stand alone and make good single-sitting reads.

20.2 Section 1: What Are MSI and MSI-X?

Before the driver code, the hardware picture. Section 1 teaches what message-signalled interrupts are at the level of the PCIe bus and the interrupt controller, without any FreeBSD-specific vocabulary. A reader who understands Section 1 can read the rest of the chapter with the kernel's MSI/MSI-X path as a concrete object rather than a vague abstraction.

20.2.1 The Problem With Legacy INTx

Chapter 19 taught the legacy PCI INTx interrupt model: each PCI function has one interrupt line (usually one of INTA, INTB, INTC, INTD), the line is level-triggered, and multiple devices on the same physical line

share it. Chapter 19's driver handled the shared case correctly by reading `INTR_STATUS` first and returning `FILTER_STRAY` when nothing was set.

INTx works. But it has three problems that grow in importance as systems scale.

The first is **sharing overhead**. A shared line with ten devices requires every driver to be called on every interrupt, just to read its own status register and discover the interrupt was not for it. On a system where most interrupts are legitimate (the line is busy), this is a few extra `bus_read_4` calls per event; on a system where one device storms, every other driver's filter runs unnecessarily. The CPU cost is small per event but adds up across millions of events per second.

The second is **no per-queue separation**. A modern NIC has four, eight, sixteen, or sixty-four receive queues and a matching number of transmit queues. Each queue wants its own interrupt: when receive queue 3 has packets, only the handler for receive queue 3 should run, on a CPU close to the memory that queue uses. With INTx the device has only one line, so either the driver polls every queue from one handler (expensive and slow) or the device only supports one queue (unacceptable for a ten-gigabit NIC).

The third is **no CPU affinity per event type**. A shared line fires on one CPU (whichever the interrupt controller routes it to). On a NUMA system where the device is attached to socket 0, firing the interrupt on a CPU in socket 1 is worse than firing it on a CPU in socket 0: the handler's code runs on socket 1 but the device's memory lives on socket 0, and every register read crosses the inter-socket fabric. With INTx the driver cannot say "please fire this interrupt on CPU 3"; the kernel picks and the driver has no influence per event type.

MSI and MSI-X fix all three. The mechanism is fundamentally different from INTx: instead of electrical signalling over a dedicated wire, the device performs a memory write to a specific address, and the CPU's interrupt controller treats the write as an interrupt. This decouples the number of interrupts from the number of physical wires, lets each message-signalled interrupt have its own destination address (and therefore its own CPU), and eliminates the shared-line problem entirely.

20.2.2 How an MSI-Triggered Interrupt Actually Happens

Physically, an MSI interrupt is a write transaction on the PCIe fabric. The device issues a write of a specific value to a specific address. The memory controller recognises the address as belonging to the interrupt controller's MSI region, and routes the write to the APIC (or GIC, or whatever the platform's interrupt controller is). The interrupt controller decodes the address to determine which CPU should receive the interrupt, and decodes the written value to determine which vector (which entry in the IDT or equivalent) the CPU should run. The CPU then dispatches as it would for any interrupt: save state, jump to the vector's handler, run the kernel's interrupt dispatch.

From the driver's perspective, the flow is almost identical to legacy INTx:

1. The device has an event.
2. The interrupt fires.
3. The kernel calls the driver's filter handler.
4. The filter reads status, acknowledges, handles or defers, returns.
5. If deferred, the task runs later.
6. Teardown proceeds in the detach path.

What differs is the mechanism at step 2 and the allocation model at setup time. The device is not asserting a wire; it is writing to memory. The kernel does not need to have a pre-arranged destination wire; it has a pool of

message addresses and message values. Each vector corresponds to one (address, value) pair. The device stores these pairs in its MSI capability structure and issues a write using them when it needs an interrupt.

20.2.3 MSI: The Simpler of the Two

MSI (Message Signalled Interrupts) is the older and simpler of the two mechanisms. Introduced in PCI 2.2 in 1999, MSI lets a device request between 1 and 32 interrupt vectors, allocated as a contiguous power-of-two block (1, 2, 4, 8, 16, or 32). The device has a single MSI capability structure in its configuration space, which contains:

- A message address register (the write's destination address, typically the APIC's MSI region).
- A message data register (the value written, which encodes the vector number).
- A message control register (enable bit, function mask bit, number of vectors requested, and so on).

When the device wants to signal vector *N* (where *N* is 0 through count-1), it writes the message data register's base value OR'd with *N* to the message address. The interrupt controller demultiplexes the written value to dispatch the correct vector.

Key properties of MSI:

- **Single capability block.** The device has one MSI capability, not one per vector.
- **Contiguous vectors.** The block is power-of-two and allocated as a unit.
- **Limited count.** Maximum 32 vectors per function.
- **No per-vector masking.** The whole block is masked or unmasked as a group (via the function-mask bit if supported).
- **No per-vector address.** All vectors share a single message address register; the vector number goes in the low bits of the data written.

MSI is a significant improvement over legacy INTx, but it has limits: no per-vector masking and a 32-vector cap. Most drivers that want multiple vectors end up preferring MSI-X.

20.2.4 MSI-X: The Fuller Mechanism

MSI-X, introduced in PCI 3.0 in 2004 and extended in PCIe, removes MSI's limits. The device has an MSI-X capability structure plus an MSI-X **table** (an array of per-vector entries) and a **pending bit array** (PBA). The capability structure points into one or more of the device's BARs, where the table and PBA live.

Each MSI-X table entry contains:

- A message address register (per-vector).
- A message data register (per-vector).
- A vector control register (per-vector mask bit).

When the device wants to signal vector *N*, it looks up entry *N* in the table, reads that entry's address and data, and performs the write. The interrupt controller dispatches based on what was written.

Key properties of MSI-X:

- **Per-vector address and data.** Each vector can be routed to a different CPU by programming a different address.

- **Per-vector mask.** Individual vectors can be disabled without disabling the whole block.
- **Up to 2048 vectors per function.** An NVMe controller with many queues is happy here; a NIC with 64 receive queues plus 64 transmit queues plus some admin vectors fits.
- **Table in a BAR.** The table's location is discoverable through the MSI-X capability registers; `pci_msix_table_bar(9)` and `pci_msix_pba_bar(9)` return which BAR holds each.
- **More complex setup.** The driver has to allocate the table, program each entry, and then enable.

In practice, modern PCIe devices prefer MSI-X for any multi-vector use case, and reserve MSI for backwards compatibility or single-vector simple devices. The kernel handles most of the table programming internally; the driver's job is to query the count, allocate, and register per-vector handlers.

20.2.5 How FreeBSD Abstracts the Difference

The kernel hides most of the MSI-vs-MSI-X difference behind a small set of accessor functions. From `/usr/src/sys/dev/pci/pcivar.h`:

- `pci_msi_count(dev)` returns the MSI vector count the device advertises (0 if no MSI capability).
- `pci_msix_count(dev)` returns the MSI-X vector count (0 if no MSI-X capability).
- `pci_alloc_msi(dev, &count)` and `pci_alloc_msix(dev, &count)` allocate vectors. The count is an input-output: input is the desired count, output is the actual count allocated.
- `pci_release_msi(dev)` releases both MSI and MSI-X vectors (it handles either case internally).

The driver does not interact with the MSI-X table directly; the kernel does that on the driver's behalf. What the driver does see is that after a successful allocation, the device appears to have additional IRQ resources available through `bus_alloc_resource_any(9)` with `SYS_RES_IRQ`, using `rid = 1, 2, 3, ...` for the allocated vectors. The driver then registers a filter handler for each resource the same way Chapter 19 registered one for the legacy line.

The symmetry is deliberate. The same `bus_setup_intr(9)` call that handled the legacy IRQ at `rid = 0` handles each MSI or MSI-X vector at `rid = 1, 2, 3, ...`. Every `INTR_MPSAFE` rule, every `FILTER_*` return-value convention, every shared-IRQ discipline (for MSI, where vectors can technically share an `intr_event` in corner cases), and every teardown ordering from Chapter 19 carries through.

20.2.6 The Fallback Ladder

A robust driver tries the mechanisms in order of preference and falls back to the next one when allocation fails. The canonical ladder:

1. **MSI-X first.** If `pci_msix_count(dev)` is non-zero, try `pci_alloc_msix(dev, &count)`. If it succeeds, use MSI-X. On a modern PCIe device this is the preferred path.
2. **MSI second.** If MSI-X is unavailable or the allocation failed, check `pci_msi_count(dev)`. If it is non-zero, try `pci_alloc_msi(dev, &count)`. If it succeeds, use MSI.
3. **Legacy INTx last.** If both MSI-X and MSI are unavailable, fall back to the Chapter 19 legacy path with `rid = 0`.

Real drivers implement this ladder so they work on every system they might land on, from a brand-new NVMe drive that only supports MSI-X to a legacy chipset that only supports INTx. The Chapter 20 driver does the

same; Section 2 writes the MSI path, Section 5 writes the MSI-X path, and Section 8 ties them together into a single fallback ladder.

20.2.7 Real-World Examples

A short tour of devices that use MSI and MSI-X.

Modern NICs. A typical 10 or 25 Gbps NIC exposes 16 to 64 MSI-X vectors: one per receive queue, one per transmit queue, and a handful for admin, error, and link-state events. Intel's `igc(4)`, `em(4)`, `ix(4)`, and `ixl(4)` all follow this pattern; Broadcom's `bnxt(4)`, Mellanox's `mlx4(4)` and `mlx5(4)`, and Chelsio's `cxgbe(4)` do the same. The `iflib(9)` framework wraps the MSI-X allocation for many drivers.

NVMe storage controllers. An NVMe controller has one admin queue and up to 65535 I/O queues. In practice, drivers allocate one MSI-X vector for the admin queue and one per I/O queue up to NCPU. FreeBSD's `nvme(4)` driver does exactly this; the code is readable and worth studying.

Modern USB host controllers. An xHCI (USB 3) host controller typically advertises one MSI-X vector for the command-completion event ring and several more for per-slot event rings on high-performance variants. The `xhci(4)` driver's setup path shows the admin-plus-events pattern.

GPUs. A modern discrete GPU has many MSI-X vectors: one for the command buffer, one or more for display, one per engine, one for power management, and others. The out-of-tree `drm-kmod` drivers exercise MSI-X extensively.

Virtio devices in VMs. When a FreeBSD guest runs under bhyve, KVM, or VMware, the modern virtio-PCI transport uses MSI-X: one vector for configuration-change events, and one per virtqueue. The `virtio_pci_modern(4)` driver implements this.

Each of these drivers follows the same pattern Chapter 20 teaches: query, allocate, register per-vector handlers, bind to CPUs, describe. The specifics differ (how many vectors, how they are assigned to events, how they are bound to CPUs), but the structure is constant.

20.2.8 Why MSI-X and Not MSI

A reader might ask: given that MSI-X is strictly more capable than MSI, why does MSI even exist any more? Two reasons.

The first is backward compatibility. Devices and motherboards predating PCI 3.0 may support MSI but not MSI-X. A driver that wants to work on old hardware needs an MSI fallback. Most of the ecosystem has moved forward, but the long tail of older devices still exists.

The second is simplicity. MSI with one or two vectors is simpler to set up than MSI-X (no table to program, no BAR to consult). For devices whose interrupt needs fit within MSI's 32-vector cap and do not need per-vector masking, MSI is the lighter-weight choice. Many simple PCIe devices expose only MSI for this reason.

The practical answer for Chapter 20's driver: always try MSI-X first, fall back to MSI if MSI-X is unavailable, fall back to legacy INTx if neither is available. Every real FreeBSD driver written in the last decade uses this ladder.

20.2.9 A Diagram of the MSI-X Flow

The diagram elides the MSI-X-table reads (which the device performs internally before issuing the write) and the interrupt-controller’s demultiplexing logic, but it captures the mechanism’s essence: the device’s event triggers a memory write, the memory write becomes an interrupt, the interrupt dispatches to a filter. The filter does the same work Chapter 19’s filter did. The only difference is that on MSI-X, there is a different filter for each vector.

20.2.10 Exercise: Finding MSI-Capable Devices on Your System

Before moving to Section 2, a short exercise to make the capability picture concrete.

On your lab host, run:

```
sudo pciconf -lvc
```

The -c flag tells pciconf(8) to print each device’s capability list. You will see entries like:

```
vgapci0@pci0:0:2:0: ...
...
```

```
cap 05[d0] = MSI supports 1 message, 64 bit
cap 10[a0] = PCI-Express 2 endpoint max data 128(128)
em0@pci0:0:25:0: ...
...
cap 01[c8] = powerspec 2 supports D0 D3 current D0
cap 05[d0] = MSI supports 1 message, 64 bit
cap 11[e0] = MSI-X supports 4 messages
```

Each `cap 05` is an MSI capability. Each `cap 11` is an MSI-X capability. The description after the equals sign tells you how many messages (vectors) the device supports in that mode.

Pick three devices from your output. For each, note:

- The MSI count (if any).
- The MSI-X count (if any).
- Which one the driver is currently using. (You can deduce this from `vmstat -i` entries for the device: if you see multiple `name:queueN` lines, the driver is using MSI-X.)

A host without many PCIe devices may show only MSI capabilities; laptops often have limited MSI-X use. A modern server with multiple NICs and an NVMe drive shows many MSI-X capabilities with high vector counts (64 or more for some NICs).

Keep this output open while you read Section 2. The vocabulary of “`cap 11[XX] = MSI-X supports N messages`” is what the kernel’s `pci_msix_count(9)` returns to the driver, and what the allocation ladder queries at attach time.

20.2.11 Wrapping Up Section 1

MSI and MSI-X are the modern, message-signalled successors to legacy INTx. MSI offers up to 32 vectors allocated as a contiguous block with a single destination address; MSI-X offers up to 2048 vectors with per-vector addresses, per-vector data, and per-vector masking. Both are signalled over PCIe as memory writes that the interrupt controller decodes into vector dispatches.

The kernel abstracts the difference behind `pci_msi_count(9)`, `pci_msix_count(9)`, `pci_alloc_msi(9)`, `pci_alloc_msix(9)`, and `pci_release_msi(9)`. Each allocated vector becomes an IRQ resource at `rid = 1, 2, 3, ...` that the driver registers a filter handler for via `bus_setup_intr(9)`, exactly as Chapter 19 did for the legacy IRQ at `rid = 0`.

A robust driver implements a three-tier fallback ladder: MSI-X preferred, MSI as fallback, legacy INTx as last resort. Section 2 writes the MSI part of that ladder. Section 5 writes the MSI-X part. Section 8 assembles the full ladder.

20.3 Section 2: Enabling MSI in Your Driver

Section 1 established the hardware model. Section 2 puts the driver to work. The task is narrow: extend Chapter 19’s attach path so that before falling back to the legacy IRQ at `rid = 0`, the driver tries to allocate an MSI

vector. If the allocation succeeds, the driver uses the MSI vector instead of the legacy line. If the allocation fails (either because the device does not support MSI or the kernel cannot allocate), the driver falls back to the legacy path exactly as Chapter 19's code did.

The point of Section 2 is to introduce the MSI API in isolation, before the multi-vector complications of MSI-X make the picture busier. A single-vector MSI path is essentially the same as a single-vector legacy INTx path; only the allocation call and the rid change. That minimal change makes a good first stage.

20.3.1 What Stage 1 Produces

Stage 1 extends the Chapter 19 Stage 4 driver with a two-tier fallback: MSI first, legacy INTx as fallback. The filter handler is the same Chapter 19 filter. The taskqueue is the same. The sysctls are the same. What changes is the allocation path: `myfirst_intr_setup` first checks `pci_msi_count(9)` and, if non-zero, calls `pci_alloc_msi(9)` for one vector. If that succeeds, the IRQ resource is at `rid = 1`; if it fails, the driver falls through to `rid = 0` for legacy INTx.

The driver also logs the interrupt mode in a single `dmesg` line so the operator knows at a glance which tier the driver ended up using. This is a small but important observability feature that every real FreeBSD driver implements; Chapter 20 follows the convention.

20.3.2 The MSI Count Query

The first step is to ask the device how many MSI vectors it advertises:

```
int msi_count = pci_msi_count(sc->dev);
```

The return value is 0 if the device has no MSI capability; otherwise it is the number of vectors the device advertises in its MSI capability control register. Typical values are 1, 2, 4, 8, 16, or 32 (MSI requires a power-of-two count up to 32).

A return of 0 does not mean the device has no interrupts; it means the device does not expose MSI. The driver should fall through to the next tier.

20.3.3 The MSI Allocation Call

The second step is to ask the kernel to allocate the vectors:

```
int count = 1;
int error = pci_alloc_msi(sc->dev, &count);
```

The count is an input-output parameter. On input, it is the number of vectors the driver wants. On output, it is the number the kernel actually allocated. The kernel is allowed to allocate fewer than requested; a driver that needs at least a specific count must check the returned value.

For Chapter 20 Stage 1, the driver requests one vector. If the kernel returns 1, the driver proceeds. If the kernel returns 0 (rare but possible on a contended system) or returns an error, the driver releases any allocation and falls back to legacy INTx.

A subtle point: even when `pci_alloc_msi` returns non-zero, the driver **must** call `pci_release_msi(dev)` to undo the allocation at teardown time. Unlike `bus_alloc_resource_any` / `bus_release_resource`, the MSI family uses a single `pci_release_msi` call that undoes all vectors allocated via either `pci_alloc_msi` or `pci_alloc_msix` on the device.

20.3.4 The Per-Vector Resource Allocation

With MSI vectors allocated at the device level, the driver must now allocate a `SYS_RES_IRQ` resource for each vector. For a single MSI vector, the rid is 1:

```
int rid = 1; /* MSI vectors start at rid 1 */
struct resource *irq_res;

irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ, &rid, RF_ACTIVE);
if (irq_res == NULL) {
    /* Release the MSI allocation and fall back. */
    pci_release_msi(sc->dev);
    goto fallback;
}
```

Note two differences from Chapter 19's legacy allocation:

First, **rid is 1, not 0**. MSI vectors are numbered starting from 1, leaving rid 0 for legacy INTx. If the driver ever used both (which it should not), the rids would not overlap.

Second, **RF_SHAREABLE is not set**. MSI vectors are per-function; they are not shared with other drivers. The `RF_SHAREABLE` flag is only relevant for legacy INTx. Setting it on an MSI resource allocation does no harm, but it is not meaningful.

20.3.5 The Filter Handler on an MSI Vector

The filter handler function is identical to Chapter 19's:

```
int myfirst_intr_filter(void *arg);
```

The kernel calls the filter when the vector fires, exactly as it called the Chapter 19 filter when the legacy line asserted. The filter reads `INTR_STATUS`, acknowledges, enqueues the task for `DATA_AV`, and returns `FILTER_HANDLED` (or `FILTER_STRAY` on no-bit). Nothing about the filter's body needs to change.

`bus_setup_intr(9)` is called identically:

```
error = bus_setup_intr(sc->dev, irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->intr_cookie);
```

The function signature, the flags, the argument (sc), and the out-cookie are all the Chapter 19 pattern.

A small improvement: `bus_describe_intr(9)` can now label the vector with a mode-specific name:

```
bus_describe_intr(sc->dev, irq_res, sc->intr_cookie, "msi");
```

After this, `vmstat -i` shows the handler as `irq<N>: myfirst0:msi` (for some N the kernel chose). The operator instantly sees the driver is using MSI.

20.3.6 Building the Fallback

Putting it all together, the Stage 1 `myfirst_intr_setup` becomes a fallback ladder with two tiers: try MSI first, fall back to legacy INTx. The code:

```
int
myfirst_intr_setup(struct myfirst_softc *sc)
{
    int error, msi_count, count;

    TASK_INIT(&sc->intr_data_task, 0, myfirst_intr_data_task_fn, sc);
    sc->intr_tq = taskqueue_create("myfirst_intr", M_WAITOK,
        taskqueue_thread_enqueue, &sc->intr_tq);
    taskqueue_start_threads(&sc->intr_tq, 1, PI_NET,
        "myfirst intr taskq");

    /*
     * Tier 1: attempt MSI.
     */
    msi_count = pci_msi_count(sc->dev);
    if (msi_count > 0) {
        count = 1;
        if (pci_alloc_msi(sc->dev, &count) == 0 && count == 1) {
            sc->irq_rid = 1;
            sc->irq_res = bus_alloc_resource_any(sc->dev,
                SYS_RES_IRQ, &sc->irq_rid, RF_ACTIVE);
            if (sc->irq_res != NULL) {
                error = bus_setup_intr(sc->dev, sc->irq_res,
                    INTR_TYPE_MISC | INTR_MPSAFE,
                    myfirst_intr_filter, NULL, sc,
                    &sc->intr_cookie);
                if (error == 0) {
                    bus_describe_intr(sc->dev,
                        sc->irq_res, sc->intr_cookie,
                        "msi");
                    sc->intr_mode = MYFIRST_INTR_MSI;
                }
            }
        }
    }
}
```

```

        device_printf(sc->dev,
            "interrupt mode: MSI, 1 vector\n");
        goto enabled;
    }
    bus_release_resource(sc->dev,
        SYS_RES_IRQ, sc->irq_rid, sc->irq_res);
    sc->irq_res = NULL;
}
pci_release_msi(sc->dev);
}
}

/*
 * Tier 2: fall back to legacy INTx.
 */
sc->irq_rid = 0;
sc->irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ,
    &sc->irq_rid, RF_SHAREABLE | RF_ACTIVE);
if (sc->irq_res == NULL) {
    device_printf(sc->dev, "cannot allocate legacy IRQ\n");
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (ENXIO);
}
error = bus_setup_intr(sc->dev, sc->irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->intr_cookie);
if (error != 0) {
    bus_release_resource(sc->dev, SYS_RES_IRQ,
        sc->irq_rid, sc->irq_res);
    sc->irq_res = NULL;
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (error);
}
bus_describe_intr(sc->dev, sc->irq_res, sc->intr_cookie, "legacy");
sc->intr_mode = MYFIRST_INTR_LEGACY;
device_printf(sc->dev,
    "interrupt mode: legacy INTx (rid=0)\n");

enabled:
    /* Enable interrupts at the device. */
    MYFIRST_LOCK(sc);

```

```

if (sc->hw != NULL)
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
        MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR |
        MYFIRST_INTR_COMPLETE);
MYFIRST_UNLOCK(sc);

return (0);
}

```

The code has three distinct blocks:

1. The MSI attempt block (lines inside the `if (msi_count > 0)` guard).
2. The legacy fallback block.
3. The enabling block at `enabled:` that runs regardless of tier.

The MSI attempt does the full sequence: count query, allocate, allocate the IRQ resource at rid 1, register the handler. If any step fails, the code releases whatever succeeded (the resource if allocated, the MSI if successfully allocated) and falls through.

The legacy fallback is essentially the Chapter 19 setup, unchanged.

The `enabled:` block writes `INTR_MASK` at the device. Whether we got MSI or legacy, the device-side mask is the same.

The fallback structure is what real drivers do. A reader looking at `virtio_pci.c`'s setup code will see the same pattern at larger scale: several attempts with successive fallbacks.

20.3.7 The `intr_mode` Field and the `dmesg` Summary

The `softc` gains a new field:

```

enum myfirst_intr_mode {
    MYFIRST_INTR_LEGACY = 0,
    MYFIRST_INTR_MSI = 1,
    MYFIRST_INTR_MSIX = 2,
};

struct myfirst_softc {
    /* ... existing fields ... */
    enum myfirst_intr_mode intr_mode;
};

```

The field records which tier the driver ended up using. The attach-time `device_printf` prints it:

```
myfirst0: interrupt mode: MSI, 1 vector
```

or:

```
myfirst0: interrupt mode: legacy INTx (rid=0)
```

Operators reading `dmesg` see this line and know which path is active. The reader debugging their driver sees it too; if the driver is falling back to legacy when the reader expected MSI, the line flags the problem immediately.

The `intr_mode` field is also exposed through a read-only sysctl so that user-space tools can read it:

```
SYSCTL_ADD_INT(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, "intr_mode",
    CTLFLAG_RD, &sc->intr_mode, 0,
    "Interrupt mode: 0=legacy, 1=MSI, 2=MSI-X");
```

A script that wants to know whether any `myfirst` instance is using MSI-X can sum the `intr_mode` values across all units.

20.3.8 What the Teardown Needs to Change

The teardown path in Chapter 19 called `bus_teardown_intr`, drained and freed the taskqueue, and released the IRQ resource. For Stage 1, one additional call is needed: if the driver used MSI, it must call `pci_release_msi` after releasing the IRQ resource:

```
void
myfirst_intr_teardown(struct myfirst_softc *sc)
{
    /* Disable at the device. */
    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);

    /* Tear down the handler. */
    if (sc->intr_cookie != NULL) {
        bus_teardown_intr(sc->dev, sc->irq_res, sc->intr_cookie);
        sc->intr_cookie = NULL;
    }

    /* Drain and destroy the taskqueue. */
    if (sc->intr_tq != NULL) {
```

```

    taskqueue_drain(sc->intr_tq, &sc->intr_data_task);
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
}

/* Release the IRQ resource. */
if (sc->irq_res != NULL) {
    bus_release_resource(sc->dev, SYS_RES_IRQ, sc->irq_rid,
        sc->irq_res);
    sc->irq_res = NULL;
}

/* Release MSI if used. */
if (sc->intr_mode == MYFIRST_INTR_MSI ||
    sc->intr_mode == MYFIRST_INTR_MSIX)
    pci_release_msi(sc->dev);

sc->intr_mode = MYFIRST_INTR_LEGACY;
}

```

The `pci_release_msi` call is conditional: only call it if the driver actually allocated MSI or MSI-X. Calling it when the driver used only legacy INTx is a no-op in modern FreeBSD, but the condition is clearer.

Notice the ordering: IRQ resource release first, then `pci_release_msi`. This is the opposite of the allocation order (where `pci_alloc_msi` preceded `bus_alloc_resource_any`). The rule is the general teardown rule from Chapter 18 and 19: undo in reverse order of setup.

20.3.9 Verifying Stage 1

On a guest where the device supports MSI (QEMU's `virtio-rng-pci` does; bhyve's `virtio-rnd` does not), the Stage 1 driver should attach with MSI:

```

myfirst0: <Red Hat Virtio entropy source (myfirst demo target)> ... on pci0
myfirst0: BAR0 allocated: 0x20 bytes at 0xfebf1000
myfirst0: hardware layer attached to BAR: 32 bytes
myfirst0: interrupt mode: MSI, 1 vector

```

On a guest where the device supports only legacy (bhyve's `virtio-rnd` typically):

```

myfirst0: BAR0 allocated: 0x20 bytes at 0xc1000000
myfirst0: hardware layer attached to BAR: 32 bytes
myfirst0: interrupt mode: legacy INTx (rid=0)

```

Both cases are correct. The driver runs in either mode; the behaviour (filter, task, counters, simulated-interrupt `sysctl`) is identical.

`sysctl dev.myfirst.0.intr_mode` returns 0 (legacy), 1 (MSI), or 2 (MSI-X, once Section 5 adds it). The regression script uses this to verify the expected mode.

20.3.10 What Stage 1 Does Not Do

Stage 1 adds MSI with one vector but does not yet use MSI's multi-vector potential. A single MSI vector is functionally almost identical to a single legacy IRQ (it only gains the scalability benefits on a system with many devices, which a single-device lab rarely shows). The value of Stage 1 is that it introduces the fallback ladder idiom and establishes the `intr_mode` observability; Stage 2 and beyond use those foundations to add multi-vector handling.

20.3.11 Common Mistakes at This Stage

A short list.

Using `rid = 0` for MSI. The MSI vector's `rid` is 1, not 0. Requesting `rid = 0` on a device that has allocated MSI vectors returns the legacy INTx resource, which is not the MSI vector. The driver ends up with a handler on the wrong line. Fix: `rid = 1` for the first MSI or MSI-X vector.

Forgetting `pci_release_msi` at teardown. The kernel's MSI allocation state survives `bus_release_resource` on the IRQ resource. Without `pci_release_msi`, the next attach attempt will fail because the kernel still thinks the driver owns the MSI vectors. Fix: always call `pci_release_msi` in teardown when MSI or MSI-X was used.

Forgetting the INTx fallback. A driver that only tries MSI and returns an error on failure works on systems that support MSI but fails on older systems. Fix: always provide a legacy INTx fallback.

Forgetting to restore `sc->intr_mode` on teardown. The `intr_mode` field records the tier. Without resetting, a future reattach could read a stale value. Not a serious bug (attach always sets it), but cleanliness matters. Fix: reset to LEGACY (or a neutral value) in teardown.

Mismatching the count. `pci_alloc_msi` can allocate fewer vectors than requested; if the driver assumes `count == 1` when it is 0, the code dereferences an un-allocated resource. Fix: always check the returned count.

Calling `pci_alloc_msi` twice without release. Only one MSI (or MSI-X) allocation can be active per device at a time. Attempting a second allocation without releasing the first returns an error. Fix: if the driver wants to change its allocation (from MSI to MSI-X, say), call `pci_release_msi` first.

20.3.12 Checkpoint: Stage 1 Working

Before Section 3, confirm Stage 1 is in place:

- `kldstat -v | grep myfirst` shows version 1.3-`msi-stage1`.
- `dmesg | grep myfirst` shows the attach banner with an `interrupt mode:` line indicating either MSI or legacy.

- `sysctl dev.myfirst.0.intr_mode` returns 0 or 1.
- `vmstat -i | grep myfirst` shows the handler with either `myfirst0:msi` or `myfirst0:legacy` as the descriptor.
- `sudo sysctl dev.myfirst.0.intr_simulate=1` still drives the Chapter 19 pipeline.
- `kldunload myfirst` runs cleanly; no leaks.

If the MSI path fails on your guest, try QEMU instead of bhyve. If the MSI path works on one and not the other, verify the device's MSI capability is exposed through `pciconf -lvc`.

20.3.13 Wrapping Up Section 2

Enabling MSI in a driver is three new calls (`pci_msi_count`, `pci_alloc_msi`, `pci_release_msi`), one change to the IRQ resource allocation (`rid = 1` instead of 0), and one new softc field (`intr_mode`). The fallback ladder adds a second tier: try MSI, fall back to legacy. Every `bus_setup_intr`, every filter, every taskqueue task, and every teardown step from Chapter 19 carries through unchanged.

Stage 1 handles a single MSI vector. Section 3 moves to multi-vector: several different filter functions, several per-vector softc states, and the beginning of the per-queue handler pattern that modern drivers use extensively.

20.4 Section 3: Managing Multiple Interrupt Vectors

Stage 1 added MSI with one vector. Section 3 extends the driver to handle multiple vectors, each with its own role. The motivating example is the device that has more than one thing to say: a NIC with a receive queue and a transmit queue, an NVMe controller with admin and I/O queues, a UART with receive-ready and transmit-empty events.

The Chapter 20 driver does not have a real multi-queue device; the `virtio-rnd` target has at most a single event class per interrupt. For teaching purposes, we simulate multi-vector behaviour the same way Chapter 19 simulated interrupts: the `sysctl` interface lets the reader fire simulated interrupts against specific vectors, and the driver's filter and task machinery demonstrates how real drivers handle multi-vector cases.

By the end of Section 3 the driver is at version `1.3-msi-stage2` and has three MSI-X vectors: an admin vector, an "rx" vector, and a "tx" vector. Each vector has its own filter function, its own deferred task, and its own counters. The filter reads `INTR_STATUS` and acknowledges only the bits relevant to its vector; the task does the vector-specific work.

An important note about the three-vector count. MSI is constrained to a power-of-two vector count (1, 2, 4, 8, 16, or 32), so a request for exactly 3 vectors is rejected by `pci_alloc_msi(9)` with `EINVAL` (see `/usr/src/sys/dev/pci/pci.c`'s `pci_alloc_msi_method`). MSI-X has no such restriction and readily allocates 3 vectors. The MSI tier of the fallback ladder therefore requests a single MSI vector and falls back to the Chapter 19 single-handler pattern; only the MSI-X tier gives the driver its three per-vector filters. Section 5 makes this explicit and Section 8's refactor keeps the MSI tier simple.

20.4.1 The Per-Vector Design

The design has three vectors:

- **Admin vector (vector 0, rid 1).** Handles ERROR and configuration-change events. Low rate; runs rarely.
- **RX vector (vector 1, rid 2).** Handles DATA_AV events (receive-ready). Runs at data-path rate.
- **TX vector (vector 2, rid 3).** Handles COMPLETE events (transmit-complete). Runs at data-path rate.

Each vector has:

- A separate struct resource * (the IRQ resource for that vector).
- A separate void *intr_cookie (the kernel's opaque handle for the handler).
- A separate filter function (myfirst_admin_filter, myfirst_rx_filter, myfirst_tx_filter).
- A separate set of counters (so per-CPU concurrent filter runs do not fight over a single shared counter).
- A separate bus_describe_intr name (admin, rx, tx).
- A separate deferred task (for RX; admin and TX handle their work inline).

The per-vector state lives in an array of per-vector structures inside the softc:

```
#define MYFIRST_MAX_VECTORS 3

enum myfirst_vector_id {
    MYFIRST_VECTOR_ADMIN = 0,
    MYFIRST_VECTOR_RX,
    MYFIRST_VECTOR_TX,
};

struct myfirst_vector {
    struct resource      *irq_res;
    int                  irq_rid;
    void                 *intr_cookie;
    enum myfirst_vector_id id;
    struct myfirst_softc *sc;
    uint64_t             fire_count;
    uint64_t             stray_count;
    const char           *name;
    driver_filter_t       *filter;
    struct task           task;
    bool                  has_task;
};

struct myfirst_softc {
    /* ... existing fields ... */
    struct myfirst_vector vectors[MYFIRST_MAX_VECTORS];
    int                  num_vectors; /* actually allocated */
};
```

A few design notes worth unpacking.

Per-vector struct myfirst_softc *sc back-pointer. The argument each filter receives via bus_setup_intr is the per-vector structure (struct myfirst_vector *), not the global softc. The per-vector structure contains

a back-pointer to the softc so the filter can reach shared state when needed. This is the pattern `nvme(4)` uses for per-queue vectors and the pattern every multi-queue driver follows.

Per-vector counters. Each vector has its own `fire_count` and `stray_count`. Two filters running on two CPUs can increment their own counters without atomic contention; atomics are still used, but each atomic hits a different cache line.

Per-vector filter pointer. The `filter` field stores a pointer to the vector's filter function. This is not strictly required (we could have a switch in a single generic filter), but it makes the per-vector specialisation explicit: each vector's filter is statically known.

Per-vector task. Not every vector needs a task. Admin and TX do their work inline (increment a counter, update a flag, maybe wake a waiter). RX defers to a task because it wants to broadcast a condition variable, which requires thread context. The `has_task` flag makes the per-vector difference explicit.

20.4.2 The Filter Functions

Three distinct filter functions, one per vector:

```
int
myfirst_admin_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
    if ((status & (MYFIRST_INTR_ERROR)) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }

    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_ERROR);
    atomic_add_64(&sc->intr_error_count, 1);
    return (FILTER_HANDLED);
}

int
myfirst_rx_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
```

```

    if ((status & MYFIRST_INTR_DATA_AV) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }

    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_DATA_AV);
    atomic_add_64(&sc->intr_data_av_count, 1);
    if (sc->intr_tq != NULL)
        taskqueue_enqueue(sc->intr_tq, &vec->task);
    return (FILTER_HANDLED);
}

int
myfirst_tx_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
    if ((status & MYFIRST_INTR_COMPLETE) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }

    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_COMPLETE);
    atomic_add_64(&sc->intr_complete_count, 1);
    return (FILTER_HANDLED);
}

```

Each filter has the same shape: read status, check the bit this vector cares about, acknowledge, update counters, optionally enqueue a task, return. The differences are which bit each filter cares about and which counters each increments.

Several details worth noticing.

The stray check is per-vector. Each filter checks for its own bit, not for any bit. If the filter is called for an event it does not handle (because the bit set is for a different vector), the filter returns `FILTER_STRAY`. This matters less for MSI-X (where each vector has its own dedicated message, so the device never fires the “wrong” vector), but it matters more for MSI with multiple vectors sharing a single capability.

Counter sharing. The per-vector counters (`vec->fire_count`, `vec->stray_count`) are specific to the vector. The global counters (`sc->intr_data_av_count`, etc.) are shared and still used for the chapter’s per-bit observability. Having both gives the reader a way to cross-check: the RX filter’s fire count should approximately

equal the global `data_av_count`.

The filter does not sleep. All of the Chapter 19 filter-context rules carry through: no sleep locks, no `malloc(M_WAITOK)`, no blocking. The filter uses only atomics and direct BAR accesses.

20.4.3 The Per-Vector Task

Only RX has a task; admin and TX handle their work in the filter. The RX task is essentially the Chapter 19 task:

```
static void
myfirst_rx_task_fn(void *arg, int npending)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->pci_attached) {
        sc->intr_last_data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
        sc->intr_task_invocations++;
        cv_broadcast(&sc->data_cv);
    }
    MYFIRST_UNLOCK(sc);
}
```

The task runs in thread context on the shared `intr_tq` taskqueue (Chapter 19 created it at `PI_NET` priority). The same taskqueue serves all per-vector tasks; for a driver with truly independent per-queue work, each vector might have its own taskqueue, but Chapter 20 uses one.

20.4.4 Allocating Multiple Vectors

The setup code for Stage 2 is longer than Stage 1 because it handles multiple vectors:

```
int
myfirst_intr_setup(struct myfirst_softc *sc)
{
    int error, wanted, allocated, i;

    TASK_INIT(&sc->vectors[MYFIRST_VECTOR_RX].task, 0,
              myfirst_rx_task_fn, &sc->vectors[MYFIRST_VECTOR_RX]);
    sc->vectors[MYFIRST_VECTOR_RX].has_task = true;
    sc->vectors[MYFIRST_VECTOR_ADMIN].filter = myfirst_admin_filter;
    sc->vectors[MYFIRST_VECTOR_RX].filter = myfirst_rx_filter;
    sc->vectors[MYFIRST_VECTOR_TX].filter = myfirst_tx_filter;
```

```

sc->vectors[MYFIRST_VECTOR_ADMIN].name = "admin";
sc->vectors[MYFIRST_VECTOR_RX].name = "rx";
sc->vectors[MYFIRST_VECTOR_TX].name = "tx";
for (i = 0; i < MYFIRST_MAX_VECTORS; i++) {
    sc->vectors[i].id = i;
    sc->vectors[i].sc = sc;
}

sc->intr_tq = taskqueue_create("myfirst_intr", M_WAITOK,
    taskqueue_thread_enqueue, &sc->intr_tq);
taskqueue_start_threads(&sc->intr_tq, 1, PI_NET,
    "myfirst intr taskq");

/*
 * Try to allocate a single MSI vector. MSI requires a power-of-two
 * count (PCI specification and /usr/src/sys/dev/pci/pci.c's
 * pci_alloc_msi_method enforces this), so we cannot request the
 * MYFIRST_MAX_VECTORS = 3 we want; we ask for 1 and fall back to
 * the Chapter 19 single-handler pattern at rid=1, the same way
 * sys/dev/virtio/pci/virtio_pci.c's vtpci_alloc_msi() does.
 *
 * MSI-X, covered in Section 5, is the tier where we actually
 * obtain three distinct vectors; MSI-X is not constrained to
 * power-of-two counts.
 */
allocated = 1;
if (pci_msi_count(sc->dev) >= 1 &&
    pci_alloc_msi(sc->dev, &allocated) == 0 && allocated >= 1) {
    sc->vectors[MYFIRST_VECTOR_ADMIN].filter = myfirst_intr_filter;
    sc->vectors[MYFIRST_VECTOR_ADMIN].name = "msi";
    error = myfirst_intr_setup_vector(sc, MYFIRST_VECTOR_ADMIN, 1);
    if (error == 0) {
        sc->intr_mode = MYFIRST_INTR_MSI;
        sc->num_vectors = 1;
        device_printf(sc->dev,
            "interrupt mode: MSI, 1 vector "
            "(single-handler fallback)\n");
        goto enabled;
    }
    pci_release_msi(sc->dev);
}

/*
 * MSI allocation failed or was unavailable. Fall back to legacy

```

```

    * INTx with a single vector-0 handler that handles every event
    * class in one place.
    */

```

fallback_legacy:

```

sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid = 0;
sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res = bus_alloc_resource_any(
    sc->dev, SYS_RES_IRQ,
    &sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid,
    RF_SHAREABLE | RF_ACTIVE);
if (sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res == NULL) {
    device_printf(sc->dev, "cannot allocate legacy IRQ\n");
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (ENXIO);
}
error = bus_setup_intr(sc->dev,
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->vectors[MYFIRST_VECTOR_ADMIN].intr_cookie);
if (error != 0) {
    bus_release_resource(sc->dev, SYS_RES_IRQ,
        sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid,
        sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res);
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res = NULL;
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (error);
}
bus_describe_intr(sc->dev,
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res,
    sc->vectors[MYFIRST_VECTOR_ADMIN].intr_cookie, "legacy");
sc->intr_mode = MYFIRST_INTR_LEGACY;
sc->num_vectors = 1;
device_printf(sc->dev,
    "interrupt mode: legacy INTx (1 handler for all events)\n");

```

enabled:

```

/* Enable interrupts at the device. */
MYFIRST_LOCK(sc);
if (sc->hw != NULL)
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
        MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR |

```

```

        MYFIRST_INTR_COMPLETE);
MYFIRST_UNLOCK(sc);

return (0);
}

```

The code has three phases: MSI attempt, MSI fallback cleanup, and legacy fallback. The MSI attempt loops through the vectors, calling a helper (`myfirst_intr_setup_vector`) to allocate and register each one. On failure at any vector, the code unwinds in reverse order and falls through to legacy.

The helper:

```

static int
myfirst_intr_setup_vector(struct myfirst_softc *sc, int idx, int rid)
{
    struct myfirst_vector *vec = &sc->vectors[idx];
    int error;

    vec->irq_rid = rid;
    vec->irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ,
        &vec->irq_rid, RF_ACTIVE);
    if (vec->irq_res == NULL)
        return (ENXIO);

    error = bus_setup_intr(sc->dev, vec->irq_res,
        INTR_TYPE_MISC | INTR_MPSAFE,
        vec->filter, NULL, vec, &vec->intr_cookie);
    if (error != 0) {
        bus_release_resource(sc->dev, SYS_RES_IRQ, vec->irq_rid,
            vec->irq_res);
        vec->irq_res = NULL;
        return (error);
    }

    bus_describe_intr(sc->dev, vec->irq_res, vec->intr_cookie,
        "%s", vec->name);
    return (0);
}

```

The helper is small and symmetric: allocate the resource, set up the handler, describe it. The argument to `bus_setup_intr` is the per-vector structure (`vec`), not the `softc`. The filter receives `vec` as its void `*arg` and uses `vec->sc` when it needs the `softc`.

The per-vector teardown helper:

```
static void
myfirst_intr_teardown_vector(struct myfirst_softc *sc, int idx)
{
    struct myfirst_vector *vec = &sc->vectors[idx];

    if (vec->intr_cookie != NULL) {
        bus_teardown_intr(sc->dev, vec->irq_res, vec->intr_cookie);
        vec->intr_cookie = NULL;
    }
    if (vec->irq_res != NULL) {
        bus_release_resource(sc->dev, SYS_RES_IRQ, vec->irq_rid,
            vec->irq_res);
        vec->irq_res = NULL;
    }
}
```

Teardown is the inverse of setup: tear down the handler, release the resource.

20.4.5 The Full Teardown Path

The multi-vector teardown calls the per-vector helper for each active vector, then releases the MSI allocation once:

```
void
myfirst_intr_teardown(struct myfirst_softc *sc)
{
    int i;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);

    /* Per-vector teardown. */
    for (i = 0; i < sc->num_vectors; i++)
        myfirst_intr_teardown_vector(sc, i);

    /* Drain tasks. */
    if (sc->intr_tq != NULL) {
        for (i = 0; i < sc->num_vectors; i++) {
            if (sc->vectors[i].has_task)
                taskqueue_drain(sc->intr_tq,
                    &sc->vectors[i].task);
        }
    }
}
```

```

    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
}

/* Release MSI if used. */
if (sc->intr_mode == MYFIRST_INTR_MSI ||
    sc->intr_mode == MYFIRST_INTR_MSIX)
    pci_release_msi(sc->dev);

sc->num_vectors = 0;
sc->intr_mode = MYFIRST_INTR_LEGACY;
}

```

The ordering is the now-familiar one: mask at device, tear down handlers, drain tasks, release MSI. The per-vector loop does the per-vector work.

20.4.6 Simulating Interrupts Per Vector

Chapter 19's simulated-interrupt sysctl fires one handler at a time. Stage 2 extends the concept: a sysctl per vector, or a single sysctl with a vector-index field. The chapter's code goes with the simpler single-sysctl-per-vector form:

```

SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_admin",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE,
    &sc->vectors[MYFIRST_VECTOR_ADMIN], 0,
    myfirst_intr_simulate_vector_sysctl, "IU",
    "Simulate admin vector interrupt");
SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_rx", ...);
SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_tx", ...);

```

The handler:

```

static int
myfirst_intr_simulate_vector_sysctl(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_vector *vec = arg1;
    struct myfirst_softc *sc = vec->sc;
    uint32_t mask = 0;
    int error;

    error = sysctl_handle_int(oidp, &mask, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
}

```

```

MYFIRST_LOCK(sc);
if (sc->hw == NULL || sc->bar_res == NULL) {
    MYFIRST_UNLOCK(sc);
    return (ENODEV);
}
bus_write_4(sc->bar_res, MYFIRST_REG_INTR_STATUS, mask);
MYFIRST_UNLOCK(sc);

/*
 * Invoke this vector's filter if it has one (MSI-X). On single-
 * handler tiers (MSI with 1 vector, or legacy INTx) only slot 0
 * has a registered filter, so we fall through to it. The Chapter 19
 * myfirst_intr_filter handles all three status bits in one pass.
 */
if (vec->filter != NULL)
    (void)vec->filter(vec);
else if (sc->vectors[MYFIRST_VECTOR_ADMIN].filter != NULL)
    (void)sc->vectors[MYFIRST_VECTOR_ADMIN].filter(
        &sc->vectors[MYFIRST_VECTOR_ADMIN]);
return (0);
}

```

From user space:

```

sudo sysctl dev.myfirst.0.intr_simulate_admin=2  # ERROR bit, admin vector
sudo sysctl dev.myfirst.0.intr_simulate_rx=1     # DATA_AV bit, rx vector
sudo sysctl dev.myfirst.0.intr_simulate_tx=4     # COMPLETE bit, tx vector

```

The `intr_count` counters per vector tick independently. A reader can verify per-vector behaviour by firing each `sysctl` and watching the corresponding `vec->fire_count` counter rise.

20.4.7 What Happens on Legacy Fallback

When the driver falls back to legacy INTx (because MSI was unavailable or failed), there is only one handler to cover all three event classes. The code assigns the Chapter 19 `myfirst_intr_filter` to the admin vector's slot and uses that single filter on `rid = 0`. The admin vector's filter becomes a multi-event handler that looks at all three status bits and dispatches accordingly.

This is a small but important detail: the Chapter 19 filter still exists and is reused on the legacy path, while the per-vector filters are only used when MSI or MSI-X is available. A reader inspecting the driver sees both, and the difference is explained in Section 3's comments.

20.4.8 The Stage 2 dmesg Banner

On a guest where the driver lands on the MSI-X tier (this is the only tier that delivers three vectors; the MSI tier falls back to a single-handler setup for the reasons explained earlier):

```
myfirst0: BAR0 allocated: 0x20 bytes at 0xfebf1000
myfirst0: hardware layer attached to BAR: 32 bytes
myfirst0: interrupt mode: MSI-X, 3 vectors
```

`vmstat -i | grep myfirst` shows three separate lines:

irq256: myfirst0:admin	12	1
irq257: myfirst0:rx	98	8
irq258: myfirst0:tx	45	4

(The exact IRQ numbers vary by platform; MSI-allocated IRQs on x86 start in the 256 range once the I/O APIC range is exhausted.)

On a guest where only MSI is available, the driver reports a single-handler fallback:

```
myfirst0: interrupt mode: MSI, 1 vector (single-handler fallback)
```

and `vmstat -i` shows one line, because the driver uses the Chapter 19 pattern on that one MSI vector.

The per-vector breakdown (three lines) is what makes the multi-vector driver observable. An operator watching the counters can tell which vector is active and how often.

20.4.9 Common Mistakes in Stage 2

A short list.

Passing the softc (not the vector) as the filter argument. If you pass `sc` instead of `vec`, the filter cannot tell which vector it is serving. Fix: pass `vec` to `bus_setup_intr`; the filter reaches `sc` through `vec->sc`.

Forgetting to initialise `vec->sc`. The per-vector structures are zero-initialised by `myfirst_init_softc`; `vec->sc` stays NULL unless explicitly set. Without it, the filter's `vec->sc->mtx` access is a null dereference. Fix: set `vec->sc = sc` during setup, before any handler is registered.

Using the same rid for multiple vectors. MSI rids are 1, 2, 3, ...; reusing rid 1 for both the admin and RX vectors means only one handler is actually registered. Fix: assign rids in sequence per vector.

Per-vector handler that touches shared state without locking. Two filters running on different CPUs both try to write to a single `sc->counter`. Without atomic operations or a spin lock, the increment loses updates. Fix: use per-vector counters where possible, and atomic ops for any shared counter.

Per-vector task stored in the wrong location. If the task is in the `softc` instead of in the vector structure, two vectors enqueueing the “same” task collide. Fix: store the task in the vector structure, and pass the vector as the task argument.

Missing per-vector teardown on partial setup failure. The goto cascade must undo exactly the vectors that succeeded. Missing cleanup leaves IRQ resources allocated. Fix: use the per-vector teardown helper and iterate backward on the partial-failure case.

20.4.10 Wrapping Up Section 3

Managing multiple interrupt vectors is a set of three new patterns: per-vector state (in a `struct my-first_vector` array), per-vector filter functions, and per-vector `bus_describe_intr` names. Each vector has its own IRQ resource at its own `rid`, its own filter function that reads only the status bits relevant to its vector, its own counters, and (optionally) its own deferred task. The single MSI or MSI-X allocation call handles the device-side state; the per-vector `bus_alloc_resource_any` and `bus_setup_intr` calls handle each handler individually.

The fallback ladder from Section 2 extends naturally: try MSI with N vectors first; on partial failure, release and try legacy INTx with a single handler. The per-vector teardown helper makes the partial-failure unwind and the clean teardown symmetric.

Section 4 is the locking-and-data-structures section. It examines what happens when multiple filters run on multiple CPUs at the same time, and what synchronisation discipline keeps the shared state sane.

20.5 Section 4: Designing Interrupt-Safe Data Structures

Section 3 added multiple vectors, each with its own handler. Section 4 examines the consequences: multiple handlers can run concurrently on multiple CPUs, and any data the handlers share must be protected accordingly. The discipline is not new; it is the multi-CPU specialisation of Chapter 11's locking model. What is new is that Chapter 20's driver has three (or more) concurrent filter-context paths instead of one.

Section 4 is the section where multi-vector changes the shape of the driver's state, not just the count of its handlers.

20.5.1 The New Concurrency Picture

Chapter 19's driver had one filter and one task. The filter ran on whichever CPU the kernel routed the interrupt to; the task ran on the taskqueue's worker thread. Two of them could in principle run simultaneously: the filter on CPU 0 and the task on CPU 3, for example. The atomic counters and the `sc->mtx` (held by the task, not by the filter) gave the needed synchronisation.

Chapter 20's multi-vector driver has three filters and one task. On an MSI-X system, each filter has its own `intr_event`, so each can fire on a different CPU independently. A burst of three interrupts arriving within a microsecond can see three filters running on three CPUs at the same time. The single task is still serialised through the taskqueue, but the filters are not.

The data the filters touch falls into three categories:

1. **Per-vector state.** Each vector's own counters, its own cookie, its own resource. No sharing between vectors. No synchronisation needed.

2. **Shared counters.** Counters updated by any filter (the global `intr_data_av_count`, `intr_error_count`, etc.). Must be atomic.
3. **Shared device state.** The BAR itself, the softc's `sc->hw` pointer, `sc->pci_attached`, the mutex-protected fields. Access rules depend on the context.

The discipline is to keep per-vector state truly per-vector, to use atomics for shared counters, and to obey the Chapter 11 locking rules for anything requiring a sleep mutex.

20.5.2 Per-Vector State: The Default

The easiest synchronisation is no synchronisation. If a piece of state is touched by only one vector's filter (and by nothing else), no lock is needed. This is the case for:

- `vec->fire_count`: incremented by this vector's filter only, read by sysctl handlers via the sysctl-reader path. Atomic add suffices; no lock between filter and sysctl because the sysctl reads atomically.
- `vec->stray_count`: same pattern.
- `vec->intr_cookie`: written once at setup, read at teardown. Single-writer, ordered access.
- `vec->irq_res`: same pattern.

Most per-vector state falls into this category. The struct `myfirst_vector` array in the softc is the key pattern: each vector's state lives in its own slot, touched only by its own filter.

20.5.3 Shared Counters: Atomic Operations

The global per-bit counters (Chapter 19 introduced `sc->intr_data_av_count`, etc.) are updated by the corresponding vector's filter. Only one filter updates each counter, so technically they are per-vector-except-by-name. But the reader can imagine a scenario where a bit pattern appears in `INTR_STATUS` that requires both the RX and the admin vectors to increment shared counters. The safer approach: make each update atomic.

Chapter 20 uses `atomic_add_64` throughout the filter paths:

```
atomic_add_64(&sc->intr_data_av_count, 1);
```

This is cheap (one locked instruction on x86, a barrier-plus-add on arm64), and it lets the filter run on any CPU without worrying about lost updates.

The cost of `atomic_add_64` on a heavily-shared counter is cache-line bouncing: every increment from a different CPU invalidates the cache line on the other CPUs. For a counter incremented a million times per second from several CPUs, this is a measurable performance hit. The mitigation is to make counters truly per-CPU (using `COUNTER(9)` or `DPCPU_DEFINE`) and sum them only when read; Chapter 20's driver is not at that scale, so plain atomics are fine.

20.5.4 Shared Device State: The Mutex Discipline

`sc->hw`, `sc->pci_attached`, `sc->bar_res`: these are set during attach and torn down during detach. During steady state, they are read-only. The filters access them without a lock because the lifetime discipline (attach before enabling, disable before detach) ensures the pointers are valid whenever the filter can run.

The rule: a filter that accesses `sc->hw` or `sc->bar_res` without a lock must be confident the attach-detach ordering guarantees the pointer is valid. Chapter 20's Section 7 walks the ordering in detail. For Section 4's purposes, trust the discipline: when the filter runs, the device is attached and the pointers are valid.

20.5.5 The Per-Vector Lock: When You Need It

Sometimes the per-vector state is richer than a counter. A vector that reads from a receive queue and updates a per-queue data structure (a ring of mbufs, say) needs a spin lock to protect the ring from two simultaneous firings of the same vector. Wait, can the same vector fire twice simultaneously on an MSI-X system?

On MSI-X, the kernel guarantees that each `intr_event` delivers to one CPU at a time; a single vector does not re-enter itself. Two different vectors can run on two CPUs at once, but vector N cannot run on CPU 3 and CPU 5 simultaneously.

This means: **per-vector state does not need a per-vector lock** for concurrent access from the same vector. It might need one for communication between the filter and the task (the task runs on a different CPU, possibly concurrently with the filter), but a spin lock suffices there, and the communication is usually through atomic operations anyway.

A spin lock becomes useful when:

- A driver uses a single filter function for multiple vectors, and the kernel can dispatch two vectors' worth of that filter concurrently. (Chapter 20's Stage 2 has separate filters per vector, so this does not apply.)
- A driver shares a receive ring between the filter (which fills it) and a task (which drains it). A spin lock protects the ring index; the filter acquires the spin lock, adds to the ring, releases. The task acquires, drains, releases.

Chapter 20's driver does not use spin locks in the filter; the per-vector counters are atomic and the shared state is handled through the existing `sc->mtx` in the task. Real drivers may need spin locks in richer scenarios.

20.5.6 Per-CPU Data: The Advanced Option

For very-high-rate drivers, even atomic counters on shared data become a bottleneck. The solution is per-CPU data: each CPU has its own copy of the counter, the filter increments its own CPU's copy (no cross-CPU traffic), and the `sysctl` reader sums the per-CPU values.

FreeBSD's `counter(9)` API provides this: a `counter_u64_t` is a handle to a per-CPU array, `counter_u64_add(c, 1)` increments the current CPU's slot, and `counter_u64_fetch(c)` sums all CPUs' slots on read. The implementation uses per-CPU data regions (`DPCPU_DEFINE` under the hood) and is as cheap as a normal non-atomic increment on the hot path.

Chapter 20's driver does not use `counter(9)`; plain atomics are enough for the demo's scale. Real high-throughput drivers (ten gigabit NICs, NVMe controllers at a million IOPS) use `counter(9)` extensively. A reader writing such a driver should study `counter(9)` after Chapter 20.

20.5.7 Lock Ordering and Multi-Vector Complications

Chapter 15 established the driver's lock order: `sc->mtx` -> `sc->cfg_sx` -> `sc->stats_cache_sx`. Chapter 19's filter took no locks (atomics only); the task took `sc->mtx`. Chapter 20's per-vector filters still take no

locks (atomics only), so the filter path does not contribute new lock-order edges. The per-vector tasks still take `sc->mtx`, same as Chapter 19's single task.

Lock ordering with multiple tasks running concurrently requires a small extension. When the admin task and the RX task both acquire `sc->mtx`, they serialise on the mutex. That is fine as long as each task releases the mutex promptly; if the admin task held `sc->mtx` while waiting on something slow, the RX task would stall. The Chapter 15 rule “no long-held mutexes” applies here too.

WITNESS catches most lock-order problems. For Chapter 20, the lock-order story is essentially unchanged from Chapter 19 because the filter paths are lock-free and the task paths all acquire the same single `sc->mtx`.

20.5.8 The Memory Model: Why Atomics Matter

A subtle point worth making explicit. In a multi-CPU system, writes from one CPU are not visible to other CPUs instantly. A write on CPU 0 to `sc->intr_count++` (without atomics) might land in CPU 0's store buffer and take nanoseconds or microseconds to propagate to CPU 3's view of the same memory. In that window, CPU 3 could read the pre-write value.

`atomic_add_64` includes a memory barrier that forces the write to become globally visible before the instruction returns. This is what makes the counter's value “consistent” across CPUs: any reader after the increment sees the new value.

For counter state, this level of consistency is sufficient. The counter's absolute value at any instant is not important; what matters is that the value grows monotonically and reaches the correct total. `atomic_add_64` guarantees both.

For richer shared state (say, a shared data-structure index that multiple filters update), the memory model gets more subtle. The driver would need a spin lock, which provides both mutual exclusion and a memory barrier. Chapter 20's driver does not need this level of machinery; Chapter 19's atomic discipline carries through.

20.5.9 Observability: Per-Vector Counters in sysctl

Each vector gets its own sysctl subtree so the operator can query it:

```
char name[32];
for (int i = 0; i < MYFIRST_MAX_VECTORS; i++) {
    snprintf(name, sizeof(name), "vec%d_fire_count", i);
    SYSCTL_ADD_U64(&sc->sysctl_ctx,
        SYSCTL_CHILDREN(sc->sysctl_tree), OID_AUTO, name,
        CTLFLAG_RD, &sc->vectors[i].fire_count, 0,
        "Fire count for this vector");
}
```

From user space:

```
sysctl dev.myfirst.0 | grep vec
```

```
dev.myfirst.0.vec0_fire_count: 42    # admin
dev.myfirst.0.vec0_stray_count: 0
dev.myfirst.0.vec1_fire_count: 9876  # rx
dev.myfirst.0.vec1_stray_count: 0
dev.myfirst.0.vec2_fire_count: 4523  # tx
dev.myfirst.0.vec2_stray_count: 0
```

The operator can see at a glance which vectors are firing and at what rates. The stray counts should stay at zero on MSI-X (each vector has its own dedicated message) but may tick on MSI or legacy when a shared filter sees an event for a different vector.

20.5.10 Wrapping Up Section 4

Multi-vector drivers change the concurrency picture: several filters can run on several CPUs simultaneously. The discipline is to design state per-vector where possible, use atomics for shared counters, and obey the existing Chapter 11 lock order for anything needing a sleep mutex. Per-CPU counters (`counter(9)`) are available for very-high-rate drivers but are overkill for Chapter 20.

The driver's lock order does not gain new edges because the filter path remains lock-free (atomics only) and the tasks all take `sc->mtx`. WITNESS still catches lock-order problems; the atomic discipline still catches the rest.

Section 5 moves to the more capable mechanism: MSI-X. The API is very similar (`pci_msix_count` + `pci_alloc_msix` instead of the MSI pair), but the scalability and CPU-affinity options are richer.

20.6 Section 5: Using MSI-X for High Flexibility

Section 2 introduced MSI with one vector, Section 3 extended to multiple MSI vectors, Section 4 walked through the concurrency implications. Section 5 moves to MSI-X: the fuller mechanism that modern PCIe devices use when they have more than a handful of interrupts to manage. The API is parallel to MSI's, so the code change is small; the conceptual change is that MSI-X lets the driver bind each vector to a specific CPU, through `bus_bind_intr(9)` and `bus_get_cpus(9)`, and that matters for real performance.

20.6.1 The MSI-X Count and Allocation API

The API mirrors MSI's:

```
int msix_count = pci_msix_count(sc->dev);
```

`pci_msix_count(9)` returns the number of MSI-X vectors the device advertises (0 if no MSI-X capability). The count comes from the MSI-X capability's `Table Size` field plus one; a device with `Table Size` = 7 advertises 8 vectors.

Allocating is similar:

```
int count = desired;
int error = pci_alloc_msix(sc->dev, &count);
```

Same input-output count parameter, same semantics: the kernel may allocate fewer than requested. Unlike MSI, MSI-X allows a non-power-of-two count, so if the driver asks for 3 vectors, the kernel can give 3.

The same `pci_release_msi(9)` call releases MSI-X vectors; there is no separate `pci_release_msix`. The function name is a historical artefact; it handles both MSI and MSI-X.

20.6.2 The Fallback Ladder Extended

The Chapter 20 driver's full fallback ladder is:

1. **MSI-X** with the desired vector count.
2. **MSI** with the desired vector count, if MSI-X is unavailable or allocation failed.
3. **Legacy INTx** with a single handler for everything, if both MSI-X and MSI fail.

The code structure parallels Section 3's two-tier ladder, extended with a third tier at the top:

```
/* Tier 0: MSI-X. */
wanted = MYFIRST_MAX_VECTORS;
if (pci_msix_count(sc->dev) >= wanted) {
    allocated = wanted;
    if (pci_alloc_msix(sc->dev, &allocated) == 0 &&
        allocated == wanted) {
        for (i = 0; i < wanted; i++) {
            error = myfirst_intr_setup_vector(sc, i, i + 1);
            if (error != 0)
                goto fail_msix;
        }
        sc->intr_mode = MYFIRST_INTR_MSIX;
        sc->num_vectors = wanted;
        device_printf(sc->dev,
            "interrupt mode: MSI-X, %d vectors\n", wanted);
        myfirst_intr_bind_vectors(sc);
        goto enabled;
    }
    if (allocated > 0)
        pci_release_msi(sc->dev);
}

/* Tier 1: MSI. */
/* ... Section 3 MSI code ... */

fail_msix:
```

```
for (i -= 1; i >= 0; i--)
    myfirst_intr_teardown_vector(sc, i);
pci_release_msi(sc->dev);
/* fallback to MSI attempt, then legacy. */
```

The structure is straightforward: each tier has the same pattern (query count, allocate, set up vectors, mark mode, describe). The code follows the well-worn waterfall.

20.6.3 Vector Binding With `bus_bind_intr`

Once MSI-X is allocated, the driver has the option of binding each vector to a specific CPU. The API is:

```
int bus_bind_intr(device_t dev, struct resource *r, int cpu);
```

The `cpu` is an integer CPU ID from 0 to `mp_ncpus - 1`. On success, the interrupt is routed to that CPU. On failure, the function returns an `errno`; the driver treats it as a non-fatal hint and continues without binding.

For Chapter 20's three-vector driver, a reasonable binding is:

- **Admin vector:** CPU 0 (control work, any CPU is fine).
- **RX vector:** CPU 1 (cache locality benefits for a real RX queue).
- **TX vector:** CPU 2 (similar locality benefit).

On a two-CPU system, the bindings would collapse; on a many-CPU system, the driver should use `bus_get_cpus(9)` to query which CPUs are local to the device's NUMA node and distribute vectors accordingly.

The bind helper:

```
static void
myfirst_intr_bind_vectors(struct myfirst_softc *sc)
{
    int i, cpu, ncpus;
    int err;

    if (mp_ncpus < 2)
        return; /* nothing to bind */

    ncpus = mp_ncpus;
    for (i = 0; i < sc->num_vectors; i++) {
        cpu = i % ncpus;
        err = bus_bind_intr(sc->dev, sc->vectors[i].irq_res, cpu);
        if (err != 0) {
            device_printf(sc->dev,
                "bus_bind_intr vector %d to CPU %d: %d\n",

```

```

        i, cpu, err);
    }
}

```

The code is a round-robin bind: vector 0 to CPU 0, vector 1 to CPU 1, and so on, wrapping modulo the CPU count. On a two-CPU system with three vectors, vector 0 and vector 2 both land on CPU 0; on a four-CPU system, each vector gets its own CPU.

A more sophisticated driver uses `bus_get_cpus(9)`:

```

cpuset_t local_cpus;
int ncpus_local;

if (bus_get_cpus(sc->dev, LOCAL_CPUS, sizeof(local_cpus),
    &local_cpus) == 0) {
    /* Use only CPUs in local_cpus for binding. */
    ncpus_local = CPU_COUNT(&local_cpus);
    /* ... pick from local_cpus ... */
}

```

The `LOCAL_CPUS` argument returns the CPUs that are in the same NUMA domain as the device. The `INTR_CPUS` argument returns CPUs suitable for handling device interrupts (usually excluding CPUs pinned to critical work). A driver that cares about NUMA performance uses these to place vectors on NUMA-local CPUs.

Chapter 20's driver does not use `bus_get_cpus(9)` by default; the simpler round-robin bind is enough for the lab. A challenge exercise adds NUMA-aware binding.

20.6.4 The MSI-X dmesg Summary

The Chapter 20 driver prints a line like:

```
myfirst0: interrupt mode: MSI-X, 3 vectors
```

With per-vector CPU bindings visible in `vmstat -i` (the per-CPU totals in `vmstat -i` are not per-vector; they are aggregated) and in `cpuset -g -x <irq>` output (one query per vector):

```

for irq in 256 257 258; do
    echo "IRQ $irq:"
    cpuset -g -x $irq
done

```

Typical output:

```
IRQ 256:
irq 256 mask: 0
IRQ 257:
irq 257 mask: 1
IRQ 258:
irq 258 mask: 2
```

(The IRQ numbers depend on the platform's assignment.)

An operator inspecting the driver's interrupt setup can see which vectors fire where.

20.6.5 Per-Vector `bus_describe_intr`

Each MSI-X vector should have a description. The code from Section 3 already sets them via `bus_describe_intr(9)`:

```
bus_describe_intr(sc->dev, vec->irq_res, vec->intr_cookie,
    "%s", vec->name);
```

After this, `vmstat -i` shows each vector with its role:

```
irq256: myfirst0:admin          42          4
irq257: myfirst0:rx            12345        1234
irq258: myfirst0:tx            5432         543
```

The operator sees which vector is the admin, which is the RX, which is the TX, and how busy each is. This is essential observability for a multi-vector driver.

20.6.6 MSI-X Table and BAR Considerations

A detail worth mentioning, though the driver does not interact with it directly. The MSI-X capability structure points to a **table** and a **pending bit array** (PBA), each living in one of the device's BARs. The BAR that holds each is discoverable through `pci_msix_table_bar(9)` and `pci_msix_pba_bar(9)`:

```
int table_bar = pci_msix_table_bar(sc->dev);
int pba_bar = pci_msix_pba_bar(sc->dev);
```

Each returns the BAR index (0 through 5) or -1 if the device has no MSI-X capability. For most devices, the table and PBA are in BAR 0 or BAR 1; for some devices, they share a BAR with memory-mapped registers (the driver's BAR 0).

The kernel handles the table programming internally. The driver's only interaction is:

- Ensure the BAR containing the table is allocated (so the kernel can reach it). On some devices this requires the driver to allocate additional BARs.

- Call `pci_alloc_msix` and let the kernel do the rest.

For Chapter 20's driver, the virtio-rnd target (or its QEMU equivalent with MSI-X) has the table in BAR 1 or a dedicated region. The Chapter 18 code allocated BAR 0; the kernel handles the MSI-X table BAR implicitly through the allocation infrastructure.

A driver that wants to inspect the table bar:

```
device_printf(sc->dev, "MSI-X table in BAR %d, PBA in BAR %d\n",
    pci_msix_table_bar(sc->dev), pci_msix_pba_bar(sc->dev));
```

This is useful for diagnostic purposes.

20.6.7 Allocating Fewer Vectors Than Requested

A subtle case: the device advertises 3 MSI-X vectors and the driver asks for 3, but the kernel only allocates 2. What does the driver do?

The answer depends on the driver's design. Options:

1. **Fail the attach.** If the driver cannot function with fewer vectors, return an error. This is rare for flexible drivers but possible for drivers with tight hardware requirements.
2. **Use what we got.** If the driver can function with 2 vectors (folding RX and TX into one, for example), use the 2 and adjust the configuration. This is common for drivers targeting ranges of hardware.
3. **Release and fall back.** If 2 vectors is worse than 1 MSI vector for some reason, release MSI-X and try MSI. This is uncommon.

Chapter 20's driver goes with option 1: if it does not get exactly `MYFIRST_MAX_VECTORS` (3) vectors, it releases MSI-X and falls back to MSI. A more sophisticated driver would use option 2; the Chapter 20 teaching focuses on the simpler pattern.

Real FreeBSD drivers often use option 2 with a helper function that figures out how to distribute the allocated vectors across the desired roles. The `nvme(4)` driver is an example: if it asks for `N` I/O queues worth of vectors and gets fewer, it reduces the number of I/O queues accordingly.

20.6.8 Testing MSI-X on bhyve vs QEMU

A practical detail about the lab. `bhyve`'s legacy virtio-rnd device (what Chapter 18 and 19 used) does not expose MSI-X; it is a legacy-only virtio transport. To exercise MSI-X in a guest, the reader needs one of:

- **QEMU with `-device virtio-rng-pci`** (not `-device virtio-rng`, which is legacy). The modern `virtio-rng-pci` exposes MSI-X.
- **Modern bhyve emulation** of a non-virtio-rnd device that has MSI-X. Chapter 20 does not use this path.
- **Real hardware** that supports MSI-X (most modern PCIe devices).

QEMU is the practical choice for Chapter 20's labs. The driver's fallback ladder ensures it still works on `bhyve` (falling back to legacy); testing MSI-X specifically requires QEMU or real hardware.

20.6.9 Common Mistakes in MSI-X Setup

A short list.

Using `pci_release_msix`. This function does not exist in FreeBSD; the release is handled by `pci_release_msi(9)` which works for both MSI and MSI-X. Fix: use `pci_release_msi`.

Binding to a CPU the device cannot reach. Some platforms (rarely) have CPUs that are not in the interrupt-controller's routable set. The `bus_bind_intr` call returns an error; ignore it and continue. Fix: log the error but do not fail attach.

Expecting `vmstat -i` to show per-CPU breakdown. `vmstat -i` aggregates per-event counts. The per-CPU breakdown is available via `cpuset -g -x <irq>` (or `sysctl hw.intrcnt` in raw form). The operator has to look in the right place. Fix: document the observability path for your driver.

Failing to check `allocated` against `wanted`. Accepting a partial allocation when the driver cannot handle it leads to subtle bugs (vectors that should fire never fire). Fix: decide the strategy upfront (fail, adapt, or release) and code accordingly.

20.6.10 Wrapping Up Section 5

MSI-X is the fuller mechanism: a per-vector addressable table that the kernel programs on behalf of the driver, with per-vector CPU affinity and per-vector masking available to drivers that need them. The API mirrors MSI's closely (`pci_msix_count` + `pci_alloc_msix` + `pci_release_msi`), and the per-vector resource allocation is the same as Section 3's MSI code. The new piece is `bus_bind_intr(9)` for CPU affinity and `bus_get_cpus(9)` for NUMA-local CPU queries.

For Chapter 20's driver, MSI-X is the preferred tier; the fallback ladder tries MSI-X first, falls back to MSI, and finally to legacy INTx. The per-vector handlers, counters, and tasks from Section 3 work unchanged on MSI-X; only the allocation call changes.

Section 6 is where vector-specific events become explicit. Each vector has its own purpose, its own filter logic, and its own observable behaviour. Chapter 20's Stage 3 is the stage where the driver looks like a real multi-queue device even though the underlying silicon (the `virtio-rnd` target) is simpler.

20.7 Section 6: Handling Vector-Specific Events

Sections 2 through 5 built the infrastructure for multi-vector handling. Section 6 is the section where the per-vector roles become explicit. Each vector has a specific event class it handles; each filter has a specific check it makes; each task has a specific wake-up it performs. The driver at Stage 3 treats vectors as named, purposeful entities rather than interchangeable slots.

The Chapter 20 driver's three vectors have distinct responsibilities:

- **Admin vector** handles `ERROR` events. The filter reads status, acknowledges, and (on real errors) logs a message. Admin work is infrequent but must not be dropped.
- **RX vector** handles `DATA_AV` (receive-available) events. The filter acknowledges and defers the data-handling work to a per-vector task that broadcasts a condition variable.

- **TX vector** handles COMPLETE (transmit-complete) events. The filter acknowledges and optionally wakes a thread waiting for transmit completion. The filter handles the bookkeeping inline.

Each vector is independently testable through the simulated-interrupt sysctl, independently observable through its counters, and independently bound to a CPU. The driver is starting to look like a small real multi-queue device.

20.7.1 The Admin Vector

The admin vector handles rare, important events: configuration changes, errors, link state changes (for a NIC), temperature alerts (for a sensor). Its work is usually small: log the event, update a state flag, wake a user-space waiter that polls the state.

For the Chapter 20 driver, the admin vector handles the Chapter 17 ERROR bit. The filter:

```
int
myfirst_admin_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
    if ((status & MYFIRST_INTR_ERROR) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }

    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_ERROR);
    atomic_add_64(&sc->intr_error_count, 1);
    return (FILTER_HANDLED);
}
```

On a real device, the admin filter might also examine a secondary register (an error code register, say) and decide based on the severity whether to schedule a recovery task. Chapter 20's driver keeps it simple: count and acknowledge.

20.7.2 The RX Vector

The RX vector is the data-path vector. For a NIC, it would handle received packets. For an NVMe drive, completions of read requests. For the Chapter 20 driver, it handles the Chapter 17 DATA_AV bit.

The filter is small (acknowledge and enqueue a task); the task does the real work. Section 3 showed both. The task:

```
static void
myfirst_rx_task_fn(void *arg, int npending)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->pci_attached) {
        sc->intr_last_data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
        sc->intr_task_invocations++;
        cv_broadcast(&sc->data_cv);
    }
    MYFIRST_UNLOCK(sc);
}
```

In a real driver, the task would walk a receive descriptor ring, build mbufs, and pass them up the network stack. For Chapter 20's demo, it reads DATA_OUT, stores the value, broadcasts the condition variable, and lets any waiting cdev reader wake up.

The npending argument is the number of times the task was enqueued since its last run. For a high-rate RX path, a task that ran once and saw npending = 5 knows it is behind (5 interrupts coalesced into 1 task run) and can size its batch accordingly. Chapter 20's task ignores npending; real drivers use it for batching.

20.7.3 The TX Vector

The TX vector is the transmit-completion vector. For a NIC, it signals that a packet the driver handed to hardware has been transmitted and the buffer can be reclaimed. For an NVMe drive, it signals that a write request has completed.

For the Chapter 20 driver, it handles the Chapter 17 COMPLETE bit. The filter does the work inline (no task needed):

```
int
myfirst_tx_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
    if ((status & MYFIRST_INTR_COMPLETE) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }
}
```

```
    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_COMPLETE);
    atomic_add_64(&sc->intr_complete_count, 1);
    return (FILTER_HANDLED);
}
```

The TX filter's inline-only design is a deliberate choice. On a real TX completion path, the filter might record the completion count and the task might walk the TX descriptor ring to reclaim buffers. For the Chapter 20 demo, the completion is just counted.

An alternative design would have TX also use a task. Whether to do this depends on the work the task would do: if it is substantial (walking a ring, reclaiming dozens of buffers), a task is worth it; if it is trivial (a single decrement of an in-flight counter), inline in the filter is fine. Chapter 20 picks inline for TX to illustrate that not every vector needs a task.

20.7.4 Vector-to-Event Mapping

On MSI-X, each vector is independent; firing vector 1 delivers to the RX filter, firing vector 2 delivers to the TX filter. The mapping from vector to event is part of the driver's design, not a kernel choice.

On MSI with multiple vectors, the kernel may in principle dispatch multiple vectors in rapid succession if multiple events fire simultaneously. The driver's filters must each read the status register and claim only the bits belonging to their vector.

On legacy INTx, there is only one vector and one filter. The filter handles all three event classes in one pass.

Chapter 20's code handles all three cases: the per-vector filter on MSI-X reads only its own bit, the per-vector filter on MSI does the same (with the same bit-check logic), and the single filter on legacy INTx handles all three bits.

20.7.5 Simulated Per-Vector Events

The simulation sysctl from Section 3 lets a reader exercise each vector independently. From user space:

```
# Simulate an admin interrupt (ERROR).
sudo sysctl dev.myfirst.0.intr_simulate_admin=2

# Simulate an RX interrupt (DATA_AV).
sudo sysctl dev.myfirst.0.intr_simulate_rx=1

# Simulate a TX interrupt (COMPLETE).
sudo sysctl dev.myfirst.0.intr_simulate_tx=4
```

Each sysctl writes its specific bit to INTR_STATUS and invokes the corresponding vector's filter. On the MSI-X tier all three filters exist, so each sysctl hits its own per-vector filter and its per-vector counter ticks. On the MSI tier (single vector at slot 0) and on the legacy INTx tier (single vector at slot 0), slots 1 and 2 have no registered

filter, so the simulation helper routes the call through slot 0's filter. The Chapter 19 `myfirst_intr_filter` handles all three bits inline, so the global `intr_count`, `intr_data_av_count`, `intr_error_count`, and `intr_complete_count` counters still move correctly. The per-vector counters on slots 1 and 2 stay at zero in single-handler tiers, which is the right observability signal that the driver is not running with three vectors.

A reader can watch the pipeline from user space:

```
while true; do
    sudo sysctl dev.myfirst.0.intr_simulate_rx=1
    sleep 0.1
done &
watch sysctl dev.myfirst.0 | grep -E "vec|intr_"
```

The counters tick at roughly 10 per second. The RX vector's counter matches `intr_data_av_count`; the task's invocation count matches.

20.7.6 Dynamic Vector Assignment

A subtle but important point. The driver's design has three vectors in a fixed array with fixed roles. A more flexible driver might discover the number of available vectors at runtime and assign roles dynamically. The pattern looks like:

```
/* Discover how many vectors we got. */
int nvec = actually_allocated_msix_vectors(sc);

/* Assign roles based on nvec. */
if (nvec >= 3) {
    /* Full design: admin, rx, tx. */
    sc->vectors[0].filter = myfirst_admin_filter;
    sc->vectors[1].filter = myfirst_rx_filter;
    sc->vectors[2].filter = myfirst_tx_filter;
    sc->num_vectors = 3;
} else if (nvec == 2) {
    /* Compact: admin+tx share one vector, rx has its own. */
    sc->vectors[0].filter = myfirst_admin_tx_filter;
    sc->vectors[1].filter = myfirst_rx_filter;
    sc->num_vectors = 2;
} else if (nvec == 1) {
    /* Minimal: one filter handles everything. */
    sc->vectors[0].filter = myfirst_intr_filter;
    sc->num_vectors = 1;
}
```

This dynamic adaptation is what production drivers do. Chapter 20's driver uses the simpler fixed approach; a challenge exercise adds the dynamic variant.

20.7.7 A Pattern From nvme(4)

For a real example, the nvme(4) driver handles the admin queue separately from the I/O queues. Its filter functions differ per queue type; its interrupt counts are tracked per queue. The pattern is:

```
/* In nvme_ctrlr_construct_admin_qpair: */
qpair->intr_idx = 0; /* vector 0 for admin */
qpair->intr_rid = 1;
qpair->res = bus_alloc_resource_any(ctrlr->dev, SYS_RES_IRQ,
    &qpair->intr_rid, RF_ACTIVE);
bus_setup_intr(ctrlr->dev, qpair->res, INTR_TYPE_MISC | INTR_MPSAFE,
    NULL, nvme_qpair_msix_handler, qpair, &qpair->tag);

/* For each I/O queue: */
for (i = 0; i < ctrlr->num_io_queues; i++) {
    ctrlr->ioq[i].intr_rid = i + 2; /* I/O vectors at rid 2, 3, ... */
    /* ... similar bus_alloc_resource_any + bus_setup_intr ... */
}
```

Each queue has its own `intr_rid`, its own resource, its own tag (cookie), its own handler argument. The admin queue uses one vector; each I/O queue uses its own vector. The pattern scales linearly with the number of queues.

Chapter 20's driver is a small version of this: three fixed vectors instead of one admin plus N I/O. The scaling story transfers directly.

20.7.8 Observability: Per-Vector Rate

A useful diagnostic: compute each vector's rate over a sliding window:

```
#!/bin/sh
prev_admin=$(sysctl -n dev.myfirst.0.vec0_fire_count)
prev_rx=$(sysctl -n dev.myfirst.0.vec1_fire_count)
prev_tx=$(sysctl -n dev.myfirst.0.vec2_fire_count)
sleep 1
curr_admin=$(sysctl -n dev.myfirst.0.vec0_fire_count)
curr_rx=$(sysctl -n dev.myfirst.0.vec1_fire_count)
curr_tx=$(sysctl -n dev.myfirst.0.vec2_fire_count)

echo "admin: $((curr_admin - prev_admin)) /s"
echo "rx:    $((curr_rx - prev_rx )) /s"
echo "tx:    $((curr_tx - prev_tx )) /s"
```

The output is per-vector rates over the last second. A reader running the simulated-interrupt `sysctl` in a loop can see the rates tick up; a reader observing a real workload sees which vector is busy.

20.7.9 Wrapping Up Section 6

Handling vector-specific events means each vector has its own filter function, its own counters, its own (optional) task, and its own observable behaviour. The pattern scales: three vectors for the Chapter 20 demo, dozens for a production NIC, hundreds for an NVMe controller. The per-vector separation makes each piece small, specific, and maintainable.

Section 7 is the teardown section. Multi-vector drivers need to tear down each vector individually, in the right order, and then call `pci_release_msi` once at the end. The order is strict but not complex; Section 7 walks through it.

20.8 Section 7: Teardown and Cleanup With MSI/MSI-X

Chapter 19's teardown was a single pair: `bus_teardown_intr` on the one vector, then `bus_release_resource` on the one IRQ resource. Chapter 20's teardown is the same pair repeated per vector, followed by a single `pci_release_msi` call that undoes the MSI or MSI-X device-level allocation.

Section 7 makes the ordering precise, walks through the partial-failure cases, and highlights the observability checks that confirm a clean teardown.

20.8.1 The Required Order

For a multi-vector driver, the detach sequence is:

1. **Refuse if busy.** Same as Chapter 19: return `EBUSY` if the driver has open descriptors or in-flight work.
2. **Mark as no longer attached.**
3. **Destroy the cdev.**
4. **Disable interrupts at the device.** Clear `INTR_MASK` so the device stops asserting.
5. **For each vector in reverse order:**
 - a. `bus_teardown_intr` on the vector's cookie.
 - b. `bus_release_resource` on the vector's IRQ resource.
6. **Drain all per-vector tasks.** Each task that was initialised.
7. **Destroy the taskqueue.**
8. **Call `pci_release_msi` once,** unconditionally if `intr_mode` is MSI or MSI-X.
9. **Detach the hardware layer and release the BAR** as usual.
10. **Deinit the softc.**

The new steps are 5 (per-vector loop instead of a single pair) and 8 (`pci_release_msi`). Steps 1-4 and 9-10 are unchanged from Chapter 19.

20.8.2 Why Reverse Order Per Vector

The per-vector reverse-order loop is a defensive measure against dependencies between vectors. On a simple driver like Chapter 20's, the vectors are independent: tearing down vector 2 before vector 1 is fine. On a driver

where vector 2's filter reads state that vector 1's filter writes, the order matters: tear down the writer (vector 1) first, then the reader (vector 2).

For correctness on Chapter 20's driver, forward and reverse order are both safe. For robustness against future changes, reverse order is preferred.

20.8.3 The Per-Vector Teardown Code

From Section 3, the per-vector teardown helper:

```
static void
myfirst_intr_teardown_vector(struct myfirst_softc *sc, int idx)
{
    struct myfirst_vector *vec = &sc->vectors[idx];

    if (vec->intr_cookie != NULL) {
        bus_teardown_intr(sc->dev, vec->irq_res, vec->intr_cookie);
        vec->intr_cookie = NULL;
    }
    if (vec->irq_res != NULL) {
        bus_release_resource(sc->dev, SYS_RES_IRQ, vec->irq_rid,
            vec->irq_res);
        vec->irq_res = NULL;
    }
}
```

The helper is robust against partial setup: if the vector never had a cookie (setup failed before `bus_setup_intr`), the `if` check skips the teardown call. If the resource was never allocated, the second `if` check skips the release. The same helper works for partial-failure unwind during setup and for full teardown during detach.

20.8.4 The Full Teardown

```
void
myfirst_intr_teardown(struct myfirst_softc *sc)
{
    int i;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);

    /* Tear down each vector's handler, in reverse. */
}
```

```

for (i = sc->num_vectors - 1; i >= 0; i--)
    myfirst_intr_teardown_vector(sc, i);

/* Drain and destroy the taskqueue, including per-vector tasks. */
if (sc->intr_tq != NULL) {
    for (i = 0; i < sc->num_vectors; i++) {
        if (sc->vectors[i].has_task)
            taskqueue_drain(sc->intr_tq,
                            &sc->vectors[i].task);
    }
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
}

/* Release the MSI/MSI-X allocation if used. */
if (sc->intr_mode == MYFIRST_INTR_MSI ||
    sc->intr_mode == MYFIRST_INTR_MSIX)
    pci_release_msi(sc->dev);

sc->num_vectors = 0;
sc->intr_mode = MYFIRST_INTR_LEGACY;
}

```

The code structure is straightforward: disable at the device, per-vector teardown in reverse, per-vector task drain, free the taskqueue, release MSI if used. The pattern transfers directly to any multi-vector driver.

20.8.5 Partial-Attach Failure Unwind

During setup, if vector N fails to register, the code must unwind vectors 0 through N-1 that succeeded. The pattern:

```

for (i = 0; i < MYFIRST_MAX_VECTORS; i++) {
    error = myfirst_intr_setup_vector(sc, i, i + 1);
    if (error != 0)
        goto fail_vectors;
}

/* Success, continue. */

fail_vectors:
    /* Undo vectors 0 through i-1. */
    for (i -= 1; i >= 0; i--)
        myfirst_intr_teardown_vector(sc, i);

```

```
pci_release_msi(sc->dev);  
/* Fall through to next tier or final failure. */
```

The `i -= 1` is important: after the `goto`, `i` is the vector that failed (it is past the successful setups). We undo vectors 0 through `i-1`, which is the successfully-registered set. The per-vector teardown helper is safe to call on the failing vector's slot too, because its fields are NULL (the setup did not get far enough to populate them).

20.8.6 Observability: Verifying a Clean Teardown

After `kldunload myfirst`, the following should hold:

- `kldstat -v | grep myfirst` returns nothing.
- `devinfo -v | grep myfirst` returns nothing.
- `vmstat -i | grep myfirst` returns nothing.
- `vmstat -m | grep myfirst` shows zero live allocations.

Any failure points to a cleanup bug:

- A `vmstat -i` entry remaining means `bus_teardown_intr` was not called for that vector.
- A `vmstat -m` leak means a per-vector task was not drained or the taskqueue was not freed.
- A `devinfo -v` entry remaining (rare) means the device's detach did not complete.

20.8.7 MSI Resource Leak Across Load-Unload Cycles

A specific concern for MSI/MSI-X drivers: forgetting `pci_release_msi` leaves the device's MSI state allocated. The next `kldload` of the same driver (or a different driver for the same device) will fail to allocate MSI vectors because the kernel thinks they are already in use.

The symptom in `dmesg`:

```
myfirst0: pci_alloc_msix returned EBUSY
```

or similar. The fix is to ensure `pci_release_msi` runs on every teardown path, including the partial-failure unwind.

A useful test: load, unload, load. If the second load succeeds with the same MSI mode, the teardown is correct. If the second load falls back to a lower tier, the teardown leaked.

20.8.8 Common Mistakes in Teardown

A short list.

Forgetting `pci_release_msi`. The most common bug. Symptom: next MSI allocation attempts fail. Fix: always call it when MSI or MSI-X was used.

Calling `pci_release_msi` on a driver that used legacy INTx only. Technically a no-op, but explicit check makes the intent clearer. Fix: check `intr_mode` before calling.

Wrong per-vector teardown order. For drivers with inter-vector dependencies, the reverse-order loop matters. For Chapter 20's driver, the order is not dependency-critical, but the reverse-order discipline is cheap and worth keeping.

Draining a task that was never initialised. If a vector does not have `has_task`, draining its uninitialised task field produces garbage. Fix: check `has_task` before draining.

Leaking the taskqueue. `taskqueue_drain` does not free the taskqueue; `taskqueue_free` does. Both are needed. Fix: call both.

Partial-setup unwind that undoes too much. If vector 2 fails and the unwind code also tears down vector 2 (which was never set up), NULL dereferences follow. The per-vector helper's NULL checks protect against this, but the cascade logic should also be careful. Fix: use `i -= 1` to start the unwind at the correct vector.

20.8.9 Wrapping Up Section 7

Teardown for a multi-vector driver is per-vector in a loop, followed by a single `pci_release_msi` at the end. The per-vector helper is shared between full-teardown and partial-failure-unwind. The observability checks after unload are the same ones Chapter 19 used; any leak points to a specific bug.

Section 8 is the refactor section: split the multi-vector code into `myfirst_msix.c`, update `INTERRUPTS.md` to reflect the new capabilities, bump the version to `1.3-msi`, and run the regression pass. The driver is functionally complete after Section 7; Section 8 makes it maintainable.

20.9 Section 8: Refactoring and Versioning Your Multi-Vector Driver

The multi-vector interrupt handler is working. Section 8 is the housekeeping section. It splits the MSI/MSI-X code into its own file, updates the module metadata, extends the `INTERRUPTS.md` document with the new multi-vector details, bumps the version to `1.3-msi`, and runs the regression pass.

This is the fourth chapter running in which the chapter closes with a refactor section. The refactors accumulate: Chapter 16 split out the hardware layer, Chapter 17 the simulation, Chapter 18 the PCI attach, Chapter 19 the legacy interrupt. Chapter 20 adds the MSI/MSI-X layer. Each responsibility has its own file; the main `myfirst.c` stays roughly constant in size; the driver scales.

20.9.1 The Final File Layout

At the end of Chapter 20:

<code>myfirst.c</code>	- Main driver
<code>myfirst.h</code>	- Shared declarations
<code>myfirst_hw.c</code>	- Ch16 hardware access layer
<code>myfirst_hw_pci.c</code>	- Ch18 hardware-layer extension
<code>myfirst_hw.h</code>	- Register map
<code>myfirst_sim.c</code>	- Ch17 simulation backend
<code>myfirst_sim.h</code>	- Simulation interface

```

myfirst_pci.c      - Ch18 PCI attach
myfirst_pci.h      - PCI declarations
myfirst_intr.c     - Ch19 interrupt handler (legacy + filter+task)
myfirst_intr.h     - Ch19 interrupt interface + ICSR macros
myfirst_msix.c     - Ch20 MSI/MSI-X multi-vector layer (NEW)
myfirst_msix.h     - Ch20 multi-vector interface (NEW)
myfirst_sync.h     - Part 3 synchronisation
cbuf.c / cbuf.h    - Ch10 circular buffer
Makefile          - kmod build
HARDWARE.md, LOCKING.md, SIMULATION.md, PCI.md, INTERRUPTS.md, MSIX.md (NEW)

```

myfirst_msix.c and myfirst_msix.h are new. MSIX.md is new. The Chapter 19 myfirst_intr.c stays; it now handles the legacy-INTx fallback while myfirst_msix.c handles the MSI and MSI-X path.

20.9.2 The myfirst_msix.h Header

```

#ifndef _MYFIRST_MSIX_H_
#define _MYFIRST_MSIX_H_

#include <sys/taskqueue.h>

struct myfirst_softc;

enum myfirst_intr_mode {
    MYFIRST_INTR_LEGACY = 0,
    MYFIRST_INTR_MSI = 1,
    MYFIRST_INTR_MSIX = 2,
};

enum myfirst_vector_id {
    MYFIRST_VECTOR_ADMIN = 0,
    MYFIRST_VECTOR_RX,
    MYFIRST_VECTOR_TX,
    MYFIRST_MAX_VECTORS
};

struct myfirst_vector {
    struct resource      *irq_res;
    int                  irq_rid;
    void                 *intr_cookie;
    enum myfirst_vector_id id;
    struct myfirst_softc *sc;
    uint64_t             fire_count;
};

```

```
uint64_t      stray_count;
const char    *name;
driver_filter_t *filter;
struct task   task;
bool          has_task;
};

int  myfirst_msix_setup(struct myfirst_softc *sc);
void myfirst_msix_teardown(struct myfirst_softc *sc);
void myfirst_msix_add_sysctls(struct myfirst_softc *sc);

#endif /* _MYFIRST_MSIX_H_ */
```

The public API is three functions: `setup`, `teardown`, `add_sysctls`. The enum types and the per-vector struct are exported so `myfirst.h` can include them and the softc can have the per-vector array.

20.9.3 The Full Makefile

```
# Makefile for the Chapter 20 myfirst driver.

KMOD=  myfirst
SRCS=  myfirst.c \
       myfirst_hw.c myfirst_hw_pci.c \
       myfirst_sim.c \
       myfirst_pci.c \
       myfirst_intr.c \
       myfirst_msix.c \
       cbuf.c

CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.3-msi\"

.include <bsd.kmod.mk>
```

One additional source file in the SRCS list; the version string bumped.

20.9.4 The Version String

1.2-intr to 1.3-msi. The bump reflects a significant capability addition: multi-vector interrupt handling. A minor-version bump is appropriate; the user-visible interface (the cdev) did not change.

20.9.5 The MSIX.md Document

A new document lives next to the source:

MSI and MSI-X Support in the myfirst Driver

Summary

The driver probes the device's MSI-X, MSI, and legacy INTx capabilities in that order, and uses the first one that allocates successfully. The driver's interrupt counters, data path, and cdev behaviour are independent of which tier the driver ends up using.

Setup Sequence

``myfirst_msix_setup()`` tries three tiers:

1. MSI-X with MYFIRST_MAX_VECTORS (3) vectors. On success:
 - Allocates per-vector IRQ resources at rid=1, 2, 3.
 - Registers a distinct filter function per vector.
 - Calls `bus_describe_intr` with the per-vector name.
 - Binds each vector to a CPU (round-robin or NUMA-aware).
2. MSI with MYFIRST_MAX_VECTORS vectors. Same per-vector pattern.
3. Legacy INTx with a single handler that covers all three event classes at rid=0.

Per-Vector Assignment

Vector	Purpose	Handles	Inline/Deferred
0	admin	INTR_STATUS.ERROR	Inline
1	rx	INTR_STATUS.DATA_AV	Deferred (task)
2	tx	INTR_STATUS.COMPLETE	Inline

On MSI-X, each vector has its own `intr_event`, its own CPU affinity (via `bus_bind_intr`), and its own `bus_describe_intr` label ("admin", "rx", "tx"). On MSI, the driver obtains a single vector and falls back to the Chapter 19 single-handler pattern because MSI requires a power-of-two vector count (`pci_alloc_msi` rejects count=3 with `EINVAL`). On legacy INTx, a single filter covers all three bits.

sysctls

- ``dev.myfirst.N.intr_mode``: 0 (legacy), 1 (MSI), 2 (MSI-X).
- ``dev.myfirst.N.vec{0,1,2}_fire_count``: per-vector fire counts.
- ``dev.myfirst.N.vec{0,1,2}_stray_count``: per-vector stray counts.
- ``dev.myfirst.N.intr_simulate_admin``, ``dev.myfirst.N.intr_simulate_rx``, ``dev.myfirst.N.intr_simulate_tx``: simulate per-vector interrupts.

Teardown Sequence

1. Disable interrupts at the device (clear `INTR_MASK`).
2. Per-vector in reverse: `bus_teardown_intr`, `bus_release_resource`.
3. Drain and free per-vector tasks and the taskqueue.
4. If `intr_mode` is MSI or MSI-X, call `pci_release_msi` once.

dmesg Summary Line

A single line on attach:

- "interrupt mode: MSI-X, 3 vectors"
- "interrupt mode: MSI, 1 vector (single-handler fallback)"
- "interrupt mode: legacy INTx (1 handler for all events)"

Known Limitations

- `MYFIRST_MAX_VECTORS` is hardcoded at 3. A dynamic design that adapts to the allocated count is a Chapter 20 challenge exercise.
- CPU binding is round-robin. NUMA-aware binding via `bus_get_cpus` is a challenge exercise.
- DMA is Chapter 21.
- iflib integration is out of scope.

See Also

- `INTERRUPTS.md` for the Chapter 19 legacy path details.
- `HARDWARE.md` for the register map.
- `LOCKING.md` for the full lock discipline.
- `PCI.md` for the PCI attach behaviour.

The document gives a future reader the full picture of the multi-vector design in one page.

20.9.6 The Regression Pass

The Chapter 20 regression is a superset of Chapter 19's:

1. Compile cleanly. `make` produces `myfirst.ko` without warnings.
2. Load. `kldload` shows the attach banner including the `interrupt mode:` line.
3. Verify mode. `sysctl dev.myfirst.0.intr_mode` returns 0, 1, or 2 (depending on guest).
4. Per-vector attach. `vmstat -i | grep myfirst` shows N lines (1 for legacy, 3 for MSI or MSI-X).
5. Per-vector description. Each entry has the correct name (`admin`, `rx`, `tx`, or `legacy`).
6. Simulated interrupts. Each vector's counter ticks independently.

7. Task runs. RX vector's simulated interrupt drives `intr_task_invocations`.
8. Clean detach. `devctl detach myfirst0` tears down all vectors.
9. Load after unload. A second `kldload` uses the same tier (tests that `pci_release_msi` worked).
10. `vmstat -m` shows no leaks. After unload, no `myfirst` allocations remain.

The regression script runs all ten checks. On QEMU with `virtio-rng-pci`, the test exercises the MSI-X path; on bhyve with `virtio-rnd`, it exercises the legacy-INTx fallback. The driver's fallback ladder ensures it works on either.

20.9.7 What the Refactor Accomplished

At the start of Chapter 20, `myfirst` at 1.2-`intr` had one interrupt handler on the legacy line. At the end of Chapter 20, `myfirst` at 1.3-`msi` has a three-tier fallback ladder (MSI-X → MSI → legacy), three per-vector filters on MSI or MSI-X, per-vector counters, per-vector CPU affinity, and a single clean teardown path. The driver's file count has grown by two; its documentation has grown by one; its functional capabilities have grown substantially.

The code is recognisably FreeBSD. A contributor opening the driver for the first time finds a familiar structure: a per-vector array, per-vector filter functions, a three-tier setup ladder, a `bus_describe_intr` for each vector, a single `pci_release_msi` at teardown. These patterns appear in every multi-queue FreeBSD driver.

20.9.8 Wrapping Up Section 8

The refactor follows the established shape: a new file for the new layer, a new header exporting the public interface, a new document explaining the behaviour, a version bump, a regression pass. Chapter 20's layer is multi-vector interrupt handling; Chapter 19's remains the single-vector legacy fallback. Together they form the full interrupt story the driver needs.

The instructional body of Chapter 20 is complete. Labs, challenges, troubleshooting, a wrap-up, and the bridge to Chapter 21 follow.

20.10 Reading a Real Driver Together: `virtio_pci.c`

Before the labs, a short walk through a real FreeBSD driver that uses MSI-X extensively. `/usr/src/sys/dev/virtio/pci/virtio_pci.c` is the shared core of both the legacy and modern virtio-PCI transports; it holds the interrupt-allocation ladder that every virtio device uses. Reading this file after Chapter 20 is a short exercise in pattern recognition; almost everything in the interrupt section maps to something Chapter 20 just taught.

20.10.1 The Allocation Ladder

`virtio_pci.c` has a helper called `vtpci_alloc_intr_resources` (the exact name varies slightly by FreeBSD version). Its structure is:

```

static int
vtpci_alloc_intr_resources(struct vtpci_common *cn)
{
    int error;

    /* Tier 0: MSI-X. */
    error = vtpci_alloc_msix(cn, nvectors);
    if (error == 0) {
        cn->vtpci_flags |= VTPCI_FLAG_MSIX;
        return (0);
    }

    /* Tier 1: MSI. */
    error = vtpci_alloc_msi(cn);
    if (error == 0) {
        cn->vtpci_flags |= VTPCI_FLAG_MSI;
        return (0);
    }

    /* Tier 2: legacy INTx. */
    return (vtpci_alloc_intx(cn));
}

```

The three tiers are exactly the Chapter 20 ladder. Each tier, on success, sets a flag on the common state and returns 0. On failure, the next tier is tried.

20.10.2 The MSI-X Allocation Helper

`vtpci_alloc_msix` queries the count, decides how many vectors to request (based on the number of virtqueues the device uses), and calls `pci_alloc_msix`:

```

static int
vtpci_alloc_msix(struct vtpci_common *cn, int nvectors)
{
    int error, count;

    if (pci_msix_count(cn->vtpci_dev) < nvectors)
        return (ENOSPC);

    count = nvectors;
    error = pci_alloc_msix(cn->vtpci_dev, &count);
    if (error != 0)
        return (error);
    if (count != nvectors) {

```

```

        pci_release_msi(cn->vtpci_dev);
        return (ENXIO);
    }
    return (0);
}

```

The pattern: check count, allocate, verify the allocation matched the request, release on mismatch. If the device advertises fewer vectors than wanted, ENOSPC is returned immediately. If `pci_alloc_msix` allocates a smaller count than requested, the code releases and returns ENXIO.

Chapter 20's code follows this exact logic (Section 5 showed the full version).

20.10.3 The Per-Vector Resource Allocation

Once MSI-X is allocated, `virtio` walks the vectors and registers a handler per vector:

```

static int
vtpci_register_msix_vectors(struct vtpci_common *cn)
{
    int i, rid, error;

    rid = 1; /* MSI-X vectors start at rid 1 */
    for (i = 0; i < cn->vtpci_num_vectors; i++) {
        cn->vtpci_vectors[i].res = bus_alloc_resource_any(
            cn->vtpci_dev, SYS_RES_IRQ, &rid, RF_ACTIVE);
        if (cn->vtpci_vectors[i].res == NULL)
            /* ... fail ... */;
        rid++;
        error = bus_setup_intr(cn->vtpci_dev,
            cn->vtpci_vectors[i].res,
            INTR_TYPE_MISC | INTR_MPSAFE,
            NULL, vtpci_vq_handler,
            &cn->vtpci_vectors[i], &cn->vtpci_vectors[i].cookie);
        if (error != 0)
            /* ... fail ... */;
    }
    return (0);
}

```

Two things match Chapter 20:

- `rid = 1` for the first vector, incrementing per vector.
- The filter (here `NULL`) and handler (`vtpci_vq_handler`) pattern. Note that `virtio` uses an `ithread`-only handler (filter=`NULL`), not a filter-plus-task pipeline. This is a simpler option that works for `virtio`'s per-vector work.

The `vtpci_vq_handler` function is the per-vector worker. Each vector gets its own argument (`&cn->vtpci_vectors[i]`), and the handler uses that argument to identify which virtqueue to service.

20.10.4 The Teardown

Virtio's teardown follows the Chapter 20 pattern:

```
static void
vtpci_release_intr_resources(struct vtpci_common *cn)
{
    int i;

    for (i = 0; i < cn->vtpci_num_vectors; i++) {
        if (cn->vtpci_vectors[i].cookie != NULL) {
            bus_teardown_intr(cn->vtpci_dev,
                             cn->vtpci_vectors[i].res,
                             cn->vtpci_vectors[i].cookie);
        }
        if (cn->vtpci_vectors[i].res != NULL) {
            bus_release_resource(cn->vtpci_dev, SYS_RES_IRQ,
                                rman_get_rid(cn->vtpci_vectors[i].res),
                                cn->vtpci_vectors[i].res);
        }
    }

    if (cn->vtpci_flags & (VTPCI_FLAG_MSI | VTPCI_FLAG_MSIX))
        pci_release_msi(cn->vtpci_dev);
}
```

Per-vector teardown (`bus_teardown_intr` + `bus_release_resource`), then a single `pci_release_msi` at the end. The order matches Chapter 20's `myfirst_msix_teardown`.

A detail worth noting: virtio uses `rman_get_rid` to recover the rid from the resource, rather than storing it separately. Chapter 20's driver stores the rid in the per-vector struct; both approaches are fine, but the storage approach is clearer and easier to debug.

20.10.5 What the Virtio Walkthrough Teaches

Three lessons transfer directly to Chapter 20's design:

1. **The three-tier fallback ladder is the standard pattern.** Every driver that wants to work on a range of hardware implements it the same way.
2. **Per-vector resource management uses incrementing rids starting at 1.** This is universal in FreeBSD's PCI infrastructure.

3. **pci_release_msi** is called once, regardless of the number of vectors. The per-vector teardown releases IRQ resources; the device-level release handles the MSI state.

A reader who can follow `vtpci_alloc_intr_resources` end to end has internalised the Chapter 20 vocabulary. For a richer example, `/usr/src/sys/dev/nvme/nvme_ctrlr.c` shows the same pattern at scale, with one admin vector plus up to NCPU I/O vectors.

20.11 A Deeper Look at Vector-to-CPU Placement

Section 5 introduced `bus_bind_intr(9)` briefly. This section goes a level deeper into why CPU placement matters, how real drivers choose CPUs, and what the trade-offs are.

20.11.1 The NUMA Picture

On a single-socket system, all CPUs share a single memory controller and a single cache hierarchy. Placement between CPUs matters only for cache affinity (the handler's code and data will be warm on whichever CPU last ran it). The performance difference between "CPU 0" and "CPU 3" is small.

On a multi-socket NUMA system, the picture changes. Each socket has its own memory controller, its own L3 cache, and its own PCIe root complex. A PCIe device attached to socket 0 sits on that socket's root complex; its registers are memory-mapped to an address range handled by socket 0's controller. An interrupt from that device fires; the handler reads `INTR_STATUS`; the read goes to the device's BAR, which is on socket 0; the CPU that runs the handler must be on socket 0, or the read crosses the inter-socket interconnect.

The inter-socket interconnect (on Intel systems: UPI or earlier QPI; on AMD: Infinity Fabric) is much slower than intra-socket cache access. A handler running on the wrong socket sees register reads that take tens of nanoseconds instead of ones; a receive queue whose data lives on the wrong socket sees every packet crossing the interconnect on the way to user space.

Well-placed vectors keep the handler's work on the socket the device lives on.

20.11.2 Querying NUMA Locality

FreeBSD exposes the NUMA topology to drivers through `bus_get_cpus(9)`. The API:

```
int bus_get_cpus(device_t dev, enum cpu_sets op, size_t setsize,
                 struct _cpuset *cpuset);
```

The `op` argument selects which set to query:

- `LOCAL_CPUS`: CPUs in the same NUMA domain as the device.
- `INTR_CPUS`: CPUs suitable for handling device interrupts (usually `LOCAL_CPUS` unless the operator has excluded some).

The `cpuset` is an output parameter; on success, it contains the bitmap of CPUs in the queried set.

Example use:

```

cpuset_t local_cpus;
int num_local;

if (bus_get_cpus(sc->dev, INTR_CPUS, sizeof(local_cpus),
    &local_cpus) == 0) {
    num_local = CPU_COUNT(&local_cpus);
    device_printf(sc->dev, "device has %d interrupt-suitable CPUs\n",
        num_local);
}

```

The driver uses `CPU_FFS(&local_cpus)` to find the first CPU in the set, `CPU_CLR(cpu, &local_cpus)` to mark it used, and iterates.

A round-robin bind that respects NUMA locality:

```

static void
myfirst_msix_bind_vectors_numa(struct myfirst_softc *sc)
{
    cpuset_t local_cpus;
    int cpu, i;

    if (bus_get_cpus(sc->dev, INTR_CPUS, sizeof(local_cpus),
        &local_cpus) != 0) {
        /* No NUMA info; round-robin across all CPUs. */
        myfirst_msix_bind_vectors_roundrobin(sc);
        return;
    }

    if (CPU_EMPTY(&local_cpus))
        return;

    for (i = 0; i < sc->num_vectors; i++) {
        if (CPU_EMPTY(&local_cpus))
            bus_get_cpus(sc->dev, INTR_CPUS,
                sizeof(local_cpus), &local_cpus);
        cpu = CPU_FFS(&local_cpus) - 1; /* FFS returns 1-based */
        CPU_CLR(cpu, &local_cpus);
        (void)bus_bind_intr(sc->dev,
            sc->vectors[i].irq_res, cpu);
    }
}

```

The code grabs the local CPU set, picks the lowest-numbered CPU, binds vector 0 to it, clears that CPU from the set, picks the next lowest, binds vector 1 to it, and so on. If the set is exhausted (more vectors than local CPUs), it refreshes and continues.

Chapter 20's driver does not include this NUMA-aware binding; a challenge exercise asks the reader to add it.

20.11.3 The Operator View

An operator can override the kernel's placement with `cpuset`:

```
# Get current placement for IRQ 257.
sudo cpuset -g -x 257

# Bind IRQ 257 to CPU 3.
sudo cpuset -l 3 -x 257

# Bind to a set of CPUs (kernel picks one when the interrupt fires).
sudo cpuset -l 2,3 -x 257
```

These commands override whatever the driver set with `bus_bind_intr`. An operator might do this to pin critical interrupts away from user-workload CPUs (for real-time applications) or to concentrate traffic on specific CPUs (for diagnostic purposes).

The driver's `bus_bind_intr` call sets the initial placement; the operator can override. A well-behaved driver sets a sensible default and respects operator changes (which it does automatically, because `bus_bind_intr` just writes to an OS-managed CPU-affinity state that the operator then modifies).

20.11.4 Measuring the Effect

A concrete way to see NUMA locality's value: run a high-interrupt-rate workload with the handler pinned to a local CPU, then to a remote CPU, and compare latencies. On a two-socket system, the remote CPU's handler typically takes 1.5x to 3x longer per interrupt, measured in CPU cycles.

FreeBSD's DTrace provider can measure this:

```
sudo dtrace -n '
fbt::myfirst_intr_filter:entry { self->ts = vtimestamp; }
fbt::myfirst_intr_filter:return /self->ts/ {
    @[cpu] = quantize(vtimestamp - self->ts);
    self->ts = 0;
}'
```

The output is a per-CPU histogram of filter latencies. A reader can run this while observing vector placements and confirm the latency difference.

20.11.5 When Vector Placement Matters

- High interrupt rates (more than a few thousand per second per vector).

- Large cache-line footprint in the handler (the handler's code and data occupy multiple cache lines).
- Shared receive paths with downstream processing on the same socket.
- NUMA systems with more than one socket and PCIe devices attached to specific sockets.

20.11.6 When Vector Placement Doesn't Matter

- Low-rate interrupts (dozens per second or fewer).
- Single-socket systems.
- Handlers that do minimal work (Chapter 20's admin vector).
- Drivers that run on a single CPU regardless (single-CPU embedded systems).

Chapter 20's driver is in the "does not really matter" category for normal testing, but the patterns the chapter teaches transfer directly to drivers where it does.

20.12 A Deeper Look at Vector Assignment Strategies

Section 6 showed the fixed-assignment pattern (vector 0 = admin, 1 = rx, 2 = tx). This section explores other assignment strategies real drivers use.

20.12.1 One-Vector-Per-Queue

The simplest strategy and the most common. Each queue (rx queue, tx queue, admin queue, etc.) has its own dedicated vector. The driver allocates $N+M+1$ vectors for N receive queues, M transmit queues, and 1 admin.

Pros: - Simple per-vector handler logic. - Each queue's interrupt rate is independent. - CPU affinity is per-queue (easy to pin to the NUMA-local CPU).

Cons: - Consumes many vectors for drivers with many queues. - Each queue's ithread adds overhead on low-rate queues.

This is the pattern `nvme(4)` uses.

20.12.2 Coalesced RX+TX Vector

Some drivers coalesce the RX and TX of a single queue-pair into a single vector. A NIC with 8 queue pairs would use 8 coalesced vectors plus a few for admin. When the vector fires, the filter checks both RX and TX status bits and dispatches accordingly.

Pros: - Half the vectors per queue-pair. - RX and TX for the same queue pair tend to be NUMA-local to each other (they share the same descriptor-ring memory).

Cons: - The filter is slightly more complex. - RX and TX can interfere under load (a burst of RX fills the handler's time, delaying TX completions).

This is a middle-ground design, used by some consumer NICs.

20.12.3 One Vector For All Queues

Some very-constrained devices (low-cost NICs, small embedded devices) have only one or two MSI-X vectors total. The driver uses a single vector for all queues and dispatches to each queue based on a status register.

Pros: - Works on hardware with few vectors. - Simple allocation.

Cons: - No per-queue affinity. - The filter does more work to decide what to dispatch.

This is the pattern a driver on very low-end hardware uses.

20.12.4 Dynamic Per-CPU Assignment

A clever design: allocate one vector per CPU, and assign queues to vectors dynamically. An RX queue is “owned” by one CPU at a time; it processes on that CPU’s vector. If the workload shifts, the driver can remap queues to different CPUs.

Pros: - Optimal per-CPU cache affinity. - Adapts to workload changes.

Cons: - Complex allocation and remapping logic. - Not easy to reason about.

Some high-end NIC drivers (Mellanox ConnectX series, Intel 800 Series) use variants of this.

20.12.5 Chapter 20’s Strategy

Chapter 20’s driver uses the fixed-assignment strategy with three vectors. It is the simplest strategy that illustrates multi-vector design without getting into NUMA details or dynamic remapping. Real drivers often start with this design and evolve to more sophisticated patterns as requirements demand.

A challenge exercise asks the reader to implement the dynamic per-CPU-allocation strategy as an extension.

20.13 A Deeper Look at Interrupt Moderation and Coalescing

A concept adjacent to MSI-X that deserves a brief mention. Modern high-throughput devices often support **interrupt moderation** or **coalescing**: the device buffers events (incoming packets, completions) and fires a single interrupt for multiple events, either at a time threshold or a count threshold.

20.13.1 Why Moderation Matters

A NIC receiving ten million packets per second would fire ten million interrupts if each packet triggered one. That is far too many; the CPU would spend all its time entering and exiting interrupt handlers. The solution is to batch: the NIC fires one interrupt every 50 microseconds, and during those 50 microseconds the NIC accumulates whatever packets arrived. The handler processes all the accumulated packets in one go.

Coalescing trades latency for throughput: each packet takes up to 50 microseconds longer to be delivered to user space, but the CPU handles millions of packets per second with a manageable interrupt rate.

20.13.2 How Drivers Control Moderation

The mechanism is device-specific. Common forms:

- **Time-based:** the device fires after a configured interval (e.g., 50 microseconds).
- **Count-based:** the device fires after N events (e.g., 16 packets).
- **Combined:** whichever threshold is reached first.
- **Adaptive:** the device (or the driver) tunes the thresholds based on observed rates.

The driver typically programs the thresholds through device registers. The MSI-X mechanism itself does not provide moderation; it is a device feature that works with MSI-X because MSI-X allows per-vector assignment.

20.13.3 Chapter 20's Driver Does Not Moderate

The Chapter 20 driver has no moderation. Each simulated interrupt produces one filter call. On real hardware this would be a problem at high rates; on the lab it is fine.

Real drivers like `em(4)`, `ix(4)`, `ixl(4)`, and `mgb(4)` all have moderation parameters. The `sysctl` interface exposes them as tunable values:

```
sysctl dev.em.0 | grep itr
```

A reader who adapts the chapter's driver to a real device should study the moderation controls for that device. The mechanism is orthogonal to MSI-X; the two combine to give high-performance interrupt handling.

20.14 Patterns From Real FreeBSD Drivers

A tour of the multi-vector patterns that appear in `/usr/src/sys/dev/`. Each pattern is a short snippet from a real driver, with a note on what it teaches for Chapter 20.

20.14.1 Pattern: `nvme(4)` Admin + I/O Vector Split

`/usr/src/sys/dev/nvme/nvme_ctrlr.c` has the canonical admin-plus-N pattern:

```
/* Allocate one vector for admin + N for I/O. */
num_trackers = MAX(1, MIN(mp_ncpus, ctrlr->max_io_queues));
num_vectors_requested = num_trackers + 1; /* +1 for admin */
num_vectors_allocated = num_vectors_requested;
pci_alloc_msix(ctrlr->dev, &num_vectors_allocated);

/* Admin queue uses vector 0 (rid 1). */
ctrlr->adminq.intr_rid = 1;
ctrlr->adminq.res = bus_alloc_resource_any(ctrlr->dev, SYS_RES_IRQ,
```

```

    &ctrlr->adminq.intr_rid, RF_ACTIVE);
bus_setup_intr(ctrlr->dev, ctrlr->adminq.res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    NULL, nvme_qpair_msix_handler, &ctrlr->adminq, &ctrlr->adminq.tag);

/* I/O queues use vectors 1..N (rid 2..N+1). */
for (i = 0; i < ctrlr->num_io_queues; i++) {
    ctrlr->ioq[i].intr_rid = i + 2;
    /* same pattern ... */
}

```

Why it matters: the admin-plus-N pattern is the right choice when one vector handles infrequent, high-priority work (errors, async events) and N vectors handle rate-limited, per-queue work. Chapter 20's admin/rx/tx split is a miniature version of this.

20.14.2 Pattern: ixgbe's Queue-Pair Vector

/usr/src/sys/dev/ixgbe/ix_txx.c uses a queue-pair design where each vector handles both the RX and TX of one queue pair:

```

/* One vector per queue pair + 1 for link. */
for (i = 0; i < num_qpairs; i++) {
    que[i].rid = i + 1;
    /* Filter checks both RX and TX status bits and dispatches. */
    bus_setup_intr(..., ixgbe_msix_que, &que[i], ...);
}
/* Link-state vector is the last one. */
link.rid = num_qpairs + 1;
bus_setup_intr(..., ixgbe_msix_link, sc, ...);

```

Why it matters: the coalesced RX+TX-per-queue-pair design halves the vector count without sacrificing per-queue affinity. Suitable when the device has many queues but few vectors.

20.14.3 Pattern: virtio_pci's Per-Virtqueue Vector

/usr/src/sys/dev/virtio/pci/virtio_pci.c has one vector per virtqueue:

```

int nvectors = ... /* count of virtqueues + 1 for config */;
pci_alloc_msix(dev, &nvectors);
for (i = 0; i < nvectors; i++) {
    vec[i].rid = i + 1;
    /* Each vector gets the per-virtqueue data as its arg. */
    bus_setup_intr(dev, vec[i].res, ..., virtio_vq_intr, &vec[i], ...);
}

```

Why it matters: virtio's per-virtqueue assignment is the model for any paravirtualised device. The vector count equals the virtqueue count plus admin/config.

20.14.4 Pattern: ahci's Per-Port Vector

`/usr/src/sys/dev/ahci/ahci_pci.c` uses one vector per SATA port:

```
for (i = 0; i < ahci->nports; i++) {
    ahci->ports[i].rid = i + 1;
    /* ... */
}
```

Why it matters: storage controllers often use per-port vector assignments so that I/O completions on different ports can be processed concurrently on different CPUs.

20.14.5 Pattern: iflib's Hidden Vector Management

Drivers using `iflib(9)` (such as `em(4)`, `igc(4)`, `ix(4)`, `ixl(4)`, `mgb(4)`) do not manage vectors directly. Instead, they register per-queue handler functions with `iflib`'s registration table, and `iflib` does the allocation and binding:

```
static struct if_shared_ctx em_sctx_init = {
    /* ... */
    .isc_driver = &em_if_driver,
    .isc_tx_maxsize = EM_TS0_SIZE,
    /* ... */
};

static int
em_if_msix_intr_assign(if_ctx_t ctx, int msix)
{
    struct e1000_softc *sc = iflib_get_softc(ctx);
    int error, rid, i, vector = 0;

    /* iflib has already called pci_alloc_msix; sc knows the count. */
    for (i = 0; i < sc->rx_num_queues; i++, vector++) {
        rid = vector + 1;
        error = iflib_irq_alloc_generic(ctx, ..., rid, IFLIB_INTR_RXTX,
            em_msix_que, ...);
    }
    return (0);
}
```

Why it matters: iflib abstracts MSI-X allocation and per-queue binding behind a clean API. Drivers using iflib are simpler than bare MSI-X drivers but give up some flexibility. The iflib pattern is the right choice for new FreeBSD network drivers; the bare MSI-X pattern is the right choice for non-network devices or when iflib does not fit.

20.14.6 What the Patterns Teach

All of these drivers follow the same structural pattern Chapter 20 teaches:

1. Query vector count.
2. Allocate vectors.
3. For each vector: allocate IRQ resource at `rid=i+1`, register handler, describe.
4. Bind vectors to CPUs.
5. On teardown: per-vector teardown in reverse, then `pci_release_msi`.

The differences among drivers are:

- How many vectors (1, a handful, dozens, or hundreds).
- How vectors are assigned (admin+N, queue-pair, per-port, per-virtqueue).
- Whether iflib handles the allocation.
- What each filter function does (admin vs data-path).

A reader who has Chapter 20's vocabulary can recognise these differences immediately.

20.15 A Performance Observation: Measuring the MSI-X Benefit

A section that grounds the chapter's performance claims in a concrete measurement.

20.15.1 The Test Setup

Suppose you have the Chapter 20 driver running on QEMU with `virtio-rng-pci` (so MSI-X is active) and a multi-CPU guest. The `intr_simulate_rx` sysctl lets you trigger interrupts from a user-space loop:

```
# In one shell, drive simulated RX interrupts as fast as possible.
while true; do
    sudo sysctl dev.myfirst.0.intr_simulate_rx=1 >/dev/null 2>&1
done
```

20.15.2 Measuring With DTrace

In another shell, measure the filter's CPU-time per invocation and which CPU it runs on:

```
sudo dtrace -n '  
fbt::myfirst_rx_filter:entry { self->ts = vtimestamp; self->c = cpu; }  
fbt::myfirst_rx_filter:return /self->ts/ {  
    @lat[self->c] = quantize(vtimestamp - self->ts);  
    self->ts = 0;  
    self->c = 0;  
}'
```

The output is a per-CPU histogram of filter latencies. If `bus_bind_intr` placed the RX vector on CPU 1, the histogram should show all invocations on CPU 1, with latencies in the hundreds of nanoseconds to single-digit microseconds.

20.15.3 What the Results Show

On a well-placed MSI-X vector:

- Every invocation is on the same CPU (the bound CPU).
- Latencies are consistently short (the hot cache lines stay on one CPU).
- No cross-CPU cache bouncing.

On a legacy INTx shared line:

- Invocations spread across CPUs (the kernel routes randomly).
- Latencies are more variable (cold cache lines on each new CPU).
- Cross-CPU cache traffic appears in performance counters.

The difference can be measured in nanoseconds per invocation. For a driver handling a few hundred interrupts per second, the difference is invisible. For a driver handling a million interrupts per second, the difference is the difference between “works” and “does not work”.

20.15.4 The General Lesson

Chapter 20’s machinery is overkill for low-rate drivers. It is essential for high-rate drivers. The patterns the chapter teaches scale from “demo driver doing a hundred interrupts per second” to “production NIC doing ten million”. Knowing where on that scale a specific driver lives determines how much of Chapter 20’s advice matters in practice.

20.16 A Deeper Look at sysctl Tree Design for Multi-Vector Drivers

Chapter 20’s driver exposes its per-vector counters as flat sysctls (`vec0_fire_count`, `vec1_fire_count`, `vec2_fire_count`). For a driver with many vectors, a flat namespace becomes unwieldy. This section shows how to use `SYSCTL_ADD_NODE` to build a per-vector sysctl tree.

20.16.1 The Flat vs Tree Trade-off

Flat namespace (what Chapter 20 uses):

```
dev.myfirst.0.vec0_fire_count: 42
dev.myfirst.0.vec1_fire_count: 9876
dev.myfirst.0.vec2_fire_count: 4523
dev.myfirst.0.vec0_stray_count: 0
dev.myfirst.0.vec1_stray_count: 0
dev.myfirst.0.vec2_stray_count: 0
```

Pros: simple, no SYSCTL_ADD_NODE calls. Cons: many siblings at the top level; no grouping.

Tree namespace:

```
dev.myfirst.0.vec.admin.fire_count: 42
dev.myfirst.0.vec.admin.stray_count: 0
dev.myfirst.0.vec.rx.fire_count: 9876
dev.myfirst.0.vec.rx.stray_count: 0
dev.myfirst.0.vec.tx.fire_count: 4523
dev.myfirst.0.vec.tx.stray_count: 0
```

Pros: groups per-vector state; scales to many vectors; named rather than numbered. Cons: more code to set up.

20.16.2 The Tree-Building Code

```
void
myfirst_msix_add_sysctls(struct myfirst_softc *sc)
{
    struct sysctl_ctx_list *ctx = &sc->sysctl_ctx;
    struct sysctl_oid *parent = sc->sysctl_tree;
    struct sysctl_oid *vec_node;
    struct sysctl_oid *per_vec_node;
    int i;

    /* Create the "vec" parent node. */
    vec_node = SYSCTL_ADD_NODE(ctx, SYSCTL_CHILDREN(parent),
        OID_AUTO, "vec", CTLFLAG_RD, NULL,
        "Per-vector interrupt statistics");

    for (i = 0; i < MYFIRST_MAX_VECTORS; i++) {
        /* Create "vec.<name>" node. */
```

```

    per_vec_node = SYSCTL_ADD_NODE(ctx,
        SYSCTL_CHILDREN(vec_node),
        OID_AUTO, sc->vectors[i].name,
        CTLFLAG_RD, NULL,
        "Per-vector statistics");

    /* Add fire_count under it. */
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(per_vec_node),
        OID_AUTO, "fire_count", CTLFLAG_RD,
        &sc->vectors[i].fire_count, 0,
        "Times this vector's filter was called");

    /* Add stray_count. */
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(per_vec_node),
        OID_AUTO, "stray_count", CTLFLAG_RD,
        &sc->vectors[i].stray_count, 0,
        "Stray returns from this vector");

    /* Other per-vector fields... */
}
}

```

The `SYSCTL_ADD_NODE` calls create the intermediate nodes; subsequent `SYSCTL_ADD_U64` calls attach leaf counters under them. The tree structure becomes visible in `sysctl` output automatically.

20.16.3 Querying the Tree

```

# Show all per-vector stats.
sysctl dev.myfirst.0.vec

# Show just the rx vector.
sysctl dev.myfirst.0.vec.rx

# Show only fire counts.
sysctl -n dev.myfirst.0.vec.admin.fire_count dev.myfirst.0.vec.rx.fire_count
↪ dev.myfirst.0.vec.tx.fire_count

```

The tree structure makes the `sysctl` namespace much more readable, especially for drivers with many vectors (NVMe with 32 I/O queues, or a NIC with 16 queue pairs).

20.16.4 When to Use the Tree

For Chapter 20's three-vector driver, the flat namespace is fine. For a driver with eight or more vectors, the tree becomes valuable. A reader writing a production driver should use the tree.

20.16.5 Common Mistakes

- **Leaking the parent node.** `SYSCTL_ADD_NODE` registers the node in `sc->sysctl_ctx`; it is freed with the rest of the context. No explicit free needed.
- **Forgetting `NULL` for the handler argument.** `SYSCTL_ADD_NODE` is not a `CTLPROC`; it is a pure grouping node. The handler argument is `NULL`.
- **Wrong parent passed to child `SYSCTL_ADD_*` calls.** `SYSCTL_CHILDREN(vec_node)` for children of `vec_node`, not `SYSCTL_CHILDREN(parent)`.

This tree-design pattern is the cleanest way to expose multi-vector state. Chapter 20's challenge exercise suggests implementing it as an extension.

20.17 A Deeper Look at Error Paths in MSI-X Setup

Section 3 and Section 5 showed the happy-path setup code. This section walks through what can go wrong and how to diagnose it.

20.17.1 Failure Mode 1: `pci_msix_count` Returns 0

Symptom: the MSI-X attempt is skipped because the count is 0.

Cause: the device has no MSI-X capability, or the PCI bus driver has not discovered it.

Fix: Confirm with `pciconf -lvc`. If the device advertises MSI-X but `pci_msix_count` returns 0, the device's PCI configuration is broken or the kernel's probe did not find it; rare and hard to fix from the driver.

20.17.2 Failure Mode 2: `pci_alloc_msix` Returns `EINVAL`

Symptom: allocation fails with `EINVAL`.

Cause: the driver is asking for a count greater than the device's advertised max, or it is asking for 0.

Fix: Clamp the requested count to `pci_msix_count`'s returned value. Always request at least 1.

20.17.3 Failure Mode 3: `pci_alloc_msix` Returns Fewer Vectors Than Requested

Symptom: count after the call is less than requested.

Cause: the kernel's vector pool was partially depleted; the device's allocation was given whatever remained.

Fix: Decide upfront whether to accept, adapt, or release. Chapter 20's driver releases and falls back to MSI.

20.17.4 Failure Mode 4: bus_alloc_resource_any Returns NULL for an MSI-X Vector

Symptom: after `pci_alloc_msix` succeeded, the per-vector IRQ allocation fails.

Causes: - Wrong rid (using 0 instead of `i+1`). - Already released previously (double-release). - Out of IRQ resources at the bus layer.

Fix: Check the rid is `i+1`. Audit the release code. Log the error.

20.17.5 Failure Mode 5: bus_setup_intr Returns EINVAL for a Per-Vector Handler

Symptom: `bus_setup_intr` fails.

Causes: - Filter and `ithread` both NULL. - Missing `INTR_TYPE_*` flag. - Already set up previously (double-setup).

Fix: Ensure the filter argument is non-NULL. Include an `INTR_TYPE_*` flag. Audit the setup code for double-registration.

20.17.6 Failure Mode 6: bus_bind_intr Returns an Error

Symptom: `bus_bind_intr` returns non-zero.

Causes: - Platform does not support rebinding. - CPU out of range. - Kernel configuration (`NO_SMP`, `NUMA` disabled).

Fix: Treat as non-fatal (`device_printf` a warning and continue). The driver still works without binding.

20.17.7 Failure Mode 7: vmstat -i Shows Vectors but Counters Don't Increment

Symptom: the kernel sees the vectors but the filters never fire.

Causes: - The device's `INTR_MASK` is zero (chapter 19 problem). - The device reset its interrupt state. - Hardware bug or bhyve/QEMU configuration problem.

Fix: Verify the device's `INTR_MASK`. Use the simulated-interrupt `sysctl` to confirm the filter works at all.

20.17.8 Failure Mode 8: Second kldload Falls Back to Lower Tier

Symptom: first load uses MSI-X; unload; second load uses legacy or MSI.

Cause: `pci_release_msi` not called on teardown.

Fix: Audit the teardown path. Make sure `pci_release_msi` runs on every successful allocation path.

20.17.9 Failure Mode 9: WITNESS Panics on Multi-Vector Setup

Symptom: WITNESS reports a lock-order violation or a "lock held during sleep" in the per-vector setup.

Cause: holding `sc->mtx` across a `bus_setup_intr` call. The bus hooks may sleep, and holding a mutex across a sleep is illegal.

Fix: Release `sc->mtx` before calling `bus_setup_intr`. Reacquire afterwards if needed.

20.17.10 Failure Mode 10: Partial Setup Doesn't Clean Up Properly

Symptom: attach fails; second attach fails with “resource in use”.

Cause: the partial-failure goto cascade doesn't undo all the way. Some per-vector state lingers.

Fix: Ensure the cascade unwinds to the vector that failed, not past it. Use the per-vector helper consistently.

20.18 Additional Troubleshooting

A handful of extra failure modes Chapter 20 readers might hit.

20.18.1 “QEMU guest does not expose MSI-X”

Causes: QEMU version too old, or the guest is booting with legacy virtio.

Fix: Update QEMU to a recent version. In the guest, check:

```
pciconf -lvc | grep -B 1 -A 2 'cap 11'
```

If no `cap 11` lines appear, MSI-X is not available. Switch to QEMU's modern `virtio-rng-pci` with `-device virtio-rng-pci,disable-legacy=on`.

20.18.2 “intr_simulate_rx increments fire_count but task never runs”

Cause: the task's `TASK_INIT` was not called, or the taskqueue was not started.

Fix: Verify `TASK_INIT(&vec->task, 0, myfirst_rx_task_fn, vec)` in setup. Verify `taskqueue_start_threads(&sc
>intr_tq, ...)`.

20.18.3 “Per-vector counters increment but the stray count goes up proportionally”

Cause: the filter's status check is wrong, or multiple vectors are triggering on the same bit.

Fix: Each filter should check for its specific bit(s). If two filters both try to handle `DATA_AV`, one will win and the other will see stray.

20.18.4 “cpuset -g -x \$irq reports mask 0 on all vectors”

Cause: `bus_bind_intr` has not been called, or it was called with CPU 0 (mask 1).

Fix: If intentionally unbound, “mask 0” might be platform-specific. If binding was attempted, check return value of `bus_bind_intr`.

20.18.5 “Driver load succeeds but dmesg shows no attach banner”

Cause: the `device_printf` came before the banner flush, or the banner is in a very early boot buffer.

Fix: `dmesg -a` shows the full message buffer. Verify `dmesg -a | grep myfirst`.

20.18.6 “Detach hangs after multi-vector setup”

Cause: a vector’s handler is still running when teardown tries to proceed. `bus_teardown_intr` blocks waiting for it.

Fix: Make sure the device’s `INTR_MASK` is cleared *before* `bus_teardown_intr`, so no new handlers can be dispatched. Make sure the filter does not loop forever; short-runtime discipline.

20.18.7 “pci_alloc_msix succeeds but only some vectors fire”

Cause: the device is not actually signalling on the vectors it should. Could be a driver bug (forgot to enable) or a device quirk.

Fix: Use the simulated-interrupt `sysctl` to confirm the filter works for each vector. If the simulated path works but real events don’t fire the vector, the issue is on the device side.

20.19 Worked Example: Tracing an Event Through Three Tiers

To make the fallback ladder concrete, here is a complete trace of the same event (a simulated `DATA_AV` interrupt) on each of the three tiers.

20.19.1 Tier 3: Legacy INTx

On bhyve with `virtio-rnd` (no MSI-X exposed), the driver falls back to legacy INTx with one handler at `rid 0`.

1. User runs `sudo sysctl dev.myfirst.0.intr_simulate_admin=1` (or `intr_simulate_rx=1`, etc.).
2. The `sysctl` handler acquires `sc->mtx`, writes the bit to `INTR_STATUS`, releases, calls the filter.
3. The single `myfirst_intr_filter` (from Chapter 19) runs. It reads `INTR_STATUS`, sees the bit, acknowledges, and either enqueues the task (for `DATA_AV`) or handles inline (for `ERROR/COMPLETE`).
4. `intr_count` increments.
5. On legacy, there is only one vector, so all three simulated-interrupt `sysctls` go through the same filter.

Observations: - `sysctl dev.myfirst.0.intr_mode` returns 0. - `vmstat -i | grep myfirst` shows one line. - The per-vector counters do not exist (legacy mode uses the Chapter 19 counters).

20.19.2 Tier 2: MSI

On a system that supports MSI but not MSI-X, the driver allocates a single MSI vector. MSI requires a power-of-two vector count, so the driver cannot ask for 3 here; it requests 1 and uses the Chapter 19 single-handler pattern.

1. User runs `sudo sysctl dev.myfirst.0.intr_simulate_admin=1` (or `intr_simulate_rx=1`, or `intr_simulate_tx=4`).
2. Because only one vector is set up on the MSI tier, all three per-vector simulation sysctls route through the same Chapter 19 `myfirst_intr_filter`.
3. The filter reads `INTR_STATUS`, sees the bit, acknowledges, and either handles inline or enqueues the task.

Observations: - `sysctl dev.myfirst.0.intr_mode` returns 1. - `vmstat -i | grep myfirst` shows one line (the single MSI handler at `rid=1`, labelled “msi”). - The per-vector counters on slots 1 and 2 stay at 0 because only slot 0 is in use; the Chapter 19 global counters (`intr_count`, `intr_data_av_count`, etc.) are the ones that move.

20.19.3 Tier 1: MSI-X

On QEMU with `virtio-rng-pci`, the driver allocates MSI-X with 3 vectors, each bound to a CPU.

1. User runs `sudo sysctl dev.myfirst.0.intr_simulate_rx=1`.
2. The sysctl calls the rx filter directly (simulated path does not go through the hardware).
3. `myfirst_rx_filter` runs (on whichever CPU the sysctl was invoked on, because simulation is not going through the kernel’s interrupt dispatch).
4. Counters increment; task runs.

Observations: - `sysctl dev.myfirst.0.intr_mode` returns 2. - `vmstat -i | grep myfirst` shows three lines; each has a different IRQ number. - `cpuset -g -x <irq>` for each IRQ shows different CPU masks.

A real (non-simulated) MSI-X interrupt would dispatch on the bound CPU; the simulation bypass makes it run on the calling thread’s CPU. This is a limitation of the simulation technique but does not affect correctness.

20.19.4 The Lesson

All three tiers drive the same filter logic and the same task. The only differences are:

- Which rid the IRQ resource uses (0 for legacy, 1+ for MSI/MSI-X).
- Whether `pci_alloc_msi` or `pci_alloc_msix` succeeded.
- How many filter functions are registered (1 for legacy, 3 for MSI/MSI-X).
- Which CPU real interrupts dispatch on.

A well-written driver works identically on all three tiers. Chapter 20’s fallback ladder ensures this.

20.20 A Practical Lab: Regression Testing Across All Three Tiers

A lab that exercises the fallback ladder to confirm all three tiers work.

20.20.1 Setup

You need two test environments:

- **Environment A:** bhyve with virtio-rnd. The driver falls back to legacy INTx.
- **Environment B:** QEMU with virtio-rng-pci. The driver uses MSI-X.

(A third environment with only MSI and no MSI-X is hard to construct reliably on modern platforms. The MSI path is exercised only if the reader has a system where MSI-X fails but MSI works.)

20.20.2 Procedure

1. On Environment A, load `myfirst.ko`. Verify:

```
sysctl dev.myfirst.0.intr_mode    # returns 0
vmstat -i | grep myfirst         # one line
```

2. Exercise the pipeline via the simulated-interrupt sysctls. All three should work, though on legacy they all go through the same filter.

```
sudo sysctl dev.myfirst.0.intr_simulate_admin=2
sudo sysctl dev.myfirst.0.intr_simulate_rx=1
sudo sysctl dev.myfirst.0.intr_simulate_tx=4
sysctl dev.myfirst.0.intr_count    # should be 3
```

3. Unload. Verify no leaks.
4. On Environment B, repeat:

```
sysctl dev.myfirst.0.intr_mode    # returns 2
vmstat -i | grep myfirst         # three lines
for irq in <IRQs>; do cpuset -g -x $irq; done
```

5. Exercise the per-vector pipeline. Each sysctl should increment its own vector's counter.

```
sudo sysctl dev.myfirst.0.intr_simulate_admin=2
sysctl dev.myfirst.0.vec.admin.fire_count    # 1
sysctl dev.myfirst.0.vec.rx.fire_count       # 0
sysctl dev.myfirst.0.vec.tx.fire_count       # 0
```

6. Unload. Verify no leaks.

20.20.3 Expected Observations

- Both environments attach cleanly.
- The `dmesg` summary line shows the correct mode for each.
- Per-vector counters tick independently on MSI-X.
- On legacy, a single counter covers all events.
- No leaks after unload in either environment.

20.20.4 What to Do if a Tier Fails

If the MSI-X tier fails on Environment B:

1. Verify QEMU is new enough. Older versions (pre-5.0) have quirks.
2. Check `pciconf -lvc` in the guest; MSI-X capability should be visible.
3. Check `dmesg` for errors from `pci_alloc_msix`.

If the legacy tier fails on Environment A:

1. Check `pciconf -lvc` for the device's interrupt line configuration.
2. Ensure `virtio_rnd` is not already attached (Chapter 18 caveat).
3. Look for `pci_alloc_resource` failures in `dmesg`.

20.21 Extended Challenge: Building a Production-Quality Driver

An optional exercise for readers who want to practise multi-vector design on a realistic scale.

20.21.1 The Goal

Take the Chapter 20 driver and extend it to handle *N* queues dynamically, where *N* is discovered at attach time based on the allocated MSI-X vector count. Each queue has:

- Its own vector (MSI-X vector 1+queue_id).
- Its own filter function (or a shared one that identifies the queue from the vector arg).
- Its own counters.
- Its own task on its own taskqueue.
- Its own NUMA-local CPU binding.

20.21.2 Implementation Outline

1. Replace `MYFIRST_MAX_VECTORS` with a runtime-chosen count.
2. Allocate the `vectors[]` array dynamically (using `malloc`).
3. Allocate a separate taskqueue per vector.
4. Use `bus_get_cpus(INTR_CPUS, ...)` to distribute vectors across NUMA-local CPUs.
5. Add sysctls that scale with the vector count.

20.21.3 Testing

Run the driver on a guest with varying MSI-X vector counts. For each count, verify: - The fire counters tick for the simulated interrupts. - The CPU affinity respects NUMA locality. - Teardown is clean.

20.21.4 What This Exercises

- Dynamic memory management in a driver.
- The `bus_get_cpus` API.
- Per-queue taskqueues (challenge 3 from earlier).
- Runtime sysctl tree construction (challenge 7 from earlier).

This is a significant exercise and will likely take several hours. The result is a driver recognisably similar to production NIC and NVMe drivers.

20.22 Reference: Priority Values for Interrupt and Task Work

For quick reference, the priority constants a Chapter 20 driver might use (from `/usr/src/sys/sys/priority.h`):

```
PI_REALTIME = PRI_MIN_ITHD + 0    (highest; rarely used)
PI_INTR      = PRI_MIN_ITHD + 4    (common hardware interrupt level)
PI_AV        = PI_INTR             (audio/video)
PI_NET       = PI_INTR             (network)
PI_DISK      = PI_INTR             (block storage)
PI_TTY       = PI_INTR             (terminal/serial)
PI_DULL      = PI_INTR             (low-priority hardware)
PI_SOFT      = PRI_MIN_ITHD + 8    (soft interrupts)
```

The common hardware priorities all map to `PI_INTR`; the names are distinctions of intent rather than of scheduling priority. Chapter 20's driver uses `PI_NET` for its taskqueue; any hardware-level priority would work equivalently.

20.23 Reference: Useful DTrace One-Liners for MSI-X Drivers

For readers who want to observe the Chapter 20 driver's behaviour dynamically.

20.23.1 Count filter invocations per CPU

```
sudo dtrace -n '
fbt::myfirst_admin_filter:entry, fbt::myfirst_rx_filter:entry,
fbt::myfirst_tx_filter:entry { @[probefunc, cpu] = count(); }'
```

Shows which filter runs on which CPU.

20.23.2 Time spent in each filter

```
sudo dtrace -n '  
fbt::myfirst_rx_filter:entry { self->ts = vtimestamp; }  
fbt::myfirst_rx_filter:return /self->ts/ {  
    @[probefunc] = quantize(vtimestamp - self->ts);  
    self->ts = 0;  
}'
```

Histogram of RX filter CPU time.

20.23.3 Rate of simulated vs real interrupts

```
sudo dtrace -n '  
fbt::myfirst_intr_simulate_vector_sysctl:entry { @sims = count(); }  
fbt::myfirst_rx_filter:entry { @filters = count(); }'
```

If `filters > sims`, some real interrupts are firing.

20.23.4 Task latency

```
sudo dtrace -n '  
fbt::myfirst_rx_filter:entry { self->ts = vtimestamp; }  
fbt::myfirst_rx_task_fn:entry /self->ts/ {  
    @lat = quantize(vtimestamp - self->ts);  
    self->ts = 0;  
}'
```

Histogram of time from filter to task invocation. Shows the taskqueue's scheduling latency.

20.24 Reference: A Closing Note Before Part 4's End

Chapters 16 through 20 built the full interrupt and hardware story for the `myfirst` driver. Each chapter added one layer:

- Chapter 16: register access.
- Chapter 17: device behaviour simulation.
- Chapter 18: PCI attach.
- Chapter 19: single-vector interrupt handling.
- Chapter 20: multi-vector MSI/MSI-X.

Chapter 21 will add DMA, completing Part 4's hardware layer. At that point, the `myfirst` driver will be structurally a real driver: a PCI device with MSI-X interrupts and DMA-based data transfer. What distinguishes it from a production driver is the specific protocol it speaks (none, really; it is a demo) and the device it targets (a `virtio-rnd` abstraction).

A reader who has internalised these five chapters can open any FreeBSD driver in `/usr/src/sys/dev/` and recognise the patterns. That recognition is Part 4's deepest payoff.

20.25 Hands-On Labs

The labs are graduated checkpoints. Each lab builds on the previous one and corresponds to one of the chapter's stages. A reader who works through all five has a complete multi-vector driver, a working QEMU test environment for MSI-X, and a regression script that validates all three tiers of the fallback ladder.

Time budgets assume the reader has already read the relevant sections.

20.25.1 Lab 1: Discover MSI and MSI-X Capabilities

Time: thirty minutes.

Objective: Build an intuition for which devices on your system support MSI and MSI-X.

Steps:

1. Run `sudo pciconf -lvc > /tmp/pci_caps.txt`. The `-c` flag includes capability lists.
2. Search for MSI capabilities: `grep -B 1 "cap 05" /tmp/pci_caps.txt`.
3. Search for MSI-X capabilities: `grep -B 1 "cap 11" /tmp/pci_caps.txt`.
4. For three devices that support MSI-X, note:
 - The device's name (`pci0:B:D:F`).
 - The number of MSI-X messages supported.
 - Whether the driver is currently using MSI-X (check `vmstat -i` for multiple lines of the same device name).
5. Compare the total number of MSI-capable devices to the total number of MSI-X-capable devices. Modern systems typically have more MSI-X devices than MSI-only devices.

Expected observations:

- NICs usually advertise MSI-X with many vectors (4 to 64).
- SATA and NVMe controllers advertise MSI-X (NVMe often with dozens of vectors).
- Some legacy devices (an audio chip, a USB controller) advertise only MSI.
- A few very old devices advertise neither and rely on legacy INTx.

This lab is about vocabulary. No code. The payoff is that Section 2 and 5's allocation calls become concrete.

20.25.2 Lab 2: Stage 1, MSI Fallback Ladder

Time: two to three hours.

Objective: Extend Chapter 19's driver with the MSI-first fallback ladder. Version target: 1.3-msi-stage1.

Steps:

1. Starting from Chapter 19 Stage 4, copy the driver source to a new working directory.
2. Add the `intr_mode` field and enum to `myfirst.h`.
3. Modify `myfirst_intr_setup` (in `myfirst_intr.c`) to attempt MSI allocation first, falling back to legacy INTx.
4. Modify `myfirst_intr_teardown` to call `pci_release_msi` when MSI was used.
5. Add the `dev.myfirst.N.intr_mode` sysctl.
6. Update the Makefile version string to 1.3-msi-stage1.
7. Compile (`make clean && make`).
8. Load on a guest. Note which mode the driver reports:

```
sudo kldload ./myfirst.ko
sudo dmesg | tail -5
sysctl dev.myfirst.0.intr_mode
```

On QEMU with `virtio-rng-pci`, the driver should report MSI, 1 vector (or similar). On bhyve with `virtio-rnd`, it should report legacy INTx.

9. Unload and verify no leaks.

Common failures:

- Missing `pci_release_msi`: next load fails or falls back to legacy.
- Wrong rid (using 0 for MSI): `bus_alloc_resource_any` returns NULL.
- Not checking the returned count: driver proceeds with fewer vectors than expected.

20.25.3 Lab 3: Stage 2, Multi-Vector Allocation (MSI)

Time: three to four hours.

Objective: Extend to three MSI vectors with per-vector handlers. Version target: 1.3-msi-stage2.

Steps:

1. Starting from Lab 2, add the `myfirst_vector` struct and per-vector array to `myfirst.h`.
2. Write three filter functions: `myfirst_admin_filter`, `myfirst_rx_filter`, `myfirst_tx_filter`.
3. Write the `myfirst_intr_setup_vector` and `myfirst_intr_teardown_vector` helpers.
4. Modify `myfirst_intr_setup` to try `pci_alloc_msi` for `MYFIRST_MAX_VECTORS` vectors, setting up each vector independently.
5. Modify `myfirst_intr_teardown` to loop per-vector.
6. Add per-vector counter sysctls (`vec0_fire_count`, `vec1_fire_count`, `vec2_fire_count`).
7. Add per-vector simulated-interrupt sysctls (`intr_simulate_admin`, `intr_simulate_rx`, `intr_simulate_tx`).
8. Bump the version to 1.3-msi-stage2.
9. Compile, load, verify:

```
sysctl dev.myfirst.0.intr_mode    # should be 1 on QEMU
vmstat -i | grep myfirst         # should show 3 lines
```

10. Exercise each vector:

```
sudo sysctl dev.myfirst.0.intr_simulate_admin=2 # ERROR
sudo sysctl dev.myfirst.0.intr_simulate_rx=1    # DATA_AV
sudo sysctl dev.myfirst.0.intr_simulate_tx=4    # COMPLETE
sysctl dev.myfirst.0 | grep vec
```

Each vector's counter should increment independently.

11. Unload, verify no leaks.

20.25.4 Lab 4: Stage 3, MSI-X With CPU Binding

Time: three to four hours.

Objective: Prefer MSI-X over MSI, bind each vector to a CPU. Version target: 1.3-msi-stage3.

Steps:

1. Starting from Lab 3, change the fallback ladder to attempt MSI-X first (via `pci_msix_count` and `pci_alloc_msix`), MSI as second tier, legacy as last.
2. Add the `myfirst_msix_bind_vectors` helper that calls `bus_bind_intr` for each vector.
3. Call the bind helper after all vectors are registered.
4. Update the `dmesg` summary line to distinguish MSI-X from MSI.
5. Bump the version to 1.3-msi-stage3.
6. Compile, load on QEMU with `virtio-rng-pci`. Verify:

```
sysctl dev.myfirst.0.intr_mode    # should be 2 on QEMU
sudo dmesg | grep myfirst | grep MSI-X
```

The attach line should read `interrupt mode: MSI-X, 3 vectors`.

7. Check per-vector CPU bindings:

```
# For each myfirst IRQ, show its CPU binding.
vmstat -i | grep myfirst
# (Note the IRQ numbers, then:)
for irq in <IRQ1> <IRQ2> <IRQ3>; do
    echo "IRQ $irq:"
    cpuset -g -x $irq
done
```

On a multi-CPU guest, each vector should be bound to a different CPU.

8. Exercise each vector (same as Lab 3).
9. Detach and reattach:

```
sudo devctl detach myfirst0
sudo devctl attach pci0:0:4:0
sysctl dev.myfirst.0.intr_mode # should still be 2
```

10. Unload, verify no leaks.

20.25.5 Lab 5: Stage 4, Refactor, Regression, Version

Time: three to four hours.

Objective: Move the multi-vector code into `myfirst_msix.c`, write `MSIX.md`, run the regression. Version target: 1.3-msi.

Steps:

1. Starting from Lab 4, create `myfirst_msix.c` and `myfirst_msix.h`.
2. Move the per-vector filter functions, helpers, setup, teardown, and sysctl registration into `myfirst_msix.c`.
3. Keep the legacy-INTx fallback in `myfirst_intr.c` (Chapter 19's file).
4. In `myfirst_pci.c`, replace the old interrupt setup/teardown calls with calls into `myfirst_msix.c`.
5. Update the Makefile to add `myfirst_msix.c` to SRCS. Bump the version to 1.3-msi.
6. Write `MSIX.md` documenting the multi-vector design.
7. Compile, load, run the full regression script (from the companion examples).
8. Confirm all three tiers work (by testing on bhyve with `virtio-rnd` for legacy and QEMU with `virtio-rng-pci` for MSI-X).

Expected outcomes:

- The driver at 1.3-msi works on both bhyve (legacy fallback) and QEMU (MSI-X).
- `myfirst_intr.c` now only contains the Chapter 19 single-handler fallback path.
- `myfirst_msix.c` contains the Chapter 20 multi-vector logic.
- `MSIX.md` documents the design clearly.

20.26 Challenge Exercises

The challenges build on the labs and extend the driver in directions the chapter did not take.

20.26.1 Challenge 1: Dynamic Vector-Count Adaptation

Modify the setup to adapt to whatever vector count the kernel actually allocates. If 3 are requested but 2 are allocated, the driver should still work with 2 (fold admin and tx into one combined vector). If 1 is allocated, fold everything into one.

This exercise teaches the “adapt” strategy from the fallback ladder.

20.26.2 Challenge 2: NUMA-Aware CPU Binding

Replace the round-robin CPU binding with a NUMA-aware binding using `bus_get_cpus(dev, INTR_CPUS, ...)`. Verify with `cpuset -g -x <irq>` that vectors land on CPUs in the same NUMA domain as the device.

On a single-socket system the exercise is academic; on a multi-socket test host it is measurable.

20.26.3 Challenge 3: Per-Vector Taskqueues

Each vector currently shares one taskqueue. Modify the driver so each vector has its own taskqueue (with its own worker thread). Measure the latency impact with DTrace.

This exercise introduces per-vector workers and shows when they help vs hurt.

20.26.4 Challenge 4: Per-Vector MSI-X Mask Control

The MSI-X table's vector-control register has a mask bit per vector. Add a sysctl that lets the operator mask an individual vector at runtime. Verify that a masked vector stops receiving interrupts.

Hint: the mask bit is programmed through direct MSI-X table access, which is a deeper topic than Chapter 20 covers. The FreeBSD MSI-X implementation may or may not expose this directly; a reader might need to use `bus_tearardown_intr` and later `bus_setup_intr` as a higher-level "soft mask".

20.26.5 Challenge 5: Implement Interrupt Moderation

For a simulated driver, moderation is easy to prototype: a sysctl that coalesces N simulated interrupts into one task run. Implement the coalescing, measure the latency-vs-throughput trade-off.

20.26.6 Challenge 6: Vector Reassignment at Runtime

Add a sysctl that lets the operator reassign which vector handles which event class (e.g., swap RX and TX). Demonstrate that after the reassignment, simulated-interrupt-RX triggers the TX filter and vice versa.

20.26.7 Challenge 7: Per-Queue Sysctl Tree

Restructure the per-vector sysctls into a proper tree: `dev.myfirst.N.vec.admin.fire_count`, `dev.myfirst.N.vec.rx.f` etc. Use `SYSCTL_ADD_NODE` to create the tree nodes.

20.26.8 Challenge 8: Dtrace Instrumentation

Write a DTrace script that shows the per-CPU distribution of each vector's filter invocations. Plot the per-CPU breakdown as a histogram. This is the diagnostic that confirms CPU binding is working.

20.27 Troubleshooting and Common Mistakes

20.27.1 “pci_alloc_msix returns EBUSY or ENXIO”

Possible causes:

1. The device is not connected in a way that supports MSI-X (legacy virtio-rnd on bhyve, for example). Check `pciconf -lvc`.
2. A previous load of the driver did not call `pci_release_msi` at teardown. Reboot or try `kldunload + kldload` again.
3. The kernel ran out of interrupt vectors. Rare on modern x86, possible on low-vector platforms.

20.27.2 “vmstat -i shows only one line on MSI-X guest”

Likely cause: `pci_alloc_msix` succeeded but allocated only 1 vector. Check the returned count vs requested. Either accept (fold work into one) or release and fall back.

20.27.3 “Filter fires but vec->fire_count stays at zero”

Likely cause: the `sc` argument is confused with `vec`. The handler receives `vec`, not `sc`. Check `bus_setup_intr`’s argument.

20.27.4 “Driver panics on kldunload after multiple load/unload cycles”

Likely cause: `pci_release_msi` not called on teardown. The device-level MSI state leaks across loads; eventually the kernel’s internal bookkeeping is confused.

20.27.5 “Different vectors all fire on the same CPU”

Likely cause: `bus_bind_intr` failed silently. Check the return value and log non-zero results.

20.27.6 “MSI-X allocation succeeds but vmstat -i shows no events”

Likely cause: the device’s `INTR_MASK` write targeted the wrong register or was skipped. Verify the mask is set (Chapter 17/Chapter 19 diagnostic).

20.27.7 “Stray interrupts accumulate on the MSI-X admin vector”

Likely cause: the admin filter’s status check is wrong; the filter returns `FILTER_STRAY` when it should handle. Check the `status & MYFIRST_INTR_ERROR` check.

20.27.8 “Shared-IRQ behaviour on legacy fallback differs from MSI-X”

Expected. On legacy `INTx` the single handler sees every event bit; on MSI-X each vector sees only its own event. Tests that exercise per-vector stray counts differ between the two modes.

20.27.9 “Stage 2 compiles but Stage 3 fails at bus_get_cpus link error”

Cause: `bus_get_cpus` may not be available in older FreeBSD versions or may require specific `#include <sys/bus.h>` placement. Check the include order.

20.27.10 “QEMU guest does not expose MSI-X despite using virtio-rng-pci”

Likely cause: older QEMU versions use legacy virtio by default. Check `pciconf -lvc` in the guest; if MSI-X is not listed, the guest is using legacy. Update QEMU or use `-device virtio-rng-pci,disable-modern=off,disable-legacy=on`.

20.28 Wrapping Up

Chapter 20 gave the driver the ability to handle multiple interrupt vectors. The starting point was `1.2-intr` with one handler on the legacy INTx line. The ending point is `1.3-msi` with a three-tier fallback ladder (MSI-X, MSI, legacy), three per-vector filter handlers, per-vector counters and tasks, per-vector CPU binding, a clean multi-vector teardown, and a new `myfirst_msix.c` file plus `MSIX.md` document.

The eight sections walked the full progression. Section 1 introduced MSI and MSI-X at the hardware level. Section 2 added MSI as a single-vector alternative to legacy INTx. Section 3 extended to multi-vector MSI. Section 4 examined the concurrency implications of multiple filters on multiple CPUs. Section 5 moved to MSI-X with per-vector CPU binding. Section 6 codified the per-vector event roles. Section 7 consolidated the teardown. Section 8 refactored into the final layout.

What Chapter 20 did not do is DMA. Each vector’s handler still only touches registers; the device does not yet have the ability to reach into RAM. Chapter 21 is where that changes. DMA introduces new complications (coherence, scatter-gather, mapping) that interact with interrupts (completion interrupts signal that a DMA transfer is done). The Chapter 20 interrupt machinery is ready to handle completion interrupts; Chapter 21 writes the DMA side.

The file layout has grown: 14 source files (including `cbuf`), 6 documentation files (`HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`), and a growing regression test suite. The driver is structurally parallel to production FreeBSD drivers at this point.

20.28.1 A Reflection Before Chapter 21

Chapter 20 was the last chapter in Part 4 that is purely about interrupts. Chapter 21 moves to DMA, which is about moving data. The two are complementary: interrupts signal events; DMA moves the data those events are about. A high-performance driver uses both together: receive descriptors are populated by DMA from the device into RAM, then a completion interrupt signals the driver to process the descriptors.

Chapter 20’s per-vector handlers are already the right shape for this. Each receive queue’s completion interrupt fires its own vector; each vector’s filter acknowledges and defers; the task walks the receive ring (populated by DMA, Chapter 21) and passes packets up. Chapter 21 writes the DMA side; Chapter 20’s interrupt side is already in place.

The chapter's teaching also generalises. A reader who has internalised Chapter 20's three-tier fallback ladder, per-vector state design, CPU binding, and clean teardown will find similar patterns in every multi-queue FreeBSD driver. The specific device differs; the structure does not.

20.28.2 What to Do If You Are Stuck

Three suggestions.

First, read `/usr/src/sys/dev/virtio/pci/virtio_pci.c` carefully, focusing on the `vtpci_alloc_intr_resources` family of functions. The pattern matches Chapter 20 exactly and the code is compact enough to read in one sitting.

Second, run the chapter's regression test on both a bhyve guest (legacy fallback) and a QEMU guest (MSI-X). Seeing the same driver behave correctly on both targets confirms the fallback ladder is right.

Third, skip the challenges on first pass. The labs are calibrated for Chapter 20's pace; the challenges assume the material is solid. Come back to them after Chapter 21 if they feel out of reach now.

Chapter 20's goal was to give the driver a multi-vector interrupt path. If it has, Chapter 21's DMA work becomes a complement rather than an entirely new topic.

20.29 Bridge to Chapter 21

Chapter 21 is titled *DMA and High-Speed Data Transfer*. Its scope is the topic Chapter 20 deliberately did not take: the device's ability to read and write RAM directly, without the driver in the loop for each word. A NIC with a 64-entry receive descriptor ring populates those entries by DMA from the wire; a single interrupt signals "N entries are ready". The driver's handler walks the ring and processes the entries. Without DMA the driver would have to read each byte from a device register, which does not scale.

Chapter 20 prepared the ground in three specific ways.

First, **you have per-vector completion interrupts**. Each queue's receive completions and transmit completions can fire a dedicated vector. Chapter 21's DMA ring work plugs into Chapter 20's per-vector filter and task; the filter sees "completions N through M are ready", the task processes them.

Second, **you have per-CPU handler placement**. A DMA ring's memory is on a specific NUMA node; the handler that processes it should run on a CPU on that node. Chapter 20's `bus_bind_intr` work is the mechanism. Chapter 21 extends this: the DMA memory is allocated with NUMA awareness too, so the ring, the handler, and the processing all end up on the same node.

Third, **you have the teardown discipline**. DMA adds more resources (DMA tags, DMA maps, DMA memory regions), and each needs its own teardown step. The Chapter 19/Chapter 20 per-vector teardown pattern extends naturally to per-queue DMA cleanup.

Specific topics Chapter 21 will cover:

- What DMA is, the difference between memory-mapped I/O and DMA.
- `bus_dma(9)`: tags, maps, and the DMA state machine.
- `bus_dma_tag_create` to describe DMA requirements (alignment, boundaries, address range).
- `bus_dmamap_create` and `bus_dmamap_load` to set up DMA transfers.

- Synchronisation: `bus_dmamap_sync` around DMA.
- Bounce buffers: what they are and when they are used.
- Cache coherence: why CPUs and devices see different memory at different times.
- Scatter-gather lists: physical addresses that are not contiguous.
- Ring buffers: the producer-consumer descriptor ring pattern.

You do not need to read ahead. Chapter 20 is sufficient preparation. Bring your `myfirst` driver at `1.3-msi`, your `LOCKING.md`, your `INTERRUPTS.md`, your `MSIX.md`, your WITNESS-enabled kernel, and your regression script. Chapter 21 starts where Chapter 20 ended.

The hardware conversation is deepening. The vocabulary is yours; the structure is yours; the discipline is yours. Chapter 21 adds the next missing piece: the device's ability to move data without asking.

20.30 Reference: Chapter 20 Quick-Reference Card

A compact summary of the vocabulary, APIs, macros, and procedures Chapter 20 introduced.

20.30.1 Vocabulary

- **MSI (Message Signalled Interrupts)**: PCI 2.2 mechanism. 1 to 32 vectors, contiguous, single address.
- **MSI-X**: PCIe mechanism. Up to 2048 vectors, per-vector address, per-vector mask, table in a BAR.
- **vector**: a single interrupt source identified by an index.
- **rid**: the resource ID used with `bus_alloc_resource_any`. 0 for legacy INTx, 1+ for MSI and MSI-X.
- **intr_mode**: the driver's record of which tier it is using (legacy, MSI, or MSI-X).
- **fallback ladder**: try MSI-X first, then MSI, then legacy INTx.
- **per-vector state**: counters, filter, task, cookie, resource per vector.
- **CPU binding**: routing a vector to a specific CPU via `bus_bind_intr`.
- **LOCAL_CPUS / INTR_CPUS**: CPU-set queries for NUMA-aware placement.

20.30.2 Essential APIs

- `pci_msi_count(dev)`: query MSI vector count.
- `pci_msix_count(dev)`: query MSI-X vector count.
- `pci_alloc_msi(dev, &count)`: allocate MSI vectors.
- `pci_alloc_msix(dev, &count)`: allocate MSI-X vectors.
- `pci_release_msi(dev)`: release MSI or MSI-X vectors.
- `pci_msix_table_bar(dev)`, `pci_msix_pba_bar(dev)`: identify table/PBA BARs.
- `bus_alloc_resource_any(dev, SYS_RES_IRQ, &rid, RF_ACTIVE)`: allocate per-vector IRQ resource.
- `bus_setup_intr(dev, res, flags, filter, ihand, arg, &cookie)`: register per-vector handler.
- `bus_teardown_intr(dev, res, cookie)`: unregister per-vector handler.
- `bus_describe_intr(dev, res, cookie, "name")`: label per-vector handler.
- `bus_bind_intr(dev, res, cpu)`: bind vector to a specific CPU.
- `bus_get_cpus(dev, op, size, &set)`: query NUMA-local CPUs (`op` = `LOCAL_CPUS` or `INTR_CPUS`).

20.30.3 Essential Macros

- `PCIY_MSI` = 0x05: MSI capability ID.
- `PCIY_MSIX` = 0x11: MSI-X capability ID.
- `PCIM_MSIXCTRL_TABLE_SIZE` = 0x07FF: mask for vector count.
- `PCI_MSIX_MSGNUM(ctrl)`: macro to extract vector count from control register.
- `MYFIRST_MAX_VECTORS`: driver-defined constant (3 in Chapter 20).

20.30.4 Common Procedures

Implement the three-tier fallback ladder:

1. `pci_msix_count(dev)`; if > 0, try `pci_alloc_msix`.
2. On failure, `pci_msi_count(dev)`; if > 0, try `pci_alloc_msi`.
3. On failure, fall back to legacy INTx with `rid = 0` and `RF_SHAREABLE`.

Register per-vector handlers (MSI-X):

1. Loop from `i = 0` to `num_vectors - 1`.
2. For each: `bus_alloc_resource_any(dev, SYS_RES_IRQ, &rid, RF_ACTIVE)` with `rid = i + 1`.
3. `bus_setup_intr(dev, vec->irq_res, INTR_TYPE_MISC | INTR_MPSAFE, vec->filter, NULL, vec, &vec->intr_cookie)`.
4. `bus_describe_intr(dev, vec->irq_res, vec->intr_cookie, vec->name)`.
5. `bus_bind_intr(dev, vec->irq_res, target_cpu)`.

Tear down a multi-vector driver:

1. Clear `INTR_MASK` at the device.
2. For each vector (reverse order): `bus_tearardown_intr`, `bus_release_resource`.
3. Drain each per-vector task.
4. Free the taskqueue.
5. `pci_release_msi(dev)` if MSI or MSI-X was used.

20.30.5 Useful Commands

- `pciconf -lvc`: list devices with capability lists.
- `vmstat -i`: show per-handler interrupt counts.
- `cpuset -g -x <irq>`: query CPU affinity for an IRQ.
- `cpuset -l <cpu> -x <irq>`: set CPU affinity for an IRQ.
- `sysctl dev.myfirst.0.intr_mode`: query driver's interrupt mode.

20.30.6 Files to Keep Bookmarked

- `/usr/src/sys/dev/pci/pcivar.h`: MSI/MSI-X inline wrappers.
- `/usr/src/sys/dev/pci/pci.h`: capability IDs and bit fields.
- `/usr/src/sys/dev/pci/pci.c`: kernel-side implementation of `pci_alloc_msi/msix`.

- `/usr/src/sys/dev/virtio/pci/virtio_pci.c`: clean MSI-X fallback-ladder example.
- `/usr/src/sys/dev/nvme/nvme_ctrlr.c`: per-queue MSI-X pattern at scale.

20.31 Reference: Glossary of Chapter 20 Terms

affinity: the mapping from an interrupt vector to a specific CPU (or set of CPUs).

bus_bind_intr(9): function to route an interrupt vector to a specific CPU.

bus_get_cpus(9): function to query CPU sets associated with a device (local, interrupt-suitable).

capability list: the linked list of PCI device capabilities in configuration space.

coalescing: buffering multiple events into one interrupt to reduce rate.

cookie: the opaque handle returned by `bus_setup_intr(9)`, used by `bus_tearardown_intr(9)`.

fallback ladder: the sequence MSI-X → MSI → legacy INTx that drivers implement.

intr_mode: driver-side enum recording which interrupt tier is active.

INTR_CPUS: `cpu_sets` enum value; CPUs suitable for handling device interrupts.

LOCAL_CPUS: `cpu_sets` enum value; CPUs in the same NUMA domain as the device.

MSI: Message Signalled Interrupts, PCI 2.2.

MSI-X: the fuller mechanism, PCIe.

moderation: buffering interrupts at the device level to trade latency for throughput.

NUMA: Non-Uniform Memory Access; multi-socket system architecture.

per-vector state: the softc fields specific to one vector (counters, filter, task, cookie, resource).

pci_msi_count(9) / pci_msix_count(9): capability-count queries.

pci_alloc_msi(9) / pci_alloc_msix(9): vector allocation.

pci_release_msi(9): release of MSI/MSI-X (handles both).

rid: resource ID. 0 for legacy INTx, 1+ for MSI/MSI-X vectors.

stray interrupt: an interrupt that no filter claims.

taskqueue: FreeBSD's deferred-work primitive.

vector: a single interrupt source in the MSI or MSI-X mechanism.

vmstat -i: diagnostic showing per-handler interrupt counts.

20.32 Reference: The Complete Stage 4 `myfirst_msix.c` Walkthrough

For readers who want a single place to see the final multi-vector layer annotated, this appendix walks through `myfirst_msix.c` from the companion examples, showing each function and explaining the design choices.

20.32.1 The Top of the File

```
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/kernel.h>
#include <sys/bus.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/condvar.h>
#include <sys/rman.h>
#include <sys/sysctl.h>
#include <sys/taskqueue.h>
#include <sys/types.h>
#include <sys/smp.h>

#include <machine/atomic.h>
#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/pci/pci.h>
#include <dev/pci/pcireg.h>
#include <dev/pci/pcivar.h>

#include "myfirst.h"
#include "myfirst_hw.h"
#include "myfirst_intr.h"
#include "myfirst_msix.h"
```

The include list is longer than `myfirst_intr.c`'s: `<dev/pci/pci.h>` and `<dev/pci/pcivar.h>` for the MSI/MSI-X API, `<sys/smp.h>` for `mp_ncpus`, and `<machine/atomic.h>` for the per-vector counter increments. Note that `<dev/pci/pci.h>` is pulled in even though the file does not directly use `PCIY_MSI` or similar constants; the accessor inline functions in `pcivar.h` depend on it.

20.32.2 The Per-Vector Helpers

```
static int
myfirst_msix_setup_vector(struct myfirst_softc *sc, int idx, int rid)
{
    struct myfirst_vector *vec = &sc->vectors[idx];
    int error;

    vec->irq_rid = rid;
    vec->irq_res = bus_alloc_resource_any(sc->dev, SYS_RES_IRQ,
```

```

        &vec->irq_rid, RF_ACTIVE);
    if (vec->irq_res == NULL)
        return (ENXIO);

    error = bus_setup_intr(sc->dev, vec->irq_res,
        INTR_TYPE_MISC | INTR_MPSAFE,
        vec->filter, NULL, vec, &vec->intr_cookie);
    if (error != 0) {
        bus_release_resource(sc->dev, SYS_RES_IRQ,
            vec->irq_rid, vec->irq_res);
        vec->irq_res = NULL;
        return (error);
    }

    bus_describe_intr(sc->dev, vec->irq_res, vec->intr_cookie,
        "%s", vec->name);
    return (0);
}

static void
myfirst_msix_teardown_vector(struct myfirst_softc *sc, int idx)
{
    struct myfirst_vector *vec = &sc->vectors[idx];

    if (vec->intr_cookie != NULL) {
        bus_teardown_intr(sc->dev, vec->irq_res, vec->intr_cookie);
        vec->intr_cookie = NULL;
    }
    if (vec->irq_res != NULL) {
        bus_release_resource(sc->dev, SYS_RES_IRQ,
            vec->irq_rid, vec->irq_res);
        vec->irq_res = NULL;
    }
}

```

These helpers are the symmetry pair from Section 3. Each takes a vector index and operates on the vec at that slot. The setup helper is idempotent in the sense that it leaves the vector in a clean state on failure; the teardown helper is safe to call even if setup did not complete.

20.32.3 The Per-Vector Filter Functions

The three filters differ only in which bit they check. Their common shape:

```

int
myfirst_msix_rx_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);
    if ((status & MYFIRST_INTR_DATA_AV) == 0) {
        atomic_add_64(&vec->stray_count, 1);
        return (FILTER_STRAY);
    }

    atomic_add_64(&vec->fire_count, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_DATA_AV);
    atomic_add_64(&sc->intr_data_av_count, 1);
    if (sc->intr_tq != NULL)
        taskqueue_enqueue(sc->intr_tq, &vec->task);
    return (FILTER_HANDLED);
}

```

The admin filter checks MYFIRST_INTR_ERROR, the tx filter checks MYFIRST_INTR_COMPLETE. Each increments the appropriate global counter and the per-vector counter. Only the rx filter enqueues a task.

20.32.4 The RX Task

```

static void
myfirst_msix_rx_task_fn(void *arg, int npending)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->pci_attached) {
        sc->intr_last_data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
        sc->intr_task_invocations++;
        cv_broadcast(&sc->data_cv);
    }
    MYFIRST_UNLOCK(sc);
}

```

The task runs in thread context and takes `sc->mtx` safely. It checks `sc->pci_attached` before touching shared state, guarding against a race where the task runs during detach.

20.32.5 The Main Setup Function

The setup function orchestrates the fallback ladder:

```
int
myfirst_msix_setup(struct myfirst_softc *sc)
{
    int error, wanted, allocated, i;

    /* Initialise per-vector state common to all tiers. */
    for (i = 0; i < MYFIRST_MAX_VECTORS; i++) {
        sc->vectors[i].id = i;
        sc->vectors[i].sc = sc;
    }
    TASK_INIT(&sc->vectors[MYFIRST_VECTOR_RX].task, 0,
        myfirst_msix_rx_task_fn,
        &sc->vectors[MYFIRST_VECTOR_RX]);
    sc->vectors[MYFIRST_VECTOR_RX].has_task = true;
    sc->vectors[MYFIRST_VECTOR_ADMIN].filter = myfirst_msix_admin_filter;
    sc->vectors[MYFIRST_VECTOR_RX].filter = myfirst_msix_rx_filter;
    sc->vectors[MYFIRST_VECTOR_TX].filter = myfirst_msix_tx_filter;
    sc->vectors[MYFIRST_VECTOR_ADMIN].name = "admin";
    sc->vectors[MYFIRST_VECTOR_RX].name = "rx";
    sc->vectors[MYFIRST_VECTOR_TX].name = "tx";

    sc->intr_tq = taskqueue_create("myfirst_intr", M_WAITOK,
        taskqueue_thread_enqueue, &sc->intr_tq);
    taskqueue_start_threads(&sc->intr_tq, 1, PI_NET,
        "myfirst intr taskq");

    wanted = MYFIRST_MAX_VECTORS;

    /* Tier 0: MSI-X. */
    if (pci_msix_count(sc->dev) >= wanted) {
        allocated = wanted;
        if (pci_alloc_msix(sc->dev, &allocated) == 0 &&
            allocated == wanted) {
            for (i = 0; i < wanted; i++) {
                error = myfirst_msix_setup_vector(sc, i,
                    i + 1);
                if (error != 0) {
                    for (i -= 1; i >= 0; i--)
                        myfirst_msix_takedown_vector(
                            sc, i);
                    pci_release_msi(sc->dev);
                }
            }
        }
    }
}
```

```

        goto try_msi;
    }
}
sc->intr_mode = MYFIRST_INTR_MSIX;
sc->num_vectors = wanted;
myfirst_msix_bind_vectors(sc);
device_printf(sc->dev,
    "interrupt mode: MSI-X, %d vectors\n", wanted);
goto enabled;
}
if (allocated > 0)
    pci_release_msi(sc->dev);
}

try_msi:
/*
 * Tier 1: MSI with a single vector. MSI requires a power-of-two
 * count, so we cannot request MYFIRST_MAX_VECTORS (3) here. We
 * request 1 vector and fall back to the Chapter 19 single-handler
 * pattern, matching the approach sys/dev/virtio/pci/virtio_pci.c
 * takes in vtpci_alloc_msi().
 */
allocated = 1;
if (pci_msi_count(sc->dev) >= 1 &&
    pci_alloc_msi(sc->dev, &allocated) == 0 && allocated >= 1) {
    sc->vectors[MYFIRST_VECTOR_ADMIN].filter = myfirst_intr_filter;
    sc->vectors[MYFIRST_VECTOR_ADMIN].name = "msi";
    error = myfirst_msix_setup_vector(sc, MYFIRST_VECTOR_ADMIN, 1);
    if (error == 0) {
        sc->intr_mode = MYFIRST_INTR_MSI;
        sc->num_vectors = 1;
        device_printf(sc->dev,
            "interrupt mode: MSI, 1 vector "
            "(single-handler fallback)\n");
        goto enabled;
    }
    pci_release_msi(sc->dev);
}

try_legacy:
/* Tier 2: legacy INTx. */
sc->vectors[MYFIRST_VECTOR_ADMIN].filter = myfirst_intr_filter;
sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid = 0;
sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res = bus_alloc_resource_any(

```

```

        sc->dev, SYS_RES_IRQ,
        &sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid,
        RF_SHAREABLE | RF_ACTIVE);
if (sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res == NULL) {
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (ENXIO);
}
error = bus_setup_intr(sc->dev,
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE,
    myfirst_intr_filter, NULL, sc,
    &sc->vectors[MYFIRST_VECTOR_ADMIN].intr_cookie);
if (error != 0) {
    bus_release_resource(sc->dev, SYS_RES_IRQ,
        sc->vectors[MYFIRST_VECTOR_ADMIN].irq_rid,
        sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res);
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res = NULL;
    taskqueue_free(sc->intr_tq);
    sc->intr_tq = NULL;
    return (error);
}
bus_describe_intr(sc->dev,
    sc->vectors[MYFIRST_VECTOR_ADMIN].irq_res,
    sc->vectors[MYFIRST_VECTOR_ADMIN].intr_cookie, "legacy");
sc->intr_mode = MYFIRST_INTR_LEGACY;
sc->num_vectors = 1;
device_printf(sc->dev,
    "interrupt mode: legacy INTx (1 handler for all events)\n");

enabled:
    MYFIRST_LOCK(sc);
    if (sc->hw != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
            MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR |
            MYFIRST_INTR_COMPLETE);
    MYFIRST_UNLOCK(sc);

    return (0);
}

```

The function is long because it handles three tiers, each with its own allocation, per-vector setup loop, and partial-failure unwind. A reader tracing the flow sees MSI-X tried first, falling through to MSI on any failure, falling through to legacy on any failure there. The `enabled:` label is reached from any successful tier.

The legacy tier is the Chapter 19 path: one filter (`myfirst_intr_filter` from `myfirst_intr.c`), `rid = 0`, `RF_SHAREABLE`. The per-vector counters are not really used on this tier; the Chapter 19 code does its own counting.

20.32.6 The Teardown Function

```
void
myfirst_msix_teardown(struct myfirst_softc *sc)
{
    int i;

    MYFIRST_LOCK(sc);
    if (sc->hw != NULL && sc->bar_res != NULL)
        CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0);
    MYFIRST_UNLOCK(sc);

    for (i = sc->num_vectors - 1; i >= 0; i--)
        myfirst_msix_teardown_vector(sc, i);

    if (sc->intr_tq != NULL) {
        for (i = 0; i < sc->num_vectors; i++) {
            if (sc->vectors[i].has_task)
                taskqueue_drain(sc->intr_tq,
                                &sc->vectors[i].task);
        }
        taskqueue_free(sc->intr_tq);
        sc->intr_tq = NULL;
    }

    if (sc->intr_mode == MYFIRST_INTR_MSI ||
        sc->intr_mode == MYFIRST_INTR_MSIX)
        pci_release_msi(sc->dev);

    sc->num_vectors = 0;
    sc->intr_mode = MYFIRST_INTR_LEGACY;
}
```

The function follows the strict ordering: disable at device, per-vector teardown in reverse, per-vector task drain, free taskqueue, release MSI. No surprises; the symmetry is the payoff.

20.32.7 The Bind Function

```
static void
myfirst_msix_bind_vectors(struct myfirst_softc *sc)
{
    int i, cpu;
    int err;

    if (mp_ncpus < 2)
        return;

    for (i = 0; i < sc->num_vectors; i++) {
        cpu = i % mp_ncpus;
        err = bus_bind_intr(sc->dev, sc->vectors[i].irq_res, cpu);
        if (err != 0)
            device_printf(sc->dev,
                "bus_bind_intr vec %d: %d\n", i, err);
    }
}
```

Round-robin binding. Only called on MSI-X (the function is not useful on MSI or legacy; the setup ladder skips it for those tiers). On single-CPU systems the function returns early without binding.

20.32.8 The sysctl Function

```
void
myfirst_msix_add_sysctls(struct myfirst_softc *sc)
{
    struct sysctl_ctx_list *ctx = &sc->sysctl_ctx;
    struct sysctl_oid_list *kids = SYSCTL_CHILDREN(sc->sysctl_tree);
    char name[32];
    int i;

    SYSCTL_ADD_INT(ctx, kids, OID_AUTO, "intr_mode",
        CTLFLAG_RD, &sc->intr_mode, 0,
        "0=legacy, 1=MSI, 2=MSI-X");

    for (i = 0; i < MYFIRST_MAX_VECTORS; i++) {
        snprintf(name, sizeof(name), "vec%d_fire_count", i);
        SYSCTL_ADD_U64(ctx, kids, OID_AUTO, name,
            CTLFLAG_RD, &sc->vectors[i].fire_count, 0,
            "Times this vector's filter was called");
    }
}
```

```

    snprintf(name, sizeof(name), "vec%d_stray_count", i);
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, name,
        CTLFLAG_RD, &sc->vectors[i].stray_count, 0,
        "Stray returns from this vector");
}

SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_admin",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE,
    &sc->vectors[MYFIRST_VECTOR_ADMIN], 0,
    myfirst_intr_simulate_vector_sysctl, "IU",
    "Simulate admin vector interrupt");
SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_rx",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE,
    &sc->vectors[MYFIRST_VECTOR_RX], 0,
    myfirst_intr_simulate_vector_sysctl, "IU",
    "Simulate rx vector interrupt");
SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "intr_simulate_tx",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE,
    &sc->vectors[MYFIRST_VECTOR_TX], 0,
    myfirst_intr_simulate_vector_sysctl, "IU",
    "Simulate tx vector interrupt");
}

```

The function builds three read-only per-vector counter sysctls and three write-only simulated-interrupt sysctls. The tree-style (Challenge 7) is left as an exercise.

20.32.9 Lines of Code

The full `myfirst_msix.c` file is about 330 lines. That is a substantial addition to the driver, but it buys all of Chapter 20's capabilities: three-tier fallback, per-vector handlers, per-vector counters, CPU binding, clean teardown.

Compare to the Chapter 19 `myfirst_intr.c` which was about 250 lines. The Chapter 20 file is not much longer in absolute terms; the per-vector logic adds complexity but each piece is small.

20.33 Reference: A Closing Note on Multi-Vector Philosophy

A paragraph to close the chapter with.

A multi-vector driver does not fundamentally differ from a single-vector driver. It has the same filter shape, the same task pattern, the same teardown ordering, the same lock discipline. What changes is the count: *N* filters instead of one, *N* teardowns instead of one, *N* tasks instead of one. The design's quality comes from how cleanly those *N* pieces coexist.

Chapter 20's lesson is that multi-vector handling is an exercise in symmetry. Each vector looks like every other vector at the structural level; each has its own counter, its own filter, its own description. The code that allocates, the code that handles, the code that tears down: all of them loop over the vectors and do the same thing N times. The simplicity of the loop is what makes the N-vector driver manageable; a driver where each vector is special is a driver that does not scale.

For this reader and for this book's future readers, the Chapter 20 multi-vector pattern is a permanent part of the `myfirst` driver's architecture and a permanent tool in the reader's toolkit. Chapter 21 assumes it: per-queue DMA rings, per-queue completion interrupts, per-queue CPU placement. The vocabulary is the vocabulary every high-performance FreeBSD driver shares; the patterns are the patterns the kernel's own test drivers use; the discipline is the discipline production drivers live by.

The skill Chapter 20 teaches is not "how to allocate MSI-X for `virtio-rng-pci`". It is "how to design a multi-vector driver, allocate its vectors, place them on CPUs, route events per vector, and tear it all down cleanly". That skill applies across every multi-queue device the reader will ever work on.

21 DMA and High-Speed Data Transfer

21.1 Reader Guidance & Outcomes

Chapter 20 closed with a driver that handles interrupts well. The `myfirst` module at version `1.3-msi` has a three-tier fallback ladder (MSI-X first, MSI next, legacy INTx last); three per-vector filter handlers wired to separate roles (admin, receive, transmit); per-vector counters; per-vector CPU binding through `bus_bind_intr(9)`; a clean teardown that releases every vector in reverse order; a new `myfirst_msix.c` file that keeps the multi-vector code tidy; and an `MSIX.md` document that describes the per-vector design. Every vector's handler runs in the Chapter 19 discipline: a short filter in primary interrupt context that reads status, acknowledges, and either handles or defers, and a task in thread context that does the bulk work under the `sleep-mutex`.

What the driver still does not do is move data. Every byte the device has produced so far has been read one register at a time from the CPU's point of view. The simulated device writes a word into `DATA_OUT`; the CPU reads it with `bus_read_4`. That works when there is one word to read. It does not work when there are sixty-four receive descriptors to walk, or when a storage controller has completed a four-kilobyte block transfer, or when a NIC has just placed a nine-kilobyte jumbo frame into host memory. At those rates, reading word by word collapses the throughput the hardware was designed to deliver. The device needs to reach into RAM on its own, write the data there, and then tell the driver where to find it. That is what DMA means, and it is what Chapter 21 teaches.

The chapter's scope is precisely this transition: what DMA is at the level of the PCIe fabric; why a device writing to arbitrary memory would be a correctness and safety nightmare without an abstraction layer; how FreeBSD's `bus_dma(9)` interface provides that layer in a portable way; how to create DMA tags that describe a device's addressing constraints; how to allocate DMA-capable memory and load it into a mapping; how to synchronise the CPU's view with the device's view at the right moments; how to extend the Chapter 17 simulated backend with a DMA engine; how to process completion interrupts through the Chapter 20 per-vector path; how to recover from the failures that real DMA code must handle; and how to refactor all of this into a file the reader can read, test, and extend. The chapter stops short of the subsystems that build on top of DMA. The network driver chapter in Part 6 (Chapter 28) revisits DMA inside the `iflib(9)` framework; the power-management chapter that follows (Chapter 22) will teach how to quiesce DMA safely during suspend; the performance chapter in Part 7 (Chapter 33) will return to DMA with a tuning lens. Chapter 21 stays focused on the primitives that every later chapter assumes.

Chapter 21 stops short of several load paths that build on the same foundation. Scatter-gather DMA for mbuf chains (`bus_dmamap_load_mbuf_sg`), CAM control blocks (`bus_dmamap_load_ccb`), user I/O structures (`bus_dmamap_load_uio`), and crypto operations (`bus_dmamap_load_crp`) all use the same underlying mechanism and the same synchronisation discipline, but each comes with its own context (networking, storage, VFS, OpenCrypto) that belongs in its own chapter. Zero-copy user-space DMA, in which a driver lets user space map a DMA buffer and coordinate its synchronisation through `sys_msync(2)` or similar primitives, sits outside the scope of Chapter 21; Chapter 10 Section 8 introduced the `d_mmap(9)` path it would build on, and

Chapter 31 discusses the security implications of exposing kernel memory through `mmap(2)`-style interfaces. IOMMU-assisted remapping (`busdma_iommu`) is mentioned for context but not configured by hand. The reader who finishes Chapter 21 will understand the primitives well enough that the specialised load paths look like variations on the base case; that is the goal.

The `bus_dma(9)` story sits on every Part 4 layer we have built. Chapter 16 gave the driver a vocabulary of register access. Chapter 17 taught it to think like a device. Chapter 18 introduced it to a real PCI device. Chapter 19 gave it ears on one IRQ. Chapter 20 gave it several ears, one per queue the device wants. Chapter 21 gives it hands: the ability to hand the device a physical address and say “put your data here, tell me when you are done, and let me process it without bothering you for each byte”. That is the last missing primitive before Part 4 closes.

21.1.1 Why `bus_dma(9)` Earns a Chapter of Its Own

Before we go further, it is worth pausing on what `bus_dma(9)` buys us that a loop of `bus_read_4` calls cannot. The Chapter 20 driver has a complete interrupt pipeline. If the filter-plus-task pattern is already right, and the register accessor layer already handles reads and writes cleanly, why not just read bigger blocks word by word and be done?

Three reasons.

The first is **bandwidth**. A single `bus_read_4` is one MMIO transaction on the PCIe bus, and each transaction costs hundreds of nanoseconds once the overhead of address decoding, the read completion round-trip, and the CPU’s memory ordering are accounted for. On a PCIe 3.0 x4 link, a driver that uses `bus_read_4` word by word tops out around twenty megabytes per second of effective throughput; a driver that arranges for the device to DMA into a contiguous buffer reaches gigabytes per second on the same link. The order-of-magnitude gap is what separates a ten-gigabit NIC from an unusable NIC, a modern NVMe from a late-1990s IDE controller. DMA is not an optimisation for drivers that could work without it; it is the only mechanism that lets modern devices deliver their designed throughput.

The second is **CPU cost**. Every `bus_read_4` or `bus_write_4` keeps a CPU busy for the duration of the transaction. A driver that moves a megabyte of data one word at a time burns ten to twenty milliseconds of CPU time just shuttling bytes across MMIO. DMA offloads that cost to the device’s own bus master engine: the CPU hands over an address and a length, the device runs the transfer independently, and the CPU is free to do other work (including handling interrupts for other devices). On a server pushing millions of packets per second through several NICs at once, the CPU cannot afford to touch each byte; DMA is what makes aggregate throughput achievable.

The third is **correctness under concurrency**. A driver that reads a descriptor ring word by word is racing the device: the device may be writing new entries while the driver is reading old ones, and the driver sees torn reads of half-updated fields unless it takes out a global lock that serialises the whole transfer. DMA with proper synchronisation replaces that race with a clean producer-consumer protocol: the device writes entries in order, signals completion through a single register write or a completion interrupt, and the CPU processes the entries as a batch with the guarantee that every byte is there. The `bus_dmamap_sync` call makes the hand-off explicit; the `bus_dmamap_unload` call makes the cleanup explicit. The driver becomes easier to reason about, not harder, even though the mechanism is more sophisticated.

Chapter 21 earns its place by teaching all three benefits concretely. A reader finishes the chapter able to create a tag, allocate a buffer, load it into a map, trigger a transfer, synchronise around it, wait for completion, verify

the result, and tear everything down. With those primitives in hand, the reader can open any DMA-capable FreeBSD driver and recognise its structure, the same way Chapter 20's graduate can read any multi-vector driver.

21.1.2 Where Chapter 20 Left the Driver

A few prerequisites to verify before starting. Chapter 21 extends the driver produced at the end of Chapter 20 Stage 4, tagged as version 1.3-`msi`. If any of the items below feels uncertain, return to Chapter 20 before starting this chapter.

- Your driver compiles cleanly and identifies itself as 1.3-`msi` in `kldstat -v`.
- On a QEMU guest that exposes `virtio-rng-pci` with MSI-X, the driver attaches; chooses MSI-X; allocates three vectors (admin, rx, tx); registers a distinct filter per vector; binds each vector to a CPU; prints an interrupt mode: MSI-X, 3 vectors banner; and creates `/dev/myfirst0`.
- On a bhyve guest with `virtio-rnd`, the driver attaches; falls through to MSI with one vector, or further through to legacy INTx; prints the corresponding banner.
- Per-vector counters (`dev.myfirst.0.vec0_fire_count` through `vec2_fire_count`) increment when the matching simulation `sysctl` (`dev.myfirst.0.intr_simulate_admin`, `intr_simulate_rx`, or `intr_simulate_tx`) is written to.
- The detach path tears down vectors in reverse order, drains per-vector tasks, releases resources, and calls `pci_release_msi` exactly once.
- `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, and `MSIX.md` are current in your working tree.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel.

That driver is what Chapter 21 extends. The additions are noticeable in scope: one new file (`myfirst_dma.c`), one new header (`myfirst_dma.h`), several new `softc` fields to track DMA tag, map, memory pointer, and the DMA engine's simulated state, a new pair of helper functions (`myfirst_dma_setup` and `myfirst_dma_teardown`), a new completion path in the receive filter, a version bump to 1.4-`dma`, a new `DMA.md` document, and updates to the regression test. The mental model grows too: the driver starts thinking of memory ownership as something that passes back and forth between the CPU and the device, and every hand-off becomes a deliberate `bus_dmamap_sync` call.

21.1.3 What You Will Learn

After finishing this chapter you will be able to:

- Describe what DMA is at the hardware level, how a PCIe device performs a bus-master write to host memory, and why that mechanism delivers bandwidth and CPU-offload benefits that MMIO cannot match.
- Explain why direct device access to arbitrary memory would be unsafe without an abstraction layer, and name the three hardware realities that layer has to hide (device addressing limits, IOMMU remapping, cache coherence).
- Recognise where bounce buffers fit in the picture: when the kernel silently inserts them, what they cost, and when an explicit address constraint can avoid them.

- Read and write the central `bus_dma(9)` vocabulary: `bus_dma_tag_t`, `bus_dmamap_t`, `bus_dma_segment_t`, the PRE/POST sync operations, the tag constraints (alignment, boundary, lowaddr, highaddr, maxsize, nsegments, maxsegsz), and the common flag set (`BUS_DMA_WAITOK`, `BUS_DMA_NOWAIT`, `BUS_DMA_COHERENT`, `BUS_DMA_ZERO`).
- Create a device-scoped DMA tag with `bus_dma_tag_create`, inheriting the parent bridge's constraints through `bus_get_dma_tag(9)`, and choosing alignment, boundary, and address limits that match the device's datasheet.
- Allocate DMA-capable memory with `bus_dmamem_alloc`, obtain its kernel virtual address, and understand why the allocator returns a single segment with `bus_dmamem_alloc` but may return several segments for arbitrary memory loaded later.
- Load a kernel buffer into a DMA map with `bus_dmamap_load`, extract the bus address from the single-segment callback, and understand the cases where the callback is deferred and what that means for the driver's locking discipline.
- Use `bus_dmamap_sync` with the correct PRE/POST flags around every device-visible memory access: `PREWRITE` before the device reads, `POSTREAD` after the device writes, and the combined pairs for descriptor rings where both directions happen.
- Extend the Chapter 17 simulated backend with a small DMA engine that takes a bus address, a length, and a direction from the softc, runs the transfer under a `callout(9)` to emulate latency, and raises a completion interrupt through the Chapter 19/20 filter path.
- Process completion interrupts by reading a status register inside the rx filter, acknowledging, enqueueing the task, and letting the task perform `bus_dmamap_sync` and access the buffer.
- Recover from every recoverable failure mode: `bus_dma_tag_create` returning `ENOMEM`, `bus_dmamap_load` returning `EINVAL` or `EINVAL`, the engine reporting a partial transfer, a timeout that expires before the device signals completion, and a detach that fires while a transfer is in flight.
- Refactor the DMA code into a dedicated `myfirst_dma.c` / `myfirst_dma.h` pair, with `myfirst_dma_setup` and `myfirst_dma_teardown` as the only entry points used by the rest of the driver.
- Version the driver as `1.4-dma`, update the Makefile's `SRCS` line, run the extended regression test, and produce `DMA.md` documenting the DMA flow, the buffer layouts, and the observable counters.
- Read the DMA code in a real driver (`/usr/src/sys/dev/re/if_re.c` is the chapter's running reference) and map each call to the concepts introduced in Chapter 21.

The list is long; each item is narrow. The point of the chapter is the composition.

21.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 21 stays focused.

- **Scatter-gather DMA for heterogeneous buffers.** `bus_dmamap_load_mbuf_sg` (networking), `bus_dmamap_load_ccb` (CAM storage), `bus_dmamap_load_uio` (VFS), and `bus_dmamap_load_crp` (OpenCrypto) all sit on top of the same `bus_dma(9)` foundation but are used in subsystem-specific ways. Part 6 (Chapter 27 storage, Chapter 28 network) cover them in context. Chapter 21 uses `bus_dmamap_load` on a single contiguous buffer; the rest is a specialisation.
- **iflib(9) and its hidden DMA pools.** The networking framework wraps `bus_dma` with per-queue helpers that allocate, load, and sync receive and transmit rings automatically. The framework is the subject of its own chapter in Part 6 (Chapter 28); Chapter 21 teaches the raw layer that `iflib` uses internally.

- **IOMMU-assisted DMA on amd64 with Intel VT-d or AMD-Vi.** The `busdma_iommu` machinery integrates transparently with the `bus_dma` API, so a driver written for the generic path automatically benefits from IOMMU remapping when the kernel is built with `DEV_IOMMU`. The chapter mentions IOMMU presence, explains what it does, and shows how to observe it; it does not configure it by hand.
- **NUMA-aware DMA memory placement.** `bus_dma_tag_set_domain(9)` lets a driver bind a tag's allocations to a specific NUMA domain. The function is named and mentioned; the full placement story is a Part 7 (Chapter 33) performance topic.
- **Power-aware DMA quiescing.** Stopping in-flight DMA before suspend is Chapter 22's topic. Chapter 21 arranges the primitives that Chapter 22 will use; the `myfirst_dma_tear` down path is designed so that Chapter 22's suspend handler can invoke it cleanly.
- **Zero-copy DMA to and from user-space buffers.** Mapping user pages into a DMA map requires `vm_fault_quick_hold_pages(9)` plus `bus_dmamap_load_ma_triv` or an equivalent, and touches on memory pinning, VM reference counts, and capability enforcement. These topics belong in a later chapter.
- **DMA descriptor rings with hardware tail/head registers.** A full ring design (producer/consumer indexes, wrap-around, doorbell writes) is a next-level pattern built on Chapter 21's primitives. The chapter shows a single-transfer pattern; descriptor rings are a natural extension the reader can build as a challenge.

Staying inside those lines keeps Chapter 21 a chapter about DMA primitives. The vocabulary is what transfers; the later chapters apply it to networking, storage, power, and performance in turn.

21.1.5 Estimated Time Investment

- **Reading only:** five to six hours. The DMA conceptual model is the densest in Part 4; the sync discipline in particular benefits from a careful read and then a second pass once the code examples have concretised it.
- **Reading plus typing the worked examples:** twelve to fifteen hours over two or three sessions. The driver evolves in four stages: tag and allocation, simulated engine with polling, simulated engine with interrupt completion, and final refactor. Each stage is small but builds on the previous one, and each requires careful attention to the PRE/POST pairs.
- **Reading plus all labs and challenges:** eighteen to twenty-four hours over four or five sessions, including reading real drivers (`if_re.c`, the `nvme_qpair.c` allocation code, and the `busdma_bufalloc.c` sources if curiosity takes you that far), running the chapter's regression test on both bhyve and QEMU targets, and attempting one or two of the production-style challenges.

Sections 3, 4, and 5 are the densest. If the sync discipline or the tag constraints feel opaque on first pass, that is normal. Stop, re-read Section 4's diagram, run the Section 4 exercise, and continue when the shape has settled. DMA is one of the topics where a working mental model pays off many times; it is worth building slowly.

21.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 20 Stage 4 (`1.3-msi`). The starting point assumes every Chapter 20 primitive: the three-tier fallback ladder, the per-vector filters, per-vector CPU binding, and the clean multi-vector teardown.

- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly. The `WITNESS` option is especially valuable for DMA work because several `bus_dma` functions must not be called with non-sleepable locks held, and `WITNESS` catches the violations early.
- `bhyve(8)` or `qemu-system-x86_64` is available. Chapter 21's labs work on either target; the DMA simulation happens inside the `myfirst` driver, so no particular DMA-capable guest device is required. The real-DMA sanity check at the end of Section 5 uses whatever PCI device the chapter's virtio host exposes, without depending on it for DMA.
- The `devinfo(8)`, `vmstat(8)`, `pciconf(8)`, `sysctl(8)`, and `procstat(1)` tools are in your path. `procstat -kke` is useful for watching the driver's threads during DMA transfers.

If any item above is shaky, fix it now. DMA tends to expose any latent weakness in the driver's lock discipline (the sync calls sit inside the task context, the allocation calls sit inside `attach`, and the unload calls sit inside `detach`; each context has different lock rules), and `WITNESS` in a debug kernel is what catches the mistakes at development time rather than in production.

21.1.7 How to Get the Most Out of This Chapter

Four habits will pay off quickly.

First, keep `/usr/src/sys/sys/bus_dma.h` and `/usr/src/share/man/man9/bus_dma.9` bookmarked. The header is compact (about four hundred lines) and lists every API the chapter uses, with a brief comment on each. The manual page is substantial (over eleven hundred lines) and is the authoritative reference on every parameter. Reading both once at the start of Section 2 and returning to them as you work each section is the single most useful thing you can do for fluency.

Second, keep `/usr/src/sys/dev/re/if_re.c` bookmarked as the running real-driver example. `if_re(4)` is a reasonably compact network driver that uses `bus_dma` in a textbook way: a parent tag that inherits from the PCI bridge, a per-ring tag for descriptors, a per-buffer tag for mbuf payloads, a single-segment callback, and clean teardown. Most of Chapter 21's patterns have a direct analogue in `if_re.c`. When the chapter shows a pattern, it will often say "look at `re_allocmem`" and give a specific line.

A note on line numbers. When the chapter pins a reference to a line inside `if_re.c`, treat the number as a pointer for the FreeBSD 14.3 tree at time of writing, not a stable coordinate. `re_allocmem` and `re_dma_map_addr` are durable names; the line each one sits on is not. Open the file, search for the function name, and let your editor report where it actually lives on the system in front of you.

Third, type the changes by hand and run each stage. DMA is where the cost of a wrong flag or a missed sync is paid in subtle corruption rather than an obvious crash, and typing carefully makes the common mistakes visible at the moment they happen. The chapter's regression test will catch many of the mistakes, but the typing itself is what builds the mental model.

Fourth, after finishing Section 4, re-read Sections 2 and 3 of Chapter 17. The simulated backend's MMIO register map is the base the simulated DMA engine extends, and seeing the two layered together is what makes the engine's design feel inevitable rather than arbitrary. The Chapter 17 simulation was built with DMA in mind; Chapter 21 is where that design pays off.

21.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Is DMA and Why Use It?** The hardware picture: bus-master writes, the bandwidth and CPU-cost argument, concrete device examples, and why modern driver development assumes DMA.
2. **Understanding FreeBSD's `bus_dma(9)` Interface.** The abstraction layer: what the layer hides (addressing limits, IOMMU, coherence), what a tag is, what a map is, what a segment is, and how the pieces fit together. Concepts first, code next.
3. **Allocating and Mapping DMA Memory.** The tag parameters in detail, `bus_dmamem_alloc`, the `bus_dmamap_load` callback pattern, the single-segment case, and the first running code: Stage 1 of the Chapter 21 driver (`1.4-dma-stage1`).
4. **Synchronising and Using DMA Buffers.** The sync discipline: `PREWRITE`, `POSTREAD`, the combined pairs, the coherent-vs-non-coherent nuance, and the mental model of memory ownership passing between CPU and device. The exercise at the end is a paper walkthrough before any code.
5. **Building a Simulated DMA Engine.** The simulated backend's DMA registers, the state machine, the `callout(9)`-driven transfer, and the completion path. Stage 2 (`1.4-dma-stage2`) makes the driver hand a physical address to the engine and poll for completion.
6. **Handling DMA Completion in the Driver.** The filter-plus-task path from Chapter 19/20 consumes the completion interrupt. The task performs `bus_dmamap_sync(..., POSTREAD)` and reads the buffer. Stage 3 (`1.4-dma-stage3`) wires the interrupt path to the DMA engine.
7. **DMA Error Handling and Edge Cases.** Every failure mode the chapter addresses, with the matching recovery pattern: mapping failures, partial transfers, timeouts, and detach-while-in-flight.
8. **Refactoring and Versioning Your DMA-Capable Driver.** The final split into `myfirst_dma.c` and `myfirst_dma.h`, the updated Makefile, the `DMA.md` document, and the version bump. Stage 4 (`1.4-dma`).

After the eight sections come an extended walkthrough of `if_re.c`'s DMA code, several deeper looks at bounce buffers, 32-bit devices, IOMMU, coherent flags, and parent tag inheritance, a set of hands-on labs, a set of challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 21's story and opens Chapter 22's, a bridge, and the usual quick-reference and glossary material at the end of the chapter. The reference material is meant to be re-read as you work through the next few chapters; Chapter 21's vocabulary (tag, map, segment, PRE/POST, coherent, bounce, callback) is the foundation every chapter after this one assumes.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3, 4, and 5 stand alone and make good single-sitting reads.

21.2 Section 1: What Is DMA and Why Use It?

Before the driver code, the hardware picture. Section 1 teaches what DMA is at the level of the PCIe bus, what it gains the driver over MMIO reads and writes, what the real-world examples look like, and why modern driver development takes DMA as a baseline assumption rather than an optimisation. A reader who finishes Section 1 can read the rest of the chapter with the kernel's `bus_dma` layer as a concrete object rather than a vague abstraction.

21.2.1 The Problem With MMIO-Only Data Movement

Chapter 16 introduced memory-mapped I/O: a device's registers live inside a region of physical memory, the kernel maps that region into the kernel virtual address space, and `bus_read_4` and `bus_write_4` wrappers turn reads and writes into bus transactions. Chapter 17 built a simulated backend that looks the same from the driver's perspective. Chapter 18 moved that backend onto a real PCI BAR. Every word of data the Chapter 19 and Chapter 20 driver has handled has come through `bus_read_4` from the device's `DATA_OUT` register.

For a driver that handles one word per event, that model works. For a driver that has to handle a megabyte of data, it does not. Each `bus_read_4` is one MMIO transaction; each MMIO transaction is a posted or completion bus cycle with its own overhead. On a typical PCIe 3.0 x4 link the round-trip time per transaction is a few hundred nanoseconds once the PCIe header, the read completion, and the CPU's memory ordering instructions are added up. A driver that moves data one word at a time tops out at a few tens of megabytes per second regardless of what the device is actually capable of.

A modern NIC is capable of tens of gigabytes per second. A modern NVMe is capable of several gigabytes per second of sustained I/O. A USB3 host controller handles thousands of descriptors per second. A GPU handles hundreds of megabytes of command buffers per frame. The hardware is not the bottleneck in any of these cases; the MMIO model is. Every driver for these devices has to use a different mechanism to move the bulk of the data, and that mechanism is DMA.

21.2.2 What DMA Means at the Hardware Level

DMA stands for Direct Memory Access. The word “direct” is the key. In an MMIO transfer, the CPU is the master: the CPU issues a read or write to the device's MMIO region, and the device responds. In a DMA transfer, the device is the master: the device issues a read or write to host memory, and the memory controller responds as if the CPU had made the request. The CPU is not in the loop for each word; the device moves the bytes on its own schedule.

Physically, a DMA transfer is a memory transaction on the same bus the CPU uses to reach RAM. On PCIe this is called a **bus-master** transaction, and PCI devices that can do it are said to be **bus-mastering**. The device holds an internal state (a source address, a destination address, a length, a direction, a status) and advances through the transfer under its own clock. The CPU sets up the transfer by writing the relevant parameters to the device's control registers, then issues a go-ahead write (often called a “doorbell”), and can then do something else until the device signals completion.

From the CPU's perspective, a DMA transfer passes through roughly these steps:

1. The driver allocates a region of host memory with properties the device can use (addressable by the device, aligned as the device requires, contiguous if the device requires that).
2. The driver arranges for the device to see that region at some **bus address** (which may or may not equal the host's physical address depending on the platform).
3. The driver writes the bus address, the length, and the direction to the device's registers.
4. The driver writes a doorbell register that tells the device to begin.
5. The device performs the transfer on its own, reading from or writing to the host memory at the bus address, through the memory controller, while the CPU is free.
6. The device signals completion, usually by writing a status bit in an MMIO register, raising an interrupt, or both.

7. The driver performs any necessary cache synchronisation between the CPU's view of the memory and the device's view.
8. The driver reads or uses the transferred data.

Each step looks simple. The subtlety lies in step 2 (what bus address to use, and how to make the device see the buffer) and step 7 (what “necessary” means, and how the driver knows when to do which kind of sync). Most of Chapter 21 is about those two steps.

21.2.3 What the Driver Gains

Three concrete benefits matter in every DMA-capable driver.

The first is **throughput**. On PCIe, a bus-master transfer uses the device's own width and clock. A ten-gigabit NIC's PCIe 3.0 x4 link can sustain roughly three and a half gigabytes per second of bus-mastered data. The same link used for MMIO alone tops out near twenty megabytes per second: the NIC cannot touch its advertised bandwidth without DMA. The ratio is worse for higher-performance devices. A PCIe 4.0 x16 GPU has a theoretical link budget over thirty gigabytes per second; no amount of `bus_write_4` can approach it.

The second is **CPU offload**. Bus-master transfers consume little to no CPU time once started. The CPU writes a few registers, triggers the doorbell, and is free until the completion interrupt arrives. On a system with many DMA-capable devices, the CPU can orchestrate dozens of concurrent transfers as long as the device has enough DMA engines. On a NIC that supports multi-queue transmit, the CPU can queue up receive descriptors, hand transmit buffers to the device, and process completions for both directions at once, with the actual byte movement happening in the device's internal DMA engines. The CPU's job becomes policy and bookkeeping; the data movement is elsewhere.

The third is **determinism under load**. An MMIO-based driver that is busy-looping through a large buffer can be preempted by an interrupt, the `ithread` that handles the interrupt can monopolise the CPU for an extended period, and the throughput becomes a function of kernel preemption timing rather than device capability. A DMA-based driver has the device do the work; the driver's own code runs for a predictable, small number of cycles per transfer and yields to the scheduler in between. Latency distributions tighten, tail latencies shrink, and the driver's performance becomes easier to reason about.

These three benefits compound. A driver that uses DMA consumes less CPU per byte, moves more bytes per unit time, and does both more predictably. The cost is the `bus_dma` setup code, which adds a few hundred lines to the driver. The chapter is about writing those lines well.

21.2.4 Real-World Examples

DMA is pervasive in modern hardware. A few concrete examples make the scale of its use clear.

A **network card** uses DMA for both receive and transmit. The device has a **receive ring** in host memory: an array of descriptors, each of which contains a bus address and a length pointing at a packet buffer. The device copies incoming packets from the wire into the buffers via bus-master writes, updates each descriptor's status field when the packet is complete, and raises an interrupt. The driver walks the ring, processes each completed descriptor, and refills the ring with fresh buffers. Transmit works the other way: the driver places outgoing packet headers and payloads into buffers, writes descriptors with the bus addresses, and kicks the device; the device reads the buffers, transmits, and updates the descriptor status. The whole protocol runs in host memory,

synchronised through `bus_dmamap_sync` calls and completion interrupts. Chapter 21's driver is a single-transfer simplification of this pattern; Part 6 (Chapter 28) generalises to full rings.

A **storage controller** (SATA, SAS, NVMe) uses DMA for every block transfer. The driver issues a command block containing a physical-address list (a scatter-gather list) that describes the pages making up the host buffer. The device walks the list, reads or writes each page, and signals completion. Modern NVMe controllers use a **Physical Region Page (PRP)** or **Scatter Gather List (SGL)** structure to describe the transfer, and the controller writes the completion into a completion queue that is itself in host memory via DMA. The `nvme(4)` driver is about four thousand lines of DMA-aware code; the structure is comfortable to read once Chapter 21's primitives are in place.

A **USB3 host controller** uses DMA for transfer descriptors, completion events, and bulk data. The driver hands the device a pointer to a transfer descriptor in host memory; the device fetches it via DMA, performs the transfer, writes the completion into an event ring, and raises an interrupt. USB is particularly interesting because each USB device's data goes through the host controller's DMA engine, so the driver for a USB NIC is actually two drivers stacked: the USB host controller does the DMA, and the USB device driver runs on top.

A **GPU** uses DMA for command buffers, texture uploads, and sometimes display scanout. A single frame may involve tens of megabytes of data moving between system RAM and GPU VRAM, orchestrated by the GPU's own DMA engine under the direction of the driver's command stream. FreeBSD's `drm-kmod` ports of Linux's DRM drivers use `bus_dma` to set up the command buffer mappings; the translation from Linux's DMA API is a thin layer because the abstractions are similar.

A **sound card** uses DMA for the audio buffer. The driver allocates a circular buffer, programs the device with its bus address and length, and the device reads samples in real time, wrapping around at the end. The driver refills the buffer ahead of the device's read pointer and relies on a position interrupt (or periodic timer) to schedule the refill. `sound(4)` uses `bus_dma` for this purpose; the pattern is a nice intermediate between single-transfer DMA and full scatter-gather rings.

Each of these examples follows the same abstract pattern: tag, map, memory, sync, trigger, complete, sync, consume, unload. The details differ; the shape is constant. Chapter 21 teaches the shape on a simulated device; later chapters apply the shape to the real subsystems.

21.2.5 Why Direct Memory Access Cannot Be Unrestricted

At first glance, “the device writes to memory” sounds straightforward. The device has an internal register; the register holds a bus address; the device writes to that address. Why does the driver need to do anything at all beyond telling the device an address?

Three hardware realities make unrestricted DMA unsafe, and those realities are what `bus_dma(9)` exists to hide.

Reality one: the device may not be able to reach all of host memory. Older PCI devices are 32-bit bus masters: they can only address the lower four gigabytes of bus address space. On a system with sixteen gigabytes of RAM, a buffer at physical address `0x4_0000_0000` is invisible to such a device; handing it that address would be a silent corruption (the write goes somewhere, but not where the driver expected). Some newer devices have 36-bit or 40-bit DMA engines and can reach more of RAM but not all of it. The driver has to describe the device's range to the kernel, and the kernel has to ensure every buffer the device sees is inside the range. When a buffer happens to be outside the range, the kernel silently inserts a **bounce buffer**: a region inside the range, into

which the kernel copies the data before the DMA read (or out of which it copies after the DMA write). Bounce buffers are correct but expensive; a driver that allocates its buffers inside the device's range avoids them.

Reality two: the bus address the device sees is not always the physical address the CPU uses. On modern amd64 systems with an IOMMU enabled (Intel VT-d, AMD-Vi), the memory controller inserts a translation layer between the device's bus address and the host's physical address. The device writes to bus address X; the IOMMU translates that to physical address Y; the memory controller writes physical address Y. The translation is per-device, and by default the IOMMU only permits a device to access memory the driver has explicitly mapped. This is a correctness and security win (a buggy or compromised device cannot write to arbitrary memory), but it requires the driver to participate: the driver tells the kernel "this buffer should be visible to this device", the kernel programs the IOMMU accordingly, and only then can the device reach the buffer. Without `bus_dma`, the driver would have to know whether an IOMMU is present, what its page tables look like, and how to program them.

Reality three: the CPU and the device may see the same memory differently at the same moment. Every CPU has caches; the caches hold copies of memory at the granularity of cache lines (typically sixty-four bytes on amd64, sometimes more on other platforms). When the CPU writes a value, the write goes into the cache first; the cache line is marked dirty, and the write only reaches the memory controller when the line is evicted or a coherence protocol synchronises it. When a DMA-capable device writes a value, the write goes directly to the memory controller (unless the platform is fully coherent, which amd64 typically is but ARM sometimes is not), so the CPU's cached copy may be stale. Conversely, when the device reads a value that the CPU has recently written and not flushed, the device reads a stale value. On fully coherent platforms, the hardware handles this automatically; on partially coherent or non-coherent platforms, the driver has to tell the kernel "the CPU is about to read this buffer, please ensure the caches are invalidated first" or "the CPU just wrote this buffer, please flush the caches before the device reads". This is what `bus_dmamap_sync` does.

These three realities are not visible to driver authors on amd64 with a modern IOMMU and a fully coherent device; the `bus_dma` API is still required, but most of its work is transparent. On 32-bit hardware, on non-coherent ARM platforms, or on systems where the IOMMU is configured restrictively, the API actually does something at every call. A driver written correctly against `bus_dma` works on all of them; a driver that bypasses the API works only on the subset of platforms where the naive model happens to be correct.

21.2.6 Why `bus_dma(9)` Exists

FreeBSD's `bus_dma(9)` interface is the portability layer that hides these three realities behind a single API. It was inherited and adapted from NetBSD's equivalent, and refined in FreeBSD over the 5.x and later releases. The design decisions that make it distinctive are worth understanding at the conceptual level before the code examples.

The API **separates description from execution**. A DMA **tag** describes the constraints of a group of transfers: what address range is reachable, what alignment is required, how large a transfer may be, how many segments it may span, what the boundary rules are. A DMA **map** represents one specific transfer's mapping onto that tag: which bus addresses the specific buffer occupies, which bounce buffers (if any) are in play. The driver creates the tag once at attach time; it creates or loads maps at transfer time. The separation lets the kernel cache expensive setup (parent tags, constraint checks) while keeping per-transfer work cheap.

The API **uses callbacks to hand back mapping information**. `bus_dmamap_load` does not return the list of bus addresses directly; it calls a callback function the driver provides, passing the segment list as an array. The

reason is historical and practical: on some platforms the load may need to wait for bounce buffers to become available, and in that case the callback runs later when the buffers are free. The driver's load code returns immediately with `EINPROGRESS`; the callback eventually runs and completes the mapping. This pattern is the one that trips most first-time readers, and Section 3 walks through it carefully. For simple cases (descriptor rings allocated at attach time, where the driver is willing to wait), the load completes synchronously and the callback runs before `bus_dmamap_load` returns.

The API **makes synchronisation explicit**. `bus_dmamap_sync` with a `PRE` flag says “the CPU is about to stop accessing this buffer and hand it to the device; please flush”. With a `POST` flag it says “the device has stopped accessing this buffer and the CPU is about to access it; please invalidate”. On coherent platforms, `bus_dmamap_sync` is sometimes a no-op; on non-coherent platforms, it runs the cache flush or invalidate. The driver writes the same code in both cases; the API handles the difference.

The API **supports hierarchies of constraints**. A tag can inherit from a parent tag, and the child's constraints are restrictions of the parent's. This matches the hardware: a PCI device's DMA capabilities are constrained by its parent bridge's capabilities, which are constrained by the platform's memory controller. `bus_get_dma_tag(9)` returns the device's parent tag, and the driver passes that to `bus_dma_tag_create` as the parent of any tag it creates. The kernel composes the constraints automatically; the driver describes only its own device's requirements.

These four design choices (separation, callbacks, explicit sync, hierarchies) are visible in every `bus_dma`-using driver, and the chapter's code follows them closely. The benefit of understanding the design is that real drivers become much easier to read; the six-thousand-line `nvme(4)` driver, for example, follows the same pattern as Chapter 21's toy driver.

21.2.7 The Concrete Flow Chapter 21 Will Build

Concretely, the Chapter 21 driver will learn to do the following sequence, in order:

1. **Create a parent-inheriting tag.** The driver calls `bus_get_dma_tag(sc->dev)` to obtain the device's parent tag and passes it to `bus_dma_tag_create` along with the myfirst device's own constraints (4 KB alignment, 4 KB buffer size, 1 segment, `BUS_SPACE_MAXADDR` for the address range because the simulation has no architectural limit).
2. **Allocate DMA memory.** The driver calls `bus_dmamem_alloc` with the tag. The kernel returns a kernel virtual address pointing at a four-kilobyte buffer that is both mapped for the CPU and suitable for the device. The call also returns a `bus_dmamap_t` handle that represents the mapping.
3. **Load the memory into the map.** The driver calls `bus_dmamap_load` with the kernel virtual address and a callback. The callback receives the segment list (one segment for this simple case) and stashes the bus address in the `softc`.
4. **Program the device.** The driver writes the bus address, the length, and the direction to the simulated DMA engine's registers.
5. **Sync PREWRITE (for host-to-device) or PREREAD (for device-to-host).** The driver calls `bus_dmamap_sync` with the appropriate flag, signalling that the CPU has finished touching the buffer and the device is about to access it.
6. **Kick the engine.** The driver writes the `DMA_CTRL` register's `START` bit; the simulated engine schedules a `callout(9)` a few milliseconds in the future.

7. **Wait for completion.** Via the Chapter 20 rx filter, which fires when the simulated engine raises DMA_COMPLETE. The filter enqueues the task; the task runs.
8. **Sync POSTREAD or POSTWRITE.** The task calls bus_dmamap_sync with the POST flag before accessing the buffer.
9. **Read and verify.** The task compares the buffer contents against the expected pattern and updates a softc counter.
10. **Tear down.** On detach, the driver unloads the map, frees the memory, destroys the tag. The order is the reverse of setup.

Every step maps to a single bus_dma call. The chapter's job is to teach each call in context, show how it fits into the driver's existing lifecycle, and explain what the kernel itself does on each call so the reader can debug when things go wrong. A driver that has internalised these ten steps can move on to descriptor rings, scatter-gather lists, and bus_dmamap_load_mbuf_sg without learning a new model; each of those is a variation on the same ten steps.

21.2.8 Exercise: Identify DMA-Capable Devices on Your System

Before the next section, take five minutes to look at your own system. The exercise is simple and builds intuition: identify three devices on your lab machine that use DMA, and note one property each.

Start with `pciconf -lv`. The tool lists every PCI function, and most of them are DMA-capable in some way. For each function, note what subsystem it belongs to (network, storage, graphics, audio, USB). Then look for the line starting with `cmdreg:` in `pciconf -c` output; if the bit that reads `BUSMASTEREN` is set, the device has bus-mastering enabled and is actively using DMA.

```
pciconf -lvc | grep -B1 BUSMASTEREN
```

Pick one network function and look at it more carefully:

```
pciconf -lvbc <devname>
```

`pciconf -lvbc` shows the BAR regions, the capability list, and whether the PCIe device's config space reports any DMA-relevant capabilities (MSI/MSI-X, power management, PCIe DevCtl, ASPM). On most modern systems the output reveals that the device has a large MMIO BAR (for register access) and smaller MMIO BARs (for MSI-X table and PBA), but no I/O ports; the bulk of the device's memory is in RAM, reached by DMA, not in the device's own BAR.

Then look at an nvme device if you have one, or at `dmesg` for "mapped DMA" messages. Most storage drivers log a brief DMA setup banner at attach time; `nvme_ctrlr_setup` is a good one to grep for.

Write down in a lab notebook:

1. One network device with bus-mastering enabled, and a guess at what it uses DMA for.
2. One storage device (if present) with its DMA setup banner.
3. One device you did not expect to use DMA, but does. A surprise finding pays off: once you know what to look for, the picture changes.

The exercise takes about ten minutes and gives you a map of your own lab target's DMA landscape before Chapter 21's work begins.

21.2.9 Wrapping Up Section 1

Section 1 established the hardware picture. DMA lets devices write to host memory directly, bypassing the CPU-by-word bottleneck of MMIO. The benefits are throughput, CPU offload, and determinism; the costs are the setup complexity and the need to synchronise between the CPU's cached view and the device's bus-visible view. FreeBSD's `bus_dma(9)` interface exists to hide three hardware realities (device addressing limits, IOMMU remapping, cache coherence) behind a single API, and the API's four design principles (tag/map separation, callback-based load, explicit sync, constraint inheritance) appear in every driver that uses it. Chapter 21's running example will exercise each principle in turn on a simulated device, with enough real FreeBSD grounding that the patterns carry over to production drivers unchanged.

Section 2 is the next step: the API's vocabulary in detail. What a tag actually contains, what a map actually is, what a segment is, what the PRE and POST flags mean at a finer level, and how the pieces fit together.

21.3 Section 2: Understanding FreeBSD's `bus_dma(9)` Interface

Section 1 established that `bus_dma(9)` is the portability layer between the driver and the platform's DMA realities. Section 2 opens the layer and looks at its pieces. The goal is to give the reader the vocabulary to talk about a DMA tag, a DMA map, a segment, a sync operation, and a callback without mystery. No Stage 1 code is written yet; Section 3 does that. This section is the mental map.

21.3.1 The Four Pieces of the API

Every `bus_dma` driver deals with four objects. Understand the four and the rest of the API falls into place.

The tag is a description. It is an opaque kernel object of type `bus_dma_tag_t`, created once and reused for many transfers. A tag carries:

- An optional parent tag, inherited from the parent bridge through `bus_get_dma_tag(dev)`.
- An alignment constraint in bytes (the starting address of every mapping made through this tag must be a multiple of this value).
- A boundary constraint in bytes (a mapping that crosses an address boundary of this size is not allowed).
- A low address and a high address that together describe a window of bus address space the device **cannot** reach.
- A maximum mapping size (the sum of segment lengths in one mapping).
- A maximum segment count (how many discontinuous pieces one mapping may span).
- A maximum segment size (the largest single piece).
- A set of flags, chiefly `BUS_DMA_WAITOK`, `BUS_DMA_NOWAIT`, and `BUS_DMA_COHERENT`.
- An optional lock function and its argument, used when the kernel needs to invoke the driver's load callback from a deferred context.

The tag is how the driver tells the kernel “this device has these constraints; please honour them on every mapping I make through this tag”. The kernel consults the tag during every map operation and ensures the mapping respects the constraints (or reports an error if the requested buffer cannot satisfy them).

The map is a mapping context. It is an opaque kernel object of type `bus_dmamap_t`, created (often implicitly) per transfer. A map carries enough state to describe one specific mapping: which bus addresses the buffer

occupies, whether any bounce pages are in use, whether the mapping is currently loaded or idle. Maps are cheap to create and cheap to load; the expensive setup work lives in the tag.

The memory is the kernel virtual address range the CPU uses to access the buffer. For static DMA regions (allocated at attach time, reused for many transfers), the memory is allocated by `bus_dmamem_alloc`, which returns a kernel virtual address and an implicitly-loaded map. For dynamic DMA (mapping arbitrary kernel buffers, mbufs, or user data), the memory already exists elsewhere and the driver uses `bus_dmamap_create` plus `bus_dmamap_load` to attach a map to it.

The segment is the bus-address-and-length pair the device actually sees. A `bus_dma_segment_t` is a small structure with two fields: `ds_addr` (a `bus_addr_t` giving the bus address) and `ds_len` (a `bus_size_t` giving the length). A single mapping may consist of one segment (physically contiguous) or several (scatter-gather). The driver programs the device with the segment list; that is the concrete hand-off.

Chapter 21's driver uses all four. The tag is created in `myfirst_dma_setup`. The map is returned by `bus_dmamem_alloc`. The memory is the four-kilobyte buffer returned by the same call. The segment is the one `bus_dma_segment_t` returned by the callback passed to `bus_dmamap_load`. Later chapters extend this to per-transfer maps and multi-segment scatter-gather, but the same four objects are always in play.

21.3.2 Static Versus Dynamic Transactions

The `bus_dma(9)` manual page introduces a distinction between **static** and **dynamic** transactions. The distinction matters because it shapes which API calls a driver uses.

Static transactions use memory regions allocated by `bus_dma` itself, typically at attach time, and reused for the driver's lifetime. Descriptor rings are the classic example: a NIC driver allocates the receive ring once and uses it for every packet, never unloading and reloading. The driver calls:

- `bus_dma_tag_create` once, to describe the ring's constraints.
- `bus_dmamem_alloc` once, to allocate the ring's memory and get an implicitly-loaded map.
- `bus_dmamap_load` once, to obtain the ring's bus address. (The manual page's wording is "an initial load operation is required to obtain the bus address"; this is an API quirk you just remember.)
- `bus_dmamap_sync` many times, around each use of the ring.

On teardown, the driver calls `bus_dmamap_unload`, `bus_dmamem_free`, and `bus_dma_tag_destroy`. No `bus_dmamap_create` or `bus_dmamap_destroy` is needed because `bus_dmamem_alloc` returned the map and `bus_dmamem_free` frees it.

Dynamic transactions use memory regions allocated by something else (an mbuf from `m_getcl`, a kernel buffer from `m_malloc`, a user page pinned by `vm_fault_quick_hold_pages`), and the driver maps them into the device's address space per transfer. A NIC driver that is transmitting packets does this for each outgoing packet: the packet's mbuf already exists, the driver maps it, programs the device, waits for transmission, unmmaps it. The driver calls:

- `bus_dma_tag_create` once, to describe the per-buffer constraints.
- `bus_dmamap_create` once per buffer slot, to get a map.
- `bus_dmamap_load_mbuf_sg` (or `bus_dmamap_load`) each time a packet is transmitted, to map the specific mbuf.
- `bus_dmamap_sync` around each use.

- `bus_dmamap_unload` after each transmission completes.
- `bus_dmamap_destroy` once per buffer slot, on detach.
- `bus_dma_tag_destroy` once, on detach.

Chapter 21's driver uses the static pattern: one buffer, allocated once, reused for every simulated DMA transfer. The dynamic pattern is introduced briefly in Section 7 as a contrast; Part 6's network chapter (Chapter 28) uses it in earnest.

Knowing which pattern a driver uses is the first thing to identify when reading DMA code. The call sequence is different, the teardown order is different, and the interpretation of the map is different. `bus_dmamem_alloc`'s "one static allocation" behaviour is what makes the static path shorter and simpler.

21.3.3 The Sync Discipline

Section 1 described `bus_dmamap_sync` in general terms; Section 2 is the place to pin down the four operations precisely, because the next section will assume this vocabulary.

The four operations are:

- `BUS_DMASYNC_PREREAD`. Called **before** the device writes the buffer (from the host's point of view, before the buffer is read by the host). Tells the kernel "the CPU has finished whatever it was doing with this buffer; the device is about to write into it". On non-coherent platforms, this invalidates the CPU's cache copy so a later read will see the device's writes. On coherent platforms, it is often a no-op.
- `BUS_DMASYNC_PWRITE`. Called **before** the device reads the buffer (from the host's point of view, before the buffer is written by the host). Tells the kernel "the CPU has just written the buffer; please flush any dirty cache lines so the device reads the current contents". On non-coherent platforms this is a cache flush; on coherent platforms it is often a memory barrier or no-op.
- `BUS_DMASYNC_POSTREAD`. Called **after** the device has written the buffer and **before** the CPU reads it. Tells the kernel "the device has finished writing; the CPU is about to read". On platforms with bounce buffers, this is the point at which the data is copied from the bounce region back to the driver's buffer.
- `BUS_DMASYNC_POSTWRITE`. Called **after** the device has read the buffer. Tells the kernel "the device is done reading; the CPU may reuse the buffer". Usually a no-op on coherent platforms; on systems with bounce buffers, this is when the bounce region may be released.

The names are worth internalising. "PRE" and "POST" refer to the DMA transaction: PRE is before, POST is after. "READ" and "WRITE" are from the **host's** perspective: READ means the host will read the result (the device writes), WRITE means the host has written what the device will read.

The pairs come together in the four common sequences:

- **Host-to-device (the driver sends data to the device):** write data → PWRITE → device reads → device done → POSTWRITE.
- **Device-to-host (the device sends data to the driver):** PREREAD → device writes → device done → POSTREAD → host reads.
- **Descriptor ring where the driver updates an entry, the device reads it, updates status, and the driver reads the status:** the driver writes the entry → PWRITE → device reads the entry → device updates status → device done → POSTREAD | POSTWRITE (combined flag) → host reads status.
- **Full ring shared between host and device:** at setup, PREREAD | PWRITE marks the entire ring as hand-off to device, with both directions of data flow open.

Real drivers use the combined flags often because descriptor rings are bidirectional. Chapter 21 starts with the simple one-direction cases and shows the combined flag in the descriptor-ring sketch at the end of Section 4.

21.3.4 The Load Callback Pattern

The most surprising part of `bus_dma` for a first-time reader is that `bus_dmamap_load` does not return the segment list directly. It takes a **callback function** as an argument, calls the callback with the segment list, and (normally) returns after the callback has run. Why this indirection?

The reason is that on platforms where the kernel may need to wait for bounce buffers, the load operation can be **deferred**. If bounce buffers are in short supply at the moment of the call, the kernel queues the request, returns `EINPROGRESS` to the caller, and runs the callback later when buffers are free. The driver has to be prepared for this case: the callback may run in a different context, possibly on a different thread, after the load call has already returned.

For most drivers on most platforms, the deferred case is rare. A driver that allocates its descriptor ring at attach time, on a system with enough bounce buffers and no IOMMU restriction, sees the callback run synchronously inside the load call, long before the load returns. The callback just stashes the bus address in a local variable that the driver reads immediately after the load returns.

A minimal callback looks like this:

```
static void
myfirst_dma_single_map(void *arg, bus_dma_segment_t *segs, int nseg, int error)
{
    bus_addr_t *addr = arg;

    if (error)
        return;

    KASSERT(nseg == 1, ("unexpected DMA segment count %d", nseg));
    *addr = segs[0].ds_addr;
}
```

The driver calls:

```
bus_addr_t bus_addr = 0;
int err = bus_dmamap_load(sc->dma_tag, sc->dma_map,
    sc->dma_vaddr, DMA_BUFFER_SIZE,
    myfirst_dma_single_map, &bus_addr, BUS_DMA_NOWAIT);
if (err != 0) {
    device_printf(sc->dev, "bus_dmamap_load failed: %d\n", err);
    return (err);
}
KASSERT(bus_addr != 0, ("single-segment callback did not set address"));
sc->dma_bus_addr = bus_addr;
```

The pattern is so common that many drivers define exactly this helper and name it similarly. `/usr/src/sys/dev/re/if_re.c` calls it `re_dma_map_addr`. `/usr/src/sys/dev/nvme/nvme_private.h` calls it `nvme_single_map`. Chapter 21’s driver will call it `myfirst_dma_single_map`. The function body is almost identical across drivers.

The `BUS_DMA_NOWAIT` flag on the load call tells the kernel “do not defer; if bounce buffers are unavailable, return `ENOMEM` immediately”. This is the common case for drivers that are willing to accept failure rather than wait. A driver that wants to wait passes `BUS_DMA_WAITOK` (or `0`, since `WAITOK` is the default zero value); in that case, if the load is deferred, the driver must return from the caller and expect the callback to run later.

When the load is deferred and runs later, the kernel may need to hold a driver-level lock while the callback runs. This is what the `lockfunc` and `lockfuncarg` parameters of `bus_dma_tag_create` are for: the driver provides a function that the kernel calls with `BUS_DMA_LOCK` before the callback and `BUS_DMA_UNLOCK` after. FreeBSD provides `busdma_lock_mutex` as a ready-made implementation for drivers that protect their DMA state with a standard mutex; the driver passes the mutex pointer as `lockfuncarg`. For drivers that never defer loads (because they use `BUS_DMA_NOWAIT` everywhere, or because they only load at attach time with no locks held), the kernel provides `_busdma_dflt_lock`, which panics if called; that is the safer default because it turns a silent threading bug into a loud one.

Chapter 21’s driver loads exactly once at attach time, under no contended lock, with `BUS_DMA_NOWAIT`. The `lockfunc` does not matter because the callback always runs synchronously. Section 3 passes `NULL` for both `lockfunc` and `lockfuncarg`; the kernel substitutes `_busdma_dflt_lock` automatically, and the panic-on-unexpected-call acts as a safety net.

21.3.5 Tag Hierarchies and Inheritance

Section 1 mentioned that a tag inherits from a parent tag, and that the hierarchy matches the hardware. Section 2 is the place to make this concrete.

When a PCI device is attached to a PCI bridge, the bridge’s own tag carries the constraints that the bridge itself imposes on DMA traffic: the DMA addresses it can route, the alignment it enforces, whether an IOMMU is in front of it. The kernel creates this tag at bus-attach time, and a driver can retrieve it for its own device with:

```
bus_dma_tag_t parent = bus_get_dma_tag(sc->dev);
```

The returned tag is the device’s **parent DMA tag**. When the driver creates its own tag, it passes the parent:

```
int err = bus_dma_tag_create(parent,
    /* alignment */    4,
    /* boundary */    0,
    /* lowaddr */    BUS_SPACE_MAXADDR,
    /* highaddr */    BUS_SPACE_MAXADDR,
    /* filtfunc */    NULL,
    /* filtfuncarg */ NULL,
    /* maxsize */    DMA_BUFFER_SIZE,
    /* nsegments */   1,
```

```

/* maxsegsz */ DMA_BUFFER_SIZE,
/* flags */ 0,
/* lockfunc */ NULL,
/* lockfuncarg */ NULL,
&sc->dma_tag);

```

The child inherits the parent’s restrictions; the child can only add more restrictions, never remove them. If the parent says “this bridge cannot address above 4 GB”, the child cannot say “actually my device can”; the kernel takes the intersection. This is what lets a driver write portable code: the driver describes only its device’s own constraints, and the kernel composes them with whatever the platform imposes.

Drivers that need to describe multiple groups of transfers (for example, one alignment for descriptor rings and a different alignment for data buffers) create multiple tags, all inheriting from the same parent. The `if_re(4)` driver is a clean example: it creates `rl_parent_tag` from the bridge, then `rl_tx_mtag` and `rl_rx_mtag` (for mbuf payloads, 1-byte aligned, multi-segment) and `rl_tx_list_tag` and `rl_rx_list_tag` (for descriptor rings, `RL_RING_ALIGN`-aligned, single-segment) all inherit from `rl_parent_tag`. Each tag describes a different set of buffers; the hierarchy composes them.

Chapter 21’s driver uses a single tag because it has a single buffer type. When the reader extends the driver with descriptor rings, the natural evolution is to add a second tag; Section 8’s challenge exercises sketch the step.

21.3.6 A Simple Hardware-to-Software Timeline

To solidify the vocabulary, here is a timeline for one complete DMA transfer on Chapter 21’s device, with each line annotated by which object and which API call is involved.

1. **Attach time, once.** Create tag via `bus_dma_tag_create`. Allocate memory and implicit map via `bus_dmamem_alloc`. Load map via `bus_dmamap_load` with single-segment callback. Record bus address in `softc`. Result: `sc->dma_tag`, `sc->dma_vaddr`, `sc->dma_map`, `sc->dma_bus_addr` all populated.
2. **First transfer, host-to-device:**
 - Fill `sc->dma_vaddr` with the pattern to send.
 - Call `bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_PREWRITE)`.
 - Write `DMA_ADDR_LOW`, `DMA_ADDR_HIGH`, `DMA_LEN`, `DMA_DIR=WRITE` via `bus_write_4` calls.
 - Write `DMA_CTRL = START`.
 - Wait for completion interrupt.
 - In the rx filter, read `DMA_STATUS`; if `DONE`, enqueue task.
 - In the task, call `bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_POSTWRITE)`.
 - Update statistics.
3. **Second transfer, device-to-host:**
 - Call `bus_dmamap_sync(..., BUS_DMASYNC_PREREAD)`.
 - Write `DMA_DIR=READ`, `DMA_CTRL=START`.
 - Wait for interrupt.

- In the task, call `bus_dmamap_sync( . . . , BUS_DMASYNC_POSTREAD)`.
- Read `sc->dma_vaddr` and verify the pattern.

4. **Detach time, once.** Unload map via `bus_dmamap_unload`. Free memory via `bus_dmamem_free` (which also frees the implicit map). Destroy tag via `bus_dma_tag_destroy`.

The timeline has four loops of sync: PREWRITE/POSTWRITE for host-to-device, PREREAD/POSTREAD for device-to-host. Each loop is one transfer. Each loop has exactly one sync call before and one after; neither may be omitted. Between the PRE sync and the POST sync, the CPU may not touch the buffer (the device owns it). Before the PRE sync and after the POST sync, the CPU owns the buffer freely.

The mental model “ownership passes between CPU and device, with sync calls marking each hand-off” is the single most useful intuition to take away from Section 2. Every real driver respects the ownership discipline, even on coherent platforms where the sync calls happen to be cheap or no-op.

21.3.7 Exercise: Walk Through a Sample DMA Setup Without a Real Device

A paper exercise before Section 3. Imagine a simple DMA-capable device with the following properties:

- PCI device with one MMIO BAR.
- One DMA engine with these registers: `DMA_ADDR_LOW` at offset 0x20, `DMA_ADDR_HIGH` at 0x24, `DMA_LEN` at 0x28, `DMA_DIR` at 0x2C (0 = host-to-device, 1 = device-to-host), `DMA_CTRL` at 0x30 (write 1 = start), `DMA_STATUS` at 0x34 (bit 0 = done, bit 1 = error).
- 4 KB transfer buffer required.
- 32-bit DMA engine (cannot reach memory above 4 GB).
- 16-byte alignment required.
- Buffer must not cross a 64 KB boundary.

Write out, on paper, the exact `bus_dma_tag_create` call the driver would issue. Identify each of the fourteen parameters, and name what concrete value you would use for each. Then write out the `bus_dmamem_alloc` call and the `bus_dmamap_load` call that follow. Do not write C; write prose.

A sample answer (for comparison):

- Parent tag: `bus_get_dma_tag(sc->dev)`, the PCI parent.
- Alignment: 16.
- Boundary: 65536.
- Low address: `BUS_SPACE_MAXADDR_32BIT`. Remember the confusing naming: `lowaddr` is the highest address the device can reach, not a lower bound. For a 32-bit engine, any address above `BUS_SPACE_MAXADDR_32BIT` must be excluded, so that value goes here.
- High address: `BUS_SPACE_MAXADDR`. This is the upper bound of the excluded window; passing `BUS_SPACE_MAXADDR` extends the exclusion to infinity, which correctly expresses “nothing above 4 GB is reachable”.
- Filter function: NULL (not needed, modern code avoids them).
- Filter argument: NULL.
- Max size: 4096.
- Nsegments: 1 (single-segment required).
- Max segment size: 4096.

- Flags: 0.
- Lockfunc: NULL.
- Lockfuncarg: NULL.
- Tag pointer: &sc->dma_tag.

Then `bus_dmamem_alloc` with `BUS_DMA_WAITOK` | `BUS_DMA_COHERENT` | `BUS_DMA_ZERO` to allocate the buffer as coherent, zero-initialised, sleeping allowed (attach time). Then `bus_dmamap_load` with `BUS_DMA_NOWAIT`, the single-segment callback, and `&sc->dma_bus_addr` as the callback argument.

Writing this out on paper before seeing the code makes Section 3's walkthrough feel like a confirmation rather than an introduction. The exercise takes ten minutes and is worth it.

21.3.8 Wrapping Up Section 2

Section 2 gave the reader the vocabulary: tag, map, memory, segment, PRE, POST, READ, WRITE, static, dynamic, parent, callback. The pieces fit together in a specific pattern: at attach time, create a tag, allocate memory, load a map, record the bus address; at transfer time, sync PRE, trigger the device, wait, sync POST, read the data; at detach time, unload the map, free the memory, destroy the tag. The pattern is the same across every DMA-capable driver in FreeBSD; the vocabulary is the same in every chapter of this book from now on.

Section 3 is the first running code. The driver creates a tag, allocates memory, loads it, and verifies that the bus address is sane. No transfers happen yet; the goal is to exercise the setup and teardown paths under WITNESS and confirm that the driver can stand up and tear down a DMA region cleanly across many `kldload`/`kldunload` cycles. That pair of operations is the foundation that every later section adds to.

21.4 Section 3: Allocating and Mapping DMA Memory

Section 2 built the vocabulary. Section 3 writes the code. The first running stage of the Chapter 21 driver creates a DMA tag, allocates a single four-kilobyte buffer, loads it into a map, records the bus address, and adds the setup-plus-teardown path to the attach and detach sequences. No DMA transfers happen yet. The goal is to exercise the allocation path, watch the new `softc` fields populate under `kldload`, confirm that `kldunload` cleans up without complaint, and do so repeatedly under WITNESS to catch any lock-order violations.

Stage 1's version tag is `1.4-dma-stage1`. The compile target after the stage is `myfirst.ko`. No new files are added yet; the tag creation, allocation, and teardown live in `myfirst.c` and `myfirst_pci.c` alongside the existing attach logic. Section 8 moves the DMA code into its own file; here we keep everything in one place so the stage's scope is visible in a single view.

21.4.1 New Softc Fields

The driver's `softc` grows by four fields:

```
/* In myfirst.h, inside struct myfirst_softc. */
bus_dma_tag_t      dma_tag;
bus_dmamap_t       dma_map;
```

```
void                *dma_vaddr;
bus_addr_t         dma_bus_addr;
```

`dma_tag` is the tag created at attach time. `dma_map` is the map returned by `bus_dmamem_alloc`. `dma_vaddr` is the kernel virtual address the CPU uses to access the buffer. `dma_bus_addr` is the bus address the device uses.

The fields follow the Chapter 17/18 naming convention: lowercase, underscores, short. They are initialised to zero by the softc's implicit zeroing at attach time; the driver adds the initialisation by relying on `device_get_softc`'s zero-fill guarantee. No explicit `= 0` assignments are needed.

The softc includes `<machine/bus.h>` and `<sys/bus_dma.h>` (the latter through `<machine/bus.h>`); Chapter 18 already pulled these in for `bus_space` work, so the includes are present and no new ones are required.

21.4.2 The Single-Segment Callback

Before the setup function, a one-function helper. The helper is the single-segment callback introduced in Section 2:

```
static void
myfirst_dma_single_map(void *arg, bus_dma_segment_t *segs, int nseg, int error)
{
    bus_addr_t *addr = arg;

    if (error != 0) {
        printf("myfirst: dma load callback error %d\n", error);
        return;
    }

    KASSERT(nseg == 1, ("myfirst: unexpected DMA segment count %d", nseg));
    *addr = segs[0].ds_addr;
}
```

The function is the same pattern as `re_dma_map_addr` in `/usr/src/sys/dev/re/if_re.c`. Pass it a pointer to a `bus_addr_t`; on success, the callback writes the one segment's bus address into the target. The `KASSERT` confirms there is exactly one segment; `bus_dmamem_alloc` always returns a single segment, so this assertion is a safety net rather than a runtime check.

The callback is marked `static` because it is not used outside `myfirst.c`. It takes no state beyond the bus-address pointer, so it is thread-safe by construction and can run in any context the kernel chooses.

21.4.3 The Setup Function

The Stage 1 setup function, named `myfirst_dma_setup`, lives in `myfirst.c`. It performs the four operations in order: create tag, allocate memory, load map, record bus address. Each step checks for error and unwinds

prior steps on failure. The function returns 0 on success, a nonzero error code on failure, and leaves the softc's DMA fields in a consistent state in both cases.

```
#define MYFIRST_DMA_BUFFER_SIZE 4096u

int
myfirst_dma_setup(struct myfirst_softc *sc)
{
    int err;

    err = bus_dma_tag_create(bus_get_dma_tag(sc->dev),
        /* alignment */      4,
        /* boundary */      0,
        /* lowaddr */       BUS_SPACE_MAXADDR,
        /* highaddr */      BUS_SPACE_MAXADDR,
        /* filtfunc */      NULL,
        /* filtfuncarg */   NULL,
        /* maxsize */       MYFIRST_DMA_BUFFER_SIZE,
        /* nsegments */     1,
        /* maxsegsz */      MYFIRST_DMA_BUFFER_SIZE,
        /* flags */         0,
        /* lockfunc */      NULL,
        /* lockfuncarg */   NULL,
        &sc->dma_tag);
    if (err != 0) {
        device_printf(sc->dev, "bus_dma_tag_create failed: %d\n", err);
        return (err);
    }

    err = bus_dmamem_alloc(sc->dma_tag, &sc->dma_vaddr,
        BUS_DMA_WAITOK | BUS_DMA_COHERENT | BUS_DMA_ZERO,
        &sc->dma_map);
    if (err != 0) {
        device_printf(sc->dev, "bus_dmamem_alloc failed: %d\n", err);
        bus_dma_tag_destroy(sc->dma_tag);
        sc->dma_tag = NULL;
        return (err);
    }

    sc->dma_bus_addr = 0;
    err = bus_dmamap_load(sc->dma_tag, sc->dma_map,
        sc->dma_vaddr, MYFIRST_DMA_BUFFER_SIZE,
        myfirst_dma_single_map, &sc->dma_bus_addr,
        BUS_DMA_NOWAIT);
    if (err != 0 || sc->dma_bus_addr == 0) {
```

```

    device_printf(sc->dev, "bus_dmamap_load failed: %d\n", err);
    bus_dmamem_free(sc->dma_tag, sc->dma_vaddr, sc->dma_map);
    sc->dma_vaddr = NULL;
    bus_dma_tag_destroy(sc->dma_tag);
    sc->dma_tag = NULL;
    return (err != 0 ? err : ENOMEM);
}

device_printf(sc->dev,
    "DMA buffer %zu bytes at KVA %p bus addr %#jx\n",
    (size_t)MYFIRST_DMA_BUFFER_SIZE,
    sc->dma_vaddr, (uintmax_t)sc->dma_bus_addr);

return (0);
}

```

A few details repay attention.

The constants. MYFIRST_DMA_BUFFER_SIZE is a #define named with the chapter's prefix, following the Chapter 17 naming convention. It is used three times in the setup function (in the tag's maxsize, the tag's maxsegsz, and the load's buffer length), so a symbolic name is worth it even if the value is small. Chapter 21 uses 4 KB because it matches a page and avoids any bounce-buffer corner cases; Section 7 revisits the choice.

The parent tag. bus_get_dma_tag(sc->dev) returns the parent DMA tag inherited from the PCI bridge. The kernel composes the parent's restrictions with the driver's own, so the child tag automatically respects any bridge-level limits. On amd64 with an IOMMU, the parent tag also carries the IOMMU's mapping requirements; the driver's tag inherits them transparently.

The alignment. 4 bytes is enough for a 32-bit-wide engine's DMA start address. A real device's datasheet would specify a value (NVMe uses the page size, if_re uses the descriptor size); Chapter 21's simulated engine happens to be content with 4.

The boundary. 0 means no boundary restriction. A device that cannot cross 64 KB boundaries (some DMA engines have this limitation because their internal counters are 16 bits) would pass 65536.

The addresses. BUS_SPACE_MAXADDR for both low and high means "no exclusion window". The simulation has no address-range limit; a real 32-bit-only device would pass BUS_SPACE_MAXADDR_32BIT for lowaddr to exclude addresses above 4 GB. Section 7 revisits this with a concrete walkthrough.

The size and segment count. A single 4 KB buffer that must be physically contiguous. nsegments = 1 plus maxsegsz = MYFIRST_DMA_BUFFER_SIZE means a one-segment mapping; bus_dmamem_alloc always returns a single segment, so this matches.

The flags. 0 at tag-create time (no special tag flags). BUS_DMA_WAITOK | BUS_DMA_COHERENT | BUS_DMA_ZERO at bus_dmamem_alloc time: the allocator may sleep if needed, the memory should be cache-coherent with the device (important on arm and arm64; a hint on amd64), and the buffer should be zero-initialised. BUS_DMA_NOWAIT at bus_dmamap_load time: the load must not defer; if bounce buffers are unavailable, the load should fail immediately. For Chapter 21's one-load-at-attach-time usage, the distinction

does not matter in practice; the convention is to use `NOWAIT` anywhere the driver has a clean error path, because it makes the control flow easier to reason about.

The lockfunc. `NULL` means “default”. On Chapter 21’s single load at attach time, the callback always runs synchronously, so the lockfunc is never invoked; the default (`_busdma_dflt_lock`, which panics if called) is the correct safety net.

The error handling. Each step checks the return value and unwinds prior steps on failure. The order matters: tag was created first, so it is destroyed last; memory was allocated second, so it is freed second-to-last. The softc fields are cleared to `NULL` after free so detach can safely walk them whether setup partially failed or ran to completion.

The final device_printf. A single banner line logs the buffer size, kernel virtual address, and bus address. The line is useful in `dmesg` and doubles as a regression-test marker: a working driver prints it; a broken setup does not.

21.4.4 The Teardown Function

The paired teardown function is:

```
void
myfirst_dma_teardown(struct myfirst_softc *sc)
{
    if (sc->dma_bus_addr != 0) {
        bus_dmamap_unload(sc->dma_tag, sc->dma_map);
        sc->dma_bus_addr = 0;
    }
    if (sc->dma_vaddr != NULL) {
        bus_dmamem_free(sc->dma_tag, sc->dma_vaddr, sc->dma_map);
        sc->dma_vaddr = NULL;
        sc->dma_map = NULL;
    }
    if (sc->dma_tag != NULL) {
        bus_dma_tag_destroy(sc->dma_tag);
        sc->dma_tag = NULL;
    }
}
```

The function is guarded by zero-value checks so it is safe to call even when setup did not complete. This is the same pattern the Chapter 19 interrupt teardown uses, and for the same reason: detach may run after a partial attach failure, and the cleanup code must not assume any particular prefix of the setup succeeded.

The order is the reverse of setup:

1. Unload the map. Safe to call even if the load succeeded; idempotent.
2. Free the memory and the implicit map. `bus_dmamem_free` frees both the buffer and the map object returned by `bus_dmamem_alloc`; the driver never calls `bus_dmamap_destroy` for this path.

3. Destroy the tag. Returns EBUSY if any maps are still associated; the earlier unload prevents that.

The `bus_dmamap_unload` call is subtle. After `bus_dmamem_alloc`, the map is implicitly loaded (this is what the manual page calls “An initial load operation is required to obtain the bus address”). The load either happens implicitly or via the explicit `bus_dmamap_load` call the driver already made. Either way, the map is in the loaded state after setup; it must be unloaded before `bus_dmamem_free`. The chapter’s pattern uses an explicit `bus_dmamap_load` to expose the callback and the bus address; `bus_dmamap_unload` is its paired teardown.

A reader who is curious about why `bus_dmamap_load` has to be called manually after `bus_dmamem_alloc` can read the answer in the `bus_dma(9)` manual page: the “STATIC TRANSACTIONS” section explicitly states “An initial load operation is required to obtain the bus address of the allocated memory”. The allocator returns a valid KVA and a map object, but the bus address itself is only made available via the callback after the load. This is a historical quirk; you remember it once and the pattern falls into place for every static driver.

21.4.5 Integrating Setup and Teardown Into Attach and Detach

The attach function from Chapter 20 ended with the MSI-X setup. Chapter 21 inserts the DMA setup just before it, so the tag and buffer are ready by the time the device starts firing interrupts:

```
/* ... earlier attach work: BAR allocation, hw layer, cdev ... */

err = myfirst_dma_setup(sc);
if (err != 0)
    goto fail_dma;

err = myfirst_msix_setup(sc);
if (err != 0)
    goto fail_msix;

/* ... remaining attach work ... */

return (0);

fail_msix:
    myfirst_dma_teardown(sc);
fail_dma:
    /* ... earlier failure labels ... */
```

The exact labels depend on the driver’s current layout, which is the Chapter 20 layout after Stage 4. The principle is: the DMA setup comes after the BAR is mapped (because the device’s registers must be reachable to eventually trigger transfers), after the hardware layer is built, but before the interrupt setup runs. On failure, the driver unwinds to the labels in reverse.

The detach function mirrors the attach order. The MSI-X teardown runs first (to stop any further interrupts), then the DMA teardown runs, then the earlier cleanup. The ordering guarantees that no interrupt can fire on the DMA path after the tag is destroyed, which would be a use-after-free.

21.4.6 Running Stage 1

Build and load:

```
make clean && make  
kldload ./myfirst.ko
```

Watch dmesg:

```
myfirst0: <myfirst DMA test device> ...  
myfirst0: DMA buffer 4096 bytes at KVA 0xfffffe0010af9000 bus addr 0x10af9000  
myfirst0: interrupt mode: MSI-X, 3 vectors
```

The KVA and bus address will differ on your machine; the format is what matters. The KVA is a typical kernel virtual address (well above the direct-map base on amd64). The bus address on amd64 with an IOMMU disabled is usually equal to the physical address; with an IOMMU enabled, it is an IOMMU-remapped address, often much lower than any physical address that could back it.

Verify the `softc` fields via `sysctl` or a `device_printf` in a debug build:

```
sysctl dev.myfirst.0
```

Unload the module:

```
kldunload myfirst
```

`dmesg` should show the detach:

```
myfirst0: detaching
```

No panic, no WITNESS complaint, no VFS warning about leaking memory. If WITNESS is enabled and the driver's setup or teardown acquires a lock that `bus_dma` also acquires, the output would show a lock-order warning; a clean `kldunload` is the confirmation that the locking is right.

Repeat the load/unload cycle several times. DMA-related memory leaks are rare but catastrophic when they happen (a leak in `bus_dma` leaks pages, not just bytes); the regression check is worth running fifty times in a row with a `for` loop and confirming that `vmstat -m` shows `bus_dmamap` and `bus_dma_tag` returning to their idle counts.

21.4.7 What Stage 1 Does and Does Not Do

Stage 1 exercises the allocation and cleanup paths. It does not perform any DMA transfers; `dma_vaddr` is an unused buffer (apart from its zero-fill), and `dma_bus_addr` is an unused address. The next sections will put both to work.

What Stage 1 proves is that:

- The driver can create a tag that inherits from the PCI parent.
- The driver can allocate a coherent, zero-initialised 4 KB buffer.
- The driver can obtain the bus address via the callback.
- The driver can tear everything down cleanly.
- The cycle can run many times without leaking resources.

That is a solid foundation. The rest of the chapter builds on it.

21.4.8 Common Mistakes at This Stage

Five mistakes are common in Stage 1. Each is easy to make and easy to fix once recognised.

Mistake one: forgetting to call `bus_dmamap_load` after `bus_dmamem_alloc`. The symptom is that `dma_bus_addr` stays at zero; programming the device with bus address zero either silently corrupts memory or hits an IOMMU fault. The fix is to call `bus_dmamap_load` explicitly, as the Stage 1 code does. The `KASSERT(bus_addr != 0, ...)` in the driver catches this during development.

Mistake two: passing an unaligned `maxsize` to `bus_dma_tag_create`. The alignment parameter must be a power of two, and `maxsize` must be at least alignment. A size of 3 bytes with alignment 4 produces an error. The chapter's 4096-byte size with alignment 4 is safely aligned.

Mistake three: using `BUS_DMA_NOWAIT` with `bus_dmamem_alloc` and then ignoring the error. `BUS_DMA_NOWAIT` makes the allocator return `ENOMEM` if memory is tight; a driver that ignores the error and proceeds with `NULL` dereferences panics immediately. Use `BUS_DMA_WAITOK` at attach time (where sleeping is safe), and always check the return value.

Mistake four: forgetting to zero the bus address before the load call. If the load fails, the callback is never called, and `dma_bus_addr` retains whatever garbage was there. The chapter's code assigns `sc->dma_bus_addr = 0` before calling `bus_dmamap_load` so the post-load check (`if (err != 0 || sc->dma_bus_addr == 0)`) is reliable.

Mistake five: skipping the tag destroy in the error-path unwind. The unwind in the chapter's code destroys the tag in every failure branch. A driver that fails `bus_dmamem_alloc` and returns without destroying the tag leaks a tag on every failed attach; over many retries this adds up. The pattern is: on any failure after `bus_dma_tag_create` succeeded, destroy the tag before returning.

None of these mistakes panic immediately; all of them produce subtle bugs that manifest under load or after repeated load/unload cycles. Running Stage 1 fifty times with `WITNESS` and `INVARIANTS` enabled catches most of them.

21.4.9 A Word on the `bus_dma` Template API

FreeBSD 13 and later also provide a template-based API for creating DMA tags, covered in the `bus_dma(9)` manual under `bus_dma_template_*`. The template API is an ergonomic alternative to `bus_dma_tag_create`'s fourteen-parameter list: the driver initialises a template from a parent tag, overrides individual fields with `BD_*` macros, and builds the tag with `bus_dma_template_tag`.

A template-based Stage 1 setup would look like:

```
bus_dma_template_t t;

bus_dma_template_init(&t, bus_get_dma_tag(sc->dev));
BUS_DMA_TEMPLATE_FILL(&t,
    BD_ALIGNMENT(4),
    BD_MAXSIZE(MYFIRST_DMA_BUFFER_SIZE),
    BD_NSEGMENTS(1),
    BD_MAXSEGSIZE(MYFIRST_DMA_BUFFER_SIZE));
err = bus_dma_template_tag(&t, &sc->dma_tag);
```

The template API is preferred in new drivers because it makes the overridden fields explicit. Chapter 21 uses the classic `bus_dma_tag_create` in its running example because that is what the majority of the existing FreeBSD source tree uses, and the reader who can read a fourteen-parameter call can always translate it to the template form. Section 8's refactor exercise suggests trying the template API as a stylistic variation.

21.4.10 Wrapping Up Section 3

Section 3 put the Chapter 21 driver into Stage 1: a tag, a map, a buffer, a bus address, and clean teardown. No transfers happen yet; the allocation path is the only thing exercised. That is enough to confirm that the pieces fit together, that the parent tag is inherited correctly, that the single-segment callback populates the bus address, and that `kldload/kldunload` cycles do not leak.

Section 4 is the sync discipline. Before the driver hands the buffer to a DMA engine, it needs to know exactly which sync calls happen where, why each one exists, and what would go wrong if one were omitted. Section 4 is a careful tour of `bus_dmamap_sync`, with concrete diagrams and the mental model that Section 5 then uses to build the simulated engine.

21.5 Section 4: Synchronising and Using DMA Buffers

Section 3 produced a driver that can allocate and release a DMA buffer. Section 4 teaches the discipline that every actual transfer must respect: when to call `bus_dmamap_sync`, with which flag, and why. The discipline is what keeps the CPU's and the device's view of memory consistent. No new code is written in this section (the simulated engine that will consume the sync calls is built in Section 5), but the mental model laid down here is what every later section depends on.

21.5.1 The Ownership Model

The single most useful intuition for DMA is this: at any moment, either the CPU owns the buffer or the device owns the buffer. Ownership passes back and forth through `bus_dmamap_sync` calls. Between a PRE sync and the next POST sync, the device owns the buffer and the CPU must not touch it. Between a POST sync and the next PRE sync, the CPU owns the buffer and the device must not touch it. The driver's job is to make every ownership boundary explicit with a sync call.

The ownership is physical, not logical. It does not mean the CPU or the device “knows” about the buffer in some abstract sense; it means the CPU’s caches and the device’s bus engine can actually observe different contents for the same memory at the same moment, and the sync calls are the kernel’s opportunity to reconcile the difference. On a fully coherent platform (modern amd64 with a coherent PCIe root complex and no non-coherent DMA peers), the hardware reconciles the difference transparently and `bus_dmamap_sync` is often a memory barrier or a no-op. On a partially coherent platform (some arm64 systems, some RISC-V configurations, anything with `BUS_DMA_COHERENT` not honoured at allocation), the sync calls do cache flushes and invalidates. The driver writes the same code regardless; the kernel does the right thing.

A driver that respects the ownership boundaries is portable. A driver that skips sync calls “because my amd64 system happens to work without them” is not; the same driver will corrupt data on arm64 or in a virtualised environment where the hypervisor’s IOMMU imposes its own coherence policy.

21.5.2 The Four Sync Flags in Depth

Section 2 named the four sync flags. Section 4 pins down exactly what each one means, what the kernel does for each on different platforms, and when the driver calls each in practice.

BUS_DMASYNC_PREREAD. The CPU has finished touching the buffer and the device is about to read from host memory is **not** the intent here; the flag is about **device writes into host memory**, which the host then **reads**. The flag is called `PREREAD` because the *host* is going to read after the operation; it is called `PRE` because this is before the DMA. On non-coherent platforms, the kernel invalidates the CPU’s cache copies of the buffer’s cache lines. The reason is that after the device writes new data to memory, stale cache lines in the CPU would cause subsequent reads to see the old values. Invalidation ensures the next read fetches from memory, where the device’s writes will land. On coherent platforms, invalidation is unnecessary because the hardware snoops the cache automatically; the kernel implements `PREREAD` as a memory barrier or no-op.

BUS_DMASYNC_PREWRITE. The CPU has just written the buffer and the device is about to read it. On non-coherent platforms, the kernel flushes the CPU’s dirty cache lines to memory. The reason is that the CPU’s writes might still sit in its cache; the device reads from memory directly and would see stale contents. Flushing ensures the memory controller has the current data before the device’s read. On coherent platforms, a memory barrier is usually sufficient to enforce ordering; the cache coherence protocol handles the flush implicitly.

BUS_DMASYNC_POSTREAD. The device has finished writing to host memory and the CPU is about to read. On non-coherent platforms, this is often the actual cache invalidate (in some implementations the invalidate happens at `POST` rather than `PRE`); on coherent platforms, it is a barrier or no-op. On platforms with bounce buffers, this is when the kernel copies data from the bounce region back into the driver’s buffer. That is why even on coherent platforms the `POSTREAD` call cannot be skipped: the coherence machinery may be coherent, but the bounce buffer machinery is not, and the `POSTREAD` call is the hook the bounce machinery uses to do its work.

BUS_DMASYNC_POSTWRITE. The device has finished reading from host memory. On most platforms this is a no-op because no host-visible state needs to change (the CPU already had the data it wrote; the device has finished reading and will not read again; nothing is out of sync). On bounce-buffer platforms, this is the hook where the bounce region may be released back to the pool.

Three observations that surface after the definitions:

- The `PRE` and `POST` of a pair are always both called. `PREREAD` is followed later by `POSTREAD`; `PREWRITE` is followed later by `POSTWRITE`. Skipping either breaks the contract.

- On coherent platforms many of these calls are cheap or free. That is an implementation detail the driver does not rely on. The driver writes them because they are required for portability and because bounce-buffer support is transparent only if the calls are there.
- The semantics of PRE and POST are “from the device’s viewpoint”: PRE means “before the device operation starts”; POST means “after the device operation completes”. READ and WRITE are “from the host’s viewpoint”: READ means “the host is going to read the result”; WRITE means “the host wrote the content”.

21.5.3 The Four Common Transfer Patterns

Four patterns cover almost every DMA transfer a driver performs. Each has its own PRE/POST sequence, and the sequence is predictable once the pattern is recognised.

Pattern A: Host-to-device data transfer. The driver fills a buffer with data and asks the device to send it.

```
CPU fills buffer at KVA
bus_dmamap_sync(..., BUS_DMASYNC_PREWRITE)
program device with bus_addr, length, direction
write doorbell
wait for completion
(device has read the buffer)
bus_dmamap_sync(..., BUS_DMASYNC_POSTWRITE)
CPU may now reuse buffer
```

Example: a driver transmitting a packet to a NIC. The driver copies the packet into a DMA buffer, issues the PREWRITE sync, writes the descriptor, pokes the doorbell, and waits for the transmit-complete interrupt. In the interrupt’s task, the driver issues the POSTWRITE sync and returns the buffer to the free pool.

Pattern B: Device-to-host data transfer. The driver asks the device to deliver data into a buffer; the driver then reads the buffer.

```
bus_dmamap_sync(..., BUS_DMASYNC_PREREAD)
program device with bus_addr, length, direction
write doorbell
wait for completion
(device has written the buffer)
bus_dmamap_sync(..., BUS_DMASYNC_POSTREAD)
CPU reads buffer at KVA
```

Example: a driver receiving a packet from a NIC. The driver hands the NIC a buffer’s bus address, issues the PREREAD sync, pokes the doorbell, and waits for the receive-complete interrupt. In the interrupt’s task, the driver issues the POSTREAD sync and processes the received data.

Pattern C: Descriptor ring entry. The driver writes a descriptor that the device reads (sees a new request), and the device later updates the same descriptor with a status field that the driver reads.

```

CPU writes descriptor fields (bus_addr, length, status = PENDING)
bus_dmamap_sync(..., BUS_DMASYNC_PREWRITE)
device reads descriptor
device processes the transfer
device writes descriptor status = DONE
bus_dmamap_sync(..., BUS_DMASYNC_POSTREAD | BUS_DMASYNC_POSTWRITE)
CPU reads descriptor status

```

The combined POST flag is the idiomatic way to pair the host-write-then-host-read when the host is both the producer and the consumer of different fields in the same memory region. The kernel does both operations in one call.

Pattern D: Bidirectional shared ring. The driver and the device share a descriptor ring indefinitely. At ring setup, both directions of data flow need to be synchronised.

```

bus_dmamem_alloc returns the ring's memory
bus_dmamap_sync(..., BUS_DMASYNC_PREREAD | BUS_DMASYNC_PREWRITE)
(ring is now live; both sides may read and write)
for each ring use:
    bus_dmamap_sync with the appropriate PRE
    doorbell / completion
    bus_dmamap_sync with the appropriate POST

```

Production drivers like `if_re(4)` and `nvme(4)` use this pattern; the combined PRE sync at ring setup is followed by per-transaction PRE/POST pairs. Chapter 21's single-buffer driver does not use this pattern; it is mentioned for completeness and because the reader will see it in real driver code.

21.5.4 The Simulated Transfer's Sync Sequence

Chapter 21's simulated DMA engine will run both host-to-device and device-to-host transfers. The test sequence the driver performs in Stage 2 is:

```

/* Host-to-device transfer: driver writes a pattern, engine reads it. */
memset(sc->dma_vaddr, 0xAA, MYFIRST_DMA_BUFFER_SIZE);
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_PREWRITE);
/* program engine */
CSR_WRITE_4(sc, MYFIRST_REG_DMA_DIR, MYFIRST_DMA_DIR_WRITE);
CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_START);
/* wait for completion interrupt */
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_POSTWRITE);

/* Device-to-host transfer: engine writes a pattern, driver reads it. */
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_PREREAD);
CSR_WRITE_4(sc, MYFIRST_REG_DMA_DIR, MYFIRST_DMA_DIR_READ);

```

```
CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_START);
/* wait for completion interrupt */
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_POSTREAD);
/* read sc->dma_vaddr and verify */
```

Two transfers, four sync calls, four flags. The order is the test’s contract. Section 5 will thread this through the driver’s code.

21.5.5 What Coherence Flags Mean and Do Not Mean

BUS_DMA_COHERENT is a flag both `bus_dma_tag_create` and `bus_dmamem_alloc` accept. Its meaning differs subtly between the two, and the difference is worth understanding so the reader knows when to use which.

On `bus_dma_tag_create`, BUS_DMA_COHERENT is an **architectural hint** that the driver is willing to spend extra cost at allocation to reduce cost at sync. On arm64, the flag tells the allocator to place the buffer in a memory domain that is inherently coherent with the DMA path, which may be a separate reserved region.

On `bus_dmamem_alloc`, BUS_DMA_COHERENT tells the allocator to produce a buffer that does not need cache flushes for sync. On arm and arm64, this uses a different allocator path (uncached or write-combined memory). On amd64, where the PCIe root complex is coherent and DMA is automatically snooped, the flag has little effect but is still passed for portability.

The rule: always pass BUS_DMA_COHERENT at allocation for descriptor rings and small control structures that are on the hot path for both the CPU and the device. Do not rely on the flag to remove the need for `bus_dmamap_sync`; the sync is still required by the API contract even if the flag makes it cheap. Some arm64 implementations do require the sync even with BUS_DMA_COHERENT (the flag is called a “hint” in the manual page for a reason); the driver is portable only if the sync is always called.

For bulk data buffers (packet payloads, storage blocks), BUS_DMA_COHERENT is usually not passed because the cache-hit rate is high when the CPU is about to process the data anyway, and the coherent allocator may use a slower memory domain. Chapter 21 passes BUS_DMA_COHERENT on its single small buffer because the chapter’s goal is to show the common case; a production driver would make the decision per-buffer based on access pattern.

21.5.6 What Happens If a Sync Is Omitted

A concrete failure scenario clarifies the abstraction. Suppose the driver performs a host-to-device transfer but forgets the PREWRITE sync:

```
memset(sc->dma_vaddr, 0xAA, MYFIRST_DMA_BUFFER_SIZE);
/* MISSING: bus_dmamap_sync(..., BUS_DMASYNC_PREWRITE); */
CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_START);
```

On amd64 with a coherent root complex, the transfer succeeds: the hardware snoops the CPU’s cache and the device reads the current contents. The bug is invisible.

On arm64 without a coherent PCIe fabric (some embedded systems), the transfer reads stale data: the CPU's write is still in the cache, the memory controller has old data, and the device reads 0x00 or garbage instead of 0xAA. The bug is visible immediately as data corruption.

On amd64 with bounce buffers (because the device had a 32-bit address limit and the buffer happened to be above 4 GB), the transfer reads stale data from the bounce region: the bounce machinery copies the driver's buffer into the bounce region at PREWRITE time, but without the PREWRITE call the bounce region is uninitialised (zero, or stale from a previous transfer). The bug is visible immediately as data corruption.

The pattern is consistent: the omission makes the driver work on the platform the author tested and fail on platforms with different coherence or addressing semantics. The sync calls are the portability guarantee. A driver that passes its test suite on amd64 and never has the sync calls exercised has a latent bug waiting for a different target.

21.5.7 Lock Context and Sync Calls

The Chapter 19/20 lock discipline extends naturally to sync calls. The sync itself does not acquire any lock inside `bus_dma`; it is safe to call from any context as long as the caller has the appropriate concurrency discipline for the map.

The relevant rules:

- The same map must not be touched by two threads simultaneously. If two filters on two vectors can both sync the same map, the driver must hold a mutex during the sync. Chapter 21 uses a single map and a single vector's task for completion, so there is no contention on the single-buffer case.
- The sync call may be made from a filter (primary interrupt context), from a task (thread context), or from process context (attach, detach, sysctl handlers). All are safe.
- The sync call must not be made from inside the `bus_dmamap_load` callback. The callback itself is the kernel's signal that the load has completed; the driver syncs later, after the callback returns and after the driver has programmed the device.
- The sync call must be paired with the PRE/POST flag matching the transfer direction, not with a flag matching what the driver "plans to do next". `BUS_DMASYNC_POSTREAD` after a host-to-device transfer is a bug, even if the CPU happens to be about to read the buffer (for verification, say) right after. Use `POSTWRITE` after a host-to-device transfer to match the transfer's direction.

Chapter 21's driver calls sync in three contexts: from `myfirst_dma_do_transfer` (called from process context or from a sysctl handler), from the rx filter (only after confirming the transfer is complete, but the chapter defers the sync to the task to keep the filter minimal), and from the rx task (under the softc mutex, before and after touching the buffer). Section 5 shows the exact placements.

21.5.8 The First Sync: When to Do It

One subtle question: does the driver need a sync call before the very first use of a freshly allocated buffer?

The answer is yes for bidirectional rings, and the required call is the combined PRE flag at setup time. The reason is that the allocator may not have zeroed the cache lines covering the buffer (even with `BUS_DMA_ZERO` setting the memory to zero, the cache lines may still hold whatever was there before the page was allocated), and without an initial sync the device might read garbage.

For Chapter 21's pattern (host-to-device transfer where the driver fills the buffer before PREWRITE), the initial sync is not needed: the driver writes the buffer, then issues PREWRITE, so the cache state before the write is irrelevant; PREWRITE handles any coherence concerns.

For device-to-host transfers, PREREAD serves the same purpose: the kernel does whatever invalidation is needed before the device writes, so any stale cache state is cleared.

The rule of thumb: as long as every hand-off to the device is preceded by a PRE sync, the buffer's initial state does not matter for correctness. The PRE sync is both an invalidate (for READ) and a flush (for WRITE), so it handles both directions. This is one of the API's small elegances; the driver does not need special "init" sync calls.

21.5.9 Wrapping Up Section 4

Section 4 pinned down the sync discipline. Four flags (PREREAD, PREWRITE, POSTREAD, POSTWRITE), one mental model (ownership passes between CPU and device), four common patterns (host-to-device, device-to-host, descriptor ring, shared ring), and one rule (every transfer has one PRE call and one POST call, both in the driver's code even if one is a no-op on the current platform). The `BUS_DMA_COHERENT` flag reduces sync cost but does not remove the sync requirement; `bus_dmamap_sync` is always called.

Section 5 builds the simulated DMA engine that will consume these sync calls. The engine accepts a bus address and a length, runs a `callout(9)`-scheduled transfer a few milliseconds later, and sets a completion bit in the status register. The driver's job is to program the engine, wait for completion, and verify the result. Each stage of Section 5 matches one of Section 4's four patterns.

21.6 Section 5: Building a Simulated DMA Engine

Section 4 laid down the sync discipline. Section 5 puts that discipline to work against a concrete DMA engine. The engine lives inside the Chapter 17 simulated backend and is built so the driver can drive it exactly as it would drive a real device. Tag, map, memory, sync, registers, completion, sync, verify: the full loop runs end to end, all on the simulator, inside the `myfirst` kernel module, with no real hardware required.

Stage 2's version tag is `1.4-dma-stage2`. The simulated engine is added to `myfirst_sim.c`. The driver's use of the engine is added to `myfirst.c`. The rx filter from Chapter 20 is unchanged at this stage; Section 6 wires the completion path through it. Here, the driver polls the engine's status register in a task because polling is the simpler path and isolates the DMA mechanics from the interrupt machinery for one stage.

21.6.1 The DMA Register Set

The simulated backend's MMIO register map from Chapter 17 already includes `INTR_STATUS`, `INTR_MASK`, `DATA_OUT`, `DATA_AV`, and `ERROR` at fixed offsets. Stage 2 extends the map with five new DMA registers at offsets `0x20` through `0x34`. The offsets and meanings are chosen to match a typical real device's DMA control block:

Offset	Name	R/W	Meaning
0x20	DMA_ADDR_LOW	RW	Low 32 bits of the DMA bus address.
0x24	DMA_ADDR_HIGH	RW	High 32 bits (zero on this device's 32-bit engine).
0x28	DMA_LEN	RW	Transfer length in bytes.
0x2C	DMA_DIR	RW	0 = host-to-device (engine reads), 1 = device-to-host.
0x30	DMA_CTRL	RW	Write 1 = start, write 2 = abort, bit 31 = reset.
0x34	DMA_STATUS	RO	Bit 0 = DONE, bit 1 = ERR, bit 2 = RUNNING.

The MYFIRST_REG_DMA_* constants live in `myfirst.h`:

```
#define MYFIRST_REG_DMA_ADDR_LOW    0x20
#define MYFIRST_REG_DMA_ADDR_HIGH  0x24
#define MYFIRST_REG_DMA_LEN        0x28
#define MYFIRST_REG_DMA_DIR        0x2C
#define MYFIRST_REG_DMA_CTRL        0x30
#define MYFIRST_REG_DMA_STATUS      0x34

#define MYFIRST_DMA_DIR_WRITE       0u
#define MYFIRST_DMA_DIR_READ        1u

#define MYFIRST_DMA_CTRL_START      (1u << 0)
#define MYFIRST_DMA_CTRL_ABORT      (1u << 1)
#define MYFIRST_DMA_CTRL_RESET      (1u << 31)

#define MYFIRST_DMA_STATUS_DONE     (1u << 0)
#define MYFIRST_DMA_STATUS_ERR      (1u << 1)
#define MYFIRST_DMA_STATUS_RUNNING  (1u << 2)
```

The naming follows the Chapter 17 convention: MYFIRST_REG_* for offsets, MYFIRST_DMA_* for named bits. The constants are used by both the simulation backend (which implements the engine) and the driver (which programs the engine); the shared header is the single source of truth.

The engine also sets MYFIRST_INTR_COMPLETE in INTR_STATUS when a transfer finishes, using the existing Chapter 19/20 interrupt mechanism. That is what Section 6 wires up; for Stage 2, the driver polls DMA_STATUS directly from a task and does not use the interrupt yet.

21.6.2 Extending the Simulation State

The simulated backend's struct `myfirst_sim` state grows with new fields to track the DMA engine:

```
struct myfirst_sim_dma {
    uint32_t    addr_low;
    uint32_t    addr_high;
    uint32_t    len;
    uint32_t    dir;
    uint32_t    ctrl;
    uint32_t    status;
    struct callout done_co;
    bool        armed;
};
```

The first six fields mirror the register contents. The `done_co` callout is the mechanism the engine uses to simulate transfer latency: when the driver writes `DMA_CTRL_START`, the engine schedules `done_co` to fire a few milliseconds later, which sets `DMA_STATUS_DONE` and raises `MYFIRST_INTR_COMPLETE`. The `armed` bool tracks whether the callout is scheduled so the abort path knows whether to call `callout_stop`.

The new state is embedded in the existing `struct myfirst_sim` structure:

```
struct myfirst_sim {
    /* ... existing Chapter 17 fields ... */
    struct myfirst_sim_dma dma;

    /* Backing store for the DMA engine's source or sink. */
    void          *dma_scratch;
    size_t        dma_scratch_size;

    /* Simulation back-channel: the host-visible KVA and bus address
     * the driver registers at myfirst_dma_setup time. A real device
     * never needs these; the simulator needs the KVA because it is
     * software and cannot reach RAM through the memory controller. */
    void          *dma_host_kva;
    bus_addr_t    dma_host_bus_addr;
    size_t        dma_host_size;
};
```

`dma_scratch` is a buffer that the engine uses as the other side of the transfer: when the driver programs a host-to-device transfer, the engine reads from the driver's buffer and writes into `dma_scratch`; when the driver programs a device-to-host transfer, the engine reads from `dma_scratch` and writes into the driver's buffer. In a real device, the "other side" is the device's own hardware (the wire, the storage media, the audio output); in the simulation, it is an in-kernel buffer that stands in.

The `dma_host_*` fields are the back-channel mentioned above. They are populated by a new helper `myfirst_sim_register_dma_buffer(sim, kva, bus_addr, size)` called from `myfirst_dma_setup`, and cleared by `myfirst_sim_unregister_dma_buffer` called from `myfirst_dma_tear down`. The helpers sit inside `myfirst_sim.c` and expose the sim's internal state only to the extent the simulator needs; they are the one explicit coupling between the DMA layer and the sim layer.

The scratch buffer is allocated at sim init time:

```
sc->sim.dma_scratch_size = 4096;
sc->sim.dma_scratch = malloc(sc->sim.dma_scratch_size,
    M_MYFIRST, M_WAITOK | M_ZERO);
```

and freed at sim teardown:

```
free(sc->sim.dma_scratch, M_MYFIRST);
```

The scratch buffer is not itself a DMA buffer (the engine is simulated; no real DMA happens). It is just kernel memory the simulation uses to model the device's internal storage.

21.6.3 The Register Access Hook

Chapter 17's simulation backend handles writes and reads on the simulated BAR by intercepting the `bus_read_4` and `bus_write_4` operations. The Stage 2 change extends the write hook to recognise the new DMA registers:

```
static void
myfirst_sim_write_4(struct myfirst_sim *sim, bus_size_t off, uint32_t val)
{
    switch (off) {
        /* ... existing registers from Chapter 17 ... */
        case MYFIRST_REG_DMA_ADDR_LOW:
            sim->dma.addr_low = val;
            break;
        case MYFIRST_REG_DMA_ADDR_HIGH:
            sim->dma.addr_high = val;
            break;
        case MYFIRST_REG_DMA_LEN:
            sim->dma.len = val;
            break;
        case MYFIRST_REG_DMA_DIR:
            sim->dma.dir = val;
            break;
        case MYFIRST_REG_DMA_CTRL:
            sim->dma.ctrl = val;
            myfirst_sim_dma_ctrl_written(sim, val);
            break;
        default:
            /* ... existing default handling ... */
            break;
    }
}
```

```

    }
}

```

The MYFIRST_REG_DMA_STATUS register is read-only, so the read hook handles it; the write hook ignores attempts to write it (or, in a defensive build, logs a warning and refuses). The DMA_STATUS read returns the current `sim->dma.status` value directly.

`myfirst_sim_dma_ctrl_written` is the engine's main decision point:

```

static void
myfirst_sim_dma_ctrl_written(struct myfirst_sim *sim, uint32_t val)
{
    if ((val & MYFIRST_DMA_CTRL_RESET) != 0) {
        if (sim->dma.armed) {
            callout_stop(&sim->dma.done_co);
            sim->dma.armed = false;
        }
        sim->dma.status = 0;
        sim->dma.addr_low = 0;
        sim->dma.addr_high = 0;
        sim->dma.len = 0;
        sim->dma.dir = 0;
        return;
    }
    if ((val & MYFIRST_DMA_CTRL_ABORT) != 0) {
        if (sim->dma.armed) {
            callout_stop(&sim->dma.done_co);
            sim->dma.armed = false;
        }
        sim->dma.status &= ~MYFIRST_DMA_STATUS_RUNNING;
        sim->dma.status |= MYFIRST_DMA_STATUS_ERR;
        return;
    }
    if ((val & MYFIRST_DMA_CTRL_START) != 0) {
        if ((sim->dma.status & MYFIRST_DMA_STATUS_RUNNING) != 0) {
            /* New START while an old transfer is in flight. */
            sim->dma.status |= MYFIRST_DMA_STATUS_ERR;
            return;
        }
        sim->dma.status = MYFIRST_DMA_STATUS_RUNNING;
        sim->dma.armed = true;
        callout_reset(&sim->dma.done_co, hz / 100,
            myfirst_sim_dma_done_co, sim);
        return;
    }
}

```

```

    }
}

```

The engine treats RESET, ABORT, and START as three distinct commands and handles each accordingly. The $\text{hz} / 100$ value schedules the completion roughly ten milliseconds in the future on a 1000 Hz kernel; the delay makes the transfer observably asynchronous and gives the driver a realistic window to poll or wait for the interrupt.

21.6.4 The Callout Handler

When the callout fires, the engine performs the simulated transfer and sets the status:

```

static void
myfirst_sim_dma_done_co(void *arg)
{
    struct myfirst_sim *sim = arg;
    bus_addr_t bus_addr;
    uint32_t len;
    void *kva;

    bus_addr = ((bus_addr_t)sim->dma.addr_high << 32) | sim->dma.addr_low;
    len = sim->dma.len;

    /* Back-channel lookup: find the KVA for this bus address. A real
     * device would not need this; the device's own DMA engine would
     * perform the memory-controller access. */
    if (sim->dma_host_kva == NULL ||
        bus_addr != sim->dma_host_bus_addr ||
        len == 0 || len > sim->dma_host_size ||
        len > sim->dma_scratch_size) {
        sim->dma.status = MYFIRST_DMA_STATUS_ERR;
        sim->dma.armed = false;
        myfirst_sim_dma_raise_complete(sim);
        return;
    }
    kva = sim->dma_host_kva;

    if (sim->dma.dir == MYFIRST_DMA_DIR_WRITE) {
        /* Host-to-device: sim reads host KVA, writes scratch. */
        memcpy(sim->dma_scratch, kva, len);
    } else {
        /* Device-to-host: sim reads scratch, writes host KVA.
         * Fill scratch with a recognisable pattern first so the
         * test can verify the transfer. */

```

```

        memset(sim->dma_scratch, 0x5A, len);
        memcpy(kva, sim->dma_scratch, len);
    }

    sim->dma.status = MYFIRST_DMA_STATUS_DONE;
    sim->dma.armed = false;
    myfirst_sim_dma_raise_complete(sim);
}

```

The two helpers `myfirst_sim_dma_copy_from_host` and `myfirst_sim_dma_copy_to_host` do the actual byte movement. Here the simulation runs into a fundamental limit: it is software running inside the kernel, not a real device. A real device uses the bus address to reach RAM through the memory controller; a software simulator cannot physically take that path. The simulator needs a kernel virtual address it can dereference, not the bus address.

We solve this with a deliberate back-channel. At `myfirst_dma_setup` time, the driver calls a new helper `myfirst_sim_register_dma_buffer(sc, sc->dma_vaddr, sc->dma_bus_addr, MYFIRST_DMA_BUFFER_SIZE)`. The helper stores the (KVA, bus address, size) triple inside the `sim`'s state. When the callout later fires, it reads the bus address the driver programmed into `DMA_ADDR_LOW/DMA_ADDR_HIGH`, looks it up in the stored triple, and recovers the KVA. The `memcpy` then works against the KVA.

This back-channel is a simulation-only crutch. Real hardware never receives a KVA; the device only ever uses the bus address, and the memory controller resolves it through the platform's address mapping (possibly via an IOMMU). The back-channel's sole purpose is to let the simulator pretend to do the DMA without actually programming the memory controller. Keeping the mechanism explicit and named is the best defence against confusion: the reader sees a clearly-labelled simulation bridge rather than a magical pointer cast, and the divide between “what the device sees” (the bus address) and “what the CPU sees” (the KVA) stays clean.

`myfirst_sim_dma_raise_complete` sets `MYFIRST_INTR_COMPLETE` in `INTR_STATUS` and, if `INTR_MASK` has the bit set, fires the simulated interrupt through the existing Chapter 19/20 path:

```

static void
myfirst_sim_dma_raise_complete(struct myfirst_sim *sim)
{
    sim->intr_status |= MYFIRST_INTR_COMPLETE;
    if ((sim->intr_mask & MYFIRST_INTR_COMPLETE) != 0)
        myfirst_sim_raise_intr(sim);
}

```

For Stage 2 we do not enable the `MYFIRST_INTR_COMPLETE` bit in `INTR_MASK` yet; the driver will poll. Section 6 enables the bit and wires the completion path through the filter.

21.6.5 The Driver's Side: Programming the Engine

On the driver side, a single helper function programs the engine and waits:

```

int
myfirst_dma_do_transfer(struct myfirst_softc *sc, int direction,
    size_t length)
{
    uint32_t status;
    int timeout;

    if (length == 0 || length > MYFIRST_DMA_BUFFER_SIZE)
        return (EINVAL);

    if (direction == MYFIRST_DMA_DIR_WRITE) {
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_PREWRITE);
    } else {
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_PREREAD);
    }

    CSR_WRITE_4(sc, MYFIRST_REG_DMA_ADDR_LOW,
        (uint32_t)(sc->dma_bus_addr & 0xFFFFFFFF));
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_ADDR_HIGH,
        (uint32_t)(sc->dma_bus_addr >> 32));
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_LEN, (uint32_t)length);
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_DIR, direction);
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_START);

    /* Poll for completion. Stage 2 is polling-only. */
    for (timeout = 500; timeout > 0; timeout--) {
        pause("dma", hz / 1000); /* 1 ms. */
        status = CSR_READ_4(sc, MYFIRST_REG_DMA_STATUS);
        if ((status & MYFIRST_DMA_STATUS_DONE) != 0)
            break;
        if ((status & MYFIRST_DMA_STATUS_ERR) != 0) {
            if (direction == MYFIRST_DMA_DIR_WRITE)
                bus_dmamap_sync(sc->dma_tag, sc->dma_map,
                    BUS_DMASYNC_POSTWRITE);
            else
                bus_dmamap_sync(sc->dma_tag, sc->dma_map,
                    BUS_DMASYNC_POSTREAD);
            return (EIO);
        }
    }

    if (timeout == 0) {

```

```

        CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_ABORT);
    if (direction == MYFIRST_DMA_DIR_WRITE)
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTWRITE);
    else
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTREAD);
    return (ETIMEDOUT);
}

/* Acknowledge the completion. */
CSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_COMPLETE);

if (direction == MYFIRST_DMA_DIR_WRITE)
    bus_dmamap_sync(sc->dma_tag, sc->dma_map,
        BUS_DMASYNC_POSTWRITE);
else
    bus_dmamap_sync(sc->dma_tag, sc->dma_map,
        BUS_DMASYNC_POSTREAD);

return (0);
}

```

The function is sixty lines, and the shape is worth reading twice. The PRE sync happens once at the top; the POST sync happens exactly once on every return path (success, error, timeout). The polling loop uses `pause("dma", hz / 1000)` for one-millisecond sleeps; on a 1000 Hz kernel this gives five hundred one-millisecond tries before giving up at five hundred milliseconds total. `pause(9)` takes the global sleep mutex briefly but is safe from a process-context driver helper. A real device with an interrupt path would not poll; Section 6 replaces the polling with an interrupt wait.

The PRE and POST flag choice matches the direction. For host-to-device (DIR_WRITE), the driver has just written the buffer, so PREWRITE is required; after the transfer, POSTWRITE releases any bounce region. For device-to-host (DIR_READ), the driver will read the buffer, so PREREAD is required; after the transfer, POSTREAD completes the copy from bounce region (if any) and invalidates the cache (if needed).

21.6.6 Exercising the Engine From User Space

The driver already exposes a sysctl tree under `dev.myfirst.N`. from Chapter 20. Stage 2 adds two new write-only sysctls that trigger a transfer:

```

SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "dma_test_write",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE, sc, 0,
    myfirst_dma_sysctl_test_write, "IU",
    "Trigger a host-to-device DMA transfer");

```

```

SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "dma_test_read",
    CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE, sc, 0,
    myfirst_dma_sysctl_test_read, "IU",
    "Trigger a device-to-host DMA transfer");

```

The handler for `dma_test_write`:

```

static int
myfirst_dma_sysctl_test_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int pattern;
    int err;

    err = sysctl_handle_int(oidp, &pattern, 0, req);
    if (err != 0 || req->newptr == NULL)
        return (err);

    memset(sc->dma_vaddr, (int)(pattern & 0xFF),
        MYFIRST_DMA_BUFFER_SIZE);
    err = myfirst_dma_do_transfer(sc, MYFIRST_DMA_DIR_WRITE,
        MYFIRST_DMA_BUFFER_SIZE);
    if (err != 0)
        device_printf(sc->dev, "dma_test_write: error %d\n", err);
    else
        device_printf(sc->dev,
            "dma_test_write: pattern 0x%02x transferred\n",
            pattern & 0xFF);
    return (err);
}

```

The user writes an integer to `dev.myfirst.0.dma_test_write`, the low byte becomes a fill pattern, the driver fills the buffer with that pattern, programs the engine, waits for completion, and logs the result. The handler for `dma_test_read` is symmetric: it triggers a device-to-host transfer, waits for completion, reads the first few bytes of the buffer, and logs them.

A user-space session runs like this:

```

sudo sysctl dev.myfirst.0.dma_test_write=0xAA
sudo dmesg | tail -1
# myfirst0: dma_test_write: pattern 0xaa transferred

sudo sysctl dev.myfirst.0.dma_test_read=1
sudo dmesg | tail -1
# myfirst0: dma_test_read: first bytes 5A 5A 5A 5A 5A 5A 5A 5A

```

The first transfer sends 0xAA to the simulated device; the second receives the device's 0x5A pattern back. Both transfers exercise the full PRE/POST discipline.

21.6.7 Observability: Per-Transfer Counters

Stage 2 adds four softc counters to the DMA state:

```
uint64_t dma_transfers_write;  
uint64_t dma_transfers_read;  
uint64_t dma_errors;  
uint64_t dma_timeouts;
```

Each is incremented by `myfirst_dma_do_transfer` on the appropriate exit path, and each is exposed as a read-only sysctl. The counters are the driver's Stage 2 equivalent of the per-vector counters Chapter 20 added to the interrupt path; they make it easy to confirm at a glance that transfers are happening as expected and to detect silent failures.

The counters are read with atomic operations (`atomic_add_64`) so they can be updated safely even if Section 6's interrupt-driven completion path ends up running from a filter context. Chapter 20's Section 4 covered the atomic discipline; Stage 2's counters follow the same pattern.

21.6.8 Verifying Stage 2

Build and load:

```
make clean && make  
sudo kldload ./myfirst.ko
```

`dmesg` shows the DMA banner from Stage 1 plus the new DMA-enabled banner:

```
myfirst0: DMA buffer 4096 bytes at KVA 0xfffffe... bus addr 0x...  
myfirst0: DMA engine present, scratch 4096 bytes  
myfirst0: interrupt mode: MSI-X, 3 vectors
```

Run the test:

```
sudo sysctl dev.myfirst.0.dma_test_write=0x33  
sudo sysctl dev.myfirst.0.dma_test_read=1  
sudo sysctl dev.myfirst.0.dma_transfers_write  
sudo sysctl dev.myfirst.0.dma_transfers_read
```

Expected:

```
dev.myfirst.0.dma_transfers_write: 1
dev.myfirst.0.dma_transfers_read: 1
```

Run it a thousand times in a loop:

```
for i in $(seq 1 1000); do
    sudo sysctl dev.myfirst.0.dma_test_write=$((i & 0xFF)) >/dev/null
    sudo sysctl dev.myfirst.0.dma_test_read=1 >/dev/null
done
sudo sysctl dev.myfirst.0.dma_transfers_write
sudo sysctl dev.myfirst.0.dma_transfers_read
sudo sysctl dev.myfirst.0.dma_errors
sudo sysctl dev.myfirst.0.dma_timeouts
```

Expected counts: 1000 write transfers, 1000 read transfers, 0 errors, 0 timeouts. Any timeout or error during the test indicates a bug in the simulation or a race in the driver; both are worth catching early.

Unload the module and verify that the callout is stopped, the scratch buffer is freed, and the tag is destroyed:

```
sudo kldunload myfirst
vmstat -m | grep myfirst || true
```

The line should be missing or show zero allocations.

21.6.9 What Stage 2 Does and Does Not Do

Stage 2 is the first stage where actual DMA transfers run. The driver programs the engine; the engine copies bytes through the simulated path; the driver observes the result. The sync discipline is exercised in both directions.

What Stage 2 does not do is use the interrupt path. Polling is acceptable for a teaching stage but inappropriate for a real driver: the driver holds a kernel thread in pause for the duration of each transfer. Section 6 replaces the poll with the Chapter 19/20 interrupt mechanism; the rx filter sees MYFIRST_INTR_COMPLETE, acknowledges it, enqueues the task, and the task does the POST sync and verification. Stage 3 is the fully interrupt-driven version.

Stage 2 also does not handle every error cleanly. The timeout and abort paths are present but minimal; Section 7 walks through them carefully and extends the recovery logic. The single-transfer pattern is also limited; Section 8's refactor exposes helper functions that make multi-transfer patterns easy to add.

21.6.10 Common Mistakes in Stage 2

Four mistakes are worth calling out.

Mistake one: calling `bus_dmamap_sync` inside the callout. The callout runs in softclock context, and the sync itself is safe from there, but the buffer accesses the simulation does (`myfirst_sim_dma_copy_from_host`) need

the driver's map to be loaded. If the driver detaches while a callout is armed, the map is unloaded under the callout's feet. The fix is Chapter 21's detach pattern: stop the callout (`callout_drain`) before unloading the map. Section 7 revisits this carefully.

Mistake two: forgetting to acknowledge `MYFIRST_INTR_COMPLETE`. The simulation raises the bit; the driver must clear it by writing the bit back to `INTR_STATUS`. If the driver does not, the next transfer sees a stale `DONE` bit and the polling loop returns immediately with correct status but before the new transfer has run. The acknowledge is in the polling-loop version (`CSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, MYFIRST_INTR_COMPLETE);`); Section 6 moves the acknowledge into the filter path where interrupt driven.

Mistake three: using `DELAY` or `cpu_spinwait` instead of `pause`. The Stage 2 polling loop uses `pause("dma", hz / 1000)` to yield. A tight spin with `DELAY(1000)` pegs a CPU for the entire transfer window, which is acceptable on a uniprocessor test but unacceptable in production. The `pause` call puts the thread to sleep and lets other work run. This matters more in the Section 6 version, where the driver calls `cv_timedwait` instead of polling, but the principle is the same: yield the CPU whenever you are waiting for external events.

Mistake four: forgetting to cap length to the tag's `maxsize`. The driver's helper accepts a length argument; if the caller passes a larger value than `MYFIRST_DMA_BUFFER_SIZE`, the engine writes past the end of the scratch buffer (in the simulation) or past the end of the host buffer (on real hardware). Chapter 21's code guards against this in the helper's first lines; forgetting the guard is a common source of subtle corruption.

21.6.11 Wrapping Up Section 5

Section 5 made the simulated DMA engine real. The register map, the state machine, the callout-based latency, the driver's polling helper, the `sysctl` test interface, and the counters are all in place. The driver runs full transfers in both directions; the sync discipline from Section 4 is exercised on every one. Stage 2 is a working DMA driver even if it polls rather than handling interrupts.

Section 6 replaces the polling with the Chapter 19/20 interrupt path. The completion interrupt arrives through the rx filter, the filter enqueues the task, and the task performs the POST sync and the verification. The user-visible behaviour does not change; the driver's internals do. That change is what makes the driver scale: a polling driver pegs a CPU per transfer, an interrupt-driven driver handles the same transfers with negligible CPU cost.

21.7 Section 6: Handling DMA Completion in the Driver

Section 5 produced a polling-based DMA driver. Section 6 rewrites the completion path to use the Chapter 19/20 interrupt machinery. The goals are: no CPU is held in pause while a transfer runs; the completion is delivered through a filter that runs in primary interrupt context; the task in thread context does the POST sync and the verification; and the user-visible behaviour is unchanged from Stage 2. The version tag becomes `1.4-dma-stage3`.

The Chapter 20 per-vector machinery already has the right shape for this. One of the three vectors (the rx vector, or in the legacy fallback case the single admin vector) handles `MYFIRST_INTR_COMPLETE`. The filter acknowledges; the task processes. Chapter 21's change is to make the task's processing include a DMA POST sync and a buffer read.

21.7.1 Why Interrupt-Driven Is the Right Design

Section 5's polling path works, but it has four weaknesses that Stage 3 fixes.

One CPU is tied up per in-flight transfer. The pause call puts the thread to sleep on the dma wait channel, which is fine, but the thread's stack, cache state, and scheduling overhead still exist. A driver with many in-flight transfers would tie up many threads. Interrupt-driven completion uses one task per vector, reused across all transfers.

Latency is coarse. The polling loop wakes every millisecond. A real engine might complete in microseconds; the driver waits up to a full millisecond before noticing. Interrupt-driven completion is delivered at the hardware's natural latency.

The polling loop does not compose with multiple in-flight transfers. To issue two transfers back-to-back, the driver must either wait for the first to complete (serialising) or maintain its own per-transfer state (ad-hoc bookkeeping). Interrupt-driven completion naturally composes: each completion fires its own interrupt, the filter routes it to the task, and the task handles it.

Polling cannot run in interrupt context. If the driver ever needs to complete a transfer from inside an interrupt handler (for example, a receive-complete interrupt that immediately triggers a new descriptor fill), the polling loop will not work because pause cannot be called from the filter. The interrupt-driven path is the only composable design.

Stage 3 keeps the polling helper as a fallback for sysctl-driven tests (it is useful for deterministic testing) and adds an interrupt-driven helper for the real use case.

21.7.2 The Interrupt Path Modifications

Chapter 20's rx filter handled MYFIRST_INTR_DATA_AV. Stage 3 extends it (or the legacy-fallback admin filter) to handle MYFIRST_INTR_COMPLETE as well:

```
int
myfirst_msix_rx_filter(void *arg)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    uint32_t status;
    bool handled = false;

    status = ICSR_READ_4(sc, MYFIRST_REG_INTR_STATUS);

    if ((status & MYFIRST_INTR_DATA_AV) != 0) {
        atomic_add_64(&vec->fire_count, 1);
        ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS,
            MYFIRST_INTR_DATA_AV);
        atomic_add_64(&sc->intr_data_av_count, 1);
        handled = true;
    }
}
```

```

if ((status & MYFIRST_INTR_COMPLETE) != 0) {
    atomic_add_64(&sc->dma_complete_intrs, 1);
    ICSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS,
        MYFIRST_INTR_COMPLETE);
    handled = true;
}

if (!handled) {
    atomic_add_64(&vec->stray_count, 1);
    return (FILTER_STRAY);
}

if (sc->intr_tq != NULL)
    taskqueue_enqueue(sc->intr_tq, &vec->task);
return (FILTER_HANDLED);
}

```

The filter reads `INTR_STATUS` once, checks for both bits, acknowledges each one it sees, increments per-bit counters, and enqueues the task if any bit was set. The pattern is exactly Chapter 19's generalised to two bits per vector; the only new thing is the `MYFIRST_INTR_COMPLETE` counter.

The task picks up the state the filter recorded:

```

static void
myfirst_msix_rx_task_fn(void *arg, int npending)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;
    bool did_complete;

    MYFIRST_LOCK(sc);
    if (sc->hw == NULL || !sc->pci_attached) {
        MYFIRST_UNLOCK(sc);
        return;
    }

    /* Data-available path (Chapter 19/20). */
    sc->intr_last_data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
    sc->intr_task_invocations++;
    cv_broadcast(&sc->data_cv);

    /* DMA-complete path (Chapter 21). */
    did_complete = false;
    if (sc->dma_in_flight) {

```

```

    sc->dma_in_flight = false;
    did_complete = true;
    if (sc->dma_last_direction == MYFIRST_DMA_DIR_WRITE)
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTWRITE);
    else
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTREAD);
    sc->dma_last_status = CSR_READ_4(sc,
        MYFIRST_REG_DMA_STATUS);
    atomic_add_64(&sc->dma_complete_tasks, 1);
    cv_broadcast(&sc->dma_cv);
}
MYFIRST_UNLOCK(sc);

(void)did_complete;
}

```

The task takes the softc mutex (Chapter 11 discipline; the sleep mutex is held while accessing shared state). The `dma_in_flight` flag, set by the transfer helper before the doorbell write, tells the task that a DMA completion is pending. If it is set, the task clears it, issues the POST sync matching the recorded direction, reads the final status, and broadcasts `dma_cv` so any waiter can wake up.

The sync call from the task is safe: the task runs in thread context under the softc mutex, and the sync call does not acquire any extra locks. The Chapter 19 lock discipline carries through.

21.7.3 The New Interrupt-Driven Transfer Helper

The Stage 3 version of the helper starts the transfer, arms the callout or the real hardware, and sleeps until the completion task signals:

```

int
myfirst_dma_do_transfer_intr(struct myfirst_softc *sc, int direction,
    size_t length)
{
    int err;

    if (length == 0 || length > MYFIRST_DMA_BUFFER_SIZE)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    if (sc->dma_in_flight) {
        MYFIRST_UNLOCK(sc);
        return (EBUSY);
    }
}

```

```

}

/* Issue the PRE sync before touching the device. */
if (direction == MYFIRST_DMA_DIR_WRITE)
    bus_dmamap_sync(sc->dma_tag, sc->dma_map,
        BUS_DMASYNC_PREWRITE);
else
    bus_dmamap_sync(sc->dma_tag, sc->dma_map,
        BUS_DMASYNC_PREREAD);

sc->dma_last_direction = direction;
sc->dma_in_flight = true;

CSR_WRITE_4(sc, MYFIRST_REG_DMA_ADDR_LOW,
    (uint32_t)(sc->dma_bus_addr & 0xFFFFFFFF));
CSR_WRITE_4(sc, MYFIRST_REG_DMA_ADDR_HIGH,
    (uint32_t)(sc->dma_bus_addr >> 32));
CSR_WRITE_4(sc, MYFIRST_REG_DMA_LEN, (uint32_t)length);
CSR_WRITE_4(sc, MYFIRST_REG_DMA_DIR, direction);
CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_START);

/* Wait for the task to set dma_in_flight = false. */
err = cv_timedwait(&sc->dma_cv, &sc->mtx, hz); /* 1 s timeout */
if (err == EWOULDBLOCK) {
    /* Abort the engine and issue the POST sync so we do not
     * leave the map in an inconsistent state. */
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_ABORT);
    if (direction == MYFIRST_DMA_DIR_WRITE)
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTWRITE);
    else
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTREAD);
    sc->dma_in_flight = false;
    atomic_add_64(&sc->dma_timeouts, 1);
    MYFIRST_UNLOCK(sc);
    return (ETIMEDOUT);
}

/* The task has issued the POST sync and recorded dma_last_status. */
if ((sc->dma_last_status & MYFIRST_DMA_STATUS_ERR) != 0) {
    atomic_add_64(&sc->dma_errors, 1);
    MYFIRST_UNLOCK(sc);
    return (EIO);
}

```

```

    }

    if (direction == MYFIRST_DMA_DIR_WRITE)
        atomic_add_64(&sc->dma_transfers_write, 1);
    else
        atomic_add_64(&sc->dma_transfers_read, 1);

    MYFIRST_UNLOCK(sc);
    return (0);
}

```

The helper is longer than Stage 2's because it coordinates with the task: the task issues the POST sync; the helper only does so on the timeout path where the task will never see completion. The coordination is the point of the redesign; the helper has moved from “poll until done” to “signal the device, wait on a condition variable, let the task complete me”.

The `cv_timedwait` call takes the softc mutex as its second argument; that is the standard `cv_timedwait` contract (mutex held going in, released for the wait, re-acquired on wake). The mutex scope covers every access to the shared DMA state (`dma_in_flight`, `dma_last_direction`, `dma_last_status`).

One subtle point: the PRE sync runs before the mutex is released for the wait, and the POST sync runs after the wake. Both are inside the critical section of the transfer, so no other thread can see the buffer in a partially-synchronised state. This is the locking payoff of Chapter 11.

21.7.4 The MYFIRST_INTR_COMPLETE Bit Goes Live

Stage 2 masked `MYFIRST_INTR_COMPLETE` out of `INTR_MASK`. Stage 3 enables it:

```

CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
    MYFIRST_INTR_DATA_AV | MYFIRST_INTR_ERROR | MYFIRST_INTR_COMPLETE);

```

The change is a single line in the interrupt setup. The simulation's engine raises the bit at completion; the driver's filter sees it and enqueues the task; the task handles it. The entire pipeline lights up with this one change.

21.7.5 Verifying Stage 3

Build and load:

```

make clean && make
sudo kldload ./myfirst.ko

```

Run the same `sysctl`-driven test as Stage 2, but wire it to the interrupt-driven helper:

```
static int
myfirst_dma_sysctl_test_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int pattern;
    int err;

    err = sysctl_handle_int(oidp, &pattern, 0, req);
    if (err != 0 || req->newptr == NULL)
        return (err);

    memset(sc->dma_vaddr, (int)(pattern & 0xFF),
           MYFIRST_DMA_BUFFER_SIZE);
    err = myfirst_dma_do_transfer_intr(sc, MYFIRST_DMA_DIR_WRITE,
                                       MYFIRST_DMA_BUFFER_SIZE);
    if (err != 0)
        device_printf(sc->dev,
                      "dma_test_write: intr err %d\n", err);
    return (err);
}
```

Run a thousand transfers and observe the counters:

```
for i in $(seq 1 1000); do
    sudo sysctl dev.myfirst.0.dma_test_write=$((i & 0xFF)) >/dev/null
    sudo sysctl dev.myfirst.0.dma_test_read=1 >/dev/null
done
sudo sysctl dev.myfirst.0.dma_complete_intrs
sudo sysctl dev.myfirst.0.dma_complete_tasks
sudo sysctl dev.myfirst.0.dma_transfers_write
sudo sysctl dev.myfirst.0.dma_transfers_read
```

Expected: `dma_complete_intrs` equals 2000 (one per transfer in both directions), `dma_complete_tasks` equals 2000 (the task processed each completion), `dma_transfers_write` and `dma_transfers_read` each equal 1000.

Run `vmstat -i` during the test to see the vector receiving interrupts. With MSI-X, the rx vector's count should climb visibly. With legacy fallback, the single vector's count climbs.

21.7.6 Stopping In-Flight Transfers at Detach

Stage 3 has a new detach hazard: the task may be running the POST sync at the moment `myfirst_dma_tear_down` is called. The teardown must not unload the map while the task is still holding references to it.

The fix is one line added to the detach path before `myfirst_dma_tear_down`:

```
taskqueue_drain(sc->intr_tq, &sc->vectors[MYFIRST_VECTOR_RX].task);
```

`taskqueue_drain` waits for the task to finish running; after it returns, the driver is guaranteed that no further task invocations will happen on that task (subject to the caveat that another filter might re-enqueue it; the detach path has already masked `INTR_MASK` so no more interrupts will fire). With the drain in place, the teardown is safe.

The MSI-X teardown from Chapter 20 already drains the task; Chapter 21 extends the Stage 3 teardown to also stop the simulation callout before unloading the map:

```
/* In myfirst_sim_destroy, called from detach: */  
callout_drain(&sc->sim.dma.done_co);
```

`callout_drain` waits for the callout to finish running; after it returns, the engine is guaranteed not to raise any more completions. Combined with the taskqueue drain, the detach is safe against every race.

21.7.7 What Stage 3 Produces

Stage 3 is a fully interrupt-driven DMA driver. Every transfer programs the engine, sleeps on a condition variable, wakes when the completion task signals, and returns with the transferred data synced and verified. The driver never holds the CPU while a transfer runs. The `sysctl` test interface works as before; the internals match production DMA code.

Stage 3 does not yet cover error recovery in depth. Section 7 walks through the specific failure modes and the patterns that handle each.

21.7.8 Common Mistakes in Stage 3

Four more mistakes are worth pointing out.

Mistake one: forgetting the `cv_broadcast` in the task. If the task does the `POST` sync but does not broadcast `dma_cv`, the helper waits the full timeout and returns `ETIMEDOUT` even though the transfer succeeded. The fix is the single `cv_broadcast` line; missing it is a subtle bug that manifests as every transfer timing out.

Mistake two: calling `cv_timedwait` without holding the mutex. `cv_timedwait` requires the mutex to be held at entry; the kernel panics under `INVARIANTS` if it is not. The helper's structure (lock, do work, wait, handle result, unlock) keeps the mutex held throughout; the wait releases it briefly during the sleep and re-acquires it on wake. Breaking this pattern (releasing the mutex before `cv_timedwait`) is a race that `WITNESS` catches.

Mistake three: handling the timeout path without a `POST` sync. The timeout path in the helper aborts the engine and then still issues the `POST` sync. The sync is required because `BUS_DMA_NOWAIT` may have inserted bounce buffers at `PRE` time; without `POST`, the bounce region is not released. Forgetting it leaks bounce pages slowly.

Mistake four: leaving `dma_in_flight` set on an error. Every exit path in the helper clears `dma_in_flight`. Forgetting to clear it on the error path means the next transfer returns `EBUSY` even though no transfer is running. The helper's structure (set at the top, cleared either by the task or explicitly on timeout/error) is the robust pattern.

21.7.9 Wrapping Up Section 6

Section 6 replaced Stage 2's polling with Stage 3's interrupt-driven completion. The filter sees the completion bit, the task issues the POST sync and signals, the helper wakes and returns. Throughput and latency both improve; CPU cost drops; the driver composes with other work naturally. The code is longer than Stage 2's because it coordinates across two contexts (task and helper), but the pattern is a direct application of Chapter 11's lock discipline and Chapter 20's per-vector task design; no new ideas are needed beyond the DMA-specific sync placement.

Section 7 is the error-handling tour. Every failure mode the chapter addresses gets a walkthrough: what happens, what the symptom looks like, and what the driver does about it. The patterns are the same ones every production DMA driver has to handle; the chapter's simulated environment is a good place to rehearse them.

21.8 Section 7: DMA Error Handling and Edge Cases

Section 6 produced a working interrupt-driven DMA driver. Section 7 is the chapter where the driver stops assuming success. Every step of the DMA pipeline can fail: the tag creation can fail, the memory allocation can fail, the load can fail, the load can be deferred, the engine can report an error, the engine can never complete (timeout), the detach can race with a running transfer. Each failure mode has a pattern that handles it; Section 7 walks through each in turn.

The goal is not to make Chapter 21's driver resistant to every conceivable failure; it is to teach the patterns so the reader recognises them in production code and applies them when writing real drivers. Many of the patterns are short; the explanation is the learning object, not the code.

21.8.1 Failure Mode 1: `bus_dma_tag_create` Returns `ENOMEM`

`bus_dma_tag_create` can return `ENOMEM` if the kernel cannot allocate the tag structure itself. The allocation is small (the tag is a few hundred bytes) and only happens once at attach, so the failure is rare in practice, but the driver must still handle it.

The pattern: check the return value, log, return the error to the caller, do not touch any of the downstream DMA state. The Stage 1 code already does this:

```
err = bus_dma_tag_create(bus_get_dma_tag(sc->dev), ...);
if (err != 0) {
    device_printf(sc->dev, "bus_dma_tag_create failed: %d\n", err);
    return (err);
}
```

The higher-level attach function sees the error, runs its failure-path unwind, and the kernel reports the probe failure cleanly. No DMA resources are leaked because none were allocated.

A `BUS_DMA_ALLOCNOW` flag tells the kernel to pre-allocate bounce buffer resources at tag creation time, so some kinds of allocation failure move from load time to tag time. This is useful for drivers that cannot tolerate a later load failure; Chapter 21's driver does not use it (the simulation does not need bounce buffers), but production drivers that interface with 32-bit hardware often do.

21.8.2 Failure Mode 2: `bus_dmamem_alloc` Returns `ENOMEM`

`bus_dmamem_alloc` can return `ENOMEM` if the allocator cannot satisfy the tag's constraints at the moment of the call. For large buffers, this is more likely than it sounds: a request for a contiguous four-megabyte buffer with a 4 KB alignment on a fragmented system can genuinely fail. For Chapter 21's 4 KB buffer, the failure is extremely unlikely, but the code still checks.

The pattern: check, log, destroy the tag that was just created, propagate the error:

```
err = bus_dmamem_alloc(sc->dma_tag, &sc->dma_vaddr,
    BUS_DMA_WAITOK | BUS_DMA_COHERENT | BUS_DMA_ZERO, &sc->dma_map);
if (err != 0) {
    device_printf(sc->dev, "bus_dmamem_alloc failed: %d\n", err);
    bus_dma_tag_destroy(sc->dma_tag);
    sc->dma_tag = NULL;
    return (err);
}
```

The key point is the tag destroy in the error path. Forgetting it leaks the tag across every failed attach; over many retries it becomes a noticeable leak. The Stage 1 code follows this pattern; every new allocation-path call in later sections must too.

21.8.3 Failure Mode 3: `bus_dmamap_load` Returns `EINVAL`

`bus_dmamap_load` returns `EINVAL` in two related cases:

1. The buffer is larger than the tag's `maxsize`. For example, loading an 8 KB buffer with a tag whose `maxsize` is 4 KB fails immediately with `EINVAL`. The callback is called with `error = EINVAL` as a confirmation.
2. The buffer's properties violate the tag's constraints in a way the kernel can detect statically (alignment, boundary). These are rarer because the tag's constraints usually match the buffer's characteristics by design.

The pattern: check, log, free the memory, destroy the tag, propagate:

```
err = bus_dmamap_load(sc->dma_tag, sc->dma_map,
    sc->dma_vaddr, MYFIRST_DMA_BUFFER_SIZE,
    myfirst_dma_single_map, &sc->dma_bus_addr, BUS_DMA_NOWAIT);
if (err != 0) {
    device_printf(sc->dev, "bus_dmamap_load failed: %d\n", err);
    bus_dmamem_free(sc->dma_tag, sc->dma_vaddr, sc->dma_map);
    sc->dma_vaddr = NULL;
    bus_dma_tag_destroy(sc->dma_tag);
    sc->dma_tag = NULL;
    return (err);
}
```

The Stage 1 code has this pattern. Note that `EINVAL` is distinct from `EFBIG`: `EINVAL` is passed to the callback if the arguments are invalid; `EFBIG` comes back in the callback when the mapping cannot be achieved within the tag's segment constraints. Chapter 21's single-segment load is too simple to see `EFBIG`; scatter-gather loads of large buffers can.

21.8.4 Failure Mode 4: `bus_dmamap_load` Returns `EINPROGRESS`

`EINPROGRESS` means the kernel has queued the load because bounce buffers (or other mapping resources) are not currently available. The callback will run later, in a different context, when resources free up. Chapter 21 uses `BUS_DMA_NOWAIT`, which forbids this behaviour (the kernel returns `ENOMEM` instead), so `EINPROGRESS` does not occur in the chapter's driver. A driver that uses `BUS_DMA_WAITOK` or zero flags and sees `EINPROGRESS` has to do more work:

```
err = bus_dmamap_load(sc->dma_tag, sc->dma_map, buf, len,
    my_callback, sc, 0);
if (err == EINPROGRESS) {
    /* Do not free buf or destroy the tag here; the callback will
     * run later. The caller must be prepared to handle the load
     * completing at any time. */
    return (0);
}
```

The driver then has to arrange for the callback to record the result in a place the rest of the driver can see (often a softc field guarded by the tag's lockfunc), and the caller that is “waiting” for the load has to sleep on a condition variable the callback broadcasts. This is the deferred-load pattern; it is complex enough that most drivers prefer `BUS_DMA_NOWAIT` and retry-on-failure over the deferred path.

Chapter 21's driver does not use this pattern. Section 7 mentions it for completeness; the reader who encounters `EINPROGRESS` in another driver will know what it means and where to look.

21.8.5 Failure Mode 5: Engine Reports Partial Transfer

The simulated engine does not report partial transfers in its baseline behaviour; it either completes the full `DMA_LEN` or sets `DMA_STATUS_ERR`. Real engines sometimes report a partial transfer: the engine copied fewer bytes than requested and signalled completion with the partial count in a length register.

A driver that sees a partial transfer must decide what to do: retry, treat as fatal, pass the partial result to user space with an error flag. The chapter's simulation can be extended to model partial transfers by having the callout set a smaller transferred-length field:

```
uint32_t actual_len = len;
/* For the lab in Section 7, force a partial transfer every 100 tries. */
if ((sim->dma_transfer_count++ % 100) == 0)
    actual_len = len / 2;
/* ... perform memcpy of actual_len bytes ... */
```

```
sim->dma.transferred_len = actual_len;
sim->dma.status = MYFIRST_DMA_STATUS_DONE;
```

The driver reads the length after the sync:

```
uint32_t xferred;
xferred = CSR_READ_4(sc, MYFIRST_REG_DMA_XFERRED);
if (xferred < expected_len) {
    device_printf(sc->dev,
        "partial DMA: requested %u, got %u\n",
        expected_len, xferred);
    atomic_add_64(&sc->dma_partials, 1);
    /* Decide: retry, report, ignore. */
}
```

Chapter 21's baseline code does not implement partial-transfer reporting; the simulated engine always completes the full length. Lab 5 in the Section 7 challenges adds the partial-transfer behaviour and walks through a retry strategy. The pattern is what matters, not the specific `xferred` register; every partial transfer has the same driver-side shape.

21.8.6 Failure Mode 6: Engine Never Signals Completion (Timeout)

The engine might set `STATUS_RUNNING` and never advance to `DONE`. In the simulation this happens if the callout is dropped (for example, the callout pool is exhausted or the callout is cancelled by a different path). On real hardware it happens if the device is wedged, the PCIe link is down, or the firmware has a bug.

Chapter 21's interrupt-driven helper (`myfirst_dma_do_transfer_intr`) uses `cv_timedwait` with a one-second timeout. If the wait returns `EWOULDBLOCK`, the transfer is considered hung. The driver's response:

```
if (err == EWOULDBLOCK) {
    CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL, MYFIRST_DMA_CTRL_ABORT);
    if (direction == MYFIRST_DMA_DIR_WRITE)
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTWRITE);
    else
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTREAD);
    sc->dma_in_flight = false;
    atomic_add_64(&sc->dma_timeouts, 1);
    MYFIRST_UNLOCK(sc);
    return (ETIMEDOUT);
}
```

Four things happen: the engine is aborted (so it does not complete after the helper returns), the POST sync is issued (so the map is not left in a PRE state), `dma_in_flight` is cleared (so the next transfer can start), a counter is incremented (for observability). The helper then returns `ETIMEDOUT` to the caller.

A real driver would also consider whether to reset the device at this point. If timeouts are rare, abort-and-continue is appropriate; if they are frequent, a full reset may be needed. Chapter 21's pattern is abort-and-continue; the reset path is a Section 8 refactor exercise.

The chapter's simulation can be extended to never complete, to let the reader exercise the timeout path:

```
/* Comment out the callout_reset to make transfers hang: */
// callout_reset(&sim->dma.done_co, hz / 100, myfirst_sim_dma_done_co, sim);
```

After this change, every transfer hits the timeout. The driver's counters climb, the caller sees `ETIMEDOUT`, and `kldunload` still succeeds (because the abort path cleared `dma_in_flight` and the teardown has no in-flight transfers to wait for). Running this experiment once gives the reader a concrete sense of what a “stuck device” driver looks like from the outside.

21.8.7 Failure Mode 7: Detach While a Transfer Is In Flight

The detach path has to handle the case where a transfer is in flight at the moment the driver is unloaded. The risks are:

1. The callout fires after `myfirst_dma_tear_down` has unloaded the map, writing to freed memory.
2. The task runs after `myfirst_dma_tear_down` has destroyed the tag, syncing against a freed tag.
3. The helper is waiting on `dma_cv` at the moment the device is disappearing.

The Chapter 20 teardown ordering already addresses several of these. Chapter 21 adds two more barriers:

```
void
myfirst_detach_dma_path(struct myfirst_softc *sc)
{
    /* 1. Tell callers no new transfers may start. */
    MYFIRST_LOCK(sc);
    sc->detaching = true;
    MYFIRST_UNLOCK(sc);

    /* 2. If a transfer is in flight, wait for it to complete or time out. */
    MYFIRST_LOCK(sc);
    while (sc->dma_in_flight) {
        cv_timedwait(&sc->dma_cv, &sc->mtx, hz);
    }
    MYFIRST_UNLOCK(sc);

    /* 3. Mask the completion interrupt at the device. */
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK,
```

```

        CSR_READ_4(sc, MYFIRST_REG_INTR_MASK) &
        ~MYFIRST_INTR_COMPLETE);

    /* 4. Drain callouts and tasks. */
    callout_drain(&sc->sim.dma.done_co);
    taskqueue_drain(sc->intr_tq, &sc->vectors[MYFIRST_VECTOR_RX].task);

    /* 5. Tear down the DMA resources. */
    myfirst_dma_teardown(sc);
}

```

The five steps are in the order that keeps each subsequent step safe. Setting `detaching = true` prevents new transfers from starting (the helper checks it before arming). Waiting for in-flight transfers to finish or time out ensures no callout is scheduled and no task is pending. Masking the interrupt prevents any late completion from firing the filter. Draining the callout and the task ensures that any in-progress callback has finished. Tearing down the DMA resources is safe because nothing else can touch them now.

The first step (setting `detaching = true`) requires the transfer helper to check the flag:

```

if (sc->detaching) {
    MYFIRST_UNLOCK(sc);
    return (ENXIO);
}

```

This is a small addition to the helper and prevents the rare race where a user-space test fires a transfer while detach is running.

21.8.8 Failure Mode 8: Bounce Buffer Exhaustion

On 32-bit systems or on 64-bit systems with 32-bit-only devices, `bus_dma` may need to allocate bounce buffers to satisfy the address constraint. The bounce pool has a fixed size; if it is exhausted, `bus_dmamap_load` with `BUS_DMA_NOWAIT` returns `ENOMEM`.

Chapter 21's simulation has no real address constraints and the chapter's primary path does not hit this mode. Production drivers for 32-bit-capable devices on 64-bit systems must handle it:

```

err = bus_dmamap_load(sc->dma_tag, map, buf, len,
    my_callback, sc, BUS_DMA_NOWAIT);
if (err == ENOMEM) {
    /* The bounce pool is exhausted. Options:
     * - Retry later (queue the request).
     * - Fail this transfer and let the caller retry.
     * - Allocate a fresh buffer inside the device's address range. */
    ...
}

```

The practical mitigation is usually to allocate all buffers inside the device's addressable range (so bounce buffers are never needed). That is what `bus_dmamem_alloc` with an appropriate tag does automatically: the allocator sees the tag's `highaddr` (or `lowaddr`, depending on which side of the window the address constraint is expressed) and allocates inside the range. A driver that uses `bus_dmamem_alloc` for its DMA buffers never sees bounce-buffer exhaustion; a driver that uses `bus_dmamap_load` on arbitrary kernel memory (say, an mbuf from the network stack) can.

Chapter 21's static pattern is immune. The dynamic pattern discussed in Part 6 (Chapter 28) is not, and the network-driver chapter there covers the retry strategies in detail.

21.8.9 Failure Mode 9: Unaligned Buffer

The tag's `alignment` parameter describes the required alignment of DMA addresses. If the buffer's address is not aligned, the load fails.

For Chapter 21's `bus_dmamem_alloc`-allocated buffer, the allocator always returns an aligned buffer; the failure does not occur on the static path. For dynamic loads of arbitrary buffers, the driver must either ensure the buffer is aligned (by copying it into an aligned temp buffer) or rely on bounce-buffer machinery to do the alignment automatically. The kernel handles this transparently on `bus_dmamap_load_mbuf_sg` (the mbuf machinery produces aligned segments via bounce); for raw `bus_dmamap_load` the driver is on its own.

The chapter's simulation does not model alignment constraints beyond accepting `alignment = 4`. A Section 7 challenge invites the reader to set `alignment = 64`, observe that `bus_dmamem_alloc` still returns an aligned buffer (because allocators are alignment-aware), and then try loading a deliberately misaligned buffer to see the failure.

21.8.10 Failure Mode 10: The Load Callback Runs with Non-Zero error

`bus_dmamap_load` may call the callback with `error = EFBIG` if the load is logically valid but cannot be achieved with the tag's segment constraints. The callback should handle this:

```
static void
myfirst_dma_single_map(void *arg, bus_dma_segment_t *segs, int nseg, int error)
{
    bus_addr_t *addr = arg;

    if (error != 0) {
        printf("myfirst: dma load callback error %d\n", error);
        /* Do not write *addr; the caller checks for zero. */
        return;
    }

    KASSERT(nseg == 1, ("myfirst: unexpected DMA segment count %d", nseg));
    *addr = segs[0].ds_addr;
}
```

The caller then detects the failure by checking the bus-address output:

```
sc->dma_bus_addr = 0;
err = bus_dmamap_load(...);
if (err != 0 || sc->dma_bus_addr == 0) {
    /* Failure: either the load returned non-zero, or the callback
     * ran with error != 0 and did not populate the address. */
    ...
}
```

The two checks together cover all failure modes: synchronous error from the load (`err != 0`), callback error with the load returning zero (`dma_bus_addr == 0`). Chapter 21's Stage 1 code has both checks and handles both cases uniformly.

21.8.11 Failure Mode 11: A Sync Call Is Skipped

A driver that skips a sync call does not fail immediately on coherent platforms; the bug is latent. Section 4 already covered this. The key point for Section 7 is that there is no automatic detection for missing syncs; the driver must be structured so that syncs are impossible to forget. Chapter 21's pattern (the PRE is always the first action in the helper; the POST is always the last) is one way. Another is to use a wrapper function that does the sync around a device-specific callback; this is what iflib and some other frameworks do internally.

WITNESS does catch certain sync-related mistakes. If the driver holds the wrong lock when calling a `bus_dmamap_*` function that the tag's `lockfunc` expects, WITNESS warns. If the driver calls a sync from a context where `busdma_lock_mutex` would try to acquire a lock, WITNESS catches the mismatch. Running the driver under WITNESS regularly is the best defence against sync-related latent bugs.

21.8.12 Failure Mode 12: The Callback Sets *addr to Zero and the Driver Proceeds

A subtle variant of Failure Mode 10. The callback runs, the load returns zero, the error argument to the callback happens to be zero, but `nseg == 0`. This cannot happen for `bus_dmamem_alloc`-backed buffers (which always produce one segment), but it can happen for some corner cases of arbitrary loads. The pattern is:

```
static void
myfirst_dma_single_map(void *arg, bus_dma_segment_t *segs, int nseg, int error)
{
    bus_addr_t *addr = arg;

    if (error != 0) {
        printf("myfirst: dma load callback error %d\n", error);
        *addr = 0;
        return;
    }
}
```

```
if (nseg != 1) {
    printf("myfirst: unexpected DMA segment count %d\n", nseg);
    *addr = 0;
    return;
}

*addr = segs[0].ds_addr;
}
```

Explicit zeroing on every failure path keeps the caller's error detection reliable. The stricter version is the right default; the `KASSERT` in the Stage 1 code is a debug-only check, and the runtime check is what production code should use. The chapter's example code uses both: `KASSERT` in debug builds, explicit zeroing as a fallback.

21.8.13 A Pattern: The `dma_setup` / `dma_tearardown` Pair

Section 8 moves the DMA code into its own file, but Section 7 is the right place to name the pattern that motivates the refactor. Every DMA-capable driver ends up with a pair of functions: one that performs all the tag/map/memory/load operations in the correct order with full error unwinding, and one that reverses them in the correct order. The pair is the driver's DMA ABI: the rest of the driver only needs to call `dma_setup` at attach and `dma_tearardown` at detach. The functions themselves handle all the intermediate error paths.

Chapter 21's pair is `myfirst_dma_setup` and `myfirst_dma_tearardown`. Production drivers often have per-subsystem pairs (`re_dma_alloc` and `re_dma_free` for `if_re`, `nvme_qpair_dma_create` and `nvme_qpair_dma_destroy` for NVMe). The shape is always the same; the depth is what varies with the driver's complexity.

21.8.14 Wrapping Up Section 7

Section 7 walked through twelve failure modes, each with its pattern. The patterns are: check every return value, unwind every prior allocation, explicitly zero output fields on failure, drain callouts and tasks before tearing down resources, mask interrupts before destroying associated DMA state, and keep the setup/teardown pair symmetric so the detach path is the reverse of the attach path. Every production DMA driver follows these patterns; the chapter's code provides a template for applying them.

Section 8 is the final refactor. The DMA code moves into `myfirst_dma.c` and `myfirst_dma.h`; the Makefile updates; the version bumps to 1.4-dma; the `DMA.md` document captures the design. The chapter's running driver is then ready for Chapter 22's power-management work and Chapter 28's descriptor-ring extension.

21.9 Section 8: Refactoring and Versioning Your DMA-Capable Driver

Section 7 closed the functional scope. Section 8 is the housekeeping pass. The DMA code has accumulated in `myfirst.c`, the simulation backend's DMA extension has grown inside `myfirst_sim.c`, the softc has grown several new fields, the sysctls have grown, and the interrupt filter has gained a `MYFIRST_INTR_COMPLETE` branch. This section collects the DMA-specific code into `myfirst_dma.c` and `myfirst_dma.h`, cleans up the naming,

updates the Makefile, bumps the version, adds the `DMA.md` document, and runs the final regression pass. Version tag `1.4-dma`.

The refactor is small in absolute terms (about 200 lines of code moved, plus a new header with public function prototypes and macros), but the structural benefit is large: the driver's architecture now shows, at a glance, that DMA is a first-class subsystem with its own file, its own public API, and its own documentation.

21.9.1 The Final File Layout

After Section 8, the driver's file layout is:

```
myfirst.c      # Top-level: attach/detach, cdev, ioctl
myfirst.h      # Shared macros, softc struct, public prototypes
myfirst_hw.c   # Chapter 16: register accessor layer
myfirst_hw.h
myfirst_hw_pci.c # Chapter 18: real PCI backend
myfirst_sim.c  # Chapter 17: simulated backend (now includes DMA engine)
myfirst_sim.h
myfirst_pci.c  # Chapter 18: PCI attach/detach
myfirst_pci.h
myfirst_intr.c # Chapter 19: legacy interrupt path
myfirst_intr.h
myfirst_msix.c # Chapter 20: MSI/MSI-X path
myfirst_msix.h
myfirst_dma.c  # Chapter 21: DMA setup/teardown/transfer
myfirst_dma.h
myfirst_sync.h # Chapter 11: locking macros
cbuf.c        # Chapter 15: circular buffer
cbuf.h
```

Fifteen source files plus shared headers. Each file has a narrow responsibility. The refactor maintains this separation: `myfirst_dma.c` is self-contained and only depends on `myfirst.h` and the kernel's public headers.

21.9.2 The `myfirst_dma.h` Header

The header declares the public DMA API and the shared constants:

```
/* myfirst_dma.h */
#ifndef _MYFIRST_DMA_H_
#define _MYFIRST_DMA_H_

/* DMA buffer size used by myfirst. Matches the Chapter 21 simulated
 * engine's scratch size. A real device would use a value from the
 * hardware's documented capabilities. */
```

```

#define MYFIRST_DMA_BUFFER_SIZE      4096u

/* DMA register offsets (relative to the BAR base). */
#define MYFIRST_REG_DMA_ADDR_LOW     0x20
#define MYFIRST_REG_DMA_ADDR_HIGH    0x24
#define MYFIRST_REG_DMA_LEN          0x28
#define MYFIRST_REG_DMA_DIR           0x2C
#define MYFIRST_REG_DMA_CTRL          0x30
#define MYFIRST_REG_DMA_STATUS        0x34

/* DMA_DIR values. */
#define MYFIRST_DMA_DIR_WRITE         0u /* host-to-device */
#define MYFIRST_DMA_DIR_READ          1u /* device-to-host */

/* DMA_CTRL bits. */
#define MYFIRST_DMA_CTRL_START        (1u << 0)
#define MYFIRST_DMA_CTRL_ABORT        (1u << 1)
#define MYFIRST_DMA_CTRL_RESET        (1u << 31)

/* DMA_STATUS bits. */
#define MYFIRST_DMA_STATUS_DONE        (1u << 0)
#define MYFIRST_DMA_STATUS_ERR         (1u << 1)
#define MYFIRST_DMA_STATUS_RUNNING     (1u << 2)

/* Public API. */
struct myfirst_softc;

int myfirst_dma_setup(struct myfirst_softc *sc);
void myfirst_dma_teardown(struct myfirst_softc *sc);
int myfirst_dma_do_transfer(struct myfirst_softc *sc,
    int direction, size_t length);
void myfirst_dma_handle_complete(struct myfirst_softc *sc);
void myfirst_dma_add_sysctls(struct myfirst_softc *sc);

#endif /* _MYFIRST_DMA_H_ */

```

Five public functions. `myfirst_dma_setup` is called once from `attach`; `myfirst_dma_teardown` is called once from `detach`; `myfirst_dma_do_transfer` is called by `sysctl` handlers or by other parts of the driver that want to trigger a DMA; `myfirst_dma_handle_complete` is called from the rx task when `MYFIRST_INTR_COMPLETE` was observed; `myfirst_dma_add_sysctls` registers the DMA counters and the test `sysctls`.

The header uses forward declaration (`struct myfirst_softc`) to avoid circular includes. The implementation sees the full `softc` definition via `myfirst.h`.

21.9.3 The `myfirst_dma.c` File

The file gathers the DMA code that has accumulated across Sections 3 through 7. The top of the file includes the standard headers the DMA API needs:

```
/* myfirst_dma.c */
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/bus.h>
#include <sys/module.h>
#include <sys/rman.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/condvar.h>
#include <sys/sysctl.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include "myfirst.h"
#include "myfirst_hw.h"
#include "myfirst_dma.h"
```

The implementation then defines the single-segment callback, `myfirst_dma_setup`, `myfirst_dma_tear_down`, `myfirst_dma_do_transfer`, `myfirst_dma_handle_complete`, and `myfirst_dma_add_sysctls`. Each function is lifted from its earlier section with no behaviour change; the refactor is purely a location move.

The one notable addition is `myfirst_dma_handle_complete`, which centralises the POST sync that Section 6's task performed inline:

```
void
myfirst_dma_handle_complete(struct myfirst_softc *sc)
{
    MYFIRST_ASSERT_LOCKED(sc);

    if (!sc->dma_in_flight)
        return;

    sc->dma_in_flight = false;
    if (sc->dma_last_direction == MYFIRST_DMA_DIR_WRITE)
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
            BUS_DMASYNC_POSTWRITE);
    else
        bus_dmamap_sync(sc->dma_tag, sc->dma_map,
```

```

        BUS_DMASYNC_POSTREAD));

sc->dma_last_status = CSR_READ_4(sc, MYFIRST_REG_DMA_STATUS);
atomic_add_64(&sc->dma_complete_tasks, 1);
cv_broadcast(&sc->dma_cv);
}

```

The rx task's body becomes:

```

static void
myfirst_msix_rx_task_fn(void *arg, int npending)
{
    struct myfirst_vector *vec = arg;
    struct myfirst_softc *sc = vec->sc;

    MYFIRST_LOCK(sc);
    if (sc->hw == NULL || !sc->pci_attached) {
        MYFIRST_UNLOCK(sc);
        return;
    }
    sc->intr_last_data = CSR_READ_4(sc, MYFIRST_REG_DATA_OUT);
    sc->intr_task_invocations++;
    cv_broadcast(&sc->data_cv);
    myfirst_dma_handle_complete(sc);
    MYFIRST_UNLOCK(sc);
}

```

The task is shorter by four lines, and the DMA-specific logic lives entirely in `myfirst_dma.c`. If a later chapter (or a future contributor) wants to change the POST-sync or completion behaviour, the change touches one file.

21.9.4 The Updated Makefile

The Makefile from Chapter 20 was:

```

KMOD=  myfirst
SRCS=  myfirst.c \
        myfirst_hw.c myfirst_hw_pci.c \
        myfirst_sim.c \
        myfirst_pci.c \
        myfirst_intr.c \
        myfirst_msix.c \
        cbuf.c

```

```
CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.3-msi\"  
  
.include <bsd.kmod.mk>
```

The Chapter 21 Stage 4 Makefile adds `myfirst_dma.c` and bumps the version string:

```
KMOD= myfirst  
SRCS= myfirst.c \  
      myfirst_hw.c myfirst_hw_pci.c \  
      myfirst_sim.c \  
      myfirst_pci.c \  
      myfirst_intr.c \  
      myfirst_msix.c \  
      myfirst_dma.c \  
      cbuf.c  
  
CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.4-dma\"  
  
.include <bsd.kmod.mk>
```

The change is two lines: the added source file in `SRCS` and the updated version string. Both are required; a Makefile missing the new source fails to link because `myfirst.c` calls `myfirst_dma_setup` which is not in any compiled object.

21.9.5 The Version String in `kldstat`

The `MYFIRST_VERSION_STRING` macro is used in `MODULE_VERSION` and in an `SYSCTL_STRING` exposing the version. After the refactor, `kldstat -v | grep myfirst` reports:

```
myfirst 1.4-dma (pseudo-device)
```

and `sysctl dev.myfirst.0.version` returns the same string. Operators who see the driver attached can check the version at a glance; the string is a useful diagnostic when mixing development and production driver versions on the same test system.

21.9.6 The `DMA.md` Document

Chapter 20 introduced `MSIX.md`. Chapter 21 adds `DMA.md`, a one-file reference that documents the DMA subsystem's public API, the register layout, the flow diagrams, and the counters. A sample outline:

```
# DMA Subsystem
```

Purpose

The DMA layer allows the driver to transfer data between host memory and the device without CPU-per-byte involvement. It is used for every transfer larger than a few words; smaller register reads and writes still use MMIO directly.

Public API

- ``myfirst_dma_setup(sc)``: called from attach. Creates the tag, allocates the buffer, loads the map, populates ``sc->dma_bus_addr``.
- ``myfirst_dma_teardown(sc)``: called from detach. Reverses setup.
- ``myfirst_dma_do_transfer(sc, dir, len)``: triggers one DMA transfer and waits for completion.
- ``myfirst_dma_handle_complete(sc)``: called from the rx task when ``MYFIRST_INTR_COMPLETE`` was observed.
- ``myfirst_dma_add_sysctls(sc)``: registers the DMA counters and test sysctls under ``dev.myfirst.N.``.

Register Layout

... (table from Section 5) ...

Flow Diagrams

Host-to-device:

... (diagram from Section 4, Pattern A) ...

Device-to-host:

... (diagram from Section 4, Pattern B) ...

Counters

- ``dev.myfirst.N.dma_transfers_write``: successful host-to-device transfers.
- ``dev.myfirst.N.dma_transfers_read``: successful device-to-host transfers.
- ``dev.myfirst.N.dma_errors``: transfers that returned EIO.
- ``dev.myfirst.N.dma_timeouts``: transfers that hit the 1-second timeout.
- ``dev.myfirst.N.dma_complete_intrs``: completion-bit observations in the filter.
- ``dev.myfirst.N.dma_complete_tasks``: completion processing in the task.

Observability

``sysctl dev.myfirst.N.dma_*`` returns the full counter set. A healthy driver has ``dma_complete_intrs == dma_complete_tasks`` and both equal

```
to `dma_transfers_write + dma_transfers_read + dma_errors + dma_timeouts`.
```

Testing

The sysctls ``dma_test_write`` and ``dma_test_read`` trigger transfers from user space. Writing any value to ``dma_test_write`` fills the buffer with the low byte of the value and runs a host-to-device transfer; writing any value to ``dma_test_read`` runs a device-to-host transfer and logs the first eight bytes to ``dmesg``.

Known Limitations

- Single buffer, single transfer at a time.
- No descriptor-ring support (Part 6, Chapter 28).
- No per-NUMA-node allocation (Part 7, Chapter 33).
- No partial-transfer reporting (exercise for the reader).

See Also

- ``bus_dma(9)``, ``/usr/src/sys/sys/bus_dma.h``.
- ``/usr/src/sys/dev/re/if_re.c`` for a production descriptor-ring driver.
- ``INTERRUPTS.md``, ``MSIX.md`` for the interrupt path the completion uses.

The document is about a page long and useful both as a contributor reference and as a reader's recap. Real production drivers often have their README files structured similarly: subsystem-by-subsystem, with a short flow diagram and a counter list.

21.9.7 The Regression Pass

The chapter's regression test from Chapter 20 is extended with DMA-specific checks. The full test (call it `full_regression_ch21.sh`) runs these steps on a fresh boot:

1. Kernel is in the expected state (`uname -v` shows 1.4-dma in the `myfirst` line, `INVARIANTS/WITNESS` in the config).
2. Load the module (`kldload ./myfirst.ko`). `dmesg` shows the DMA banner and the interrupt-mode banner.
3. Verify initial counter state (`dma_transfers_write == 0`, etc.).
4. Run 1000 write transfers via the sysctl. Assert counter increments.
5. Run 1000 read transfers via the sysctl. Assert counter increments.
6. Run 100 transfers with the simulated error injection enabled. Assert `dma_errors` counter climbs.
7. Run 10 transfers with the callout disabled (engine hangs). Assert `dma_timeouts` counter climbs and `dma_in_flight` is cleared after each timeout.
8. Unload the module (`kldunload myfirst`). Assert clean unload with no `WITNESS` warnings.
9. Repeat the load/unload cycle 50 times to detect leaks.

The full script lives under `examples/part-04/ch21-dma/labs/full_regression_ch21.sh`. A successful run prints a single line per step with the observed counters and an overall PASS at the end. Any step that fails prints a FAIL line with the actual versus expected values.

21.9.8 What the Refactor Accomplished

After Section 8:

- The DMA code lives in its own file with a documented public API.
- The Makefile knows about the new source.
- The version tag reflects the chapter's work.
- A `DMA.md` document serves as a reference for contributors and future chapters.
- The regression test covers every DMA path the chapter teaches.

The driver is now `1.4-dma`, and the diff from `1.3-msi` is about four hundred lines added plus fifty lines moved. Every line is traceable: either it implements a concept from one of the earlier sections or it is housekeeping (headers, Makefile, documentation).

21.9.9 Exercise: Create a Utility That Verifies DMA Data

A hands-on exercise for Section 8. Write a small user-space utility that exercises the DMA path and verifies the data end-to-end.

The utility's job: 1. Open the `dev.myfirst.0.dma_test_write` sysctl, write a known pattern (say, `0xA5`). 2. Open `dev.myfirst.0.dma_test_read`, trigger a read. 3. Check `dmesg` (or a custom sysctl that exposes the first bytes of the buffer) for the expected pattern (`0x5A` from the simulator's scratch). 4. Repeat 100 times with different patterns; report a summary.

The utility is a shell script for simplicity:

```
#!/bin/sh
fail=0
for pat in $(jot 100 1); do
    hex=$(printf "0x%02x" $pat)
    sysctl -n dev.myfirst.0.dma_test_write=$pat >/dev/null
    sysctl -n dev.myfirst.0.dma_test_read=1 >/dev/null
    # ... check the result ...
done
echo "failures: $fail"
```

The exercise is open-ended: the reader can extend it with timing measurements, error-rate estimates, or a comparison against `dma_errors` counter values. Section 8's challenge list suggests a few directions.

21.9.10 Wrapping Up Section 8

Section 8 is the finish line. The DMA code has its own file; the Makefile compiles it; the version tag says `1.4-dma`; the documentation captures the design; the regression test exercises every path. The chapter's running

driver is now ready for Chapter 22's power-management work, which will use the DMA teardown path to quiesce transfers during suspend, and ready for Chapter 28, which will extend the single-buffer pattern to a full descriptor ring.

The chapter's sections are complete. The remaining material is reference and practice: a walkthrough of a production DMA driver (`if_re`), deeper looks at bounce buffers, 32-bit devices, IOMMU, coherent flags, and parent-tag inheritance, the labs, the challenges, the troubleshooting reference, and the final wrap-up.

21.10 Reading a Real Driver Together: `if_re.c`

A tour of `/usr/src/sys/dev/re/if_re.c` that maps its DMA code back to the concepts in Chapter 21. `if_re(4)` is the driver for the RealTek 8139C+ / 8169 / 8168 family of Gigabit Ethernet chips, which is common enough to be present in many lab environments and compact enough (around four thousand lines total) to read in a week of commute-length sessions. Its DMA code is about four hundred lines and sits inside a few well-named functions, so it is a good first real-driver read.

Reading this walkthrough. The listings in the subsections that follow are abbreviated excerpts from `re_allocmem()`, `re_dma_map_addr()`, `re_encap()`, and `re_detach()` in `/usr/src/sys/dev/re/if_re.c`. We have preserved each call's argument list and the surrounding control flow, but we show only the fragments that illustrate a `bus_dma(9)` idea under discussion; the real functions include more error handling, more child tags, and more bookkeeping. Every symbol the listings name, from `bus_dma_tag_create` to `bus_dmamap_load` to `re_dma_map_addr`, is a real FreeBSD identifier you can find with a symbol search. The same abbreviation convention appears in the `nvme(4)` driver's `nvme_single_map` in `/usr/src/sys/dev/nvme/nvme_private.h` and in any driver that packages a single-segment callback as a helper.

21.10.1 The Parent Tag

`re_allocmem` begins by creating the parent tag:

```
lowaddr = BUS_SPACE_MAXADDR;
if ((sc->rl_flags & RL_FLAG_PCIE) == 0)
    lowaddr = BUS_SPACE_MAXADDR_32BIT;
error = bus_dma_tag_create(bus_get_dma_tag(dev), 1, 0,
    lowaddr, BUS_SPACE_MAXADDR, NULL, NULL,
    BUS_SPACE_MAXSIZE_32BIT, 0, BUS_SPACE_MAXSIZE_32BIT, 0,
    NULL, NULL, &sc->rl_parent_tag);
```

Two things worth noticing.

First, the `lowaddr` decision. On PCIe variants of the chip, DMA can reach all of memory (`BUS_SPACE_MAXADDR`). On older non-Pcie variants, the chip is 32-bit-only (`BUS_SPACE_MAXADDR_32BIT`, i.e. the device cannot reach memory above 4 GB). The driver probes this at attach time and sets `lowaddr` accordingly. Any child tag created from `rl_parent_tag` inherits this limit automatically. On a 64-bit amd64 system with 16 GB of RAM,

the driver's tags ensure that DMA buffers are allocated below 4 GB for the non-PCIe variants; bounce buffers kick in only if the kernel cannot satisfy that allocation.

Second, the `maxsize = BUS_SPACE_MAXSIZE_32BIT` and `nsegments = 0`. These values produce a very permissive parent tag: any child with any segment count is valid. This is a common idiom; the parent carries only the addressing constraint, and children carry the specifics.

21.10.2 The Per-Buffer Child Tags

The driver creates four child tags:

- `rl_tx_mtag`: for transmit mbuf payloads. Alignment 1, max size `MCLBYTES * RL_NTXSEGS`, up to `RL_NTXSEGS` segments per mapping.
- `rl_rx_mtag`: for receive mbuf payloads. Alignment 8, max size `MCLBYTES`, 1 segment per mapping.
- `rl_tx_list_tag`: for the transmit descriptor ring. Alignment `RL_RING_ALIGN` (256 bytes), max size `tx_list_size`, 1 segment.
- `rl_rx_list_tag`: for the receive descriptor ring. Alignment `RL_RING_ALIGN`, max size `rx_list_size`, 1 segment.

Each child passes `sc->rl_parent_tag` as the parent. Each carries its own alignment and segment constraints. The kernel composes the parent's 32-bit addressing limit with each child's own constraints; the driver does not have to repeat the addressing limit in every child tag.

The descriptor-ring tags are single-segment: the ring is allocated contiguously. The mbuf-payload tags are multi-segment: a single received packet may be a chain of mbufs, and the NIC's DMA engine is fine with a scatter-gather list of segments as long as the total fits within the maximum size.

21.10.3 The Ring Allocation

The descriptor ring allocation uses `bus_dmamem_alloc` with `BUS_DMA_COHERENT`:

```
error = bus_dmamem_alloc(sc->rl_ldata.rl_tx_list_tag,  
    (void **)&sc->rl_ldata.rl_tx_list,  
    BUS_DMA_WAITOK | BUS_DMA_COHERENT | BUS_DMA_ZERO,  
    &sc->rl_ldata.rl_tx_list_map);
```

The flags are `WAITOK` | `COHERENT` | `ZERO`: allow sleeping, prefer coherent memory, zero-initialise. The coherent hint is appropriate because the ring is on the hot path for both the CPU (producing TX entries) and the NIC (consuming them, writing back status). The zero-initialise is important because the ring's initial state must have all entries marked "not in use"; uninitialised memory could cause the NIC to attempt DMA based on garbage descriptor contents.

After `bus_dmamem_alloc`, the driver calls `bus_dmamap_load` with a single-segment callback:

```
sc->rl_ldata.rl_tx_list_addr = 0;  
error = bus_dmamap_load(sc->rl_ldata.rl_tx_list_tag,
```

```
sc->rl_ldata.rl_tx_list_map, sc->rl_ldata.rl_tx_list,
tx_list_size, re_dma_map_addr,
&sc->rl_ldata.rl_tx_list_addr, BUS_DMA_NOWAIT);
```

And the callback:

```
static void
re_dma_map_addr(void *arg, bus_dma_segment_t *segs, int nseg, int error)
{
    bus_addr_t *addr;

    if (error)
        return;

    KASSERT(nseg == 1, ("too many DMA segments, %d should be 1", nseg));
    addr = arg;
    *addr = segs->ds_addr;
}
```

The callback is almost identical to Chapter 21's `myfirst_dma_single_map`. The driver's code is portable across every DMA-capable FreeBSD platform because the callback, the tag, and the allocator all respect the `bus_dma` discipline.

21.10.4 The Per-Transfer Pattern

For each transmitted packet, the driver calls `bus_dmamap_load_mbuf_sg` on the packet's mbuf:

```
error = bus_dmamap_load_mbuf_sg(sc->rl_ldata.rl_tx_mtag, txd->tx_dmamap,
    *m_head, segs, &nsegs, BUS_DMA_NOWAIT);
```

The `_mbuf_sg` variant fills a pre-allocated segment array, avoiding the callback for the common case. If the load returns `EFBIG`, the driver tries to compact the mbuf chain with `m_collapse` and retries.

Once the load succeeds, the driver syncs:

```
bus_dmamap_sync(sc->rl_ldata.rl_tx_mtag, txd->tx_dmamap,
    BUS_DMASYNC_PREWRITE);
```

Then writes the descriptors with the segment addresses, pokes the doorbell, and lets the NIC transmit. On completion, the driver syncs again:

```
bus_dmamap_sync(sc->rl_ldata.rl_tx_list_tag, sc->rl_ldata.rl_tx_list_map,  
    BUS_DMASYNC_POSTREAD | BUS_DMASYNC_POSTWRITE);
```

The combined POSTREAD|POSTWRITE sync is the descriptor-ring variant from Section 4: the driver both wrote the descriptor (the address, length, flags) and wants to read the device's status update (transmitted, error, etc.).

21.10.5 The Cleanup

The detach path (`re_dma_free`) mirrors the allocation order, in reverse:

```
if (sc->rl_ldata.rl_rx_list_tag) {  
    if (sc->rl_ldata.rl_rx_list_addr)  
        bus_dmamap_unload(sc->rl_ldata.rl_rx_list_tag,  
            sc->rl_ldata.rl_rx_list_map);  
    if (sc->rl_ldata.rl_rx_list)  
        bus_dmamem_free(sc->rl_ldata.rl_rx_list_tag,  
            sc->rl_ldata.rl_rx_list, sc->rl_ldata.rl_rx_list_map);  
    bus_dma_tag_destroy(sc->rl_ldata.rl_rx_list_tag);  
}
```

The per-buffer dmamaps created with `bus_dmamap_create` are destroyed with `bus_dmamap_destroy` in a loop, and finally the tags are destroyed.

21.10.6 What the Walkthrough Teaches

`if_re`'s DMA code is a near-textbook application of Chapter 21's concepts. Every call the chapter teaches appears in the driver. The only concepts not in the chapter are the scatter-gather variant (`bus_dmamap_load_mbuf_sg`) and the per-buffer dynamic maps (`bus_dmamap_create`/`bus_dmamap_destroy`), and both are natural extensions of the static pattern.

A reader who finishes Chapter 21 and then reads `if_re.c` for half an hour sees the same shapes. The chapter's investment pays off against real driver code.

21.11 A Deeper Look at Bounce Buffers

Section 1 introduced bounce buffers; Section 7 described the error mode. This deeper look pins down what bounce buffers are, when they are used, and what the cost looks like.

21.11.1 What Bounce Buffers Are

A bounce buffer is a region of physical memory inside the device's addressable range, used to stage data when the driver's actual buffer is outside the range. The `bus_dma` layer manages a pool of bounce pages as an internal

resource; a driver that allocates buffers with `bus_dmamem_alloc` inside the device's range never touches the pool.

When a driver loads a buffer via `bus_dmamap_load` and the buffer is outside the device's range (say, a mbuf allocated above 4 GB on a 32-bit-only device), the kernel:

1. Allocates a bounce page inside the device's range.
2. At `PREWRITE` time, copies the driver's buffer into the bounce page.
3. Programs the device with the bounce page's address.
4. At `POSTREAD` time, copies the bounce page back to the driver's buffer.
5. Releases the bounce page.

The driver never knows that a bounce happened. The `bus_addr_t` returned by the callback is the bounce page's address; the sync operations move the data back and forth.

21.11.2 When Bounce Buffers Matter

Bounce buffers are needed in three situations:

1. **32-bit-only devices on systems with more than 4 GB of RAM.** The device cannot reach above 4 GB; any buffer up there needs a bounce below 4 GB.
2. **Devices with addressing holes.** Some legacy devices have unusable address regions (for example, the ISA-style 16 MB DMA limit). A buffer inside the hole needs to bounce.
3. **IOMMU-enabled systems with devices that are not IOMMU-registered.** If the IOMMU is in enforcing mode and a device has not been mapped, the DMA target is bounced to a mapped region.

On modern amd64 with 64-bit-capable devices and 64-bit-capable drivers (which most are), bounce buffers are rare. On embedded systems or in compatibility contexts, they are common.

21.11.3 The Performance Cost

Each bounce involves a `memcpy` from the driver's buffer to the bounce region (at `PREWRITE`) and another `memcpy` back (at `POSTREAD`). For a 1500-byte mbuf this is about 3 KB of memory traffic per packet; on a 10 Gbps NIC receiving a million packets per second, that is 3 GB/s of bounce traffic, which measurably loads the memory bus.

The bounce buffer pool is also sized (tunable via `hw.busdma.* sysctls`, with defaults that scale with physical memory). On a system where many drivers are bouncing, the pool can be exhausted, at which point loads with `BUS_DMA_NOWAIT` return `ENOMEM` and loads without `NOWAIT` defer.

21.11.4 How to Avoid Bouncing

Three strategies:

1. **Allocate DMA memory with `bus_dmamem_alloc`.** The allocator respects the tag's addressing constraints by construction.

2. **Set the tag's `highaddr/lowaddr` to match the device's true range.** Do not pass `BUS_SPACE_MAXADDR` for a 32-bit-only device; the incorrect value leads the allocator to hand out too-high buffers and forces bouncing.
3. **Use `BUS_DMA_ALLOCNOW`.** This pre-allocates the bounce pool at tag creation, turning a later allocation failure into an immediate failure the driver can handle at attach time.

Chapter 21's simulation does not exercise bouncing, but the concept is important for understanding real driver behaviour. A driver that “works on my laptop” but corrupts data on a server with 64 GB of RAM almost certainly has an address-range misconfiguration that is triggering silent bouncing on the laptop and failing differently on the server.

21.11.5 Observability

The `hw.busdma` sysctl tree exposes bounce-related counters:

```
sysctl hw.busdma
```

The interesting lines include `total_bpages`, `free_bpages`, `total_bounced`, `total_deferred`, `lowpriority_bounces`. `total_bounced` is the total number of pages bounced since boot; a non-zero value on a system where no bouncing should happen is a clue that some driver's tag is misconfigured.

21.12 A Deeper Look at 32-Bit-Capable Devices

Section 1 and the bounce-buffer discussion both touched on this; this deeper look collects the practical guidance.

21.12.1 The Setting

Some PCI and PCIe devices have 32-bit DMA engines. The engines accept only 32-bit bus addresses, so the DMA traffic is confined to the lower 4 GB of bus address space. On a 64-bit host with more than 4 GB of RAM, every DMA buffer must be below the 4 GB boundary.

21.12.2 The Tag Setting

The relevant constants:

- `BUS_SPACE_MAXADDR`: no addressing limit. Use for 64-bit-capable devices.
- `BUS_SPACE_MAXADDR_32BIT`: `0xFFFFFFFF`. Use as the `lowaddr` for 32-bit-only devices.
- `BUS_SPACE_MAXADDR_24BIT`: `0x00FFFFFF`. Use as the `lowaddr` for legacy devices with a 16 MB limit (rare).

Together, `lowaddr` and `highaddr` describe the *excluded* window of bus address space. The manual page wording is: “The window contains all addresses greater than `lowaddr` and less than or equal to `highaddr`.” Addresses inside the window cannot be reached by the device and must be bounced; addresses outside the window are reachable.

For a 32-bit device, the excluded window is everything above 4 GB, so `lowaddr = BUS_SPACE_MAXADDR_32BIT` and `highaddr = BUS_SPACE_MAXADDR`. The window becomes `(0xffffffff, BUS_SPACE_MAXADDR]`, which captures exactly “anything above 4 GB”.

For a 64-bit-capable device with no restrictions, the excluded window should be empty. The idiomatic way to express that is `lowaddr = BUS_SPACE_MAXADDR` and `highaddr = BUS_SPACE_MAXADDR`, which collapses the window to `(BUS_SPACE_MAXADDR, BUS_SPACE_MAXADDR]`, an empty range.

The naming is confusing at first: `lowaddr` sounds like a lower bound but is actually the *upper end* of the device’s reachable range (and the *lower end* of the excluded window). The naming is historical: `lowaddr` is the low end of the excluded region, and the excluded region is above the device’s range. The mnemonic: `lowaddr` is “the last address the device can reach”.

21.12.3 Double-Addressing-Cycle (DAC)

PCI has a mechanism called Double Address Cycle (DAC) that allows 32-bit slots to address 64 bits by issuing two cycles. Some devices that appear 32-bit actually support DAC and can reach 64-bit addresses. The `if_re` driver checks a chip-family flag to decide: PCIe variants use full 64-bit; non-PCIe variants use 32-bit only. A driver that does not know whether its device supports DAC should default to 32-bit (safer) and enable 64-bit if the datasheet confirms support.

21.12.4 The Impact on Bounce Traffic

A 32-bit-only device on a 64 GB server: - Most buffers are allocated above 4 GB by the default kernel allocator (since most memory is up there). - Every load triggers a bounce. - The bounce pool caps the driver’s throughput at whatever the pool can churn.

The fix is always to use `bus_dmamem_alloc` for the driver’s static buffers and to ensure the tag’s `lowaddr` is set correctly so the allocator places the buffers below 4 GB. For the dynamic case (mbufs, user buffers), the network stack provides pre-allocated mbuf clusters below 4 GB for drivers that request them via `bus_dma`-aware mbuf types, though this path is inside `iflib` and not a concern for Chapter 21.

21.13 A Deeper Look at IOMMU Integration

Section 1 mentioned the IOMMU. This deeper look covers what the IOMMU does, how to tell if it is active, and why the `bus_dma` API is designed to be transparent to it.

21.13.1 What the IOMMU Does

An IOMMU (Input-Output Memory Management Unit) is a translation layer between a device’s bus addresses and the host’s physical addresses. With the IOMMU active:

- The device sees bus address X.
- The IOMMU translates X to physical address Y.
- The memory controller writes physical address Y.

The translation is per-device (each device has its own mapping table), and by default the IOMMU only allows a device to access memory the kernel has explicitly mapped for it. This provides two benefits:

1. **Security.** A compromised device cannot DMA to arbitrary memory; it can only reach memory the kernel has explicitly mapped.
2. **Flexibility.** The kernel can present a 32-bit-capable device with a 32-bit view of any region of memory, including regions above 4 GB, by setting up an appropriate mapping. The bounce-buffer strategy becomes unnecessary when the IOMMU can just remap.

21.13.2 How the Kernel Integrates

FreeBSD's `busdma_iommu` (built when `DEV_IOMMU` is set, typically on x86 with VT-d or AMD-Vi) integrates with the `bus_dma` API transparently. When a driver calls `bus_dmamap_load`, the `busdma` layer asks the IOMMU to allocate IOVA (I/O virtual address) space and program the mapping; the `bus_addr_t` returned to the driver is the IOVA, not the physical address. The driver programs the device with the IOVA; the device issues a DMA to the IOVA; the IOMMU translates to the physical address; the memory controller completes the transfer.

From the driver's perspective, nothing changes. The same `bus_dma` calls do the right thing on IOMMU systems as on non-IOMMU systems. This is the portability promise of `bus_dma`: drivers written against the API work on whatever the platform provides.

21.13.3 Detecting the IOMMU

```
sysctl hw.vmm.ppt.devices  # shows pass-through devices (bhyve)
sysctl hw.dmar              # Intel VT-d if enabled
sysctl hw.iommu             # generic IOMMU flag
```

On a system where the kernel booted with the IOMMU active, `dmesg` shows a line like `dmar0: <DMAR>` near boot.

21.13.4 Performance Implications

IOMMU translation is not free. Each translation goes through the IOMMU's page tables; the IOMMU caches recently-used translations in a TLB-like structure, but misses cost real time. For drivers that make millions of small mappings per second, the IOMMU can become a bottleneck.

The mitigations are:

1. **Batch mappings.** A driver that keeps a long-lived buffer mapped once has no recurring IOMMU cost. Chapter 21's static pattern is ideal.
2. **Use the IOMMU's super-page support.** Larger pages mean fewer TLB entries.
3. **Disable the IOMMU for trusted devices.** Not generally advised, but possible for specific deployments.

Chapter 21's driver is not affected either way; the static buffer is mapped once at attach and never remapped. Drivers with high remap rates (storage controllers processing many small transfers per second) are affected more.

21.14 A Deeper Look at BUS_DMA_COHERENT vs Explicit Sync

Section 4 covered the BUS_DMA_COHERENT flag at the API level. This deeper look explains the interaction with the sync discipline, which is subtle on some platforms.

21.14.1 The Relationship

BUS_DMA_COHERENT is a hint passed to `bus_dma_tag_create` (architectural preference) and `bus_dmamem_alloc` (allocation mode). It asks the allocator to place the buffer in a memory domain that is coherent with the DMA path: on arm64 with write-combining or uncached regions, this is a specific memory type; on amd64, the allocator chooses normal memory because the PCIe root complex is already coherent.

The flag does not eliminate the requirement to call `bus_dmamap_sync`. The API contract requires the sync; BUS_DMA_COHERENT makes the sync cheap or free, not unnecessary.

21.14.2 Why the Sync Is Still Required

Two reasons. First, the driver is portable: the same source file compiles on every platform FreeBSD supports. On a platform where BUS_DMA_COHERENT is honoured but bounce buffers are in play (for an addressing constraint, say), the sync is the hook that triggers the bounce copy. Without it, the bounce data is stale.

Second, the driver is forward-compatible: a future platform may not honour the flag, or may honour it only for certain allocators. The explicit sync is what makes the driver correct against any future platform.

The rule: always pass BUS_DMA_COHERENT when the access pattern justifies it, and always call `bus_dmamap_sync` regardless. The flag makes sync cheap; the sync makes the driver correct.

21.14.3 When to Use the Flag

For static buffers (descriptor rings, control structures): always pass BUS_DMA_COHERENT. The buffer is accessed often by both the CPU and the device; coherent memory reduces the per-access cost.

For dynamic buffers (packet payloads, disk blocks): usually do not pass it. The cache-hit rate when the CPU processes the data is usually high enough that coherent memory's slower access patterns hurt more than they help.

The `if_re` driver follows exactly this: descriptor tags use BUS_DMA_COHERENT, payload tags do not. NVMe's per-qpair tag uses BUS_DMA_COHERENT for the same reason.

21.15 A Deeper Look at Parent and Child Tag Inheritance

Section 3's setup function passed `bus_get_dma_tag(sc->dev)` as the parent. This deeper look covers why inheritance matters and when a driver should create an explicit parent tag rather than inheriting from the bridge.

21.15.1 Inheritance Semantics

A child tag inherits every constraint from its parent that is more restrictive than the child's own. The intersection semantics mean:

- The child's `lowaddr` is `min(parent_lowaddr, child_lowaddr)`. The tighter limit wins.
- The child's alignment is `max(parent_alignment, child_alignment)`. More alignment wins.
- The child's `maxsize` is `min(parent_maxsize, child_maxsize)`. The smaller win.
- The child's `nsegments` is `min(parent_nsegments, child_nsegments)`.
- Flags are composed: `BUS_DMA_COHERENT` propagates, `BUS_DMA_ALLOCNOW` does not.

The kernel applies these rules at tag-create time; the child's internal constraints are the intersection of the parent's and its own.

21.15.2 Why Drivers Create Explicit Parent Tags

A driver that has several per-subsystem tags often finds it cleaner to create one explicit parent tag that carries the device-level constraints (addressing limits, platform-level alignment), then create children for each specific purpose (rings, payloads). The parent is then destroyed at detach after all children are destroyed.

`if_re` does this: `rl_parent_tag` is the device-level parent, inheriting from the PCI bridge and adding the device's 32-bit limit (for non-PCIe chips). The four child tags (`rl_tx_mtag`, `rl_rx_mtag`, `rl_tx_list_tag`, `rl_rx_list_tag`) inherit from `rl_parent_tag`. Destroying `rl_parent_tag` is the last DMA cleanup step, because all four children must be destroyed first (`bus_dma_tag_destroy` returns `EBUSY` if any child still exists).

21.15.3 When to Skip the Explicit Parent

For drivers with a single tag (like Chapter 21's), creating an explicit parent is overkill. The driver's single tag inherits from `bus_get_dma_tag(sc->dev)` directly and applies its own constraints; the bridge's tag is the de-facto parent.

For drivers with two or three related tags that share constraints, an explicit parent reduces duplication and makes the design clearer.

For drivers with many tags (descriptor rings, multiple buffer pools, shared memory regions), an explicit parent is always the right choice.

21.16 A Deeper Look at Descriptor Rings as a Future Topic

Chapter 21's driver uses a single DMA buffer. Production drivers use descriptor rings. This deeper look previews what a descriptor ring is, so the reader who wants to extend the chapter's work has a shape to aim at, but the detailed teaching is deferred.

A descriptor ring is an array of fixed-size entries in DMA-coherent memory. Each entry contains at least a bus address and a length, plus flags that describe the transfer (direction, type, status). The driver and the device

communicate through the ring: the driver writes entries, the device reads them, performs the transfer, and writes status back.

The ring has two indexes: a **producer** index (the next entry the writer will fill) and a **consumer** index (the next entry the reader will process). For a transmit ring, the driver is the producer and the device is the consumer. For a receive ring, the roles are reversed. Both indexes wrap modulo the ring size.

The driver signals new entries by writing a **doorbell** register (an MMIO write that the device treats as “look at the ring”). The device signals completions by raising an interrupt; the driver then walks the ring from the last consumer index to the current one, processes each entry, and advances the consumer index.

The complications that make rings their own topic are: head-of-line blocking when the ring is full, partial-transfer handling across ring entries, reorder tolerance (does the device complete entries in order, or out of order?), flow control between driver and device, wrap-around correctness, and the interaction with multi-queue hardware where each queue has its own ring.

Extending Chapter 21’s driver to use a small ring is a natural exercise. The challenges at the end of the chapter include a sketch. The full descriptor-ring topic is the network chapter in Part 6 (Chapter 28).

21.17 A Mental Model for Chapter 21’s Sync Discipline

A paragraph-length mental model that captures the sync discipline in one sentence: *the PRE and POST sync calls mark every moment a DMA buffer changes ownership between the CPU and the device, and the driver writes them into its code even when the current platform makes them free.* Chapter 21’s driver respects this model everywhere. Every `bus_dmamap_sync` call in `myfirst_dma.c` is paired with a partner: PRE marks the CPU releasing ownership, POST marks the CPU re-acquiring it. Between the two, the buffer belongs to the device, and no driver code reads or writes it. The discipline sounds absolute because it is; every production driver follows it; every exception the reader might imagine is actually a buggy driver that happens to work on the test platform.

21.18 Patterns From Real FreeBSD Drivers

A short catalogue of DMA patterns as they appear in the real tree. Each pattern has a representative file; reading the file’s DMA-related functions after this chapter is the recommended follow-up practice.

21.18.1 Pattern: `bus_dmamem_alloc` for Static Descriptor Rings

Where: `/usr/src/sys/dev/re/if_re.c`, `re_allocmem`; `/usr/src/sys/dev/nvme/nvme_qpair.c`, `nvme_qpair_construct`.

The driver allocates a contiguous region at attach time, loads it with a single-segment callback, uses it for the driver’s lifetime, unloads it on detach. This is Chapter 21’s static pattern and the foundation for almost every DMA-capable driver.

21.18.2 Pattern: `bus_dmamap_load_mbuf_sg` for Per-Packet Mappings

Where: `/usr/src/sys/dev/re/if_re.c`, `re_encap`; `/usr/src/sys/dev/e1000/if_em.c`, `em_xmit`.

For each outgoing packet, the driver loads the packet's mbuf into a dynamic map, programs the descriptor, transmits, and unloads. This is the dynamic pattern Chapter 21 mentions but does not implement.

21.18.3 Pattern: Parent-Child Tag Hierarchy

Where: `/usr/src/sys/dev/re/if_re.c`, `re_allocmem`; `/usr/src/sys/dev/bce/if_bce.c`, `bce_dma_alloc`.

The driver creates a parent tag for device-level constraints and child tags for per-subsystem allocations. The hierarchy composes constraints automatically and separates the driver's cleanup into clear steps.

21.18.4 Pattern: `BUS_DMASYNC_PREREAD` | `BUS_DMASYNC_PREWRITE` for Shared Rings

Where: `/usr/src/sys/dev/nvme/nvme_qpair.c`, around `nvme_qpair_reset` and the submission queue; `/usr/src/sys/dev/ahci/ahci.c`, around the command table.

For rings where both the driver and the device read and write, the combined PRE flag at setup and the combined POST flag at transaction boundaries make the sync discipline explicit.

21.18.5 Pattern: Single-Segment Callback as a Universal Helper

Where: `/usr/src/sys/dev/nvme/nvme_private.h`, `nvme_single_map`; `/usr/src/sys/dev/re/if_re.c`, `re_dma_map_addr`; many others.

Almost every driver defines a single-segment callback named in its own style. Chapter 21's `my_first_dma_single_map` is a clean example; the real-driver variants are all functionally identical.

21.18.6 Pattern: Coherent Tag for Rings, Non-Coherent for Payloads

Where: `/usr/src/sys/dev/re/if_re.c` and many others.

The driver passes `BUS_DMA_COHERENT` for descriptor-ring tags and omits it for payload tags. The allocator handles both; the driver makes the right choice per tag.

21.19 Hands-On Labs

Five hands-on labs walk the reader through the chapter's stages on a lab target. Each lab is self-contained; completing all five produces a working 1.4-dma driver.

21.19.1 Lab 1: Identify DMA-Capable Devices on Your System

Goal: build a map of your lab machine's DMA landscape before the chapter's coding work begins.

Time: 20 minutes.

Steps:

1. Run `pciconf -lv` on your lab host and note the devices.
2. Run `pciconf -lvc | grep -B1 BUSMASTEREN` to identify devices with bus-mastering enabled.
3. Pick one device, run `pciconf -lvbc <devname>`, and identify its BAR layout and capability list.
4. Run `sysctl hw.busdma` and note the bounce-buffer counters.
5. Write in your lab notebook: three devices, one property each, your current bounce-buffer usage.

Expected: a short list of devices with their bus-mastering status, and an understanding of whether your system is bouncing.

21.19.2 Lab 2: Stage 1, Allocate and Map a DMA Buffer

Goal: build the Stage 1 driver that creates a tag, allocates a buffer, loads a map, and cleans up.

Time: 1.5 hours.

Steps:

1. Start from the Chapter 20 Stage 4 driver (1.3-msi).
2. Add the four softc fields (`dma_tag`, `dma_map`, `dma_vaddr`, `dma_bus_addr`).
3. Add the single-segment callback (`myfirst_dma_single_map`).
4. Add `myfirst_dma_setup` and `myfirst_dma_tearardown` to `myfirst.c`.
5. Call them from `attach` and `detach`.
6. Build and load. Verify the `dmesg` banner shows the KVA and bus address.
7. Unload and reload 50 times; check that `vmstat -m` does not show leaks.

Expected: a driver that stands up and tears down a DMA region cleanly. `dmesg` shows the banner on each load; no panic on unload.

Hint: if the load fails immediately with `EINVAL`, check that `MYFIRST_DMA_BUFFER_SIZE` is both the tag's `maxsize` and the argument to `bus_dmamap_load`; a mismatch is the most common cause.

21.19.3 Lab 3: Stage 2, Simulated DMA Engine with Polling

Goal: extend the driver with the simulated DMA engine and the polling-based transfer helper.

Time: 2 hours.

Steps:

1. Add the `MYFIRST_REG_DMA_*` constants to `myfirst.h`.
2. Extend `struct myfirst_sim` with the DMA engine state.
3. Implement the engine's callout handler and the write hook.
4. Implement `myfirst_dma_do_transfer` (polling version).

5. Add the `dma_test_write` and `dma_test_read` sysctls.
6. Build and load.
7. Run `sudo sysctl dev.myfirst.0.dma_test_write=0xAA` and verify the `dmesg` output.
8. Run the 1000-iteration test from Section 5 and check the counters.

Expected: 1000 successful transfers in each direction; zero errors; zero timeouts.

Hint: if the transfer times out every time, the simulation's callout is probably not scheduling. Check `callout_reset` is called and that `hz / 100` matches your kernel's `hz` (use `sysctl kern.hz` to verify).

21.19.4 Lab 4: Stage 3, Interrupt-Driven Completion

Goal: replace the polling helper with the interrupt-driven helper.

Time: 2 hours.

Steps:

1. Extend the rx filter to handle `MYFIRST_INTR_COMPLETE`.
2. Extend the rx task to call `myfirst_dma_handle_complete`.
3. Add `myfirst_dma_do_transfer_intr` to `myfirst.c`.
4. Enable `MYFIRST_INTR_COMPLETE` in the `INTR_MASK` write.
5. Rewire the sysctl handlers to use the interrupt-driven version.
6. Build and load.
7. Run the 1000-iteration test. Verify `dma_complete_intrs` and `dma_complete_tasks` climb together.
8. Verify no CPU is pegged during the test (`top` or `vmstat` should show low system CPU).

Expected: 1000 interrupts, 1000 tasks, 1000 completions. No CPU pegged.

Hint: if the completion counter increments but the helper hangs in `cv_timedwait` until the 1-second timeout, the task is not calling `cv_broadcast` on `dma_cv`. The wake-up is what unblocks the helper.

21.19.5 Lab 5: Stage 4, Refactor and Regression

Goal: complete the refactor into `myfirst_dma.c` and `myfirst_dma.h`; run the final regression test.

Time: 1.5 hours.

Steps:

1. Create `myfirst_dma.h` with the public API.
2. Create `myfirst_dma.c` with the DMA code moved from `myfirst.c`.
3. Update the Makefile to include `myfirst_dma.c` and bump the version to 1.4-dma.
4. Create `DMA.md` with the subsystem reference.
5. Run `make clean && make` and confirm a clean build.
6. Load the driver, verify the version string.
7. Run the full regression script (`labs/full_regression_ch21.sh`) and confirm it prints PASS.

Expected: clean build, clean load, clean regression pass, clean unload.

Hint: if the link fails with an undefined symbol referring to one of the DMA functions, the SRCS line in the Makefile has not been updated to include `myfirst_dma.c`. Run `make clean` after changing the Makefile to ensure the new source is compiled.

21.20 Challenge Exercises

Challenge exercises that stretch Chapter 21's scope without introducing foundations from later chapters. Pick the ones that interest you; the list is meant to be a menu, not a checklist.

21.20.1 Challenge 1: Multi-Buffer Rotation

Extend the driver to maintain a pool of four DMA buffers instead of one. Each transfer picks the next buffer in rotation. The test program runs four transfers back-to-back without waiting for completions and observes that all four complete before the fifth is submitted.

What it exercises: the allocation and load paths in a loop; per-buffer softc state; the interaction with a single completion vector when multiple transfers are in flight.

21.20.2 Challenge 2: Scatter-Gather Load

Extend the driver to accept a scatter-gather list of up to three segments per transfer. Use `bus_dmamap_load` with a multi-segment callback; store the segment list in the softc; program the simulated engine with three (address, length) pairs.

What it exercises: the non-single-segment callback; the tag's `nsegments` parameter; the engine's ability to handle multiple segments.

21.20.3 Challenge 3: Descriptor Ring Sketch

Extend the driver with a small descriptor ring (eight entries). Each entry is a struct with a bus address, a length, a direction, and a status. The driver fills entries, writes the ring's head doorbell, and the simulated engine walks the ring and updates status.

What it exercises: the full producer-consumer ring pattern; the combined sync flag for bidirectional rings; the head/tail doorbell protocol.

21.20.4 Challenge 4: Partial Transfer Reporting

Modify the simulated engine to occasionally (say, every fifth transfer) report a partial transfer. Modify the driver to detect the partial result, log it, and retry the remainder.

What it exercises: the partial-transfer pattern from Section 7; retry logic; per-transfer state tracking.

21.20.5 Challenge 5: IOMMU Awareness

On a system with the IOMMU active, add sysctls that expose the difference between the driver's bus address and the underlying physical address. Use `pmap_kextract` to get the physical address of the buffer's KVA, and compare it against `sc->dma_bus_addr`.

What it exercises: understanding the IOMMU's transparent remapping; observability of the abstraction.

21.20.6 Challenge 6: Bounce Buffer Observability

Create a tag with `lowaddr = BUS_SPACE_MAXADDR_32BIT` to force 32-bit-only addressing. Allocate buffers above 4 GB (via `contigmalloc` with appropriate flags) and observe that `bus_dmamap_load` triggers bouncing. Expose counters for `total_bounced` from the driver's perspective.

What it exercises: understanding when bouncing happens; observability of the bounce path.

21.20.7 Challenge 7: Tag Template Refactor

Rewrite the Stage 4 setup function to use the `bus_dma_template_*` API instead of `bus_dma_tag_create`. The behaviour should be identical; only the syntax changes.

What it exercises: the modern template API; the equivalence between the two tag-creation styles.

21.20.8 Challenge 8: DTrace-Based Transfer Profiling

Write a DTrace script that measures the latency of DMA transfers from the helper's perspective. Attach to `myfirst_dma_do_transfer_intr` entry and exit; print a histogram of elapsed times; compare against the one-millisecond engine delay.

What it exercises: DTrace FBT probes; DMA timing observability; understanding of the cost breakdown.

21.21 Troubleshooting and Common Mistakes

A reference guide to the most common problems and their fixes. Each entry has the symptom, the likely cause, and the fix.

21.21.1 “bus_dma_tag_create fails with EINVAL”

Symptom: `device_printf` reports `bus_dma_tag_create` failed: 22.

Likely cause: the tag parameters are inconsistent. The alignment must be a power of two; the boundary must be a power of two and at least as large as `maxsegsz`; `maxsize` must be at least `alignment`.

Fix: check the parameters against the `bus_dma(9)` manual page's constraint descriptions. Common mistakes: alignment of 3 (not a power of two); boundary smaller than `maxsegsz`.

21.21.2 “bus_dmamap_load callback runs with error != 0”

Symptom: the single-segment callback’s error argument is non-zero; dma_bus_addr is zero.

Likely cause: the buffer is larger than the tag’s maxsize, or the mapping cannot satisfy the tag’s segment constraints (EFBIG).

Fix: check that the load’s buflen matches the tag’s maxsize; check that the buffer is contiguous if the tag allows only one segment.

21.21.3 “dma_bus_addr is zero after bus_dmamap_load returned zero”

Symptom: the load returns success but the bus address is not populated.

Likely cause: the callback was not called (unlikely, but possible if the kernel’s internal state is inconsistent), or the callback did not write *addr because of an internal error it swallowed.

Fix: check the callback for early returns that do not populate the output. Chapter 21’s pattern is to zero dma_bus_addr before the load and check for zero after.

21.21.4 “Transfers succeed but the buffer contents are wrong”

Symptom: the transfer completes successfully according to the counters, but the data in the buffer is not what the sender sent.

Likely cause: a missing or wrong-flavour bus_dmamap_sync call. On a coherent platform the bug may be invisible; on a non-coherent platform or with bounce buffers active it is visible.

Fix: verify every transfer has exactly one PRE sync and one POST sync matching the transfer direction. PREWRITE/POSTWRITE for host-to-device; PREREAD/POSTREAD for device-to-host.

21.21.5 “bus_dmamap_unload panics with ‘map not loaded’ ”

Symptom: kldunload panics (or prints a WITNESS warning) at bus_dmamap_unload.

Likely cause: the driver’s teardown runs bus_dmamap_unload twice, or runs it when the map was never loaded.

Fix: guard the call with if (sc->dma_bus_addr != 0) and zero the field after unload. Chapter 21’s teardown pattern is correct; verify the driver’s teardown matches.

21.21.6 “bus_dmamem_free panics with ‘no allocation’ ”

Symptom: kldunload panics at bus_dmamem_free.

Likely cause: dma_vaddr is stale (was freed but not zeroed), and the teardown is running again on a second unload path.

Fix: set dma_vaddr = NULL immediately after bus_dmamem_free. Chapter 21’s teardown pattern is correct; verify.

21.21.7 “dma_complete_intrs is zero even though transfers succeed”

Symptom: the transfer helper returns success (via the polling path), but the completion-interrupt counter stays at zero.

Likely cause: MYFIRST_INTR_COMPLETE is not enabled in the INTR_MASK write, or the filter is not checking the bit.

Fix: verify the mask write enables MYFIRST_INTR_COMPLETE; verify the filter has the second if for the complete bit. Stage 3’s changes include both.

21.21.8 “cv_timedwait always returns EWOULDBLOCK”

Symptom: every interrupt-driven transfer times out after one second.

Likely cause: the task never calls cv_broadcast(&sc->dma_cv), or the task is not running because the filter did not enqueue it.

Fix: verify the task calls cv_broadcast(&sc->dma_cv) in myfirst_dma_handle_complete. Verify the filter calls taskqueue_enqueue after detecting the complete bit.

21.21.9 “Driver hangs on kldunload”

Symptom: kldunload myfirst blocks indefinitely.

Likely cause: a transfer is in flight and the helper is waiting on dma_cv; the detach path is waiting for dma_in_flight to clear; but the device is not completing.

Fix: the detach path must call callout_drain before waiting for dma_in_flight. If the callout has not been drained, the simulation can complete the transfer and the detach proceeds. Verify the order: set detaching = true, drain callout, wait for in-flight to clear, tear down.

21.21.10 “WITNESS warns about lock order reversal”

Symptom: dmesg shows a WITNESS warning involving sc->mtx, dma_cv, or the taskqueue lock.

Likely cause: the helper holds sc->mtx while calling cv_timedwait, which is correct; but an assertion may be triggered if a different path also holds a conflicting lock.

Fix: review the lock ordering. The Chapter 11/19/20 discipline: sc->mtx before dma_cv; no taskqueue locks held by the driver; no dma_cv wait while holding an atomic lock. Chapter 21’s patterns are correct; the warning likely indicates a driver-local issue.

21.21.11 “Counters climb but the buffer is not populated”

Symptom: dma_transfers_read counter increases, but sc->dma_vaddr is all zeros after the transfer.

Likely cause: the simulation’s dma_scratch pattern is not being copied into the host buffer, or the POST sync is skipped.

Fix: verify the simulated engine's `myfirst_sim_dma_copy_to_host` is called with the correct length; verify the POST sync runs. If the simulation uses a simplified mapping (bus address == KVA), verify that the host's KVA actually corresponds to the tag's allocated buffer.

21.21.12 “Load-unload cycle leaks memory”

Symptom: after 50 load-unload cycles, `vmstat -m` shows `bus_dmamap` or `bus_dma_tag` with non-zero counts.

Likely cause: a failure path in setup did not destroy the tag or free the memory before returning.

Fix: review every failure return in `myfirst_dma_setup`. Chapter 21's pattern destroys the tag on any post-tag-create failure, frees memory on any post-alloc failure, unloads the map on any post-load failure. Verify each failure path unwinds correctly.

21.21.13 “Transfers are slow compared to expected”

Symptom: the 1000-transfer test takes many seconds instead of milliseconds.

Likely cause: the polling loop's pause is too coarse, or the interrupt path is mis-configured so every transfer hits the 1-second timeout.

Fix: if using the polling helper, reduce the pause interval; if using the interrupt helper, verify the complete bit is reaching the filter (Stage 3's `dma_complete_intrs` should match the transfer count exactly).

21.22 Worked Example: Tracing a DMA Transfer End to End

A detailed walk through a single host-to-device DMA transfer in Chapter 21's Stage 4 driver, annotated at every step with which line of code runs, what the kernel is doing underneath, what WITNESS would check, and what an operator would see in `dmesg` or a counter. The goal is to give the reader a mental picture of the full pipeline as a sequence of concrete events.

21.22.1 The Starting State

The driver has attached. `dma_tag`, `dma_map`, `dma_vaddr`, and `dma_bus_addr` are populated. The interrupt mask has `MYFIRST_INTR_COMPLETE` set. The rx vector's task is initialised. All counters are at zero. A user logs in and types:

```
sudo sysctl dev.myfirst.0.dma_test_write=0xAA
```

21.22.2 Event 1: The sysctl Handler Runs

The sysctl framework calls `myfirst_dma_sysctl_test_write`. The handler parses the value (0xAA), fills `sc->dma_vaddr` with 0xAA bytes, and calls `myfirst_dma_do_transfer_intr(sc, MYFIRST_DMA_DIR_WRITE, MYFIRST_DMA_BUFFER_SIZE)`.

Context: process context, the user's `sysctl` binary's kernel side. No locks held yet. WITNESS has nothing to check.

21.22.3 Event 2: The Helper Takes the Softc Lock

`myfirst_dma_do_transfer_intr` acquires `sc->mtx` via `MYFIRST_LOCK(sc)`. WITNESS checks the lock order: the softc mutex is an `MTX_DEF` lock, no higher-ordered locks are held, the acquisition is valid.

The helper checks `sc->dma_in_flight`. It is false (no transfer is running). The helper proceeds.

21.22.4 Event 3: The PRE Sync

`bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_PREWRITE)` runs. On amd64, this is a memory barrier (`mfence`). On arm64 with `BUS_DMA_COHERENT` honoured, it is a data-memory barrier. On older arm without coherent DMA, it would be a cache flush of the buffer's lines.

The kernel's internal state: the tag's map tracker marks the map as pending PRE. If bounce pages were in use (they are not on Chapter 21's amd64 test), the bounce data would be copied now.

21.22.5 Event 4: The Device Programming

The helper writes four registers in sequence: `DMA_ADDR_LOW`, `DMA_ADDR_HIGH`, `DMA_LEN`, `DMA_DIR`. Each write goes through `bus_write_4`, which dispatches through the Chapter 16 accessor to the simulation's write hook. The simulation records the values in `sim->dma`.

The helper writes `DMA_CTRL = MYFIRST_DMA_CTRL_START`. The write triggers `myfirst_sim_dma_ctrl_written` in the simulation.

21.22.6 Event 5: The Simulation Arms the Callout

Inside the simulation, `myfirst_sim_dma_ctrl_written` sees `MYFIRST_DMA_CTRL_START`, checks that no transfer is already running, sets `status = RUNNING`, sets `armed = true`, and calls `callout_reset(&sim->dma.done_co, hz / 100, myfirst_sim_dma_done_co, sim)`.

The callout is scheduled ten milliseconds in the future. The simulation returns; the helper's `CSR_WRITE_4` returns.

21.22.7 Event 6: The Helper Waits

The helper sets `sc->dma_last_direction = MYFIRST_DMA_DIR_WRITE`, sets `sc->dma_in_flight = true`, and calls `cv_timedwait(&sc->dma_cv, &sc->mtx, hz)`.

`cv_timedwait` releases `sc->mtx`, puts the thread to sleep on `dma_cv`, and schedules a wakeup at `hz` (1 second) in the future. The thread is now off the run queue.

Context: the kernel scheduler is free to run other work. WITNESS tracks that the thread went to sleep while holding no non-sleepable locks; this is correct because the mutex was released.

21.22.8 Event 7: The Callout Fires

Ten milliseconds later, the callout subsystem runs `myfirst_sim_dma_done_co` on a softclock thread. The function extracts the bus address (`((sim->dma.addr_high << 32) | sim->dma.addr_low)`), confirms `len <= scratch_size`, and calls `myfirst_sim_dma_copy_from_host` to copy the 0xAA pattern from the host buffer into the scratch buffer.

The function sets `sim->dma.status = DONE` and calls `myfirst_sim_dma_raise_complete`.

Context: softclock thread. No driver lock held. WITNESS checks that the callout's callback is not acquiring driver locks in a way that conflicts with the `callout_mtx`; the sim's data is protected by per-sim state or atomic updates.

21.22.9 Event 8: The Simulation Raises the Completion Bit

`myfirst_sim_dma_raise_complete` sets `MYFIRST_INTR_COMPLETE` in `sim->intr_status` and, since the bit is enabled in `intr_mask`, calls `myfirst_sim_raise_intr`. The latter queues the simulated interrupt event through the Chapter 19/20 path.

21.22.10 Event 9: The Filter Runs

The kernel's interrupt machinery dispatches the rx vector. The filter (`myfirst_msix_rx_filter`) runs in primary interrupt context. It reads `INTR_STATUS`, sees `MYFIRST_INTR_COMPLETE` set, acknowledges the bit, increments `sc->dma_complete_intrs` via `atomic_add_64`, and enqueues the rx task.

The filter returns `FILTER_HANDLED`. The kernel's interrupt dispatch ends.

Context: primary interrupt context. No sleep, no malloc, no lock above the spinlock level. WITNESS checks that the atomic increment does not imply any lock.

21.22.11 Event 10: The Task Runs

The taskqueue machinery schedules the rx task on its thread. The thread acquires `sc->mtx` via `MYFIRST_LOCK(sc)`. It reads `DATA_OUT` (from the Chapter 19/20 pipeline) and broadcasts `data_cv`. Then it calls `myfirst_dma_handle_complete(sc)`.

21.22.12 Event 11: The POST Sync

`myfirst_dma_handle_complete` sees `sc->dma_in_flight == true`. It clears the flag, checks the direction (`DIR_WRITE`), issues `bus_dmamap_sync(..., BUS_DMASYNC_POSTWRITE)`, reads `DMA_STATUS` (which shows `DONE`), increments `dma_complete_tasks`, and calls `cv_broadcast(&sc->dma_cv)`.

The POST sync on amd64 is a barrier. On arm64 with coherent memory, a barrier. On systems with bounce buffers, the bounce data would be copied back now (for a POSTREAD; POSTWRITE usually just releases the bounce page).

21.22.13 Event 12: The Task Releases the Lock

The task's body completes. It releases `sc->mtx` via `MYFIRST_UNLOCK(sc)`. The task returns.

21.22.14 Event 13: The Helper Wakes

`cv_broadcast(&sc->dma_cv)` in Event 11 scheduled the helper's thread back to the run queue. The helper wakes inside `cv_timedwait`, re-acquires `sc->mtx`, and returns from the wait with `err = 0` (not `EWOULD-BLOCK`).

21.22.15 Event 14: The Helper Examines the Status

The helper reads `sc->dma_last_status`. It is `DONE` with `ERR = 0`. The helper increments `dma_transfers_write` via `atomic_add_64`. It releases `sc->mtx` and returns 0.

21.22.16 Event 15: The Sysctl Handler Returns

`myfirst_dma_sysctl_test_write` sees the successful return, prints a banner (`dma_test_write: pattern 0xaa transferred`), and returns 0 to the sysctl framework.

21.22.17 Event 16: The User Sees the Result

The user's sysctl command returns. A subsequent `dmesg | tail` shows the banner. The counters now show:

```
dma_transfers_write: 1
dma_complete_intrs: 1
dma_complete_tasks: 1
```

21.22.18 The Total Time

The critical path's wall-clock time is roughly: 10 ms for the callout delay, plus a few microseconds for the filter dispatch, plus a few microseconds for the task, plus the context-switch latency for the helper's wakeup. Total: about 10-11 ms.

If the helper had used the Stage 2 polling path instead, the wall-clock would be similar (the callout delay dominates), but the helper would hold a CPU busy polling for the entire ten milliseconds. The interrupt-driven version frees the CPU to do other work.

21.22.19 The Lesson

Sixteen events across five contexts: process (helper), softclock (callout), primary interrupt (filter), taskqueue thread (task), process (helper wake). Each context has its own lock discipline; the transitions between contexts

happen via the kernel's scheduling and interrupt machinery, not through driver code. The driver's code lives inside each context; the kernel moves the execution between them.

A reader who can trace this sequence from beginning to end understands Chapter 21. A reader who cannot can re-read Sections 5 and 6 with the sequence in mind; the individual steps become concrete when mapped to the narrative.

21.23 A Deeper Look at Locking and DMA

Chapter 11 and Chapter 19 established the driver's lock discipline. Chapter 21 applies it to the DMA path, which introduces a few specifics worth calling out.

21.23.1 The Softc Mutex Covers the DMA State

The softc mutex (`sc->mtx`) protects every DMA field that is read or written outside of attach/detach: `dma_in_flight`, `dma_last_direction`, `dma_last_status`, the per-transfer counters. Every code path that touches these fields acquires `sc->mtx` first.

The counters are updated with `atomic_add_64` so the filter (which cannot acquire a sleep mutex) can increment them without taking the lock. The same counters are read with `atomic_load_64` (implicitly via the `sysctl` handler's copy) when the reader wants a consistent snapshot. Using atomics instead of the mutex for counters is the Chapter 11 pattern; it is faster and filter-safe.

The condition variable `dma_cv` is waited on and broadcast under `sc->mtx`. This is standard `cv_*` discipline.

21.23.2 The Tag's Lockfunc

The `lockfunc` parameter of `bus_dma_tag_create` is for deferred loads. Chapter 21 passes `NULL`, which substitutes `_busdma_dflt_lock`, which panics if called. The panic is the safety net: it tells the developer that a deferred load happened (which Chapter 21's `BUS_DMA_NOWAIT` usage should prevent), at which point the developer would add a proper `lockfunc`.

For drivers that do use deferred loads, the common pattern is:

```
err = bus_dma_tag_create(parent, align, bdry, lowaddr, highaddr,
    NULL, NULL, maxsize, nseg, maxsegsz, 0,
    busdma_lock_mutex, &sc->mtx, &sc->tag);
```

`busdma_lock_mutex` is a kernel-provided implementation that acquires and releases the mutex passed as the last argument. The kernel calls it before and after the deferred callback.

21.23.3 No Locks in the Sync Path

`bus_dmamap_sync` does not internally acquire any driver lock. It is safe to call from filter, task, or process context, as long as the caller has the appropriate concurrency discipline for the map. Chapter 21 calls `sync` from the helper (with `sc->mtx` held) and from the task (with `sc->mtx` held, inside `myfirst_dma_handle_complete`). Both are safe because no thread outside the lock scope can concurrently sync the same map.

21.23.4 The Detach Race

The detach path's race is between “transfer is completing” and “driver is being unloaded”. Chapter 21's pattern uses the detaching flag plus the `dma_in_flight` wait to ensure the detach cannot tear down resources while a transfer is in progress. The `callout_drain` and `taskqueue_drain` ensure no callback is pending.

This pattern is the Chapter 11 detach discipline generalised to one more kind of in-flight work (DMA transfers). The pattern composes: interrupts were drained in Chapter 19, per-vector tasks in Chapter 20, DMA transfers in Chapter 21. Chapter 22 will add one more (power-transition callbacks).

21.24 A Deeper Look at Observability for DMA Drivers

Chapter 21's driver exposes several observability hooks. This deeper look covers what each one provides and how an operator would use them.

21.24.1 The Per-Transfer Counters

```
dev.myfirst.N.dma_transfers_write  
dev.myfirst.N.dma_transfers_read  
dev.myfirst.N.dma_errors  
dev.myfirst.N.dma_timeouts  
dev.myfirst.N.dma_complete_intrs  
dev.myfirst.N.dma_complete_tasks
```

Six counters, each a 64-bit atomic. The invariants:

- `dma_complete_intrs == dma_complete_tasks`: every filter-observed completion produced a task invocation.
- `dma_complete_intrs == dma_transfers_write + dma_transfers_read + dma_errors + dma_timeouts`: every completion interrupt eventually produced a transfer outcome.

Violations of either invariant indicate a bug. The regression test checks both.

21.24.2 The Ring Buffer of Recent Transfers

A challenge exercise would add a small circular buffer of recent transfers, each recording the direction, length, result, and time. A read-only `sysctl` exposes the last `N` transfers as a kernel-formatted string. This is useful for post-mortem debugging (when the driver has hung, the ring buffer shows what was happening just before).

21.24.3 DTrace Probes

The driver has no explicit DTrace probes, but FBT (function boundary tracing) works automatically. Useful one-liners:

```
# Count DMA transfer calls
dtrace -n 'fbt::myfirst_dma_do_transfer_intr:entry { @[probecount] = count(); }'

# Histogram of transfer durations
dtrace -n 'fbt::myfirst_dma_do_transfer_intr:entry { self->start = vtimestamp; }
↳ fbt::myfirst_dma_do_transfer_intr:return /self->start/ { @[probecount] =
↳ quantize(vtimestamp - self->start); self->start = 0; }'

# Interrupt rate per vector
dtrace -n 'fbt::myfirst_msix_rx_filter:entry { @ = count(); } tick-1s { printa(@);
↳ clear(@); }'
```

DTrace is the best tool for understanding driver behaviour under load. The probes run with low overhead (tens of nanoseconds per hit on amd64) and can be enabled on a production system.

21.24.4 vmstat -i and systat -vmstat

`vmstat -i` shows the interrupt count per vector. For Chapter 21's driver with MSI-X, three vectors appear with their `bus_describe_intr` labels (admin, rx, tx). The rx line's count should equal `dma_complete_intrs` plus `data_av_count` (the combined activity on that vector).

`systat -vmstat` provides a live view. Running it in a second terminal while the test runs shows the vector's rate changing in real time.

21.24.5 procstat -kke

`procstat -kke` shows the kernel stack of every thread. The rx task's thread, when running the DMA handler, has a stack containing `myfirst_dma_handle_complete` and `bus_dmamap_sync`. Observing the stack confirms the thread is in the expected place; an unexpected stack suggests a hang or deadlock.

21.24.6 sysctl hw.busdma

The `hw.busdma` `sysctl` tree exposes DMA-subsystem-wide counters:

```
hw.busdma.total_bpages
hw.busdma.free_bpages
hw.busdma.reserved_bpages
hw.busdma.active_bpages
hw.busdma.total_bounced
hw.busdma.total_deferred
```

`total_bounced` is the most useful for Chapter 21 purposes: on a system where no driver should be bouncing, this stays at zero. A climbing value indicates some driver's tag constraints are forcing bouncing; this is usually a configuration issue.

21.25 A Deeper Look at Performance of DMA Transfers

Chapter 21's simulation runs every transfer in about ten milliseconds (the callout delay). Real hardware is much faster. This deeper look covers what the measurements tell us and what they do not.

21.25.1 The Latency Budget

A modern PCIe 3.0 device's DMA latency is dominated by:

1. **The PCIe posted-write latency.** The device writes to the CPU's memory controller via a posted write, which takes a few hundred nanoseconds round-trip.
2. **The cache flush/invalidate overhead.** On coherent systems this is tens of nanoseconds via snooping; on non-coherent systems it is microseconds.
3. **The interrupt delivery latency.** MSI-X delivery to a CPU takes microseconds including the ithread wakeup.
4. **The task dispatch latency.** The rx task's wakeup and dispatch takes microseconds.

Total: a DMA transfer of a 4 KB buffer on a modern amd64 system takes about 5-10 microseconds from kick to completion, for a sustained throughput of several gigabytes per second.

21.25.2 The Throughput Ceiling

With a 4 KB buffer and 10 microseconds per transfer, the throughput is 400 MB/s. To reach the link's 3.5 GB/s, the driver has to batch: multiple transfers in flight simultaneously. A descriptor ring with N entries can have N transfers in flight, and if each takes 10 microseconds but the driver issues one per microsecond, the aggregate throughput is 4 GB/s.

Chapter 21's single-buffer driver cannot batch; it issues one transfer at a time. The descriptor-ring extension (challenge exercise) can. Part 6's network driver (Chapter 28) uses this pattern in full.

21.25.3 Measuring the Chapter's Driver

A simple timing test:

```
struct timespec start, end;
nanouptime(&start);
for (int i = 0; i < 1000; i++) {
    myfirst_dma_do_transfer_intr(sc, DIR_WRITE, 4096);
}
nanouptime(&end);
elapsed = timespec_sub(end, start);
```

With the simulation's ten-millisecond callout, 1000 transfers should take about 10 seconds total, for a throughput of 400 KB/s. Small, because the simulation is designed to be observably asynchronous rather than fast. Real hardware would be orders of magnitude faster.

21.25.4 What the Measurement Tells Us

The measurement confirms the pipeline is end-to-end functional. The absolute number is not interesting (it is a simulation, not real hardware). What matters is that 1000 transfers complete without error, without timeout, without the helper hanging, and without the counters diverging from their invariants. That is the regression criterion for Chapter 21.

On a real DMA-capable device, replacing the simulation backend with the real hardware driver would swap the 10 ms callout delay for the hardware's actual latency. The Chapter 21 code is otherwise unchanged; this is the portability payoff of building against `bus_dma`.

21.26 Additional Troubleshooting: Ten More Failure Patterns

Ten more common problems that surface in Chapter 21-style DMA drivers, each with diagnosis and fix.

21.26.1 “Kernel panics on first transfer with ‘null pointer dereference’ ”

The likely cause is that `sc->dma_tag` or `sc->dma_map` is NULL because the setup failed silently. The Stage 1 setup's error paths must propagate failure up so `attach` fails cleanly; if they do not, `attach` appears to succeed but the transfer path hits the NULL pointer.

The fix: review every return path in `myfirst_dma_setup`. Each post-allocation failure must free the preceding allocations and set the `softc` fields to NULL.

21.26.2 “First transfer works, subsequent transfers hang”

Likely cause: `dma_in_flight` is not being cleared on the first transfer's completion. The task's `dma_handle_complete` must clear it; the helper's timeout path must also clear it.

The fix: verify `dma_in_flight = false` is set in both `dma_handle_complete` and the helper's `EWOLDBLOCK` branch.

21.26.3 “Transfers succeed but `dma_complete_intrs` is zero”

Likely cause: the polling helper is in use, not the interrupt helper. The polling path does not increment `dma_complete_intrs`.

The fix: verify the `sysctl` handler calls `myfirst_dma_do_transfer_intr`, not the Stage 2 polling version. The Stage 3 refactor should have replaced the callers.

21.26.4 “Buffer contents are correct but verification fails”

Likely cause: a stride mismatch between what the simulator wrote and what the driver expected. The driver expects 0x5A bytes; the simulator writes 0x5A; but the driver checks a different offset.

The fix: verify the sim's `memset` matches the driver's verification. This is almost always a test-code bug rather than a DMA bug.

21.26.5 “dma_errors counter climbs but the driver does not propagate the error”

Likely cause: the helper increments the counter but returns 0 instead of EIO.

The fix: verify the error branch returns EIO and the sysctl handler propagates the error to the caller.

21.26.6 “taskqueue_drain hangs on kldunload”

Likely cause: a task is pending, but something keeps re-enqueueing it. Most commonly, the filter is still running because the interrupt mask was not set to zero.

The fix: mask the interrupt before draining the taskqueue. The detach order matters: mask, drain callout, drain task, unload map.

21.26.7 “bus_dmamem_alloc returns a buffer above 4 GB despite lowaddr = MAXADDR_32BIT”

Likely cause: the tag’s highaddr is BUS_SPACE_MAXADDR_32BIT instead of BUS_SPACE_MAXADDR. The meaning of lowaddr is “the lowest address in the excluded window”; highaddr is “the highest address in the excluded window”. To exclude addresses above 4 GB, set lowaddr = BUS_SPACE_MAXADDR_32BIT and highaddr = BUS_SPACE_MAXADDR.

The fix: swap the addresses. The idiom is: lowaddr is “the last address the device can reach”; highaddr is usually BUS_SPACE_MAXADDR.

21.26.8 “Test script runs fine once, fails after module reload”

Likely cause: the module’s module-level state is not being reset on reload. A static variable in myfirst_sim.c that holds the sim state across loads would cause this.

The fix: verify every module-level variable is initialised at module_init time and cleared at module_fini. Chapter 17’s simulation backend should be doing this correctly.

21.26.9 “WITNESS warns about ‘DMA map used while not loaded’ or similar”

Likely cause: the sync call runs after the map has been unloaded, or before it has been loaded. The order of operations must be: load, sync, unload.

The fix: review the teardown path; the unload must come after the last sync and before the tag destroy.

21.26.10 “Transfers work on my amd64 test VM but fail on the arm64 build server”

Likely cause: platform-dependent coherence behaviour. The driver may be skipping a sync call that is a no-op on amd64 but required on arm64.

The fix: verify every transfer has both PRE and POST syncs; re-run the test with INVARIANTS on arm64 and inspect any panic.

21.27 Reference: The Complete Stage 4 `myfirst_dma.c` Walkthrough

A section-by-section tour of the refactored `myfirst_dma.c` file. The file is about 250 lines; this walkthrough explains each function's shape.

21.27.1 The Includes and Macros

```
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/kernel.h>
#include <sys/bus.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/condvar.h>
#include <sys/sysctl.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include "myfirst.h"
#include "myfirst_hw.h"
#include "myfirst_dma.h"
```

Standard set. `<sys/bus_dma.h>` is included transitively through `<machine/bus.h>`; no need to include it explicitly.

21.27.2 The Single-Segment Callback

Covered in Section 3. Ten lines.

21.27.3 The Setup Function

Covered in Section 3. About 50 lines with extensive error handling.

21.27.4 The Teardown Function

Covered in Section 3. About 15 lines.

21.27.5 The Polling Transfer Helper

Covered in Section 5. About 60 lines. Kept in Stage 4 as a fallback or a debug path; the `sysctl` handlers can be pointed at it for comparative testing.

21.27.6 The Interrupt-Driven Transfer Helper

Covered in Section 6. About 70 lines.

21.27.7 The Completion Handler

Covered in Section 8. About 20 lines.

21.27.8 The Sysctl Registration

```
void
myfirst_dma_add_sysctls(struct myfirst_softc *sc)
{
    struct sysctl_ctx_list *ctx = &sc->sysctl_ctx;
    struct sysctl_oid_list *kids = SYSCTL_CHILDREN(sc->sysctl_tree);

    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_transfers_write",
        CTLFLAG_RD, &sc->dma_transfers_write, 0,
        "Successful host-to-device DMA transfers");
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_transfers_read",
        CTLFLAG_RD, &sc->dma_transfers_read, 0,
        "Successful device-to-host DMA transfers");
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_errors",
        CTLFLAG_RD, &sc->dma_errors, 0,
        "DMA transfers that returned EIO");
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_timeouts",
        CTLFLAG_RD, &sc->dma_timeouts, 0,
        "DMA transfers that timed out");
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_complete_intrs",
        CTLFLAG_RD, &sc->dma_complete_intrs, 0,
        "DMA completion interrupts observed");
    SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "dma_complete_tasks",
        CTLFLAG_RD, &sc->dma_complete_tasks, 0,
        "DMA completion task invocations");
    SYSCTL_ADD_UQUAD(ctx, kids, OID_AUTO, "dma_bus_addr",
        CTLFLAG_RD, &sc->dma_bus_addr,
        "Bus address of the DMA buffer");

    SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "dma_test_write",
        CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE, sc, 0,
        myfirst_dma_sysctl_test_write, "IU",
        "Trigger a host-to-device DMA transfer");
    SYSCTL_ADD_PROC(ctx, kids, OID_AUTO, "dma_test_read",
```

```

        CTLTYPE_UINT | CTLFLAG_WR | CTLFLAG_MPSAFE, sc, 0,
        myfirst_dma_sysctl_test_read, "IU",
        "Trigger a device-to-host DMA transfer");
}

```

Seven read-only counters, one UQUAD bus address (for operator visibility), two write-only test sysctls.

21.27.9 The Sysctl Handlers

```

static int
myfirst_dma_sysctl_test_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int pattern;
    int err;

    err = sysctl_handle_int(oidp, &pattern, 0, req);
    if (err != 0 || req->newptr == NULL)
        return (err);

    memset(sc->dma_vaddr, (int)(pattern & 0xFF),
           MYFIRST_DMA_BUFFER_SIZE);
    err = myfirst_dma_do_transfer_intr(sc, MYFIRST_DMA_DIR_WRITE,
                                       MYFIRST_DMA_BUFFER_SIZE);
    if (err != 0)
        device_printf(sc->dev,
                      "dma_test_write: err %d\n", err);
    else
        device_printf(sc->dev,
                      "dma_test_write: pattern 0x%02x transferred\n",
                      pattern & 0xFF);
    return (err);
}

static int
myfirst_dma_sysctl_test_read(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int ignore;
    int err;
    uint8_t *bytes;

    err = sysctl_handle_int(oidp, &ignore, 0, req);

```

```

if (err != 0 || req->newptr == NULL)
    return (err);

err = myfirst_dma_do_transfer_intr(sc, MYFIRST_DMA_DIR_READ,
    MYFIRST_DMA_BUFFER_SIZE);
if (err != 0) {
    device_printf(sc->dev, "dma_test_read: err %d\n", err);
    return (err);
}

bytes = (uint8_t *)sc->dma_vaddr;
device_printf(sc->dev,
    "dma_test_read: first bytes %02x %02x %02x %02x "
    "%02x %02x %02x %02x\n",
    bytes[0], bytes[1], bytes[2], bytes[3],
    bytes[4], bytes[5], bytes[6], bytes[7]);
return (0);
}

```

The write handler fills the buffer and triggers host-to-device. The read handler triggers device-to-host and logs the first eight bytes. Both are small; both make the DMA subsystem user-accessible without requiring a custom ioctl.

21.27.10 Lines of Code

The full `myfirst_dma.c` file is about 280 lines. For comparison, Chapter 20's `myfirst_msix.c` was 330 lines; Chapter 19's `myfirst_intr.c` was 250 lines. Chapter 21's file is in the middle of that range, which matches the complexity: DMA setup is more intricate than single-vector interrupt setup, but less than multi-vector routing.

Taken together with the 330-line `myfirst_msix.c` and the 250-line `myfirst_intr.c`, the three Chapter 19-21 files account for about 860 lines. A reader who has written and understood them has written three production-grade driver subsystems in miniature.

21.28 Reference: FreeBSD Manual Pages for Chapter 21

The manual pages Chapter 21 has drawn on directly. Each is worth a read after the chapter's material has settled.

- `bus_dma(9)`: the central reference for the bus-DMA API.
- `bus_space(9)`: the accessor layer the driver builds on (Chapter 16).
- `contigmalloc(9)`: the contiguous allocator used by `bus_dma` underneath.
- `busdma(9)` cross-references, including the `bus_dma_tag_template(9)` entry.
- `callout(9)`: the timer subsystem the simulation's engine uses.
- `condvar(9)`: the `cv_*` discipline the helper uses.

- `device(9)`: the general device framework.

The manual pages are maintained with the kernel and track changes to the API. Reading them once per major release (or after a significant change in the book's coverage) is a useful habit.

21.29 A Deeper Look at How DMA and Interrupts Fit Together

Chapters 19, 20, and 21 have built three interlocking pieces: interrupts, multiple vectors, DMA. This deeper look explains how they fit together in a complete high-performance driver, so the reader has a mental model of the whole before Chapter 22's power-management discipline arrives.

21.29.1 The Three-Piece Architecture

A modern DMA-capable driver has three cooperating subsystems:

1. **The DMA subsystem** (Chapter 21) owns the data path. It sets up buffers, programs the device, synchronises caches, and handles the transfer's data. Any time the driver moves data of non-trivial size, DMA is involved.
2. **The interrupt subsystem** (Chapters 19 and 20) owns the signalling path. The device signals events (data arrival, transfer completion, errors) via interrupts. The filter handles the signal in primary interrupt context; the task handles the follow-up in thread context.
3. **The coordination layer** (the `softc` and its mutex plus condition variables) owns the state between the two. The DMA subsystem writes `dma_in_flight` before triggering a transfer; the interrupt subsystem reads it during completion processing. The condition variable lets the DMA subsystem wait for the interrupt subsystem to signal completion.

The three pieces are designed to compose. A driver can have many DMA operations in flight, each signalling its completion through its own interrupt vector; the per-vector machinery from Chapter 20 handles this naturally, and the per-transfer state from Chapter 21 plugs into the per-vector tasks.

21.29.2 The Common Flow

For every DMA transfer in a production driver, the flow is:

1. Driver code wants to transfer data.
2. Driver locks the `softc`, sets up the per-transfer state.
3. Driver issues the PRE sync on the map.
4. Driver programs the device's registers with the bus address, length, direction, and flags.
5. Driver writes the doorbell.
6. Driver releases the lock (or sleeps on a condition variable under the lock).
7. Kernel does other work.
8. Device completes the transfer and raises its interrupt.
9. Filter runs, acknowledges, enqueues a task.
10. Task runs, acquires the `softc` lock, processes the completion: POST sync, status read, result recording.

11. Task broadcasts the condition variable and releases the lock.
12. Driver code (or its waiter) wakes up, reads the result, and proceeds.

The flow is the same for a simple single-buffer driver and for a multi-queue network driver with thousands of transfers in flight. The difference is scale: the network driver has many concurrent transfers, each with its own per-transfer state, but each one follows the same twelve-step flow.

21.29.3 The Scale Story

On Chapter 21's single-buffer simulation, the flow runs once per ten milliseconds. On a modern NIC, the flow runs millions of times per second across many queues. The machinery scales because:

- Interrupts are per-queue via MSI-X (Chapter 20).
- DMA buffers are per-queue via descriptor rings (a future chapter).
- The filter is short and filter-safe (Chapter 19).
- The task is per-queue and CPU-bound to a NUMA-local core (Chapter 20).
- The softc state is partitioned per-queue to avoid contention.

The cumulative design decisions Parts 4 and 5 teach are what make this scaling possible. A driver that respects the discipline scales naturally; a driver that violates it (a global lock instead of per-queue locks, a shared DMA map instead of per-transfer maps) hits scaling limits early.

21.29.4 The Interaction Patterns

Three specific interaction patterns worth recognising:

Pattern A: Interrupt delivers “new data is in the DMA ring”. The filter reads a completion index register, acknowledges, enqueues the task. The task walks the ring from the last index to the current, processes each entry, and updates its per-queue state. This is how a NIC's receive path works.

Pattern B: Interrupt delivers “DMA transfer N is complete”. The filter looks up transfer N in a per-transfer state array, enqueues the task. The task looks at transfer N's recorded state, performs the POST sync, and calls the completion callback. This is how a storage controller's command-completion path works.

Pattern C: Interrupt delivers “error occurred on DMA engine”. The filter may need more care here because errors often require device-level reset, which cannot happen in filter context. The filter enqueues a task with an error-specific payload; the task quiesces the engine, logs the error, and decides whether to reset.

Chapter 21's driver exercises a simplified Pattern B. Real drivers exercise all three, sometimes on separate vectors.

21.30 A Deeper Look at Comparisons with Other Kernel DMA APIs

For readers who come from other kernel contexts, a brief comparison between FreeBSD's `bus_dma(9)` and the equivalent APIs elsewhere. Not exhaustive; just enough to orient a reader who needs to translate between mental models.

21.30.1 Linux's DMA API

Linux uses `dma_alloc_coherent` / `dma_map_single` / `dma_sync_single_for_cpu` / `dma_sync_single_for_device` / `dma_unmap_single` for what FreeBSD calls `bus_dmamem_alloc` / `bus_dmamap_load` / `bus_dmamap_sync` (POST) / `bus_dmamap_sync` (PRE) / `bus_dmamap_unload`.

The semantic model is nearly identical:

- `dma_alloc_coherent` returns a CPU-visible virtual address and a DMA-visible bus address for a coherent buffer; `bus_dmamem_alloc` plus `bus_dmamap_load` does the same in two steps.
- `dma_map_single` maps an arbitrary buffer to a bus address, similar to `bus_dmamap_load` with a single-segment callback.
- `dma_sync_single_for_cpu` corresponds to `bus_dmamap_sync(..., POSTREAD)`; `for_device` corresponds to `PREWRITE` or `PREREAD`.
- `dma_unmap_single` is the Linux version of `bus_dmamap_unload`.

The FreeBSD API's distinctive features are the tag (an explicit constraint descriptor; Linux's approach is more implicit), the callback (for deferred loads; Linux uses DMA fence APIs instead), and the hierarchical tag inheritance (which Linux does not formalise the same way).

For Linux driver code being ported to FreeBSD, the rough translation is:

- Define a `bus_dma_tag_t` tag with the device's constraints.
- Replace `dma_alloc_coherent` with `bus_dma_tag_create` (once) plus `bus_dmamem_alloc` plus `bus_dmamap_load`.
- Replace `dma_map_single` per-transfer with `bus_dmamap_create` plus `bus_dmamap_load` (for dynamic maps).
- Replace every `dma_sync_*_for_cpu` with `bus_dmamap_sync(..., POSTREAD)` or `POSTWRITE`.
- Replace every `dma_sync_*_for_device` with `bus_dmamap_sync(..., PREREAD)` or `PREWRITE`.
- Replace `dma_unmap_single` with `bus_dmamap_unload`.

The DRM-kmod ports of Linux GPU drivers to FreeBSD use this translation extensively; a driver ported from Linux to FreeBSD typically gains explicit tag setup and explicit PRE/POST pairs where Linux had implicit ones.

21.30.2 NetBSD's `bus_dma`

NetBSD has the original `bus_dma` API that FreeBSD's is derived from. The function names are almost identical; the semantics are almost identical. The differences are mostly in peripheral APIs (template support, IOMMU integration, platform-specific extensions).

A driver written for NetBSD's `bus_dma` generally compiles on FreeBSD with minor adjustments. The portability is not accidental; it is the API's design goal.

21.30.3 Windows's DMA Abstractions

Windows uses a different abstraction (`AllocateCommonBuffer`, `IoMapTransfer`, `FlushAdapterBuffers`) with different semantics. Translating a Windows driver to FreeBSD is a more involved task because the Windows model does not have FreeBSD's tag concept and its synchronisation is less explicit.

A reader who works in both ecosystems benefits from understanding that the underlying hardware realities are the same everywhere; only the API surface differs. The `bus_dma` discipline from Chapter 21 transfers, albeit with a translation layer, to every kernel environment.

21.31 Reference: A Short Tour of `/usr/src/sys/kern/subr_bus_dma.c`

The kernel's implementation of the `bus_dma` API lives under `/usr/src/sys/kern/subr_bus_dma.c` and the architecture-specific `busdma_*.c` files. A short tour of the central file gives the curious reader a sense of where the machinery actually runs.

The file contains generic helpers that the architecture-specific backends call. The key entry points:

- `bus_dmamap_load_uio`: load a struct `uio` (user I/O).
- `bus_dmamap_load_mbuf_sg`: load an mbuf chain with a pre-allocated segment array.
- `bus_dmamap_load_ccb`: load a CAM control block.
- `bus_dmamap_load_bio`: load a struct `bio`.
- `bus_dmamap_load_crp`: load a crypto operation.

Each of these is a thin wrapper around the platform's `bus_dmamap_load_ma` (load array-of-mappings) or `bus_dmamap_load_phys` (load physical address), which are the architecture-specific primitives.

The file also contains the template API (`bus_dma_template_*`) and its helpers. The template code is about 200 lines and straightforward to read.

The generic file does not contain the per-architecture sync or bounce logic; that lives in `/usr/src/sys/x86/x86/busdma_bounce.c` for amd64 and i386, or in the equivalent platform directory. A reader who wants to understand what `bus_dmamap_sync` actually does on amd64 can read `busdma_bounce.c`'s `bounce_bus_dmamap_sync` function; it is about 100 lines and shows the bounce-copy logic plus the memory barriers.

21.32 Reference: Driver Memorable Phrases

A short list of the phrases worth memorising because they compress the chapter's discipline into a few words.

- “Tag describes, map is specific, sync signals ownership, unload reverses load.”
- “Every PRE has a POST; every setup has a teardown.”
- “`BUS_DMA_COHERENT` makes sync cheap, not unnecessary.”
- “The bus address is not always the physical address.”
- “`BUS_SPACE_MAXADDR_32BIT` is `lowaddr` for 32-bit devices; `highaddr` stays `BUS_SPACE_MAXADDR`.”
- “The callback may run later; use `BUS_DMA_NOWAIT` to avoid that case.”
- “The tag lockfunc is for deferred loads; `NULL` panics if deferred, which is the safer default.”
- “Single-segment callbacks look the same in every driver; the pattern is universal.”
- “Drain callouts before unloading maps; drain tasks before destroying tags.”

21.33 Reference: A Comparison Table Across Part 4

A table that summarises what each Part 4 chapter added, how the driver's version tag changed, and what new resource type the driver gained access to.

Chapter	Version	Added Subsystem	New Resource Types
16	0.9-mmio	Register access via <code>bus_space</code>	<code>bus_space_tag_t</code> , <code>bus_space_handle_t</code>
17	1.0-sim	Simulated hardware backend	sim backend, simulated register map
18	1.1-pci	Real PCI attach	BAR resource, PCI config access
19	1.2-intr	Legacy interrupt handling	IRQ resource, filter, task
20	1.3-msi	MSI/MSI-X multi-vector	per-vector IRQ resources, per-vector tasks
21	1.4-dma	DMA with <code>bus_dma(9)</code>	DMA tag, DMA map, DMA memory, bus address

Each chapter adds exactly one subsystem; the driver's complexity grows monotonically with its capability. A reader tracing the version history can see at a glance what the driver can do at any stage.

Part 4 closes with Chapter 22's power-management work, which does not add a new subsystem but adds discipline across all existing ones: every subsystem must be quiescable and resumable.

21.34 Reference: What the Reader Should Now Be Able to Do

A one-page self-check. After finishing Chapter 21 and completing the labs, the reader should be able to:

1. Open a random DMA-capable driver in `/usr/src/sys/dev/` and identify its tag creation, memory allocation, map loading, sync pattern, and teardown.
2. Explain why a driver calls `bus_dmamap_sync` with a PRE flag before triggering the device and a POST flag after the device completes.
3. Write a tag-creation call for a hypothetical device with documented constraints (alignment, size, addressing range).
4. Write a single-segment callback and use it to extract the bus address from a `bus_dmamap_load` call.
5. Recognise when a driver is using the static pattern versus the dynamic pattern.
6. Identify and explain the three portability realities `bus_dma(9)` hides: addressing limits, IOMMU remapping, cache coherence.
7. Debug a transfer that succeeds in terms of counters but produces corrupt data, by checking for missing or wrong-flavour syncs.
8. Construct a clean detach path that drains callouts, drains tasks, masks interrupts, unloads maps, frees memory, and destroys tags in the right order.
9. Distinguish between `BUS_DMA_COHERENT` at tag-create time (architectural hint) and at `bus_dmamem_alloc` time (allocation mode).
10. Explain why `BUS_DMA_NOWAIT` is the safer default for most drivers and when `BUS_DMA_WAITOK` is appropriate.

11. Write a correct single-buffer DMA driver from scratch, given a datasheet that specifies the register layout and the engine's behaviour.
12. Explain why the `bus_dma(9)` layer exists and what happens when a driver bypasses it.

A reader who checks off ten or more of these has internalised the chapter. The remaining items come with practice on real drivers.

21.35 Reference: When to Reach for Each API Variant

The `bus_dma(9)` API has several load variants; a quick reference to help readers choose correctly in future work:

- **`bus_dmamap_load`**: a generic kernel buffer at a known KVA and length. The simplest and most common call. Used by Chapter 21.
- **`bus_dmamap_load_mbuf_sg`**: an mbuf chain, common in network drivers. The `_sg` variant fills a pre-allocated segment array and avoids the callback.
- **`bus_dmamap_load_ccb`**: a CAM control block, used by storage drivers.
- **`bus_dmamap_load_uio`**: a struct `uio`, used when mapping user-supplied buffers.
- **`bus_dmamap_load_bio`**: a block I/O request, used in GEOM consumers.
- **`bus_dmamap_load_crp`**: a crypto operation, used by OpenCrypto transforms.

The chapter uses only the first. The reader who moves to networking, storage, or crypto later will see the specialised variants; each is a thin wrapper around the same underlying mechanism, with a helper that unpacks the subsystem's preferred buffer representation into segments.

For dynamic transactions where the driver maintains its own pool of maps, `bus_dmamap_create` and `bus_dmamap_destroy` complement the load calls. Chapter 21's static pattern does not use these; the dynamic pattern in Part 6's network chapter (Chapter 28) does.

A subtle point worth remembering: `bus_dmamem_alloc` both allocates memory and creates an implicit map. The map does not need `bus_dmamap_create` or `bus_dmamap_destroy`. The driver still calls `bus_dmamap_load` once to obtain the bus address (via the callback), and `bus_dmamap_unload` once at tear-down; but the map itself is managed by the allocator, not by the driver. A driver that calls `bus_dmamap_destroy` on an allocator-returned map triggers a panic. Keep the two lifecycles distinct.

21.36 Wrapping Up

Chapter 21 gave the driver the ability to move data. At the start, `myfirst` at version 1.3-`msi` could listen to its device through multiple interrupt vectors but touched every byte through `bus_read_4`. At the end, `myfirst` at version 1.4-`dma` has a `bus_dma(9)` setup and teardown path, a simulated DMA engine with a callout-driven completion, an interrupt-driven transfer helper that sleeps on a condition variable while the device works, a full PRE/POST sync discipline on every transfer, per-transfer counters for observability, a refactored `myfirst_dma.c` file, a `DMA.md` document, and a regression test that exercises every code path the chapter teaches.

The eight sections walked the full progression. Section 1 established the hardware picture: what DMA is, why it matters, what the real-world examples look like. Section 2 pinned down the `bus_dma(9)` vocabulary: tag, map,

memory, segment, PRE, POST, static, dynamic, parent, callback. Section 3 wrote the first running code: tag creation, memory allocation, map load, clean teardown. Section 4 laid down the sync discipline: the ownership model, the four flags, the four common patterns. Section 5 built the simulated DMA engine with register map, state machine, callout, and a polling-based driver helper. Section 6 rewrote the completion path to use the Chapter 20 per-vector interrupt machinery. Section 7 walked through twelve failure modes and the patterns that handle each. Section 8 refactored the code into `myfirst_dma.c`, updated the Makefile, bumped the version, added documentation, and closed the chapter's scope.

What Chapter 21 did not do is scatter-gather, descriptor rings, iflib integration, or user-space buffer mapping. Each of those is a natural extension built on Chapter 21's primitives, and each belongs in a later chapter (Part 6 for networking specifics, Part 7 for performance tuning). The foundation is in place; the specialisations add vocabulary without needing to rebuild the foundation.

The file layout has grown: 15 source files (including `cbuf`), 7 documentation files (`HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, `DMA.md`), and an extended regression suite. The driver is structurally parallel to production FreeBSD drivers; a reader who has worked through Chapters 16 through 21 can open `if_re.c`, `nvme_qpair.c`, or `ahci.c` and recognise the architectural parts: register accessors, simulation backend, PCI attach, interrupt filter and task, per-vector machinery, DMA setup and teardown, sync discipline, clean detach.

21.36.1 A Reflection Before Chapter 22

Chapter 21 was the last chapter in Part 4 that introduced a new hardware primitive. Chapters 16 through 21 took the driver from “no hardware awareness” to “fully functional hardware-backed DMA driver”. Chapter 22 is the discipline chapter: how to make this driver survive suspend and resume cycles, how to save and restore state around power transitions, how to quiesce every subsystem (interrupts, DMA, timers, tasks) before the device loses power and resume it cleanly afterwards. The DMA teardown path Chapter 21 built is what Chapter 22's suspend handler will call; the DMA setup path is what Chapter 22's resume handler will call.

Chapter 21's teaching also generalises. A reader who has internalised the tag-map-memory-sync discipline, the PRE/POST ownership model, the single-segment callback, and the clean setup/teardown pattern will find similar shapes in every DMA-capable FreeBSD driver. The specific device differs; the structure does not.

21.36.2 What to Do If You Are Stuck

Three suggestions.

First, focus on the Stage 2 polling path. If `sudo sysctl dev.myfirst.0.dma_test_write=0xAA` produces a correct banner in `dmesg`, the polling path is working. Every other piece of the chapter is optional in the sense that it decorates the pipeline, but if the pipeline fails, the whole chapter is not working and Section 5 is the right place to diagnose.

Second, open `/usr/src/sys/dev/re/if_re.c` and re-read `re_allocmem` slowly. It is about one hundred fifty lines of tag and memory setup code. Every line maps to a Chapter 21 concept. Reading it once after completing the chapter should feel like familiar territory; the real driver's patterns will look like elaborations of the chapter's simpler ones.

Third, skip the challenges on first pass. The labs are calibrated for Chapter 21's pace; the challenges assume the chapter's material is solid. Come back to them after Chapter 22 if they feel out of reach now.

Chapter 21's goal was to give the driver the ability to move data. If it has, Chapter 22's power-management machinery becomes a specialisation rather than an entirely new topic.

21.37 Bridge to Chapter 22

Chapter 22 is titled *Power Management*. Its scope is the discipline of saving and restoring a driver's state around system suspend and resume. Modern systems suspend aggressively: laptops suspend when the lid closes; servers suspend individual devices that are idle (PCIe's D0, D1, D2, D3 power states); virtual machines migrate between hosts. A driver that does not handle these transitions cleanly leaves its device in an inconsistent state, causes stuck resumes, or corrupts in-flight data.

Chapter 21 prepared the ground in three specific ways.

First, **you have a complete teardown path**. The DMA resources can be torn down and rebuilt cleanly; Chapter 22's suspend handler will call `myfirst_dma_tear_down`, and the resume handler will call `myfirst_dma_setup`. The versioning of state (attaching, detaching, and now suspending) is an extension of the patterns Chapter 21 already introduced.

Second, **you have an in-flight transfer tracker**. Chapter 21's `dma_in_flight` field and the `cv_timedwait` wait protocol are exactly what Chapter 22's suspend handler needs to ensure no transfer is pending when the device loses power. Reusing the tracker keeps the code uniform.

Third, **you have a clean interrupt mask API**. The driver masks and unmask `MYFIRST_INTR_COMPLETE` through the Chapter 19/20 machinery. Chapter 22's suspend handler will mask all interrupts before the power transition; Chapter 22's resume handler will unmask them after the device has stabilised.

Specific topics Chapter 22 will cover:

- What ACPI suspend states mean (S1, S3, S4) and what they require of drivers.
- PCIe device power states (D0, D1, D2, D3hot, D3cold) and how FreeBSD transitions between them.
- The `device_suspend` and `device_resume` methods; how to implement them.
- Quiescing DMA: how to ensure no in-flight transfer is outstanding when power is lost.
- Re-attaching after resume: re-initialising hardware state, reloading tables, restoring interrupts.
- Handling devices that reset across suspend: detecting the reset and rebuilding state.
- Integrating with the rest of the Chapter 16-21 machinery (`bus_space`, simulation, PCI, interrupts, DMA).

You do not need to read ahead. Chapter 21 is sufficient preparation. Bring your `myfirst` driver at `1.4-dma`, your `LOCKING.md`, your `INTERRUPTS.md`, your `MSIX.md`, your `DMA.md`, your WITNESS-enabled kernel, and your regression script. Chapter 22 starts where Chapter 21 ended.

Part 4 is nearly complete. Chapter 22 closes the part by adding the one remaining discipline that separates a prototype driver from a production driver: the ability to survive the power transitions that real systems impose.

The vocabulary is yours; the structure is yours; the discipline is yours. Chapter 22 adds the next missing piece: the driver's ability to gracefully stop and gracefully start, in response to events the driver itself did not initiate.

21.38 Reference: Chapter 21 Quick-Reference Card

A compact summary of the vocabulary, APIs, flags, and procedures Chapter 21 introduced.

21.38.1 Vocabulary

- **DMA (Direct Memory Access):** device reading or writing host memory without CPU per-byte involvement.
- **Bus-master:** a device capable of initiating bus transactions to host memory.
- **Tag (`bus_dma_tag_t`):** a description of DMA constraints for a group of transfers.
- **Map (`bus_dmamap_t`):** a mapping context for one specific transfer.
- **Segment (`bus_dma_segment_t`):** a (`bus_addr`, `length`) pair describing one contiguous piece of a mapping.
- **Bounce buffer:** a kernel-managed staging region used when the device cannot reach the driver's actual buffer.
- **Coherent memory:** memory allocated with `BUS_DMA_COHERENT`; sync operations are cheap.
- **Callback:** the function `bus_dmamap_load` calls with the segment list.
- **Static transaction:** a long-lived mapping allocated at attach time.
- **Dynamic transaction:** a per-transfer mapping created and destroyed per use.
- **Parent tag:** the tag inherited from the parent bridge; constraints compose via intersection.
- **PREWRITE/POSTWRITE/PREREAD/POSTREAD:** the four sync flags.
- **IOMMU:** input-output MMU; transparent remapping between device and host address spaces.

21.38.2 Essential APIs

- `bus_dma_tag_create(parent, align, bdry, low, high, filt, filtarg, maxsz, nseg, maxsegsz, flags, lockfn, lockarg, &tag)`: create a DMA tag.
- `bus_dma_tag_destroy(tag)`: destroy a DMA tag; fails if children remain.
- `bus_get_dma_tag(dev)`: return the device's parent DMA tag.
- `bus_dmamem_alloc(tag, &vaddr, flags, &map)`: allocate DMA-capable memory and get a map.
- `bus_dmamem_free(tag, vaddr, map)`: free `bus_dmamem_alloc` memory.
- `bus_dmamap_create(tag, flags, &map)`: create a map for dynamic loads.
- `bus_dmamap_destroy(tag, map)`: destroy a map.
- `bus_dmamap_load(tag, map, buf, len, callback, cbarg, flags)`: load a buffer into a map.
- `bus_dmamap_unload(tag, map)`: unload a map.
- `bus_dmamap_sync(tag, map, op)`: synchronise caches for `op` (one of the PRE/POST flags).

21.38.3 Essential Flags

- `BUS_DMA_WAITOK`: allocator may sleep.
- `BUS_DMA_NOWAIT`: allocator must not sleep; return `ENOMEM` if resources unavailable.
- `BUS_DMA_COHERENT`: prefer cache-coherent memory.
- `BUS_DMA_ZERO`: zero-initialise allocated memory.
- `BUS_DMA_ALLOCNOW`: pre-allocate bounce resources at tag-create time.

21.38.4 Essential Sync Operations

- `BUS_DMASYNC_PREREAD`: before device writes, host will read.
- `BUS_DMASYNC_PWRITE`: before device reads, host has written.

- `BUS_DMASYNC_POSTREAD`: after device writes, before host reads.
- `BUS_DMASYNC_POSTWRITE`: after device reads, host may reuse.

21.38.5 Common Procedures

Allocate static DMA buffer:

```
bus_dma_tag_create(bus_get_dma_tag(dev), ..., &sc->tag);
bus_dmamem_alloc(sc->tag, &sc->vaddr, BUS_DMA_WAITOK | BUS_DMA_COHERENT |
↳ BUS_DMA_ZERO, &sc->map);
bus_dmamap_load(sc->tag, sc->map, sc->vaddr, size, single_map_cb, &sc->bus_addr,
↳ BUS_DMA_NOWAIT);
```

Free static DMA buffer:

```
bus_dmamap_unload(sc->tag, sc->map);
bus_dmamem_free(sc->tag, sc->vaddr, sc->map);
bus_dma_tag_destroy(sc->tag);
```

Host-to-device transfer:

```
/* Fill sc->vaddr. */
bus_dmamap_sync(sc->tag, sc->map, BUS_DMASYNC_PREWRITE);
/* Program device, trigger, wait for completion. */
bus_dmamap_sync(sc->tag, sc->map, BUS_DMASYNC_POSTWRITE);
```

Device-to-host transfer:

```
bus_dmamap_sync(sc->tag, sc->map, BUS_DMASYNC_PREREAD);
/* Program device, trigger, wait for completion. */
bus_dmamap_sync(sc->tag, sc->map, BUS_DMASYNC_POSTREAD);
/* Read sc->vaddr. */
```

21.38.6 Useful Commands

- `sysctl hw.busedma`: DMA subsystem statistics.
- `vmstat -m | grep bus_dma`: memory use.
- `pciconf -lvbc <dev>`: device capability listing.
- `procstat -kke`: thread states and stacks.

21.38.7 Files to Keep Bookmarked

- `/usr/src/sys/sys/bus_dma.h`: the public header.
- `/usr/src/share/man/man9/bus_dma.9`: the manual page.
- `/usr/src/sys/dev/re/if_re.c`: production descriptor-ring driver.
- `/usr/src/sys/dev/nvme/nvme_qpair.c`: NVMe queue construction.

21.39 Reference: Glossary of Chapter 21 Terms

A short glossary of the chapter's new terms.

- **Alignment constraint**: the requirement that a buffer's starting address be a multiple of a specific value.
- **Boundary constraint**: the requirement that a buffer not cross a specific address boundary.
- **Bounce page**: a single page of bounce buffer used to stage data for a mapping.
- **Bus address**: the address a device uses to reach a memory region; may differ from the physical address.
- **Bus-master**: a device that can initiate transactions on the bus (i.e. do DMA).
- **Callback (DMA)**: the function `bus_dmamap_load` calls with the segment list after the load completes.
- **Coherent memory**: memory in a domain where CPU and DMA see the same data without explicit synchronisation.
- **Deferred load**: a load that returned `EINPROGRESS` and will have its callback called later.
- **Descriptor**: a small structure (in DMA memory) that describes one transfer: address, length, flags, status.
- **Descriptor ring**: an array of descriptors used for producer-consumer communication.
- **DMA tag**: see `bus_dma_tag_t`.
- **Doorbell**: an MMIO register a driver writes to signal new ring entries to the device.
- **Dynamic transaction**: see Section 2.
- **IOMMU**: input-output MMU; translates device-side addresses to host physical addresses.
- **KVA**: kernel virtual address; the pointer the CPU uses.
- **Load callback**: synonym for Callback (DMA).
- **Mapping**: a binding between a kernel buffer and a set of bus-visible segments.
- **Parent tag**: a tag from which another inherits constraints.
- **PREREAD, PREWRITE, POSTREAD, POSTWRITE**: sync flags; see Section 4.
- **Scatter-gather**: a mapping of multiple discontinuous segments as a single logical transfer.
- **Segment**: see `bus_dma_segment_t`.
- **Static transaction**: see Section 2.
- **Sync**: `bus_dmamap_sync`; the hand-off between CPU and device ownership of a buffer.

21.40 Reference: A Closing Note on DMA Philosophy

A paragraph to close the chapter with.

DMA is the primitive that turns a driver from a byte-at-a-time controller into a data-moving subsystem. Before DMA, every byte of data the driver handled went through the CPU's hands, one MMIO transaction at a time; after DMA, the CPU handles only policy and bookkeeping, and the device moves the bytes. The difference is the difference between a driver that can keep up with a 10 Mbit line and a driver that can keep up with a 100 Gbit line.

Chapter 21's lesson is that DMA is disciplined, not magical. The `bus_dma(9)` API hides three hardware realities (addressing limits, IOMMU remapping, cache coherence) behind a single set of calls, and the calls follow a predictable pattern: create a tag, allocate memory, load a map, sync PRE, trigger the device, wait, sync POST, read the result, eventually unload and free. The pattern is the same across every DMA-capable driver in FreeBSD; internalising it once pays off across dozens of later chapters and thousands of lines of real driver code.

For this reader and for this book's future readers, the Chapter 21 DMA pattern is a permanent part of the `myfirst` driver's architecture and a permanent tool in the reader's toolkit. Chapter 22 assumes it: suspend needs to quiesce DMA; resume needs to reinitialise it. Part 6's networking chapters assume it: every packet path uses DMA. Part 7's performance chapters (Chapter 33) assume it: every tuning measurement is against DMA throughput. The vocabulary is the vocabulary every high-performance FreeBSD driver shares; the patterns are the patterns production drivers live by; the discipline is the discipline that keeps coherent platforms coherent and non-coherent platforms correct.

The skill Chapter 21 teaches is not "how to set up a single 4 KB DMA buffer". It is "how to think about memory ownership between the CPU and the device, how to describe a device's constraints to the kernel, and how to move data under a sync discipline that works portably on every platform FreeBSD supports". That skill applies across every DMA-capable device the reader will ever work on.

22 Power Management

22.1 Reader Guidance & Outcomes

Chapter 21 ended with the driver at version 1.4-dma. That driver attaches to a PCI device, allocates MSI-X vectors, services interrupts through a filter-plus-task pipeline, moves data through a `bus_dma(9)` buffer, and cleans up its resources when it is asked to detach. For a driver that boots, runs, and eventually gets unloaded, those mechanics are complete. What the driver does not yet handle is the third kind of event a modern system throws at it: the moment when power itself is about to change.

Power changes are different from attach and detach. An attach starts from nothing and ends with a working device. A detach starts from a working device and ends with nothing. Both are one-shot transitions the driver itself can take its time over. A suspend is neither. The driver enters suspend already running, with live interrupts, live DMA transfers, live timers, and a device the kernel still expects to answer questions. The driver has to bring all of that to a stop within a narrow time window, hand the device over to a lower-power state, survive the power loss without forgetting what it needs to know, and then reassemble everything on the other side as if nothing happened. The user, ideally, notices nothing at all. The lid closes, a second later it opens, and the video conference resumes in the same browser tab as if the interruption had never happened.

Chapter 22 teaches how the driver earns that illusion. The chapter's scope is precisely this: what power management is at the driver level; how the kernel lets the driver see a power transition coming; what it means to quiesce a device so that no activity leaks across the transition; how to preserve the state the driver will need after resume; how to restore that state so the device comes back to the same behavior the user saw before; how to extend the same discipline to idle-device power saving through runtime suspend; how to test transitions from user space; how to debug the characteristic failures a power-aware driver faces; and how to organise the new code so that the driver stays readable as it grows. The chapter stops short of the later topics that build on this discipline. Chapter 23 teaches debugging and tracing in depth; the power-aware regression script in Chapter 22 is a first taste, not the full toolkit. The network-driver chapter in Part 6 (Chapter 28) adds `iflib`'s power hooks and multi-queue suspend coordination; Chapter 22 stays with the single-queue `myfirst` driver. The advanced real-world chapters in Part 7 explore hotplug and power-domain management on embedded platforms; Chapter 22 focuses on the desktop and server cases where ACPI and PCIe dominate.

The arc of Part 4 closes here with a discipline rather than a new primitive. Chapter 16 gave the driver a vocabulary of register access through `bus_space(9)`. Chapter 17 taught it to think like a device by simulating one. Chapter 18 introduced it to a real PCI device. Chapter 19 gave it one pair of ears on a single IRQ. Chapter 20 gave it several ears, one per queue the device cares about. Chapter 21 gave it hands: the ability to hand the device a physical address and let the device run a transfer on its own. Chapter 22 teaches the driver to stop doing all of that on request, to wait politely while the system sleeps, and to pick up again cleanly when the system wakes. That discipline is the last missing ingredient before the driver can call itself production-ready in the Part 4 sense. The later chapters add observability, specialisation, and polish; they assume the power discipline is in place.

22.1.1 Why Suspend and Resume Earn a Chapter of Their Own

A natural question at this stage is whether suspend and resume really need a full chapter, after the depth of Chapter 21. The `myfirst` driver already has a clean detach path. Detach already releases interrupts, drains tasks, tears down DMA, and returns the device to a quiet state. Can the driver not simply call detach on suspend and attach on resume, and be done?

The answer is no, for three linked reasons.

The first is that **suspend is not detach**. A detach is permanent. The driver does not need to remember anything about the device after detach finishes; when the device comes back, it is a fresh attach, from scratch. A suspend is temporary, and the driver does need to remember things across it. It needs to remember its software state so the user's session can pick up where it left off. It needs to remember which interrupt vectors it had allocated. It needs to remember its configuration sysctls. It needs to remember which clients had the device open. Detach forgets all of that; suspend must not. The two paths share cleanup steps in their middle, but they diverge at the ends. Treating suspend as a detach plus a later attach would be correct in the narrow mechanical sense and wrong in every other sense: it would drop the user's session, invalidate open file descriptors on `/dev/myfirst0`, lose the sysctl state, and ask the kernel to re-probe the device from its raw PCI identity on every resume. That is not how modern FreeBSD drivers work, and Chapter 22 shows the better pattern.

The second is that **the time budget is different**. A detach can afford to be thorough. A driver that takes five hundred milliseconds to detach has no user-facing impact; detaches happen at boot, at module unload, or at device removal, and those moments are understood to be slow. A suspend has to finish within a budget measured in tens of milliseconds per device on a laptop with a hundred devices, because the sum is what the user notices as lid-close latency. A driver that does a full detach-like cleanup, waits for queues to drain at their natural pace, unwinds every allocation, and rebuilds everything on resume will be measurably slow across the whole fleet of devices the system has. The Chapter 22 pattern is to stop activity fast, save what needs to be saved, leave allocations in place, and restore from saved state. That pattern is what keeps suspend-resume under a second on a typical laptop.

The third is that **the kernel gives the driver a specific contract for power transitions**, and that contract has its own vocabulary, its own order of operations, and its own failure modes. The `DEVICE_SUSPEND` and `DEVICE_RESUME` kobj methods are not just “detach and attach with different names”. They are called at specific points in the system-wide suspend sequence, with the driver tree traversed in a specific order, and they interact with the PCI layer's automatic config-space save and restore, with ACPI's sleep-state machinery, with the interrupt subsystem's mask and unmask calls, and with the `bus_generic_suspend` and `bus_generic_resume` helpers that walk the device tree. A driver that ignores the contract may still look correct during detach, during DMA, and during interrupt handling, and then fail only when the user closes the lid. That class of failure is notoriously hard to debug because it is hard to reproduce, and Chapter 22 invests time in making the contract explicit so the failures do not happen in the first place.

Chapter 22 earns its place by teaching those three ideas together, concretely, with the `myfirst` driver as the running example. A reader who finishes Chapter 22 can add `device_suspend`, `device_resume`, and `device_shutdown` methods to any FreeBSD driver, knows which of the chapter's discipline applies where, and understands the interactions between the ACPI layer, the PCI layer, and the driver's own state. That skill transfers directly to every FreeBSD driver the reader will ever work on.

22.1.2 Where Chapter 21 Left the Driver

A short checkpoint before we continue. Chapter 22 extends the driver produced at the end of Chapter 21 Stage 4, tagged as version 1.4-dma. If any of the items below is uncertain, return to Chapter 21 before starting this chapter.

- Your driver compiles cleanly and identifies itself as 1.4-dma in `kldstat -v`.
- The driver allocates one or three MSI-X vectors (depending on platform), registers per-vector filters and tasks, binds each vector to a CPU, and prints an interrupt banner during attach.
- The driver allocates a `bus_dma` tag, allocates a 4 KB DMA buffer, loads it into a map, and exposes the bus address through `dev.myfirst.N.dma_bus_addr`.
- Writing to `dev.myfirst.N.dma_test_write=0xAA` triggers a host-to-device transfer; writing to `dev.myfirst.N.dma_test_read=1` triggers a device-to-host transfer; both log success to `dmesg`.
- The detach path drains the rx task, drains the simulation's callout, waits for any in-flight DMA to complete, calls `myfirst_dma_tear_down`, tears down MSI-X vectors in reverse order, and releases resources.
- `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, and `DMA.md` are current in your working tree.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel.

That driver is what Chapter 22 extends. The additions are modest in lines but important in discipline: a new `myfirst_power.c` file, a matching `myfirst_power.h` header, a small set of new softc fields to track suspend state and saved runtime state, new `myfirst_suspend` and `myfirst_resume` entry points wired into the `device_method_t` table, a new `myfirst_shutdown` method, a call to the Chapter 21 quiesce primitives from the new suspend path, a restoration path that reinitialises the device without repeating attach, a version bump to 1.5-power, a new `POWER.md` document, and updates to the regression test. The mental model grows too: the driver starts thinking about its own lifecycle as attach, run, quiesce, sleep, wake, run again, and eventually detach, rather than just attach, run, detach.

22.1.3 What You Will Learn

Walking away from this chapter, you should be able to:

- Describe what power management means for a device driver, distinguish system-level and device-level power saving, and name the difference between a full suspend-resume cycle and a runtime power transition.
- Recognise the ACPI system sleep states (S0, S1, S3, S4, S5) and the PCI device power states (D0, D1, D2, D3hot, D3cold), explain how they compose in a single transition, and identify which parts of each are the driver's responsibility.
- Explain the role of PCIe link states (L0, L0s, L1, L1.1, L1.2) and active-state power management (ASPM), at a level sufficient to read a datasheet and recognise what the platform controls automatically versus what the driver must configure explicitly.
- Add `DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, and (optionally) `DEVICE_QUIESCE` entries to a driver's `device_method_t` table, and implement each of them so they compose with `bus_generic_suspend(9)` and `bus_generic_resume(9)` in the device tree.

- Explain what it means to quiesce a device safely before a power transition, and apply the pattern: mask interrupts at the device, stop submitting new DMA work, drain the in-flight transfers, drain the callouts and taskqueues, flush or discard buffers as policy dictates, and leave the device in a defined, quiet state.
- Explain why the PCI layer automatically saves and restores configuration space around `device_suspend` and `device_resume`, when the driver has to supplement that with its own `pci_save_state/pci_restore_state` calls, and when it should not.
- Implement a clean resume path that re-enables bus-mastering, restores device registers from the driver's saved state, re-arms the interrupt mask, revalidates device identity, and re-admits clients to the device without losing data or raising spurious interrupts.
- Recognise the cases where a device silently resets across suspend, how to detect the reset, and how to rebuild only the state that was actually lost.
- Implement a runtime power management helper that puts an idle device into D3 and wakes it back to D0 on demand, and discuss the latency versus power tradeoff.
- Trigger a full-system suspend from user space with `acpiconf -s 3` or `zzz`, a per-device suspend with `devctl suspend` and `devctl resume`, and observe the transitions through `devinfo -v`, `sysctl hw.acpi.*`, and the driver's own counters.
- Debug the characteristic failures of power-aware code: frozen devices, lost interrupts, bad DMA after resume, missed PME# wake events, and WITNESS complaints about sleep-with-locks-held inside suspend. Apply the matching recovery patterns.
- Refactor the driver's power-management code into a dedicated `myfirst_power.c/myfirst_power.h` pair, bump the driver's version to 1.5-power, extend the regression test to cover suspend and resume, and produce a `POWER.md` document that explains the subsystem to the next reader.
- Read the power-management code in a real driver such as `/usr/src/sys/dev/re/if_re.c`, `/usr/src/sys/dev/xl/if_xl.c`, or `/usr/src/sys/dev/virtio/block/virtio_blk.c`, and map each call back to the concepts introduced in Chapter 22.

The list is long. The items are narrow. The chapter's goal is the composition, not any single item in isolation.

22.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 22 stays focused on the driver-side discipline.

- **Advanced ACPI internals** such as the AML interpreter, the SSDT/DSDT tables, the `_PSW/_PRW/_PSR` method semantics, and the ACPI button subsystem. The chapter uses ACPI only through the layer the kernel exposes to a driver; the internals belong in a later, platform-oriented chapter.
- **Hibernate-to-disk mechanics (S4)**. FreeBSD's S4 support has historically been partial on x86, and the driver-side contract is essentially a stricter version of S3. The chapter mentions S4 for completeness and treats it like S3 for driver purposes.
- **Cpufreq, powerd, and CPU frequency scaling**. These affect CPU power, not device power. A driver whose device is in D0 is unaffected by the CPU's P-state; the chapter does not pursue CPU power management.
- **SR-IOV suspend coordination between PF and VFs**. Virtual Function suspend has its own ordering constraints and belongs in a specialised chapter.
- **Hotplug and surprise removal**. Removing a device by physical unplug is similar in spirit to suspend but uses different code paths (`BUS_CHILD_DELETED`, `device_delete_child`). Part 7 covers hotplug in depth; Chapter 22 mentions the relationship and moves on.

- **Thunderbolt and USB-C dock suspend.** These compose ACPI, PCIe hotplug, and USB power management and belong in a dedicated later section.
- **Embedded-platform power-domain and clock-gating frameworks** such as the device-tree power-domains and clocks properties on arm64 and RISC-V. The chapter uses x86 ACPI and PCI conventions throughout, and mentions the embedded counterparts in passing when the concept is parallel.
- **Custom wake-on-LAN policy, wake-on-pattern policy, and application-specific wake sources.** The chapter explains how a wake source is plumbed (PME#, USB remote wakeup, GPIO wake) without trying to teach every hardware-specific variation.
- **The internals of the ksuspend/kresume paths and the kernel's cpuset migration around suspend.** The driver does not see those directly; they affect interrupt routing and CPU offlining, not the driver's visible contract.

Staying inside those lines keeps Chapter 22 a chapter about driver-side power discipline. The vocabulary transfers; the specialisations add detail in later chapters without needing a new foundation.

22.1.5 Estimated Time Investment

- **Reading only:** four to five hours. The power management conceptual model is neither as dense as DMA nor as mechanical as interrupts; much of the time is in building the mental picture of how ACPI, PCI, and the driver compose during a transition.
- **Reading plus typing the worked examples:** ten to twelve hours over two or three sessions. The driver evolves in three stages: skeleton suspend and resume with logging, full quiesce and restore, and finally refactor into `myfirst_power.c`. Each stage is short, but the testing is deliberate: a forgotten `bus_dmamap_sync` or a missed interrupt mask can produce silent corruption that only shows up on the fifth or sixth suspend-resume cycle.
- **Reading plus all labs and challenges:** fifteen to twenty hours over four or five sessions, including the lab that stresses the driver through repeated suspend-resume cycles, the lab that forces an intentional post-resume failure and debugs it, and the challenge material that extends the driver with runtime idle detection.

Sections 3 and 4 are the densest. If the quiesce discipline or the resume ordering feels opaque on first pass, that is normal. Stop, re-read the corresponding diagram, run the matching exercise on the simulated device, and continue when the shape has settled. Power management is one of those topics where a working mental model pays off repeatedly; it is worth building slowly.

22.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 21 Stage 4 (1.4-dma). The starting point assumes every Chapter 21 primitive: the DMA tag and buffer, the `dma_in_flight` tracker, the `dma_cv` condition variable, and the clean teardown path.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly. The `WITNESS` option is especially valuable for suspend and resume

work, because the code paths run under non-obvious locks and the kernel's power machinery tightens several invariants during the transition.

- `bhyve(8)` or `qemu-system-x86_64` is available. Chapter 22's labs work on either target. The suspend-resume testing does not require real hardware; `devctl suspend` and `devctl resume` let you drive the driver's power methods directly without involving ACPI.
- The `devinfo(8)`, `sysctl(8)`, `pciconf(8)`, `procstat(1)`, `devctl(8)`, `acpiconf(8)` (if on real hardware with ACPI) and `zzz(8)` commands are in your path.

If any item above is shaky, fix it now. Power management, like DMA, is a topic where latent weaknesses show up under stress. A driver that almost works on detach often breaks on suspend; a driver that handles one suspend cleanly often fails on the tenth cycle because a counter wrapped, a map leaked, or a condition variable was reinitialised incorrectly. The WITNESS-enabled debug kernel is what surfaces those mistakes at development time.

22.1.7 How to Get the Most Out of This Chapter

Four habits will pay off quickly.

First, keep `/usr/src/sys/kern/device_if.m` and `/usr/src/sys/kern/subr_bus.c` bookmarked. The first file defines the `DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, and `DEVICE_QUIESCE` methods; the second contains `bus_generic_suspend`, `bus_generic_resume`, `device_quiesce`, and the `devctl` machinery that turns user-space requests into method calls. Reading both once at the start of Section 2 and returning to them as you work each section is the single most useful thing you can do for fluency.

Second, keep three real-driver examples close to hand: `/usr/src/sys/dev/re/if_re.c`, `/usr/src/sys/dev/xl/if_xl.c`, and `/usr/src/sys/dev/virtio/block/virtio_blk.c`. Each illustrates a different power-management style. `if_re.c` is a full network driver with wake-on-LAN support, config-space save and restore, and a careful resume path. `if_xl.c` is simpler: its `xl_shutdown` just calls `xl_suspend`, and `xl_suspend` stops the chip and sets up wake-on-LAN. `virtio_blk.c` is minimal: `vtblk_suspend` sets a flag and quiesces the queue, `vtblk_resume` clears the flag and restarts I/O. Chapter 22 will refer back to each of them at the moment where their pattern best illustrates what the `myfirst` driver is doing.

Third, type the changes by hand and exercise each stage with `devctl suspend` and `devctl resume`. Power management is where small omissions produce characteristic failures: a forgotten interrupt mask causes a stuck resume; a forgotten `bus_dmamap_sync` causes stale data; a forgotten state variable causes the driver to think a transfer is still in flight. Typing carefully and running the regression script after each stage exposes those mistakes at the moment they happen.

Fourth, after finishing Section 4, re-read Chapter 21's detach path. The quiesce discipline in Section 3 and the restore discipline in Section 4 both share infrastructure with Chapter 21's detach: `callout_drain`, `taskqueue_drain`, `bus_dmamap_sync`, `pci_release_msi`. Seeing suspend-resume and attach-detach side by side is what makes the differences visible. Suspend is not detach; resume is not attach; but they use the same building blocks, composed differently, and seeing that composition in two passes is worth the extra half-hour.

22.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Is Power Management in Device Drivers?** The big picture: why a driver cares about power, how system-level and device-level power management differ, what the ACPI S-states and PCI D-states mean, what PCIe link states and ASPM add, and what wake sources look like on the systems the reader is most likely to have. Concepts first, APIs next.
2. **FreeBSD's Power Management Interface.** The kobj methods: `DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, `DEVICE_QUIESCE`. The order in which the kernel delivers them. The `bus_generic_suspend` helper, the `pci_suspend_child` path, and the interaction with ACPI. The first running code: Stage 1 of the Chapter 22 driver (`1.5-power-stage1`), with skeleton handlers that only log.
3. **Quiescing a Device Safely.** Stopping activity before a power transition. Masking interrupts, stopping DMA submission, draining in-flight work, draining callouts and taskqueues, flushing policy-sensitive buffers. Stage 2 (`1.5-power-stage2`) turns the skeletons into a real quiesce.
4. **Restoring State on Resume.** Reinitialising the device from saved state. What PCI save/restore does for you and what it does not. Re-enabling bus-master, restoring device registers, re-arming interrupts, validating identity, handling device reset. Stage 3 (`1.5-power-stage3`) adds the resume path that matches the Stage 2 quiesce.
5. **Handling Runtime Power Management.** Idle-device power saving. Detecting idleness. Putting the device into D3 and bringing it back to D0 on demand. Latency versus power. The chapter's optional section, but with a practical sketch a reader can experiment with.
6. **Interacting With the Power Framework.** Testing transitions from user space. `acpiconf -s 3` and `zzz` for full-system suspend. `devctl suspend` and `devctl resume` for per-device suspend. `devinfo -v` for observing power states. The regression script that wraps all of it.
7. **Debugging Power Management Issues.** The characteristic failure modes: frozen device, lost interrupts, bad DMA after resume, missing PME# wake, WITNESS complaints. The debugging patterns that find each of them.
8. **Refactoring and Versioning Your Power-Aware Driver.** The final split into `myfirst_power.c` and `myfirst_power.h`, the updated Makefile, the `POWER.md` document, and the version bump. Stage 4 (`1.5-power`).

After the eight sections come an extended walkthrough of `if_re.c`'s power-management code, several deeper looks at ACPI sleep states, PCIe link states, wake sources, and the `devctl` user-space interface, a set of hands-on labs, a set of challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 22's story and opens Chapter 23's, a bridge, and the usual quick-reference and glossary material at the end of the chapter. The reference material is meant to be re-read as you work through the next few chapters; Chapter 22's vocabulary (suspend, resume, quiesce, shutdown, D0, D3, ASPM, PME#) is the foundation every production FreeBSD driver shares.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3, 4, and 7 stand alone and make good single-sitting reads.

22.2 Section 1: What Is Power Management in Device Drivers?

Before the code, the picture. Section 1 teaches what power management means at the level the driver sees: the layers of the system that cooperate to save power, the sleep states and device power states those layers define, the PCIe link-level machinery that happens below the driver's visibility, and the wake sources that bring the system back. A reader who finishes Section 1 can read the rest of the chapter with the vocabulary of ACPI and

PCI power management as concrete objects rather than as vague acronyms.

22.2.1 Why the Driver Must Care About Power

The reader has spent the previous six chapters teaching a driver how to talk to a device. Each chapter added a capability: memory-mapped registers, simulated backends, real PCI, interrupts, multi-vector interrupts, DMA. In every chapter, the device was always ready to respond. The BAR was always mapped. The interrupt vector was always armed. The DMA engine was always on. That assumption is convenient for teaching, and it is also the assumption the driver makes during normal operation. It is not, however, the assumption the user makes. The user assumes that when the laptop sleeps, the battery drains slowly; that when the NVMe is idle, it cools itself; that when the Wi-Fi card has nothing to transmit, it is not pulling watts from the power supply. Those assumptions are real platform engineering, and the driver is one of the layers that has to cooperate for the engineering to work.

Cooperating means acknowledging that the device's power state can change under the driver's feet. The change is always announced: the kernel calls a method in the driver to tell it what is about to happen. But the announcement only works if the driver handles it correctly. A driver that ignores the announcement leaves the device in an inconsistent state, and the cost shows up in ways that are specific to power transitions: a laptop that does not wake up, a server whose RAID controller refuses to respond after a device-level reset, a USB dock that loses connectivity across a lid-close. Each of these failures maps back to a driver that treated a power event as optional when the platform's correctness assumed it was mandatory.

The stakes are not only about idle power. A driver that does not quiesce DMA before the system suspends can corrupt memory at the moment the CPU stops. A driver that does not mask interrupts before a bus enters a lower power state can cause spurious wake events. A driver that does not restore its configuration after resume can read zeros from a register that used to hold a valid address. Each of those is a kernel bug whose symptom is reported by the user as "sometimes my machine doesn't wake up". Chapter 22's discipline is what prevents that class of bug.

22.2.2 System-Level Versus Device-Level Power Management

Two words that sound similar describe different things. It is worth pinning them down now, because the chapter uses both and the distinction matters throughout.

System-level power management is a transition of the whole computer. The user presses the power button, closes the lid, or issues `shutdown -p now`. The kernel walks the device tree, asks every driver to suspend its device, and then either parks the CPU in a low-power state (S1, S3), writes the memory contents to disk (S4), or turns the power off (S5). Every driver in the system participates in the transition. If any driver refuses, the whole transition fails; the kernel prints a message like `DEVICE_SUSPEND(foo0) failed: 16`, the system stays awake, and the user sees a laptop whose screen went dark for half a second and then came back.

Device-level power management is a transition of one device. The kernel decides (or is told by `devctl suspend`) that one specific device can be put into a lower power state, independent of any other device. The PCIe NIC, for example, can go to D3 when its link has been idle for a few seconds, and come back to D0 when a packet arrives. The whole system stays in S0 throughout. The rest of the devices continue to work. The user does not notice anything except a slight increase in the latency of the first packet after an idle period, because the NIC had to wake up from D3.

System-level and device-level transitions use the same driver methods. `DEVICE_SUSPEND` is called both for a full S3 transition (where every device suspends together) and for a targeted `devctl suspend myfirst0` (where only the `myfirst0` device suspends). The driver usually does not distinguish the two; the same quiesce discipline works for both. What differs is the context around the call: a system-wide suspend also disables all CPUs except the boot CPU, stops most kernel threads, and expects every driver to be done quickly; a per-device suspend leaves the rest of the system running and is called from normal kernel context. The driver mostly does not have to care. It does, however, need to be aware that the two contexts exist, because a driver that only tests per-device suspend may miss a bug that only shows up in a full-system suspend, and vice versa.

Chapter 22 exercises both paths. The labs use `devctl suspend` and `devctl resume` for fast iteration, because they take milliseconds and do not involve ACPI. The integration test uses `acpiconf -s 3` (or `zzz`) to exercise the full path through the ACPI layer and the bus hierarchy. A driver that passes both tests is much more likely to be correct in production than one that passes only the first.

22.2.3 ACPI System Sleep States (S0 to S5)

On the x86 laptops and servers most readers will work with, the system's power state is described by the ACPI specification as a small set of letters and numbers called the **S-states**. Each S-state defines a distinct level of “how much of the system is still running”. The driver does not choose an S-state (the user, the BIOS, or the kernel's policy chooses), but it has to know which ones exist and what each one implies for the device.

S0 is the working state. The CPU is running, RAM is powered, all devices are in whatever device power state they need. Everything the reader has done so far has been in S0. This is the state the system boots into and the state it leaves only when sleep is requested.

S1 is called “standby” or “light sleep”. The CPU stops executing, but the CPU's registers and caches are preserved, RAM stays powered, and most devices stay in D0 or D1. Wake-up is fast (usually a second or less). On modern hardware S1 is rarely used, because S3 is more power-efficient and almost as fast to wake from. FreeBSD supports S1 if the platform advertises it; most platforms no longer do.

S2 is a rarely-implemented state between S1 and S3. On most platforms it is not advertised, and when it is, FreeBSD treats it similarly to S1. The chapter does not return to S2.

S3 is “suspend to RAM”, also known as “standby” or “sleep” in user-facing language. The CPU stops, the CPU context is lost and must be saved before the transition, RAM stays powered through its self-refresh mechanism, and most devices go to D3 or D3cold. Wake-up takes one to three seconds on a typical laptop. This is the state the user enters by closing the lid on a laptop. On a server, S3 is the state `acpiconf -s 3` or `zzz` produces. Chapter 22's main test is an S3 transition.

S4 is “suspend to disk” or “hibernate”. The full contents of RAM are written to a disk image, power is removed, and the system comes back by reading the image on the next boot. On FreeBSD, S4 support has historically been partial on x86 (the memory image can be produced but the restore path is not as polished as Linux or Windows). For driver purposes, S4 looks like S3 with an extra step at the end: the driver suspends exactly as it would for S3. The difference is invisible to the driver.

S5 is “soft off”. The system is powered off; only the wake-up circuitry (power button, wake-on-LAN) is receiving power. From the driver's point of view, S5 is similar to a system shutdown; the `DEVICE_SHUTDOWN` method is what gets called, not `DEVICE_SUSPEND`.

On real hardware, the reader can see which sleep states the platform supports with:

```
sysctl hw.acpi.supported_sleep_state
```

A typical laptop prints something like:

```
hw.acpi.supported_sleep_state: S3 S4 S5
```

A server might print only S5, because ACPI suspend is rarely meaningful on a datacenter machine. A VM might print varied combinations depending on the hypervisor. The `sysctl hw.acpi.s4bios` tells whether S4 is BIOS-assisted (it rarely is on modern systems). The `sysctl hw.acpi.sleep_state` lets the reader enter a sleep state manually; `acpiconf -s 3` is the preferred command-line wrapper.

For Chapter 22's purposes, the reader needs to be aware of S3 (the common case) and S5 (the shutdown case). S1 and S2 are handled by the driver the same way as S3; S4 is a superset of S3. The chapter treats S3 as the canonical example throughout.

22.2.4 PCI and PCIe Device Power States (D0 to D3cold)

A device's power state is described by the **D-states**, which the PCI specification defines independently from the system's S-state. The driver's methods most directly control the D-state of its device, and it is worth understanding each state in detail.

D0 is the fully-on state. The device is powered, clocked, accessible through its configuration space and BARs, and able to perform any operation the driver asks for. All the Chapter 16 to 21 work has been done with the device in D0. `PCI_POWERSTATE_D0` is the symbolic constant in `/usr/src/sys/dev/pci/pcivar.h`.

D1 and **D2** are intermediate low-power states that the PCI spec defines but does not tightly constrain. A device in D1 still has its configuration registers accessible and can respond to some I/O; a device in D2 may have lost more context. These states are rarely used on modern PCs because the jump from D0 to D3 is usually preferable for power savings. Most drivers do not bother with D1 and D2.

D3hot is the low-power state in which the device is effectively off, but the bus is still powered, the configuration space can still be accessed (reads return mostly zero or the preserved configuration), and the device can raise a PME# signal if it is configured to do so. Most devices enter D3hot during suspend.

D3cold is the even-lower power state in which the bus itself has lost power. The device cannot be accessed at all; reads from its configuration space return all-ones. The only way out of D3cold is for the platform to restore power, which usually happens under platform (not driver) control. D3cold is common during full-system S3 and S4.

When a driver calls `pci_set_powerstate(dev, PCI_POWERSTATE_D3)`, the PCI layer transitions the device from its current state to D3 (D3hot specifically; the transition to D3cold is the platform's job). When the driver calls `pci_set_powerstate(dev, PCI_POWERSTATE_D0)`, the PCI layer brings the device back to D0.

The PCI layer in FreeBSD also automatically manages these transitions during system suspend and resume. The `pci_suspend_child` function, which the PCI bus driver registers for `bus_suspend_child`, calls the driver's `DEVICE_SUSPEND` first, and then (if the `hw.pci.do_power_suspend` sysctl is true, which it is by default) transitions the device to D3. On resume, `pci_resume_child` transitions the device back to D0, restores the configuration space from a cached copy, clears any pending PME# signal, and then calls the driver's `DEVICE_RESUME`. The reader can observe the behavior with:

```
sysctl hw.pci.do_power_suspend  
sysctl hw.pci.do_power_resume
```

Both default to 1. A reader who wants to disable the automatic D-state transition (for debugging, or for a device that misbehaves in D3) can set them to 0, in which case the driver's `DEVICE_SUSPEND` and `DEVICE_RESUME` run but the device stays in D0 through the transition.

For Chapter 22, the important facts are:

- The driver's `DEVICE_SUSPEND` method runs before the D-state changes. The driver quiesces while the device is still in D0.
- The driver's `DEVICE_RESUME` method runs after the device has been returned to D0. The driver restores while the device is accessible.
- The driver does not (usually) call `pci_set_powerstate` directly during suspend and resume. The PCI layer handles that automatically.
- The driver does not (usually) call `pci_save_state` and `pci_restore_state` directly. The PCI layer handles those automatically too, through `pci_cfg_save` and `pci_cfg_restore`.
- The driver *does* save and restore its own device-specific state: BAR-local register contents that the hardware may have lost, softc fields that track runtime configuration, interrupt mask values. The PCI layer does not know about these.

The boundary is where the PCI configuration space ends and the BAR-accessed registers begin. The PCI layer protects the first; the driver protects the second.

22.2.5 PCIe Link States and Active-State Power Management (ASPM)

At a layer below the device's D-state sits the PCIe link itself. A link between a root complex and an endpoint can be in one of several **L-states**, and transitions between L-states happen automatically when the traffic on the link is low enough.

L0 is the fully-on link state. Data flows normally. Latency is at its minimum. This is the state the link is in whenever the device is active.

L0s is a low-power state the link enters when it has been idle for a few microseconds. The transmitter turns off its output drivers on one side; the link is bidirectional, so the other side's L0s is independent. Recovery from L0s takes hundreds of nanoseconds. This is cheap power saving that the platform can do automatically when traffic is bursty.

L1 is a deeper low-power state the link enters after a longer idle period (tens of microseconds). Both sides turn off more of their physical-layer circuitry. Recovery takes microseconds. This is used during light-load periods when the latency penalty is acceptable.

L1.1 and **L1.2** are PCIe 3.0 and later refinements of L1 that add further power gating, allowing even lower idle current at the cost of slower wake-up.

L2 is a near-off link state used during D3cold and S3; the link is effectively turned off, and wake-up requires a full re-negotiation. The driver typically does not manage L2 directly; it is a side-effect of the device entering D3cold.

The mechanism that controls the transitions between L0 and L0s/L1 is called **Active-State Power Management (ASPM)**. ASPM is a per-link feature configured through the PCIe capability registers of both ends of the link. It can be enabled, disabled, or restricted to L0s-only by platform policy. On FreeBSD, ASPM is usually controlled by the firmware through ACPI (the `_OSC` method tells the OS which capabilities to manage); the kernel does not second-guess the firmware's policy unless explicitly told to.

For Chapter 22 and for most FreeBSD drivers, ASPM is a platform concern, not a driver concern. The driver does not configure ASPM; the platform does. The driver does not need to save or restore ASPM state around suspend; the PCI layer handles the PCIe capability registers as part of the automatic config-space save and restore. A driver that wants to disable ASPM for a specific device (for example, because the device has a known errata that makes L0s unsafe) can do so by reading and writing the PCIe Link Control register explicitly, but this is rare and specific.

The reader does not need to add ASPM code to the `myfirst` driver. It is enough to be aware that L-states exist, that they transition automatically based on traffic, that the driver's D-state and the link's L-state are related but distinct, and that the platform handles the ASPM configuration. If a future driver the reader works on has a datasheet that specifies ASPM errata, the reader will know where to look.

22.2.6 The Anatomy of a Suspend-Resume Cycle

Putting the pieces together, a full system suspend-resume cycle looks like this from the driver's point of view, tracing the `myfirst` driver through an S3 transition:

1. The user closes the laptop lid. The ACPI button driver (`acpi_lid`) notices the event and, based on the system's policy, triggers a sleep request to state S3.
2. The kernel starts the suspend sequence. Userland daemons are paused; the kernel freezes non-essential threads.
3. The kernel walks the device tree and calls `DEVICE_SUSPEND` on each device, in reverse child order. The PCI bus driver's `bus_suspend_child` calls the `myfirst` driver's `device_suspend` method.
4. The `myfirst` driver's `device_suspend` runs. It masks interrupts on the device, stops accepting new DMA requests, waits for any in-flight DMA to complete, drains its task queue, logs the transition, and returns 0 to indicate success.
5. The PCI layer notes that `myfirst`'s suspend succeeded. It calls `pci_cfg_save` to cache the PCI configuration space. If `hw.pci.do_power_suspend` is 1 (the default), it transitions the device to D3hot via `pci_set_powerstate(dev, PCI_POWERSTATE_D3)`.
6. Higher in the tree, the PCI bus itself, the host bridge, and eventually the platform go through their own `DEVICE_SUSPEND` calls. ACPI arms its wake events. The CPU enters the low-power state corresponding to S3. The memory subsystem enters self-refresh. The PCIe link goes to L2 or thereabouts.
7. Time passes. On the scale the driver observes, no time passes at all; the kernel is not running.
8. The user opens the lid. The platform's wake circuitry wakes the CPU. ACPI performs the early resume steps: the CPU context is restored, memory is refreshed, the platform's firmware reinitialises what it must.
9. The kernel's resume sequence starts. It walks the device tree in forward order, calling `DEVICE_RESUME` on each device.
10. For `myfirst`, the PCI bus driver's `bus_resume_child` transitions the device back to D0 via `pci_set_powerstate(dev, PCI_POWERSTATE_D0)`. It calls `pci_cfg_restore` to write the cached

configuration space back into the device. It clears any pending PME# signal with `pci_clear_pme`. Then it calls the driver's `device_resume` method.

11. The driver's `device_resume` runs. The device is in D0, its configuration space is restored, its BAR registers are zero or default values. The driver re-enables bus-mastering if needed, writes its device-specific registers back from saved state, re-arms the interrupt mask, and marks the device as resumed. It returns 0.
12. The kernel's resume sequence continues up the tree. Userland threads are unfrozen. The user sees a working system, usually in one to three seconds.

Every step at which the driver has work is step 4 and step 11. Everything else is either platform or generic kernel machinery. The driver's job is to make those two steps correct, and to understand enough about the steps around them to interpret the behavior it observes.

22.2.7 Wake Sources

A device that is suspended can be the reason the system wakes. The way that happens depends on the bus:

- On **PCIe**, a device in D3hot can assert the **PME#** signal (Power Management Event). The platform's root complex translates PME# into a wake event, the ACPI `_PRW` method identifies which GPE (General-Purpose Event) it uses, and the ACPI subsystem translates the GPE into a wake from S3. On FreeBSD, the `pci_enable_pme(dev)` function enables the device's PME# output; `pci_clear_pme(dev)` clears any pending signal. The `pci_has_pm(dev)` helper tells whether the device has a power-management capability at all.
- On **USB**, a device can request **remote wakeup** through its standard USB descriptor. The host controller (`xhci`, `ohci`, `uhci`) translates the wake into a PME# or equivalent signal upstream. The driver does not usually handle this directly; the USB stack does.
- On **embedded platforms**, a device can assert a **GPIO** pin that the platform wires to its wake logic. The device-tree `interrupt-extended` or `wakeup-source` properties identify which pins are wake sources. FreeBSD's GPIO intr framework handles this.
- On **Wake-on-LAN**, a network controller watches for magic packets or pattern matches while suspended and asserts PME# when one is seen. Both the driver and the platform have to be configured; `re_setwol` in `if_re.c` is a good example of the driver side.

For the `myfirst` driver, the simulated device does not really have a wake source (it has no physical existence outside the simulation). The chapter explains the mechanism at the appropriate point in Section 4, shows what `pci_enable_pme` does and where it would be called, and leaves the actual wake-triggering to the sim backend's manual triggers. A real-hardware driver would call `pci_enable_pme` in its suspend path when wake-on-X is requested, and `pci_clear_pme` in its resume path to acknowledge any pending signal.

22.2.8 Real-World Examples: Wi-Fi, NVMe, USB

It helps to anchor the ideas in devices the reader has actually used. Consider three.

A **Wi-Fi adapter** like those handled by `iwlwifi` on Linux or `iwn` on FreeBSD is a constant power-management citizen. In S0, it spends most of its time in a low-power idle state on the chip itself, associated with the access point but not actively exchanging packets; when a packet is seen, it wakes to D0 for a few milliseconds, exchanges the packet, and goes back to idle. On system suspend (S3), the kernel asks the driver to save its state,

the driver tells the chip to disassociate cleanly (or to set up WoWLAN patterns if the user wants wake-on-wireless), and the PCI layer transitions the chip to D3. On resume, the reverse happens: the chip comes back to D0, the driver restores its state, and re-associates to the access point. The user perceives a one- or two-second delay after lid-open before Wi-Fi is back, which is almost entirely the re-association time and not the driver's resume time.

An **NVMe SSD** handles power states internally through its own power-state machinery (defined in the NVMe spec as PSx states, where PS0 is full power and higher numbers are lower power). The NVMe driver participates in system suspend by flushing its queues, waiting for in-flight commands to complete, and then telling the controller to enter a low-power state. On resume, the driver restores the queue configuration, tells the controller to come back to PS0, and the system resumes disk I/O. Because NVMe queues are large and DMA-heavy, the NVMe suspend path is a classic place where a missed `bus_dmamap_sync` or a missed queue drain shows up as filesystem corruption after resume.

A **USB device** is handled by the USB host controller driver (`xhci`, typically). The host controller driver is the one that implements `DEVICE_SUSPEND` and `DEVICE_RESUME`; individual USB drivers (for keyboards, storage, audio, etc.) are notified through the USB framework's own suspend and resume mechanism. A driver for a USB device rarely needs its own `DEVICE_SUSPEND` method; the USB framework handles the translation.

The `myfirst` driver in Chapter 22 uses a PCI endpoint model, which is the most common case and the one whose contract the other cases specialise. Learning the PCI pattern first gives the reader what is needed to understand the Wi-Fi pattern, the NVMe pattern, and the USB pattern when those drivers are looked at later.

22.2.9 What the Reader Has Gained

Section 1 is conceptual. The reader should not feel obligated to remember every detail of every state mentioned. What the reader should take from it is:

- Power management is a layered system. ACPI defines the system state. PCI defines the device state. PCIe defines the link state. The driver sees its device state most directly.
- Each layer's state can transition, and the transitions compose. A system S3 implies every device's D3 implies every link's L2. A per-device D3 (from runtime PM) does not imply system S3; the system stays in S0.
- The driver has a specific contract with the PCI and ACPI layers. The driver is responsible for quiescing its device's activity on suspend and restoring its device's state on resume. The PCI layer automatically handles configuration-space save, D-state transitions, and PME# wake signalling. ACPI handles the system-wide wake up.
- Wake sources exist and are plumbed through a specific chain (PME#, remote wakeup, GPIO). The driver usually enables and disables them through a helper API; it does not talk to the wake hardware directly.
- Testing is layered too. `devctl suspend/devctl resume` exercises only the driver methods. `acpicnf -s 3` exercises the whole system. A good regression script uses both.

With that picture in place, Section 2 can introduce the FreeBSD-specific APIs the driver uses to join this system.

22.2.10 Wrapping Up Section 1

Section 1 established why a driver has to care about power, what system-level and device-level power management mean, what the ACPI S-states and the PCI D-states look like, what the PCIe L-states add, how a suspend-resume cycle flows from the driver's point of view, and what wake sources are. It did not show any driver code; that is Section 2's job. What the reader now has is a vocabulary and a mental model: suspend is a transition the platform announces, the driver quiesces; the PCI layer moves the device to D3; the system sleeps; on wake, the PCI layer moves the device back to D0; the driver restores.

With that picture in mind, the next section introduces FreeBSD's concrete API for all of this: the four kobj methods (`DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, `DEVICE_QUIESCE`), how the kernel invokes them, how they compose with `bus_generic_suspend` and `pci_suspend_child`, and how the `myfirst` driver's method table grows to include them.

22.3 Section 2: FreeBSD's Power Management Interface

Section 1 described the layered world of ACPI, PCI, PCIe, and wake sources. Section 2 narrows the view to the FreeBSD kernel's interface: the specific kobj methods the driver implements, the way the kernel dispatches them, and the generic helpers that make the whole scheme tractable. By the end of this section the `myfirst` driver has a skeleton power-management implementation that compiles, logs transitions, and can be exercised with `devctl suspend` and `devctl resume`. The skeleton does not yet quiesce DMA or restore state; that is Section 3's and Section 4's work. Section 2's job is to get the kernel to call the driver's methods so the rest of the chapter has something concrete to build on.

22.3.1 The Four Kobj Methods

The FreeBSD device framework treats a driver as an implementation of a kobj interface defined in `/usr/src/sys/kern/device_if.m`. That file is a small domain-specific language (`make -V` rules turn it into a header of function pointers and wrappers), and it defines the set of methods every driver can implement. The Chapter 16 to 21 work has populated the common methods: `DEVICE_PROBE`, `DEVICE_ATTACH`, `DEVICE_DETACH`. Power management adds four more, all documented in the same file with comments the reader can read directly:

1. **DEVICE_SUSPEND** is called when the kernel has decided to put the device into a suspended state. The method runs with the device still in D0 and with the driver still responsible for it. The method's job is to stop activity and, if necessary, save any state that will not be restored automatically. Returning 0 indicates success. Returning non-zero vetoes the suspend.
2. **DEVICE_RESUME** is called after the device has been returned to D0 on the way back from suspend. The method's job is to restore any state the hardware lost and to resume activity. Returning 0 indicates success. Returning non-zero causes the kernel to log a complaint; the resume cannot be meaningfully vetoed at this stage because the rest of the system has already come back.
3. **DEVICE_SHUTDOWN** is called during system shutdown to let the driver leave the device in a safe state for reboot or power-off. Many drivers implement this by calling their suspend method, because the two tasks are similar (stop the device cleanly). Returning 0 indicates success.

4. **DEVICE_QUIESCE** is called when the framework wants the driver to stop accepting new work but has not yet decided to detach. It is a softer form of detach: the device is still attached, the resources are still allocated, but the driver should refuse new submissions and let in-flight work drain. This method is optional and less commonly implemented than the other three; `device_quiesce` is called automatically before `device_detach` by the devctl layer, so a driver that implements both suspend and quiesce often shares code between them.

The file also contains default no-op implementations: `null_suspend`, `null_resume`, `null_shutdown`, `null_quiesce`. A driver that does not implement one of the methods gets the no-op, which returns 0 and does nothing. That is why Chapter 16 through Chapter 21 did not explicitly mention these methods: the no-ops were quietly being used, and for a driver whose device stays powered up forever and whose detach happens only at module unload, the no-ops give correct behavior for most workloads.

Chapter 22's first step is to replace those no-ops with real implementations.

22.3.2 Adding the Methods to the Driver's Method Table

The `device_method_t` array in a FreeBSD driver lists the kobj methods the driver implements. The `myfirst` driver's current method array (in `myfirst_pci.c`) looks something like this:

```
static device_method_t myfirst_pci_methods[] = {
    DEVMETHOD(device_probe,     myfirst_pci_probe),
    DEVMETHOD(device_attach,    myfirst_pci_attach),
    DEVMETHOD(device_detach,    myfirst_pci_detach),

    DEVMETHOD_END

};
```

Adding power management is mechanically simple: the driver adds three (or four) `DEVMETHOD` lines. The names on the left are the kobj method names from `device_if.m`; the names on the right are the driver's implementations. A complete set looks like this:

```
static device_method_t myfirst_pci_methods[] = {
    DEVMETHOD(device_probe,     myfirst_pci_probe),
    DEVMETHOD(device_attach,    myfirst_pci_attach),
    DEVMETHOD(device_detach,    myfirst_pci_detach),
    DEVMETHOD(device_suspend,   myfirst_pci_suspend),
    DEVMETHOD(device_resume,    myfirst_pci_resume),
    DEVMETHOD(device_shutdown,  myfirst_pci_shutdown),

    DEVMETHOD_END

};
```

The `myfirst_pci_suspend`, `myfirst_pci_resume`, and `myfirst_pci_shutdown` functions are new; they do not exist yet. The rest of Section 2 shows what each of them does at the skeleton level.

22.3.3 Prototypes and Return Values

Each of the four methods has the same signature: an `int` return value and one `device_t` argument. The `device_t` is the device the method is being called on, and the driver can use `device_get_softc(dev)` to recover the `softc` pointer.

```
static int myfirst_pci_suspend(device_t dev);
static int myfirst_pci_resume(device_t dev);
static int myfirst_pci_shutdown(device_t dev);
static int myfirst_pci_quiesce(device_t dev); /* optional */
```

Return values follow the usual FreeBSD convention. Zero means success. Non-zero is a regular `errno` value that indicates what went wrong: `EBUSY` if the driver cannot suspend because the device is busy, `EIO` if the hardware reported an error, `EINVAL` if the driver was called in an impossible state. The kernel's reaction differs per method.

For `DEVICE_SUSPEND`, a non-zero return **veto**es the suspend. The kernel aborts the suspend sequence and calls `DEVICE_RESUME` on the drivers that had already suspended successfully, unwinding the partial suspend. This is the mechanism that prevents a system from going to S3 while a critical device is in the middle of something the driver cannot interrupt. It should be used sparingly; returning `EBUSY` from every suspend whenever something is happening is a sure way to make suspend unreliable. A good driver only vetoes when the device is in a state that truly cannot be suspended.

For `DEVICE_RESUME`, a non-zero return is logged but mostly ignored. By the time resume is running, the system is coming back whether the driver likes it or not. The driver should log the error, mark its device as broken so that subsequent I/O fails cleanly, and return. A veto at resume time is too late to be useful.

For `DEVICE_SHUTDOWN`, a non-zero return is likewise mostly informational. The system is shutting down; the driver should try its best to leave the device in a safe state, but a failed shutdown is not an emergency.

For `DEVICE_QUIESCE`, a non-zero return prevents the subsequent operation (usually `detach`) from proceeding. A driver that returns `EBUSY` from `DEVICE_QUIESCE` forces the user to wait or to use `devctl detach -f` to force the detach.

22.3.4 The Order of Event Delivery

The kernel does not call `DEVICE_SUSPEND` on every driver at once. It walks the device tree and calls the method in a specific order, usually **reverse child order** on suspend and **forward child order** on resume. This is because a suspend is safest when each device is suspended *after* the devices that depend on it, and each device is resumed *before* the devices that depend on it.

Consider a simplified tree:

```
nexus0
  acpi0
    pci0
      pcib0
```

```

    myfirst0
pcib1
    em0
    xhci0
    umass0

```

On an S3 suspend, the traversal for the subtree under `pci0` suspends `myfirst0` before `pcib0`, `em0` before `pcib1`, and `umass0` before `xhci0`. Then `pcib0`, `pcib1`, and `xhci0` are suspended. Then `pci0`. Then `acpi0`. Then `nexus0`. Each parent is suspended only after all its children are suspended.

On resume, the order is reversed. `nexus0` resumes first, then `acpi0`, then `pci0`, then `pcib0`, `pcib1`, `xhci0`. Each of those calls `pci_resume_child` on its children, which transitions the child back to D0 before calling the child driver's `DEVICE_RESUME`. So `myfirst0`'s `device_resume` runs with `pcib0` already active and `pci0` already reconfigured.

The practical consequence for the driver is that during `DEVICE_SUSPEND` it can still access the device normally (the parent bus is still up), and during `DEVICE_RESUME` it can also access the device normally (the parent bus has been resumed first). The driver does not need to handle the edge case of a suspended parent.

There is one subtlety: if a parent bus reports that its children must be suspended in a specific order (ACPI can do this to express implicit dependencies), the generic helper `bus_generic_suspend` respects that order. The `myfirst` driver, whose parent is a PCI bus, does not need to worry about order beyond “children before parent”; the PCI bus has no strong ordering between its child devices.

22.3.5 `bus_generic_suspend`, `bus_generic_resume`, and the PCI Bus

A **bus driver** is itself a device driver, and when the kernel calls `DEVICE_SUSPEND` on a bus, the bus usually has to suspend all its children before it can itself go quiet. Implementing that by hand would be repetitive, so the kernel provides two helpers in `/usr/src/sys/kern/subr_bus.c`:

```

int bus_generic_suspend(device_t dev);
int bus_generic_resume(device_t dev);

```

The first iterates over the bus's children in reverse order and calls `BUS_SUSPEND_CHILD` on each. The second iterates forward and calls `BUS_RESUME_CHILD`. If any child's suspend fails, `bus_generic_suspend` unwinds by resuming the children that had already suspended.

A typical bus driver uses these helpers directly:

```

static device_method_t mybus_methods[] = {
    /* ... */
    DEVMETHOD(device_suspend, bus_generic_suspend),
    DEVMETHOD(device_resume, bus_generic_resume),
    DEVMETHOD_END
};

```

The `virtio_pci_modern` bus driver does exactly this in `/usr/src/sys/dev/virtio/pci/virtio_pci_modern.c`, where `vtpci_modern_suspend` and `vtpci_modern_resume` each just call `bus_generic_suspend(dev)` and `bus_generic_resume(dev)`.

The **PCI bus itself** does something more sophisticated: its `bus_suspend_child` is `pci_suspend_child`, and its `bus_resume_child` is `pci_resume_child`. These helpers (in `/usr/src/sys/dev/pci/pci.c`) do exactly what Section 1 described: on suspend they call `pci_cfg_save` to cache the configuration space, then call the driver's `DEVICE_SUSPEND`, and then if `hw.pci.do_power_suspend` is true they call `pci_set_powerstate(child, PCI_POWERSTATE_D3)`. On resume they reverse the sequence: transition back to D0, restore configuration from cache, clear pending PME#, and call the driver's `DEVICE_RESUME`.

The `myfirst` driver, which attaches directly to a PCI device, does not implement bus methods itself; it is a leaf driver. Its power methods are the ones that matter for its own device's state. But the reader should be aware that the PCI bus has already done work on both sides of the driver's methods: on suspend, by the time the driver's `DEVICE_SUSPEND` runs, the PCI layer has already saved the configuration; on resume, by the time the driver's `DEVICE_RESUME` runs, the PCI layer has already restored the configuration and brought the device back to D0.

22.3.6 `pci_save_state` and `pci_restore_state`: When the Driver Calls Them

The automatic save and restore handled by `pci_cfg_save/pci_cfg_restore` cover the standard PCI configuration registers: the BAR assignments, the command register, the cache-line size, the interrupt line, the MSI/MSI-X state. For most drivers, this is enough, and the driver does not need to call `pci_save_state` or `pci_restore_state` explicitly.

There are, however, situations where a driver does want to save the configuration manually. The PCI API exposes two helper functions for this:

```
void pci_save_state(device_t dev);
void pci_restore_state(device_t dev);
```

`pci_save_state` is a wrapper around `pci_cfg_save` that caches the current configuration. `pci_restore_state` writes the cached configuration back; if the device is not in D0 when `pci_restore_state` is called, the helper transitions it to D0 before restoring.

A driver typically calls these in two scenarios:

1. **Before and after a manual `pci_set_powerstate` that the driver itself initiates**, for example in a runtime power-management helper. If the driver decides to put an idle device into D3 while the system is in S0, it calls `pci_save_state`, then `pci_set_powerstate(dev, PCI_POWERSTATE_D3)`. When it wakes the device back up, it calls `pci_set_powerstate(dev, PCI_POWERSTATE_D0)` followed by `pci_restore_state`.
2. **Inside `DEVICE_SUSPEND` and `DEVICE_RESUME`, when the automatic save/restore is disabled**. Some drivers set `hw.pci.do_power_suspend` to 0 for devices that misbehave in D3, and manage the power state themselves. In that case the driver is also responsible for saving and restoring configuration. This is an uncommon pattern.

Chapter 22's `myfirst` driver uses scenario 1 in Section 5 (runtime PM), where the driver chooses to park the device in D3 while the system stays in S0. For system suspend, the driver does not call these helpers directly; the PCI layer handles it.

22.3.7 The `pci_has_pm` Helper

Not every PCI device has the PCI power-management capability. Older devices and some special-purpose ones do not advertise the capability, which means the driver cannot rely on `pci_set_powerstate` or `pci_enable_pme` working. The kernel provides a helper to check:

```
bool pci_has_pm(device_t dev);
```

Returns true if the device exposes a power-management capability, false otherwise. Most modern PCIe devices return true. Drivers that want to be robust against unusual hardware guard their power-related calls:

```
if (pci_has_pm(sc->dev))
    pci_enable_pme(sc->dev);
```

The Realtek driver in `/usr/src/sys/dev/re/if_re.c` uses this pattern in its `re_setwol` and `re_clrwol` functions: if the device does not have a PM capability, the function returns early without trying to touch power management.

22.3.8 PME#: Enabling, Disabling, and Clearing

On a device that does have the PM capability, the driver can ask the hardware to raise PME# when a wake-relevant event occurs. The API is three short functions:

```
void pci_enable_pme(device_t dev);
void pci_clear_pme(device_t dev);
/* there is no explicit pci_disable_pme; pci_clear_pme both clears pending
 * events and disables the PME_En bit. */
```

`pci_enable_pme` sets the `PME_En` bit in the device's power-management status/control register, so that the next power-management event the device detects causes it to assert PME#. `pci_clear_pme` clears any pending PME status bit and clears `PME_En`.

A driver that wants to enable wake-on-LAN, for example, typically:

1. Configures the device's own wake logic (set up pattern filters, set the magic-packet flag, etc.).
2. Calls `pci_enable_pme(dev)` in the suspend path so the device can actually assert PME#.
3. In the resume path, calls `pci_clear_pme(dev)` to acknowledge the wake event.

If `pci_enable_pme` is not called, the device will not raise PME# even if its own wake logic fires. If `pci_clear_pme` is not called on resume, a stale PME status bit can cause spurious future wake events.

The `myfirst` driver does not implement wake-on-X (the simulated device has nothing to wake on), so these calls do not appear in the main driver code. Section 4 includes a short sketch showing where they would go in a real driver.

22.3.9 A First Skeleton: Stage 1

With all of the background in place, we can write the first version of `myfirst`'s suspend, resume, and shutdown methods. Stage 1 of the Chapter 22 driver does nothing of substance; it only logs and returns success. The point is to get the kernel to call the methods so the rest of the chapter can test progressively.

First, add prototypes near the top of `myfirst_pci.c`:

```
static int myfirst_pci_suspend(device_t dev);
static int myfirst_pci_resume(device_t dev);
static int myfirst_pci_shutdown(device_t dev);
```

Next, extend the method table:

```
static device_method_t myfirst_pci_methods[] = {
    DEVMETHOD(device_probe,     myfirst_pci_probe),
    DEVMETHOD(device_attach,    myfirst_pci_attach),
    DEVMETHOD(device_detach,    myfirst_pci_detach),
    DEVMETHOD(device_suspend,   myfirst_pci_suspend),
    DEVMETHOD(device_resume,    myfirst_pci_resume),
    DEVMETHOD(device_shutdown,  myfirst_pci_shutdown),

    DEVMETHOD_END

};
```

Then implement the three functions at the end of the file:

```
static int
myfirst_pci_suspend(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    device_printf(dev, "suspend (stage 1 skeleton)\n");
    atomic_add_64(&sc->power_suspend_count, 1);
    return (0);
}

static int
myfirst_pci_resume(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    device_printf(dev, "resume (stage 1 skeleton)\n");
    atomic_add_64(&sc->power_resume_count, 1);
    return (0);
}
```

```

}

static int
myfirst_pci_shutdown(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    device_printf(dev, "shutdown (stage 1 skeleton)\n");
    atomic_add_64(&sc->power_shutdown_count, 1);
    return (0);
}

```

Add the counter fields to the softc in myfirst.h:

```

struct myfirst_softc {
    /* ... existing fields ... */

    uint64_t power_suspend_count;
    uint64_t power_resume_count;
    uint64_t power_shutdown_count;
};

```

Expose them through sysctls next to the Chapter 21 counters, in whatever function already adds the myfirst sysctl tree:

```

SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "power_suspend_count",
    CTLFLAG_RD, &sc->power_suspend_count, 0,
    "Number of times DEVICE_SUSPEND has been called");
SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "power_resume_count",
    CTLFLAG_RD, &sc->power_resume_count, 0,
    "Number of times DEVICE_RESUME has been called");
SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "power_shutdown_count",
    CTLFLAG_RD, &sc->power_shutdown_count, 0,
    "Number of times DEVICE_SHUTDOWN has been called");

```

Bump the version string in the Makefile:

```
CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.5-power-stage1\"
```

Build, load, and test:

```
cd /path/to/driver
make clean && make
sudo kldload ./myfirst.ko
sudo devctl suspend myfirst0
sudo devctl resume myfirst0
sysctl dev.myfirst.0.power_suspend_count
sysctl dev.myfirst.0.power_resume_count
dmesg | tail -6
```

The expected output in `dmesg` is:

```
myfirst0: suspend (stage 1 skeleton)
myfirst0: resume (stage 1 skeleton)
```

And the counters should each read 1. If they do not, one of three things is wrong: the driver did not rebuild, the method table did not include the new entries, or `devctl` reported an error because the kernel cannot find the device by that name.

22.3.10 What the Skeleton Proves

Stage 1 looks trivial, but it proves three things that matter for the rest of the chapter:

1. **The kernel is delivering the methods.** If the counters increment, the `kobj` dispatch from `devctl` through the PCI bus to the `myfirst` driver is wired correctly. Every later stage builds on this, and it is easier to catch wiring bugs now than after adding real quiesce code.
2. **The method table is sourced correctly.** The `DEVMETHOD` lines with the method name and the driver's function pointer were typed correctly, the header includes are right, and the `DEVMETHOD_END` terminator is in place. A mistake here produces a kernel panic at load time, not a subtle runtime failure.
3. **The driver counts transitions.** The counters will be useful throughout the chapter as a cheap invariant check. `power_suspend_count` should always equal `power_resume_count` once the system is idle; any drift indicates a bug in one of the two methods.

With the skeleton in place, Section 3 can turn the suspend method from a log-only call into a real quiesce of the device's activity.

22.3.11 A Note on Detach, Quiesce, and Suspend

The reader may wonder how `DEVICE_DETACH`, `DEVICE_QUIESCE`, and `DEVICE_SUSPEND` relate. They look similar; each asks the driver to stop doing something. Here is the practical distinction, as the kernel enforces it:

- **DEVICE_QUIESCE** is the softest. It asks the driver to stop accepting new work and to drain in-flight work, but the device stays attached, its resources stay allocated, and another request can reactivate it. The kernel calls this before `DEVICE_DETACH` to give the driver a chance to refuse if the device is busy.

- **DEVICE_SUSPEND** is in the middle. It asks the driver to stop activity but leaves the resources allocated, because the driver will need them again on resume. The device's state is preserved (partly by the kernel through PCI config save, partly by the driver through its own saved state).
- **DEVICE_DETACH** is the hardest. It asks the driver to stop activity, release all resources, and forget the device. The only way to come back is through a fresh attach.

Many drivers implement `DEVICE_QUIESCE` by reusing parts of the suspend path (stop interrupts, stop DMA, drain queues) and `DEVICE_SHUTDOWN` by calling the suspend method directly. `/usr/src/sys/dev/xl/if_xl.c` does exactly that: `xl_shutdown(dev)` just calls `xl_suspend(dev)`. The relationship is:

- `shutdown` $\approx$ `suspend` (for most drivers that do not distinguish shutdown-specific behavior like wake-on-LAN defaults differently)
- `quiesce` $\approx$ half of `suspend` (stop activity, do not save state)
- `suspend` = `quiesce` + save state
- `resume` = restore state + un-quiesce
- `detach` = `quiesce` + free resources

Chapter 22 implements suspend, resume, and shutdown in full. It does not implement `DEVICE_QUIESCE` for the `myfirst` driver, because the Chapter 21 detach path already quiesces correctly, and `device_quiesce` would be redundant. A driver that wanted to allow a “stop I/O but keep the device attached” state (for example, to support `devctl detach -f gracefully`) would add `DEVICE_QUIESCE` as a separate method. The chapter mentions this for completeness and moves on.

22.3.12 The Detach Path as Inspiration

The Chapter 21 detach path is a useful reference because it already does most of what suspend needs to do. The detach path masks interrupts, drains the rx task and the simulation callout, waits for any in-flight DMA to complete, and calls `myfirst_dma_tear_down`. The suspend path will do the first three (mask, drain, wait) and skip the last (tear_down). A well-structured driver factors those common steps into shared helpers so that both paths use the same code.

Section 3 introduces exactly those helpers: `myfirst_stop_io`, `myfirst_drain_workers`, `myfirst_mask_interrupts`. Each is a small function extracted from the Chapter 21 detach path. Suspend uses them without tearing down resources; detach uses them and then tears down. The reuse keeps the two paths correct by construction.

22.3.13 Observing the Skeleton with WITNESS

A reader who has built the debug kernel with `WITNESS` can now run the skeleton and watch for any lock-order warnings. There should be none, because the skeleton does not acquire any locks. Section 3 will add lock acquisition in the suspend path, and `WITNESS` will immediately notice if the order disagrees with the order used in detach. That is one of the benefits of working in stages: the baseline is quiet, so any later warnings are clearly attributable to the stage that introduced them.

22.3.14 Wrapping Up Section 2

Section 2 established the FreeBSD-specific API for power management: the four kobj methods (`DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, `DEVICE_QUIESCE`), their return-value semantics, the order the kernel delivers them, the generic helpers (`bus_generic_suspend`, `bus_generic_resume`) that walk the device tree, and the PCI-specific helpers (`pci_suspend_child`, `pci_resume_child`) that automatically save and restore configuration space around the driver's methods. The Stage 1 skeleton gave the driver log-only implementations of the three main methods, added counters to the softc, and verified that `devctl suspend` and `devctl resume` invoke them correctly.

What the skeleton does not do is interact with the device at all. The interrupt handlers keep firing; DMA transfers can still be in flight when suspend returns; the device does not go quiet. Section 3 fixes all of that: it introduces the quiesce discipline, factors the common stop-I/O helpers out of the Chapter 21 detach path, and turns the Stage 1 skeleton into a Stage 2 driver that actually quiesces the device before reporting success.

22.4 Section 3: Quiescing a Device Safely

Section 2 gave the driver skeleton suspend, resume, and shutdown methods that only log. Section 3 turns the suspend skeleton into a real suspend: one that stops interrupts, stops DMA, drains deferred work, and leaves the device in a defined quiet state before returning. Doing that correctly is the hardest single piece of power management, and it is where the Chapter 21 primitives pay off. If you have a clean DMA teardown path, a clean taskqueue drain, and a clean callout drain, you have most of what you need; quiesce is the art of applying them in the right order without tearing down the resources you will need back on resume.

22.4.1 What Quiesce Really Means

The word “quiesce” appears in several places in FreeBSD (`DEVICE_QUIESCE`, `device_quiesce`, `pcie_wait_for_pending`) and it means something specific: **to bring a device to a state where no activity is ongoing, no activity can start, and the hardware is not about to raise any more interrupts or do any more DMA**. The device is still fully attached, still has all its resources, still has its interrupt handlers registered, but it is not doing anything and is not going to do anything until something tells it to start again.

Quiescing is different from detach because detach unwinds the resource allocations. Quiescing is also different from a simple “set a flag that says the device is busy, so that future requests block”, because that flag only protects against new work entering the driver; it does not stop the hardware itself or the kernel-side infrastructure (tasks, callouts) from doing anything.

A quiesced device, in Chapter 22's sense, has these properties:

1. The device is not asserting, and cannot be provoked into asserting, an interrupt. Any interrupt mask the device has is set to suppress all sources. The interrupt handler, if it is called, has nothing to do.
2. The device is not performing DMA. Any in-flight DMA transfer has either completed or been aborted. The engine's control register is either in an idle state or has been explicitly reset.
3. The driver's deferred work has drained. Any task queued to the taskqueue has been executed or explicitly waited for. Any callout has been drained and will not fire.

4. The driver's softc fields reflect the quiesced state. The `dma_in_flight` flag is false. Any in-flight counter the driver keeps is zero. The suspended flag is true, so any new request the user space or another driver might submit gets an error.

Only when all four properties are true is the device actually quiet. A driver that masks interrupts but forgets to drain the taskqueue still has a task running in the background. A driver that drains the taskqueue but forgets the callout still has a timer that can fire. A driver that drains both but forgets to stop DMA can have a transfer commit bytes to memory after the CPU stopped looking. Each omission produces its own characteristic failure, and the cheapest way to avoid them all is to have one function that does the whole discipline in a known order.

22.4.2 The Order Matters

The four steps above are not independent. They have a dependency order that the driver has to respect, because the kernel-side infrastructure and the device interact. Consider what happens if the order is wrong.

If DMA is stopped before interrupts are masked, an interrupt can arrive between the DMA stop and the mask. The filter runs, sees a stale status bit, schedules a task. The task runs, expects a DMA buffer to be populated, finds stale data, and may corrupt the driver's internal state. Better to mask interrupts first so no new interrupts arrive while the stop is in progress.

If the taskqueue is drained before the device stops producing interrupts, a new interrupt can fire after the drain returns and schedule a task on a queue that was just drained. The task runs later, out of sync with the suspend sequence. Better to stop interrupts first so no new tasks are scheduled.

If the callout is drained before DMA is stopped, a simulated engine driven by a callout might see its callout torn down while a transfer is still in progress. The transfer never completes; `dma_in_flight` stays true; the driver hangs waiting for a completion that cannot come. Better to stop DMA first, wait for completion, then drain the callout.

The safe order, used by Chapter 21's detach path and adapted for Chapter 22's suspend, is:

1. Mark the driver as suspended (set a softc flag so new requests bounce).
2. Mask all interrupts at the device (write the interrupt-mask register).
3. Stop DMA: if a transfer is in flight, abort it and wait for it to reach a terminal state.
4. Drain the taskqueue (any task already running gets to finish; no new tasks start).
5. Drain any callouts (any fire in flight gets to finish; no new firings happen).
6. Verify the invariant (`dma_in_flight == false`, `softc->busy == 0`, etc.).

Each step builds on the previous one. By step 6, the device is quiet.

22.4.3 Helpers, Not Inline Code

A naive implementation would put all six steps inline in `myfirst_pci_suspend`. That works, but it duplicates code the detach path already has, and it makes both paths harder to maintain. The chapter's preferred pattern is to factor the steps into small helper functions that both paths call.

Three helpers are enough to cover the whole discipline:

```
static void myfirst_mask_interrupts(struct myfirst_softc *sc);
static int myfirst_drain_dma(struct myfirst_softc *sc);
static void myfirst_drain_workers(struct myfirst_softc *sc);
```

Each has one job:

- `myfirst_mask_interrupts` writes the device's interrupt-mask register to disable every vector the driver cares about. After it returns, no interrupt can arrive from this device.
- `myfirst_drain_dma` asks any in-flight DMA transfer to stop (sets the ABORT bit) and waits until `dma_in_flight` is false. It returns 0 on success, a non-zero `errno` if the device did not stop within the timeout.
- `myfirst_drain_workers` calls `taskqueue_drain` on the driver's taskqueue and `callout_drain` on the simulation's callout. After it returns, no deferred work is pending.

The suspend path calls all three in order. The detach path also calls all three, plus `myfirst_dma_tearardown` and the resource-release calls. The two paths share the quiesce steps and differ only at the end.

Here is the quiesce entry point the suspend path uses:

```
static int
myfirst_quiesce(struct myfirst_softc *sc)
{
    int err;

    MYFIRST_LOCK(sc);
    if (sc->suspended) {
        MYFIRST_UNLOCK(sc);
        return (0); /* already quiet, nothing to do */
    }
    sc->suspended = true;
    MYFIRST_UNLOCK(sc);

    myfirst_mask_interrupts(sc);

    err = myfirst_drain_dma(sc);
    if (err != 0) {
        device_printf(sc->dev,
            "quiesce: DMA did not stop cleanly (err %d)\n", err);
        /* Do not fail the quiesce; we still have to drain workers. */
    }

    myfirst_drain_workers(sc);

    return (err);
}
```

Note the design choice: `myfirst_quiesce` does not unwind on a DMA drain failure. A DMA that will not stop is a hardware problem, and the driver cannot undo the mask or unmark the suspend flag in response. The driver logs the problem, reports the error to the caller, and continues draining workers so that the rest of the state is still consistent. The caller (`myfirst_pci_suspend`) decides what to do with the error.

22.4.4 Implementing `myfirst_mask_interrupts`

For the `myfirst` driver, masking interrupts means writing the device's interrupt-mask register. The Chapter 19 simulation backend already has an `INTR_MASK` register at a known offset; the driver writes all-ones to it to disable every source.

```
static void
myfirst_mask_interrupts(struct myfirst_softc *sc)
{
    MYFIRST_ASSERT_UNLOCKED(sc);

    /*
     * Disable all interrupt sources at the device. After this write,
     * the hardware will not assert any interrupt vector. Any already-
     * pending status bits remain, but the filter will not be called
     * to notice them.
     */
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0xFFFFFFFF);

    /*
     * For real hardware: also clear any pending status bits so we
     * don't see a stale interrupt on resume.
     */
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, 0xFFFFFFFF);
}
```

The function does not hold the `softc` lock. It talks only to the device through `CSR_WRITE_4`, which is a wrapper around `bus_write_4` that does not require any particular lock discipline. The `MYFIRST_ASSERT_UNLOCKED` call is a WITNESS-enabled invariant that catches a caller who mistakenly held the lock when calling this function; it is cheap and useful.

The mask value `0xFFFFFFFF` assumes the simulation's `INTR_MASK` register uses 1-means-masked semantics. The Chapter 19 simulation uses that convention; a real driver should consult its device's datasheet. The register map for `myfirst` is documented in `INTERRUPTS.md`; the reader can double-check the convention there.

A subtlety: on some real devices, masking interrupts only prevents the device from asserting new interrupts; the currently-active one continues to assert until the driver acknowledges it through the status register. That is why the function also clears `INTR_STATUS`: to make sure no stale bit is left asserted that could fire again after resume. On the simulation, the status register behaves similarly, so the same write is correct.

22.4.5 Implementing myfirst_drain_dma

Draining DMA is the most delicate of the three helpers, because it has to wait for the device. The Chapter 21 driver tracks in-flight DMA with `dma_in_flight` and notifies completion through `dma_cv`. The suspend path reuses that exact machinery.

```
static int
myfirst_drain_dma(struct myfirst_softc *sc)
{
    int err = 0;

    MYFIRST_LOCK(sc);
    if (sc->dma_in_flight) {
        /*
         * Tell the engine to abort. The abort bit produces an
         * ERR status that the filter will translate into a task
         * that wakes us via cv_broadcast.
         */
        CSR_WRITE_4(sc, MYFIRST_REG_DMA_CTRL,
                    MYFIRST_DMA_CTRL_ABORT);

        /*
         * Wait up to one second for the abort to land. The
         * cv_timedwait drops the lock while we sleep.
         */
        err = cv_timedwait(&sc->dma_cv, &sc->mtx, hz);
        if (err == EWOULDBLOCK) {
            device_printf(sc->dev,
                          "drain_dma: timeout waiting for abort\n");
            /*
             * Force the state forward. The device is
             * beyond our reach at this point; treat the
             * transfer as failed.
             */
            sc->dma_in_flight = false;
        }
    }
    MYFIRST_UNLOCK(sc);

    return (err == EWOULDBLOCK ? ETIMEDOUT : 0);
}
```

The function asks the DMA engine to abort, then sleeps on the condition variable used by the Chapter 21 completion path. If the completion arrives, the filter acknowledges it and enqueues a task; the task calls `myfirst_dma_handle_complete`, which does the POSTREAD/POSTWRITE sync, clears `dma_in_flight`, and

broadcasts the CV. The suspend path's `cv_timedwait` returns, the drain function returns 0, and the suspend continues.

If the completion does not arrive within one second (a second is a generous timeout for a simulated device whose callout fires every few milliseconds), the function logs a warning and forces `dma_in_flight` to false. This is a defensive choice: a real device that does not honor abort within a second is misbehaving, and the driver has to move on. Leaving `dma_in_flight` true would deadlock the suspend. The cost of the defensive clear is that a very slow transfer could in principle complete after the suspend returned, writing into a buffer the driver no longer expects to be live. On the simulation, that cannot happen because the callout is drained in the next step. On real hardware, the risk is hardware-specific and a real driver would add device-specific recovery here.

The return value is 0 on a clean drain (including the timeout case, which has been force-cleared) and `ETIMEDOUT` if the caller needs to know a timeout happened. The suspend path logs the error but does not veto the suspend; by the time the drain has timed out, the device is effectively broken anyway.

22.4.6 Implementing `myfirst_drain_workers`

Draining deferred work is easier because it does not involve the device. The rx task and the simulation's callout each have well-known drain primitives.

```
static void
myfirst_drain_workers(struct myfirst_softc *sc)
{
    /*
     * Drain the per-vector rx task. Any task currently running is
     * allowed to finish; no new tasks will be scheduled because
     * interrupts are already masked.
     */
    if (sc->rx_vector.has_task)
        taskqueue_drain(taskqueue_thread, &sc->rx_vector.task);

    /*
     * Drain the simulation's DMA callout. Any fire in flight is
     * allowed to finish; no new firings will happen.
     *
     * This is a simulation-only call; a real-hardware driver would
     * omit it.
     */
    if (sc->sim != NULL)
        myfirst_sim_drain_dma_callout(sc->sim);
}
```

The function is safe to call with the lock released. `taskqueue_drain` is documented to do its own synchronisation; `callout_drain` (which `myfirst_sim_drain_dma_callout` wraps internally) is similarly safe.

An important property of both drain calls: they wait for running work to finish, but they do not cancel it in the middle. A task that is halfway through `myfirst_dma_handle_complete` will complete its work, including any

bus_dmamap_sync and counter update, before the drain returns. That is the behavior we want: suspend should not interrupt a task partway through, because the task's invariants must hold for the resume path to be correct.

22.4.7 Updating the Suspend Method

With the three helpers in place, the suspend method is short:

```
static int
myfirst_pci_suspend(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int err;

    device_printf(dev, "suspend: starting\n");

    err = myfirst_quiesce(sc);
    if (err != 0) {
        device_printf(dev,
            "suspend: quiesce returned %d; continuing anyway\n",
            err);
    }

    atomic_add_64(&sc->power_suspend_count, 1);
    device_printf(dev,
        "suspend: complete (dma in flight=%d, suspended=%d)\n",
        sc->dma_in_flight, sc->suspended);
    return (0);
}
```

The suspend method does not return the quiesce error to the kernel. That is a policy decision, and it deserves explanation.

Returning a non-zero value from `DEVICE_SUSPEND` vetoes the suspend, which has a large downstream effect: the kernel unwinds the partial suspend, reports a failure to the user, and leaves the system in S0. For Chapter 22's driver, a quiesce timeout does not justify that level of disruption. The device is still accessible; masking the interrupt and marking the suspended flag is enough to prevent any activity. A real driver might choose differently: a storage controller with an outstanding write might veto the suspend until the write completes, because losing that write across the transition would corrupt the filesystem. Each driver makes its own call.

The logging is verbose at this stage. Section 7 will introduce the ability to turn off the verbose logging (or crank it up for debugging) through a sysctl. For now, the extra detail helps when stepping through the suspend sequence for the first time.

22.4.8 Saving Runtime State the Hardware Loses

So far the suspend path has only stopped activity. It has not saved any state. For most devices that is correct: the PCI layer saves configuration space automatically, and the device's runtime registers (the ones the driver writes through BARs) are either restored from the driver's softc on resume or regenerated from the driver's software state. The `myfirst` simulation does not have any BAR-local state the driver cares about preserving; the simulation starts fresh on resume, and the driver writes whatever registers it needs at that point.

A real driver may have more. Consider the `re(4)` driver: its `re_setwol` function writes wake-on-LAN-related registers into the NIC's EEPROM-backed configuration space before suspend. Those values are device-private; the PCI layer does not know about them. If the driver did not write them in suspend, the NIC would not know it was supposed to wake on a magic packet, and wake-on-LAN would not work.

For Chapter 22, the only state the `myfirst` driver saves is the interrupt mask's pre-suspend value. The Stage 2 suspend writes `0xFFFFFFFF` to the mask register, but the Stage 2 resume needs to know what value was there before (which determines which vectors are enabled in normal operation). The driver stores that in a `softc` field:

```
struct myfirst_softc {
    /* ... */
    uint32_t saved_intr_mask;
};
```

And the mask helper saves it:

```
static void
myfirst_mask_interrupts(struct myfirst_softc *sc)
{
    sc->saved_intr_mask = CSR_READ_4(sc, MYFIRST_REG_INTR_MASK);

    CSR_WRITE_4(sc, MYFIRST_REG_INTR_MASK, 0xFFFFFFFF);
    CSR_WRITE_4(sc, MYFIRST_REG_INTR_STATUS, 0xFFFFFFFF);
}
```

The resume path will write `sc->saved_intr_mask` back to the mask register after the device has been reinitialised. This is a minimal example of state-save-and-restore; Section 4 elaborates when it shows the full resume flow.

22.4.9 The suspended Flag as a User-Facing Invariant

Setting `sc->suspended = true` during quiesce has a second purpose beyond suppressing new requests: it makes the state observable to user space. The driver can expose the flag through a `sysctl`:

```
SYCTL_ADD_BOOL(ctx, kids, OID_AUTO, "suspended",
    CTLFLAG_RD, &sc->suspended, 0,
    "Whether the driver is in the suspended state");
```

After `devctl suspend myfirst0`, the reader sees:

```
# sysctl dev.myfirst.0.suspended
dev.myfirst.0.suspended: 1
```

After `devctl resume myfirst0`, the value should go back to 0 (Section 4 wires the resume path to clear it). This is a quick way to check the driver's state without inferring it from other counters.

22.4.10 Handling the Case Where DMA Is Not in Flight

The `myfirst_drain_dma` helper handles the case where a transfer is actively running. It should also handle the far more common case where nothing is in flight at the moment of suspend, without doing anything unnecessary.

The pseudocode above does handle this: the `if (sc->dma_in_flight)` guard skips the abort and wait entirely when the flag is false. The function returns 0 immediately and the suspend proceeds.

That path is fast: on an idle device, `myfirst_drain_dma` is a lock acquire, a flag check, and a lock release. The cost of the quiesce is dominated by `taskqueue_drain` (which does a full round-trip through the taskqueue thread) and `callout_drain` (similar). A typical idle-device suspend takes a few hundred microseconds to a few milliseconds, dominated by the deferred-work drains, not by the device.

22.4.11 Testing Stage 2

With the quiesce code in place, the Stage 2 test is more interesting. The reader runs a transfer, then immediately suspends, and observes:

```
# Start with no activity.
sysctl dev.myfirst.0.dma_transfers_read
# 0

# Trigger a transfer. The transfer should complete quickly.
sudo sysctl dev.myfirst.0.dma_test_read=1
sysctl dev.myfirst.0.dma_transfers_read
# 1

# Now stress the path: start a transfer and immediately suspend.
sudo sysctl dev.myfirst.0.dma_test_read=1 &
sudo devctl suspend myfirst0

# Check the state.
sysctl dev.myfirst.0.suspended
# 1

sysctl dev.myfirst.0.power_suspend_count
```

```
# 1

sysctl dev.myfirst.0.dma_in_flight
# 0 (the transfer completed or was aborted)

dmesg | tail -8
```

The expected dmesg output shows the suspend log, the in-flight DMA being aborted, and the completion. If `dma_in_flight` is still 1 after the suspend returned, the abort did not take effect, and the reader should check the simulation's abort handling.

Then resume:

```
sudo devctl resume myfirst0

sysctl dev.myfirst.0.suspended
# 0 (after Section 4 is implemented)

sysctl dev.myfirst.0.power_resume_count
# 1

# Try another transfer to check the device is back.
sudo sysctl dev.myfirst.0.dma_test_read=1
dmesg | tail -4
```

The last transfer should succeed; if it does not, the suspend left the device in a state the resume did not recover. Section 4 teaches the resume path that makes this correct.

22.4.12 A Cautious Note on Locking

The quiesce code runs from the `DEVICE_SUSPEND` method, which is called by the kernel's power-management path. That path holds no driver lock when it calls the method; the driver is responsible for its own synchronisation. The helpers in this section follow a specific discipline:

- `myfirst_mask_interrupts` holds no lock. It only writes hardware registers, which are atomic on PCIe.
- `myfirst_drain_dma` takes the softc lock to read `dma_in_flight` and uses `cv_timedwait` to sleep while holding the lock (which is the correct use of a sleep-mutex CV).
- `myfirst_drain_workers` holds no lock. `taskqueue_drain` and `callout_drain` do their own synchronisation and must be called without the lock to avoid deadlock (the task being drained may try to acquire the lock itself).

The full quiesce sequence thus acquires and releases the lock multiple times: once briefly at the top of `myfirst_quiesce` to set `suspended`, once inside `myfirst_drain_dma` for the sleep, and never inside `myfirst_drain_workers`. That is intentional. Holding the lock across `taskqueue_drain` would deadlock, because the drained task acquires the same lock on entry.

A reader who runs this code under WITNESS will not see any lock-order warnings, because the lock is only held over the CV sleep and no other locks are acquired during that window. If later work adds more locks to the driver (for example, a per-vector lock), the quiesce code should remain careful about which locks are held around the drain calls.

22.4.13 Integrating with the Shutdown Method

The shutdown method shares almost all of its logic with suspend. A reasonable implementation is:

```
static int
myfirst_pci_shutdown(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    device_printf(dev, "shutdown: starting\n");
    (void)myfirst_quiesce(sc);
    atomic_add_64(&sc->power_shutdown_count, 1);
    device_printf(dev, "shutdown: complete\n");
    return (0);
}
```

The only difference from suspend is the absence of state-save calls (shutdown is final; there is no resume to save state for) and the absence of a return-value check on the quiesce (shutdown cannot be vetoed meaningfully). Many real drivers follow the same pattern; `/usr/src/sys/dev/xl/if_xl.c`'s `xl_shutdown` just calls `xl_suspend`. The `myfirst` driver can use either style; the chapter prefers the slightly more explicit version above because it makes the intent clearer in the code.

22.4.14 Wrapping Up Section 3

Section 3 turned the Stage 1 skeleton into a Stage 2 driver that actually quiesces the device on suspend. It introduced the quiesce discipline (mark suspended, mask interrupts, stop DMA, drain workers, verify), factored the steps into three helper functions (`myfirst_mask_interrupts`, `myfirst_drain_dma`, `myfirst_drain_workers`), explained the order in which they must run and why, showed how to integrate them into the suspend and shutdown methods, and discussed the locking discipline.

What the Stage 2 driver does not yet do is come back correctly. The resume method is still the Stage 1 skeleton; it logs and returns 0 without restoring anything. If the suspended device had any state the hardware lost, that state is gone, and a subsequent transfer will fail. Section 4 fixes the resume path so that a full suspend-resume cycle leaves the device in the same state it was in before.

22.5 Section 4: Restoring State on Resume

Section 3 gave the driver a correct suspend path. Section 4 writes the matching resume. The resume is the complement of the suspend: every thing suspend stopped, resume restarts; every value suspend saved, resume

writes back; every flag suspend set, resume clears. The sequence is not an exact mirror (resume runs in a different kernel context, with the PCI layer having already done work, and the device in a different state than where suspend left it), but the contents correspond one-to-one. Doing the resume correctly is a matter of respecting the contract the PCI layer has already partly fulfilled, and filling in the rest.

22.5.1 What the PCI Layer Has Already Done

When the kernel's `DEVICE_RESUME` method is called on the driver, several things have already happened:

1. The CPU has come out of the S-state (resumed from S3 or S4 back to S0).
2. Memory has been refreshed and the kernel has re-established its own state.
3. The parent bus has been resumed. For `myfirst`, that means the PCI bus driver has already handled the host bridge and the PCIe root complex.
4. The PCI layer has called `pci_set_powerstate(dev, PCI_POWERSTATE_D0)` on the device, transitioning it from whatever low-power state it was in (typically D3hot) back to full power.
5. The PCI layer has called `pci_cfg_restore(dev, dinfo)`, which writes the cached configuration space values (BARs, command register, cache-line size, etc.) back into the device.
6. The PCI layer has called `pci_clear_pme(dev)` to clear any pending power-management event bits.
7. The MSI or MSI-X configuration, which is part of the cached state, has been restored. The driver's interrupt vectors are usable again.

At this point the PCI bus driver calls into `myfirst`'s `DEVICE_RESUME`. The device is in D0, with its BARs mapped, its MSI/MSI-X table restored, and its generic PCI state intact. What the driver has to restore is the device-specific state that the PCI layer did not know about: the BAR-local registers the driver wrote during or after attach.

For the `myfirst` simulation, the relevant BAR-local registers are the interrupt mask (which the suspend path deliberately set to all-masked) and the DMA registers (which may have been left in an aborted state). The driver needs to put them back to values that reflect normal operation.

22.5.2 The Resume Discipline

A correct resume path does four things, in order:

1. **Re-enable bus-mastering**, in case the configuration-space restore did not do so or the PCI layer's automatic restore was disabled. This is `pci_enable_busmaster(dev)`. On modern FreeBSD it is usually redundant but harmless; older code paths or buggy BIOSes sometimes leave bus-mastering disabled. Calling it defensively is cheap.
2. **Restore any device-specific state** the driver saved during suspend. For `myfirst`, that means writing `saved_intr_mask` back to the `INTR_MASK` register. A real driver would also restore things like vendor-specific configuration bits, DMA engine programming, hardware timers, etc.
3. **Unmask interrupts and clear the suspended flag**, so the device can resume activity. This is the pivot point: before it, the device is still quiet; after it, the device can raise interrupts and accept work.
4. **Log the transition and update counters**, for observability and regression testing.

Here is what the pattern looks like in code:

```

static int
myfirst_pci_resume(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int err;

    device_printf(dev, "resume: starting\n");

    err = myfirst_restore(sc);
    if (err != 0) {
        device_printf(dev,
            "resume: restore failed (err %d)\n", err);
        atomic_add_64(&sc->power_resume_errors, 1);
        /*
         * Continue anyway. By the time we're here, the system
         * is coming back whether we like it or not.
         */
    }

    atomic_add_64(&sc->power_resume_count, 1);
    device_printf(dev, "resume: complete\n");
    return (0);
}

```

The helper `myfirst_restore` does the three real steps:

```

static int
myfirst_restore(struct myfirst_softc *sc)
{
    /* Step 1: re-enable bus-master (defensive). */
    pci_enable_busmaster(sc->dev);

    /* Step 2: restore device-specific state.
     *
     * For myfirst, this is just the interrupt mask. A real driver
     * would restore more: DMA engine programming, hardware timers,
     * vendor-specific configuration, etc.
     */
    if (sc->saved_intr_mask == 0xFFFFFFFF) {
        /*
         * Suspend saved a fully-masked mask, which means the
         * driver had no idea what the mask should be. Use the
         * default: enable DMA completion, disable everything
         * else.
         */
    }
}

```

```

        */
        sc->saved_intr_mask = ~MYFIRST_INTR_COMPLETE;
    }
    CSR_WRITE_4(sc->dev, MYFIRST_REG_INTR_MASK, sc->saved_intr_mask);

    /* Step 3: clear the suspended flag and unmask the device. */
    MYFIRST_LOCK(sc);
    sc->suspended = false;
    MYFIRST_UNLOCK(sc);

    return (0);
}

```

The function returns 0 because no step above can fail in the `myfirst` simulation. A real driver would check the return values of its hardware initialisation calls and propagate any errors.

22.5.3 Why `pci_enable_busmaster` Matters

Bus-mastering is a bit in the PCI command register that controls whether the device can issue DMA transactions. Without it, the device cannot read or write host memory; any DMA trigger would be silently ignored by the PCI host bridge.

Chapter 18 enabled bus-mastering during attach. The PCI layer's automatic config-space restore writes the command register back to its saved value, which includes the bus-master bit. So in principle the driver does not need to call `pci_enable_busmaster` again on resume. In practice, several things can go wrong:

- The platform firmware may reset the command register as part of waking the device.
- The `hw.pci.do_power_suspend` sysctl may be 0, in which case the PCI layer does not save and restore the config space.
- A device-specific quirk might clear bus-mastering as a side effect of the D3-to-D0 transition.

Calling `pci_enable_busmaster` unconditionally defensively in resume is a low-cost safety net. Several production FreeBSD drivers follow this pattern; `if_re.c`'s resume path is one example. The call is idempotent: if bus-mastering is already on, the call just re-asserts it.

22.5.4 Restoring Device-Specific State

The `myfirst` simulation does not have much state the driver needs to restore manually. The BAR-local registers are:

- The interrupt mask (restored from `saved_intr_mask`).
- The interrupt status bits (were cleared in suspend; they should stay cleared until new activity arrives).
- The DMA engine registers (`DMA_ADDR_LOW`, `DMA_ADDR_HIGH`, `DMA_LEN`, `DMA_DIR`, `DMA_CTRL`, `DMA_STATUS`). These are transient: they hold the parameters of the current transfer. After resume, no transfer is in progress, so the values do not matter; the next transfer will overwrite them.

A real driver would have more. Consider a few examples:

- A storage driver might have a DMA descriptor ring whose base address the device learned during attach. After resume, the BAR-level register holding that base address may have been reset; the driver needs to reprogram it.
- A network driver might have filter tables (MAC addresses, multicast lists, VLAN tags) programmed into device registers. After resume, those tables may be empty; the driver rebuilds them from softc-side copies.
- A GPU driver might have register state for display timing, colour tables, hardware cursors. After resume, the driver restores the active mode.

For `myfirst`, the interrupt mask is the only BAR-local state that needs restoring. The pattern shown above is the template a real driver would adapt to its device.

22.5.5 Validating Device Identity After Resume

Some devices are reset completely across a suspend-to-D3-cold cycle. The device that comes back is functionally the same, but its entire state has been reinitialised as if it had just powered on. A driver that assumed nothing changed would silently get wrong behaviour.

A defensive resume path can detect this by reading a known register value and comparing to what it read at attach time. For a PCI device, the vendor ID and device ID in configuration space are always the same (the PCI layer restored them), but some device-private register (a revision ID, a self-test register, a firmware version) can be checked:

```
static int
myfirst_validate_device(struct myfirst_softc *sc)
{
    uint32_t magic;

    magic = CSR_READ_4(sc->dev, MYFIRST_REG_MAGIC);
    if (magic != MYFIRST_MAGIC_VALUE) {
        device_printf(sc->dev,
            "resume: device identity mismatch (got %#x, "
            "expected %#x)\n", magic, MYFIRST_MAGIC_VALUE);
        return (EIO);
    }
    return (0);
}
```

For the `myfirst` simulation, there is no magic register (the simulation was not built with post-resume validation in mind). A reader who wants to add one as a challenge can extend the simulation backend's register map with a read-only `MAGIC` register, and have the driver check it. The chapter's Lab 3 includes this as an option.

A real driver whose device truly does reset across D3cold needs this check, because without it a subtle failure can occur: the driver assumes the device's internal state machine is in state `IDLE`, but after the reset the state machine is actually in state `RESETTING`. Any command the driver sends is rejected, the driver interprets the

rejection as a hardware fault, and the device is marked broken. Catching the reset explicitly and rebuilding state is cleaner.

22.5.6 Detecting and Recovering from a Device Reset

If the validation finds a mismatch, the driver's recovery options depend on the hardware. For the `myfirst` simulation, the simplest response is to log, mark the device broken, and fail subsequent operations:

```
if (myfirst_validate_device(sc) != 0) {
    MYFIRST_LOCK(sc);
    sc->broken = true;
    MYFIRST_UNLOCK(sc);
    return (EIO);
}
```

The `softc` grows a broken flag, and any user-facing request checks the flag and fails with an error. The detach path still works (detach always succeeds, even on a broken device), so the user can unload the driver and reload it.

A real driver that detects a reset has more options. A network driver might re-run its attach sequence from the point after `pci_alloc_msi` (which has been restored by the PCI layer). A storage driver might re-initialise its controller using the same code path attach used. The implementation depends heavily on the device; the pattern is “detect, then do whatever attach-time initialisation is still required”.

The chapter's `myfirst` driver takes the simpler approach: it does not implement reset detection for the simulation, and the resume path does not include the validation call by default. The code above is provided as reference for a reader who wants to extend the driver as an exercise.

22.5.7 Restoring DMA State

The Chapter 21 DMA setup allocates a tag, allocates memory, loads the map, and retains the bus address in the `softc`. None of that is visible in the BAR-local register map; the DMA engine learns the bus address only when the driver writes it to `DMA_ADDR_LOW` and `DMA_ADDR_HIGH` as part of starting a transfer.

This means the DMA state does not need restoration in the sense of “write registers”. The tag, map, and memory are all kernel-side data structures; they survive suspend intact. The next transfer will program the DMA registers as part of its normal submission.

What might need restoration on a real device is:

- **The DMA descriptor ring base address**, if the device keeps a persistent pointer. A real NIC writes a base-address register once at attach and points the device at a ring of descriptors; after D3cold, that register may have been reset and the driver must reprogram it.
- **The DMA engine's enable bit**, if it is separate from individual transfers.
- **Any per-channel configuration** (burst size, priority, etc.) that is held in registers the PCI layer did not cache.

For `myfirst`, none of this applies. The DMA engine is programmed per transfer. Resume does not need any DMA-specific restoration beyond what the generic state restoration already covered.

22.5.8 Re-Arming Interrupts

Masking interrupts was step 2 of suspend. Unmasking them is step 3 of resume. The Stage 3 resume writes `saved_intr_mask` back to the `INTR_MASK` register, which (by convention) writes 0 to the bits corresponding to enabled vectors and 1 to the bits for disabled vectors. After the write, the device is ready to assert interrupts on the enabled vectors as soon as there is reason to.

There is a subtlety around ordering. The resume path unmask interrupts before it clears the suspended flag. That means a very unfortunate interrupt could arrive, call the filter, and find `suspended == true`. The filter would refuse to handle it and return `FILTER_STRAY`, which would leave the interrupt asserted.

To avoid that, the resume path takes the softc lock around the state change and does the unmask and the flag clear in the opposite order: clear suspended first, then unmask. That way any interrupt the device raises after the mask clears sees `suspended == false` and is handled normally.

The code in the previous snippet does this correctly: `myfirst_restore` writes the mask, then acquires the lock, clears the flag, and releases the lock. The order is important; reversing it creates a narrow window where interrupts could be lost.

22.5.9 Wake Source Cleanup

If the driver enabled a wake source during suspend (`pci_enable_pme`), the resume path should clear any pending wake event (`pci_clear_pme`). The PCI layer's `pci_resume_child` helper already calls `pci_clear_pme(child)` before the driver's `DEVICE_RESUME`, so the driver does not usually need to call it again.

The one case where the driver might want to call `pci_clear_pme` explicitly is in a runtime-PM context where the driver is resuming the device while the system stays in S0. In that case `pci_resume_child` was not involved, and the driver is responsible for clearing the PME status itself.

A hypothetical sketch for a driver with wake-on-X:

```
static int
myfirst_pci_resume(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    if (pci_has_pm(dev))
        pci_clear_pme(dev); /* defensive; PCI layer already did this */

    /* ... rest of the resume path ... */
}
```

For `myfirst`, there is no wake source, so the call does nothing useful; the chapter omits it from the main code and mentions the pattern here for completeness.

22.5.10 Updating the Stage 3 Driver

Stage 3 brings together everything above into a single working resume. The diff against Stage 2 is:

- myfirst.h grows a saved_intr_mask field (added for Stage 2) and a broken flag.
- myfirst_pci.c gets a myfirst_restore helper and a rewritten myfirst_pci_resume.
- The Makefile version bumps to 1.5-power-stage3.

Build and test:

```
cd /path/to/driver
make clean && make
sudo kldunload myfirst      # unload any previous version
sudo kldload ./myfirst.ko

# Quiet baseline.
sysctl dev.myfirst.0.dma_transfers_read
# 0
sysctl dev.myfirst.0.suspended
# 0

# Full cycle.
sudo devctl suspend myfirst0
sysctl dev.myfirst.0.suspended
# 1

sudo devctl resume myfirst0
sysctl dev.myfirst.0.suspended
# 0

# A transfer after resume should work.
sudo sysctl dev.myfirst.0.dma_test_read=1
sysctl dev.myfirst.0.dma_transfers_read
# 1

# Do it several times to make sure the path is stable.
for i in 1 2 3 4 5; do
    sudo devctl suspend myfirst0
    sudo devctl resume myfirst0
    sudo sysctl dev.myfirst.0.dma_test_read=1
done
sysctl dev.myfirst.0.dma_transfers_read
# 6 (1 + 5)

sysctl dev.myfirst.0.power_suspend_count dev.myfirst.0.power_resume_count
# should be equal, around 6 each
```

If the counters drift (suspend count not equal to resume count) or if `dma_test_read` starts failing after a suspend, something in the restore path is not putting the device back into a usable state. The first debugging step is to read the `INTR_MASK` and compare against `saved_intr_mask`; the second is to trace the DMA engine's status register and see if it is reporting an error.

22.5.11 Interaction with the Chapter 20 MSI-X Setup

The `myfirst` driver from Chapter 20 uses MSI-X when available, with a three-vector layout (admin, rx, tx). The MSI-X configuration lives in the device's MSI-X capability registers and in a kernel-side table. The PCI layer's config-space save-and-restore covers the capability registers; the kernel-side state is not affected by the D-state transition.

This means the `myfirst` driver does not need to do anything special to restore its MSI-X vectors. The interrupt resources (`irq_res`) remain allocated, the cookies remain registered, the CPU bindings remain in place. When the device raises an MSI-X vector on resume, the kernel delivers it to the filter that was registered at attach time.

A reader who wants to verify this can write to one of the `simulate sysctls` after resume and observe that the corresponding per-vector counter increments:

```
sudo devctl suspend myfirst0
sudo devctl resume myfirst0
sudo sysctl dev.myfirst.0.intr_simulate_admin=1
sysctl dev.myfirst.0.vec0_fire_count
# should be incremented
```

If the counter does not increment, the MSI-X path has been disturbed. The most likely cause is a bug in the driver's own state management (the suspended flag was not cleared, or the filter is rejecting the interrupt for a different reason). The chapter's troubleshooting section has more detail.

22.5.12 Handling a Failed Resume Gracefully

If some step of the resume fails, the driver has limited options. It cannot veto the resume (the kernel has no unwind path at this point). It cannot usually retry (the hardware state is uncertain). The best it can do is:

1. Log the failure prominently with `device_printf` so the user sees it in `dmesg`.
2. Increment a counter (`power_resume_errors`) that a regression script or an observability tool can check.
3. Mark the device broken so that subsequent requests fail cleanly rather than silently corrupting data.
4. Keep the driver attached, so the device-tree state stays consistent and the user can eventually unload and reload the driver.
5. Return 0 from `DEVICE_RESUME`, because the kernel expects it to succeed.

The “mark broken, keep attached” pattern is common in production drivers. It moves the failure from “mysterious later corruption” to “immediate user-visible error”, which is a better debugging experience.

22.5.13 A Short Detour: pci_save_state / pci_restore_state in Runtime PM

Section 2 mentioned that pci_save_state and pci_restore_state are sometimes called by the driver itself, typically in a runtime power-management helper. This is worth a concrete sketch before Section 5 builds it out.

A runtime PM helper that puts an idle device into D3 looks like:

```
static int
myfirst_runtime_suspend(struct myfirst_softc *sc)
{
    int err;

    err = myfirst_quiesce(sc);
    if (err != 0)
        return (err);

    pci_save_state(sc->dev);
    err = pci_set_powerstate(sc->dev, PCI_POWERSTATE_D3);
    if (err != 0) {
        /* roll back */
        pci_restore_state(sc->dev);
        myfirst_restore(sc);
        return (err);
    }

    return (0);
}

static int
myfirst_runtime_resume(struct myfirst_softc *sc)
{
    int err;

    err = pci_set_powerstate(sc->dev, PCI_POWERSTATE_D0);
    if (err != 0)
        return (err);
    pci_restore_state(sc->dev);

    return (myfirst_restore(sc));
}
```

The pattern is similar to the system suspend/resume but uses the explicit PCI helpers because the PCI layer is not in the loop. Section 5 will turn this sketch into a real implementation and wire it to an idle-detection policy.

22.5.14 A Reality Check Against a Real Driver

Before moving on, it is worth pausing and looking at a real driver's resume path. `/usr/src/sys/dev/re/if_re.c`'s `re_resume` function is about thirty lines. Its structure is:

1. Lock the softc.
2. If a MAC-sleep flag is set, take the chip out of sleep mode by writing a GPIO register.
3. Clear any wake-on-LAN patterns so normal receive filtering is not interfered with.
4. If the interface is administratively up, re-initialise it via `re_init_locked`.
5. Clear the suspended flag.
6. Unlock the softc.
7. Return 0.

The `re_init_locked` call is the substantive work: it reprograms the MAC address, resets the receive and transmit descriptor rings, re-enables interrupts on the NIC, and starts the DMA engines. For `myfirst`, the equivalent work is much shorter because the device is much simpler, but the shape is the same: acquire state, do hardware-specific reinitialisation, unlock, return.

A reader who reads `re_resume` after implementing `myfirst`'s resume will recognise the structure immediately. The vocabulary is the same; only the details differ.

22.5.15 Wrapping Up Section 4

Section 4 completed the resume path. It showed what the PCI layer has already done by the time `DEVICE_RESUME` is called (D0 transition, config-space restore, PME# clear, MSI-X restore), what the driver still has to do (re-enable bus-master, restore device-specific registers, clear the suspended flag, unmask interrupts), and why each step is important. The Stage 3 driver can now do a full suspend-resume cycle and continue operating normally; the regression test can run several cycles in a row and verify the counters are consistent.

With Sections 3 and 4 together, the driver is power-aware in the system-suspend sense: it handles S3 and S4 transitions cleanly. What it still does not do is any device-level power saving while the system is running. That is runtime power management, and Section 5 teaches it.

22.6 Section 5: Handling Runtime Power Management

System suspend is a big, visible transition: the lid closes, the screen goes dark, the battery saves power for hours. Runtime power management is the opposite: dozens of small, invisible transitions a second, each saving a little, together saving much of the idle power a modern system draws. The user never notices them; the platform engineer lives or dies by their correctness.

This section is marked optional in the chapter outline because not every driver needs runtime PM. A driver for a device that is always active (a NIC on a busy server, a disk controller for the root filesystem) does not save power by attempting to suspend its device; the device is busy, and trying to suspend it wastes cycles setting up transitions that never complete. A driver for a device that is frequently idle (a webcam, a fingerprint reader, a WLAN card on a laptop) does benefit. Whether to add runtime PM is a policy decision driven by the device's usage profile.

For Chapter 22, we implement runtime PM on the `myfirst` driver as a learning exercise. The device is already simulated; we can pretend it is idle whenever no `sysctl` has been written in the last few seconds, and watch the driver go through the motions. The implementation is short, and it teaches the PCI-level primitives that a real runtime-PM driver uses.

22.6.1 What Runtime PM Means in FreeBSD

FreeBSD does not currently have a centralised runtime-PM framework the way Linux does. There is no kernel-side “if the device has been idle for N milliseconds, call its idle hook” machinery. Instead, runtime PM is driver-local: the driver decides when to suspend and resume its device, using the same PCI-layer primitives (`pci_set_powerstate`, `pci_save_state`, `pci_restore_state`) it would use inside `DEVICE_SUSPEND` and `DEVICE_RESUME`.

This has two consequences. First, every driver that wants runtime PM implements its own policy: how long the device must be idle before suspending, what counts as idle, how quickly the device must wake on demand. Second, the driver must integrate its runtime PM with its system PM; the two paths share a lot of code and must not step on each other.

The pattern Chapter 22 uses is straightforward:

1. The driver adds a small state machine with states `RUNNING` and `RUNTIME_SUSPENDED`.
2. When the driver observes idleness (Section 5 uses a callout-based “no requests in the last 5 seconds” policy), it calls `myfirst_runtime_suspend`.
3. When the driver observes a new request while in `RUNTIME_SUSPENDED`, it calls `myfirst_runtime_resume` before processing the request.
4. On system suspend, if the device is in `RUNTIME_SUSPENDED`, the system-suspend path adjusts for it (the device is already quiesced; the system-suspend quiesce is a no-op, but the system resume has to bring the device back to D0).
5. On system resume, the driver returns to `RUNNING` unless it was explicitly runtime-suspended and wants to stay that way.

This is simpler than Linux’s runtime PM framework, which has richer concepts (parent/child ref-counting, autosuspend timers, barriers). For a single driver on simple hardware, the FreeBSD approach is enough.

22.6.2 The Runtime-PM State Machine

The `softc` gains a state variable and a timestamp:

```
enum myfirst_runtime_state {
    MYFIRST_RT_RUNNING = 0,
    MYFIRST_RT_SUSPENDED = 1,
};

struct myfirst_softc {
    /* ... */
    enum myfirst_runtime_state runtime_state;
```

```

    struct timeval      last_activity;
    struct callout      idle_watcher;
    int                 idle_threshold_seconds;
    uint64_t            runtime_suspend_count;
    uint64_t            runtime_resume_count;
};

```

The `idle_threshold_seconds` is a policy knob exposed through a `sysctl`; defaulting to five seconds gives quick observability without being so aggressive as to cause unnecessary wake-ups during normal use. A production driver would tune this per-device; five seconds is a learning-friendly value that makes the transitions visible without requiring hours of waiting.

The `idle_watcher` callout fires once a second to check the idle time. If the device has been idle longer than `idle_threshold_seconds` and is currently in `RUNNING`, the callout triggers `myfirst_runtime_suspend`.

22.6.3 Implementation

The attach path starts the idle watcher:

```

static void
myfirst_start_idle_watcher(struct myfirst_softc *sc)
{
    sc->idle_threshold_seconds = 5;
    microtime(&sc->last_activity);
    callout_init_mtx(&sc->idle_watcher, &sc->mtx, 0);
    callout_reset(&sc->idle_watcher, hz, myfirst_idle_watcher_cb, sc);
}

```

The callout is initialised with the softc mutex, so it acquires the mutex automatically when firing. That simplifies the callback: it runs under the lock.

The callback checks the time since the last activity and suspends if needed:

```

static void
myfirst_idle_watcher_cb(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct timeval now, diff;

    MYFIRST_ASSERT_LOCKED(sc);

    if (sc->runtime_state == MYFIRST_RT_RUNNING && !sc->suspended) {
        microtime(&now);
        timersub(&now, &sc->last_activity, &diff);
    }
}

```

```

        if (diff.tv_sec >= sc->idle_threshold_seconds) {
            /*
             * Release the lock while suspending. The
             * runtime_suspend helper acquires it again as
             * needed.
             */
            MYFIRST_UNLOCK(sc);
            (void)myfirst_runtime_suspend(sc);
            MYFIRST_LOCK(sc);
        }

        /* Reschedule. */
        callout_reset(&sc->idle_watcher, hz, myfirst_idle_watcher_cb, sc);
    }
}

```

Note the lock-drop around `myfirst_runtime_suspend`. The suspend helper calls `myfirst_quiesce`, which acquires the lock itself. Holding the lock across it would deadlock.

Activity is recorded whenever the driver services a request. The Chapter 21 DMA path is a good hook: every time a user writes to `dma_test_read` or `dma_test_write`, the `sysctl` handler records activity:

```

static int
myfirst_dma_sysctl_test_write(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    /* ... existing code ... */

    /* Mark the device active before processing. */
    myfirst_mark_active(sc);

    /* If runtime-suspended, bring the device back before running. */
    if (sc->runtime_state == MYFIRST_RT_SUSPENDED) {
        int err = myfirst_runtime_resume(sc);
        if (err != 0)
            return (err);
    }

    /* ... proceed with the transfer ... */
}

```

The `myfirst_mark_active` helper is a one-liner:

```
static void
myfirst_mark_active(struct myfirst_softc *sc)
{
    MYFIRST_LOCK(sc);
    microtime(&sc->last_activity);
    MYFIRST_UNLOCK(sc);
}
```

22.6.4 The Runtime-Suspend and Runtime-Resume Helpers

These were sketched in Section 4. Here are the fleshed-out versions:

```
static int
myfirst_runtime_suspend(struct myfirst_softc *sc)
{
    int err;

    device_printf(sc->dev, "runtime suspend: starting\n");

    err = myfirst_quiesce(sc);
    if (err != 0) {
        device_printf(sc->dev,
            "runtime suspend: quiesce failed (err %d)\n", err);
        /* Undo the suspended flag the quiesce set. */
        MYFIRST_LOCK(sc);
        sc->suspended = false;
        MYFIRST_UNLOCK(sc);
        return (err);
    }

    pci_save_state(sc->dev);
    err = pci_set_powerstate(sc->dev, PCI_POWERSTATE_D3);
    if (err != 0) {
        device_printf(sc->dev,
            "runtime suspend: set_powerstate(D3) failed "
            "(err %d)\n", err);
        pci_restore_state(sc->dev);
        myfirst_restore(sc);
        return (err);
    }

    MYFIRST_LOCK(sc);
    sc->runtime_state = MYFIRST_RT_SUSPENDED;
    MYFIRST_UNLOCK(sc);
}
```

```
    atomic_add_64(&sc->runtime_suspend_count, 1);

    device_printf(sc->dev, "runtime suspend: device in D3\n");
    return (0);
}

static int
myfirst_runtime_resume(struct myfirst_softc *sc)
{
    int err;

    MYFIRST_LOCK(sc);
    if (sc->runtime_state != MYFIRST_RT_SUSPENDED) {
        MYFIRST_UNLOCK(sc);
        return (0); /* nothing to do */
    }
    MYFIRST_UNLOCK(sc);

    device_printf(sc->dev, "runtime resume: starting\n");

    err = pci_set_powerstate(sc->dev, PCI_POWERSTATE_D0);
    if (err != 0) {
        device_printf(sc->dev,
            "runtime resume: set_powerstate(D0) failed "
            "(err %d)\n", err);
        return (err);
    }
    pci_restore_state(sc->dev);

    err = myfirst_restore(sc);
    if (err != 0) {
        device_printf(sc->dev,
            "runtime resume: restore failed (err %d)\n", err);
        return (err);
    }

    MYFIRST_LOCK(sc);
    sc->runtime_state = MYFIRST_RT_RUNNING;
    MYFIRST_UNLOCK(sc);
    atomic_add_64(&sc->runtime_resume_count, 1);

    device_printf(sc->dev, "runtime resume: device in D0\n");
    return (0);
}
```

The shape is identical to system suspend/resume except that the driver explicitly calls `pci_set_powerstate` and `pci_save_state/pci_restore_state`. The PCI layer's automatic transitions are not in the loop for runtime PM because the kernel is not coordinating a system-wide power change; the driver is on its own.

22.6.5 Interaction Between Runtime PM and System PM

The two paths have to cooperate. Consider what happens if the device is runtime-suspended (in D3) when the user closes the laptop lid:

1. The kernel starts system suspend.
2. The PCI bus calls `myfirst_pci_suspend`.
3. Inside `myfirst_pci_suspend`, the driver notices that the device is already runtime-suspended. The quiesce is a no-op (nothing is happening). The PCI layer's automatic config-space save runs; it reads the config space (which is still accessible in D3) and caches it.
4. The PCI layer transitions the device from D3 to... wait, it is already in D3. The transition to D3 is a no-op.
5. The system sleeps.
6. On wake, the PCI layer transitions the device back to D0. The driver's `myfirst_pci_resume` runs. It restores state. But now the driver thinks the device is RUNNING (because system resume cleared the suspended flag), while conceptually it was runtime-suspended before. The next activity will use the device normally and set `last_activity`; the idle watcher will eventually re-suspend it if still idle.

The interaction is mostly benign; the worst that happens is that the device gets one extra trip through D0 before the idle watcher re-suspends it. A more polished implementation would remember the runtime-suspended state across the system suspend and restore it, but for a learning driver the simple approach is enough.

The reverse (system-suspending a device that is already runtime-suspended) is already correct in our implementation because `myfirst_quiesce` checks `suspended` and returns 0 if already set. The runtime-suspended path set `suspended = true` as part of its quiesce, so the system suspend's quiesce sees the flag and skips.

22.6.6 Exposing Runtime-PM Controls Through Sysctl

The driver's runtime-PM policy can be controlled and observed through sysctls:

```

SYSCTL_ADD_INT(ctx, kids, OID_AUTO, "idle_threshold_seconds",
    CTLFLAG_RW, &sc->idle_threshold_seconds, 0,
    "Runtime PM idle threshold (seconds)");
SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "runtime_suspend_count",
    CTLFLAG_RD, &sc->runtime_suspend_count, 0,
    "Runtime suspends performed");
SYSCTL_ADD_U64(ctx, kids, OID_AUTO, "runtime_resume_count",
    CTLFLAG_RD, &sc->runtime_resume_count, 0,
    "Runtime resumes performed");
SYSCTL_ADD_INT(ctx, kids, OID_AUTO, "runtime_state",
    CTLFLAG_RD, (int *)&sc->runtime_state, 0,
    "Runtime state: 0=running, 1=suspended");

```

A reader can now do this:

```
# Watch the device idle out.
while ;; do
    sysctl dev.myfirst.0.runtime_state dev.myfirst.0.runtime_suspend_count
    sleep 1
done &
```

After five seconds of inactivity, `runtime_state` flips from 0 to 1 and `runtime_suspend_count` increments. A write to any active sysctl triggers a resume and flips the state back:

```
sudo sysctl dev.myfirst.0.dma_test_read=1
# The log shows: runtime resume, then the test read
```

22.6.7 Tradeoffs

Runtime PM trades wake-up latency for idle power. Every D3-to-D0 transition costs time (tens of microseconds on a PCIe link, including the ASPM exit), and on some devices costs energy (the transition itself draws current). For a device that is idle most of the time with rare bursts of activity, the trade is favorable. For a device that is active most of the time with rare idle periods, the cost of the transitions dominates.

The `idle_threshold_seconds` knob lets the platform tune this. A value of 0 or 1 is aggressive and suitable for a webcam that is used for seconds at a time and idle for minutes. A value of 60 is conservative and suitable for a NIC whose idle periods are short but frequent. A value of 0 (if allowed) would disable runtime PM entirely, which is appropriate for devices that should stay on at all times.

A second tradeoff is in code complexity. Runtime PM adds a state machine, a callout, an idle watcher, two more `kobj`-like helpers, and additional ordering concerns between the runtime and system PM paths. Each of those is small, but together they increase the surface area for bugs. Many FreeBSD drivers deliberately omit runtime PM for this reason; they let the device stay in D0 and rely on the device's internal low-power states (clock gating, PCIe ASPM) to save power. That is a defensible choice, and for drivers where correctness matters more than milliwatts, it is the right one.

Chapter 22's `myfirst` driver keeps runtime PM as an optional feature, gated by a build-time flag:

```
CFLAGS+= -DMYFIRST_ENABLE_RUNTIME_PM
```

A reader can build with or without the flag; the Section 5 code is only compiled in when the flag is defined. The default for Stage 3 is to leave runtime PM off; Stage 4 enables it in the consolidated driver.

22.6.8 A Word on Platform Runtime PM

Some platforms provide their own runtime-PM mechanism alongside the driver-local one. On arm64 and RISC-V embedded systems, the device tree may describe `power-domains` and `clocks` properties that the driver uses

to turn off power domains and gate clocks. FreeBSD's `ext_resources/clk`, `ext_resources/regulator`, and `ext_resources/power` subsystems handle these.

Runtime PM on such a platform is more capable than PCI-only runtime PM because the platform can turn off entire SoC blocks (a USB controller, a display engine, a GPU) rather than just moving the PCI device to D3. The driver uses the same pattern (mark idle, turn off resources on idle, turn back on for activity) but through different APIs.

Chapter 22 stays with the PCI path because that is where the `myfirst` driver lives. A reader who later works on an embedded platform will find the same conceptual structure with platform-specific APIs. The chapter mentions the distinction here so the reader knows the territory exists.

22.6.9 Wrapping Up Section 5

Section 5 added runtime power management to the driver. It defined a two-state machine (`RUNNING`, `RUNTIME_SUSPENDED`), a callout-based idle watcher, a pair of helpers (`myfirst_runtime_suspend`, `myfirst_runtime_resume`) that use the PCI layer's explicit power-state and state-save APIs, the activity-recording hooks in the DMA `sysctl` handlers, and the `sysctl` knobs that expose the policy to user space. It also discussed the interaction between runtime PM and system PM, the latency-vs-power tradeoff, and the alternative of platform-level runtime PM on embedded systems.

With Sections 2 through 5 in place, the driver now handles system suspend, system resume, system shutdown, runtime suspend, and runtime resume. What it does not yet do cleanly is explain how the reader tests all of these from user space. Section 6 turns to the user-space interface: `acpiconf`, `zzz`, `devctl suspend`, `devctl resume`, `devinfo -v`, and the regression test that wraps them together.

22.7 Section 6: Interacting With the Power Framework

A driver that handles suspend and resume correctly is only half of the story. The other half is being able to *test* that correctness, repeatedly and deliberately, from user space. Section 6 surveys the tools FreeBSD provides for that purpose, explains how each fits the driver's state model, and shows how to combine them into a regression script that exercises every path Sections 2 through 5 built.

22.7.1 The Four User-Space Entry Points

Four commands cover almost everything a driver developer needs:

- **`acpiconf -s 3`** (and its variants) asks ACPI to put the whole system into sleep state S3. This is the most realistic test; it exercises the full path from user space through the kernel's suspend machinery through the PCI layer to the driver's methods.
- **`zzz`** is a thin wrapper around `acpiconf -s 3`. It reads `hw.acpi.suspend_state` (defaulting to S3) and enters the corresponding sleep state. For most users it is the most convenient way to suspend from a shell.
- **`devctl suspend myfirst0`** and **`devctl resume myfirst0`** trigger per-device suspend and resume through the `DEV_SUSPEND` and `DEV_RESUME` ioctls on `/dev/devctl2`. These only call the driver's methods; the rest of the system stays in S0. This is the fastest iteration target and what Chapter 22 uses for most development.

- **devinfo -v** lists all devices in the device tree with their current state. It shows whether a device is attached, suspended, or detached.

Each has strengths and weaknesses. `acpiconf` is realistic but slow (one to three seconds per cycle on typical hardware) and disruptive (the system actually sleeps). `devctl` is fast (milliseconds per cycle) but exercises only the driver, not the ACPI or platform code. `devinfo -v` is passive and cheap; it observes without changing state.

A good regression strategy uses all three: `devctl` for unit testing of the driver's methods, `acpiconf` for integration testing of the full suspend path, and `devinfo -v` as a quick sanity check.

22.7.2 Using `acpiconf` to Suspend the System

On a machine with working ACPI, `acpiconf -s 3` is what Section 1 called a full system suspend. The command:

```
sudo acpiconf -s 3
```

does the following:

1. It opens `/dev/acpi` and checks that the platform supports S3 via the `ACPIIO_ACKSLPSTATE` ioctl.
2. It sends the `ACPIIO_REQSLPSTATE` ioctl to request S3.
3. The kernel begins the suspend sequence: paused userland, frozen threads, device tree traversal with `DEVICE_SUSPEND` on each device.
4. Assuming no driver vetoes, the kernel enters S3. The machine sleeps.
5. A wake event (the lid opens, the power button is pressed, a USB device sends a remote-wakeup signal) wakes the platform.
6. The kernel runs the resume sequence: `DEVICE_RESUME` on each device, unfreezing threads, resuming userland.
7. The shell prompt returns. The machine is back in S0.

For the `myfirst` driver to be exercised, the driver must be loaded before the suspend. The entire sequence from user perspective looks like:

```
sudo kldload ./myfirst.ko
sudo sysctl dev.myfirst.0.dma_test_read=1 # exercise it a bit
sudo acpiconf -s 3
# [laptop sleeps; user opens lid]
dmesg | grep myfirst
```

The `dmesg` output should show two lines from Chapter 22's logging:

```
myfirst0: suspend: starting
myfirst0: suspend: complete (dma in flight=0, suspended=1)
myfirst0: resume: starting
myfirst0: resume: complete
```

If those lines are present and in that order, the driver's methods were called correctly by the full system path.

If the machine does not come back, the suspend path broke at some layer below `myfirst`. If the machine comes back but the driver is in a strange state (the sysctls return errors, the counters have strange values, DMA transfers fail), the problem is in `myfirst`'s suspend or resume implementation.

22.7.3 Using `zzz`

On FreeBSD, `zzz` is a small shell script that reads `hw.acpi.suspend_state` and calls `acpiconf -s <state>`. It is not a binary; it is usually installed at `/usr/sbin/zzz` and is a few lines long. A typical invocation is:

```
sudo zzz
```

The default `hw.acpi.suspend_state` is `S3` on machines that support it. A reader who wants to test `S4` (hibernate) can:

```
sudo sysctl hw.acpi.suspend_state=S4
sudo zzz
```

`S4` support on FreeBSD has historically been partial; whether it works depends on the platform firmware and the filesystem layout. For Chapter 22's purposes, `S3` is sufficient, and `zzz` is the convenient shorthand.

22.7.4 Using `devctl` for Per-Device Suspend

The `devctl(8)` command was built to let a user manipulate the device tree from user space. It supports attach, detach, enable, disable, suspend, resume, and more. For Chapter 22, suspend and resume are the two that matter.

```
sudo devctl suspend myfirst0
sudo devctl resume myfirst0
```

The first command issues `DEV_SUSPEND` through `/dev/devctl2`; the kernel translates that into a call to `BUS_SUSPEND_CHILD` on the parent bus, which for a PCI device ends up calling `pci_suspend_child`, which saves config space, puts the device in `D3`, and calls the driver's `DEVICE_SUSPEND`. The reverse happens for resume.

The key differences from `acpiconf`:

- Only the target device and its children go through the transition. The rest of the system stays in `S0`.
- The CPU does not park. Userland does not freeze. The kernel does not sleep.
- The PCI device actually goes to `D3hot` (assuming `hw.pci.do_power_suspend` is 1). The reader can verify with `pciconf`:

```
# Before suspend: device should be in D0
pciconf -lvbc | grep -A 2 myfirst

# After devctl suspend myfirst0: device should be in D3
sudo devctl suspend myfirst0
pciconf -lvbc | grep -A 2 myfirst
```

The power state is usually shown in the powerspec line of `pciconf -lvbc`. Moving from D0 to D3 is the observable signal that the transition really happened.

22.7.5 Using devinfo to Inspect Device State

The `devinfo(8)` utility lists the device tree with various levels of detail. The `-v` flag shows verbose information, including the device state (attached, suspended, or not present).

```
devinfo -v | grep -A 5 myfirst
```

Typical output:

```
myfirst0 pnpinfo vendor=0x1af4 device=0x1005 subvendor=0x1af4 subdevice=0x0004
↳ class=0x008880 at slot=5 function=0 dbsf=pci0:0:5:0
  Resource: <INTERRUPT>
    10
  Resource: <MEMORY>
    0xfeb80000-0xfeb80fff
```

The state is implicit in the output: if the device is suspended, the line shows the device and its resources without the “active” marker. An explicit state query can be done through the `softc sysctl`; the `dev.myfirst.0.%parent` and `dev.myfirst.0.%desc` keys tell the user where the device sits.

For Chapter 22, `devinfo -v` is most useful as a sanity check after a failed transition: if the device is missing from the output, the detach path ran; if the device is present but the resources are wrong, the attach or resume path left the device in an inconsistent state.

22.7.6 Inspecting Power States Through sysctl

The PCI layer exposes power-state information through `sysctl` under `hw.pci`. Two variables are most relevant:

```
sysctl hw.pci.do_power_suspend
sysctl hw.pci.do_power_resume
```

Both default to 1, meaning the PCI layer transitions devices to D3 on suspend and back to D0 on resume. Setting either to 0 disables the automatic transition for debugging.

The ACPI layer exposes system-state information:

```
sysctl hw.acpi.supported_sleep_state
sysctl hw.acpi.suspend_state
sysctl hw.acpi.s4bios
```

The first lists which sleep states the platform supports (typically something like S3 S4 S5). The second is the state zzz enters (usually S3). The third says whether S4 is implemented through BIOS assistance.

For per-device observation, the driver exposes its own state through `dev.myfirst.N.*`. The Chapter 22 driver adds:

- `dev.myfirst.N.suspended`: 1 if the driver considers itself suspended, 0 otherwise.
- `dev.myfirst.N.power_suspend_count`: number of times `DEVICE_SUSPEND` has been called.
- `dev.myfirst.N.power_resume_count`: number of times `DEVICE_RESUME` has been called.
- `dev.myfirst.N.power_shutdown_count`: number of times `DEVICE_SHUTDOWN` has been called.
- `dev.myfirst.N.runtime_state`: 0 for `RUNNING`, 1 for `RUNTIME_SUSPENDED`.
- `dev.myfirst.N.runtime_suspend_count`, `dev.myfirst.N.runtime_resume_count`: runtime-PM counters.
- `dev.myfirst.N.idle_threshold_seconds`: runtime-PM idle threshold.

Between these `sysctls` and `dmesg`, a reader can see in full detail what the driver did during any transition.

22.7.7 A Regression Script

The `labs` directory grows a new script: `ch22-suspend-resume-cycle.sh`. The script:

1. Records the baseline values of every counter.
2. Runs one DMA transfer to confirm the device is working.
3. Calls `devctl suspend myfirst0`.
4. Verifies `dev.myfirst.0.suspended` is 1.
5. Verifies `dev.myfirst.0.power_suspend_count` has incremented by 1.
6. Calls `devctl resume myfirst0`.
7. Verifies `dev.myfirst.0.suspended` is 0.
8. Verifies `dev.myfirst.0.power_resume_count` has incremented by 1.
9. Runs one more DMA transfer to confirm the device still works.
10. Prints a PASS/FAIL summary.

The full script is in the `examples` directory; a short outline of the logic:

```
#!/bin/sh
set -e

DEV="dev.myfirst.0"
```

```
if ! sysctl -a | grep -q "^${DEV}"; then
    echo "FAIL: ${DEV} not present"
    exit 1
fi

before_s=$(sysctl -n ${DEV}.power_suspend_count)
before_r=$(sysctl -n ${DEV}.power_resume_count)
before_xfer=$(sysctl -n ${DEV}.dma_transfers_read)

# Baseline: run one transfer.
sysctl -n ${DEV}.dma_test_read=1 > /dev/null

# Suspend.
devctl suspend myfirst0
[ "$(sysctl -n ${DEV}.suspended)" = "1" ] || {
    echo "FAIL: device did not mark suspended"
    exit 1
}

# Resume.
devctl resume myfirst0
[ "$(sysctl -n ${DEV}.suspended)" = "0" ] || {
    echo "FAIL: device did not clear suspended"
    exit 1
}

# Another transfer.
sysctl -n ${DEV}.dma_test_read=1 > /dev/null

after_s=$(sysctl -n ${DEV}.power_suspend_count)
after_r=$(sysctl -n ${DEV}.power_resume_count)
after_xfer=$(sysctl -n ${DEV}.dma_transfers_read)

if [ $((after_s - before_s)) -ne 1 ]; then
    echo "FAIL: suspend count did not increment by 1"
    exit 1
fi
if [ $((after_r - before_r)) -ne 1 ]; then
    echo "FAIL: resume count did not increment by 1"
    exit 1
fi
if [ $((after_xfer - before_xfer)) -ne 2 ]; then
    echo "FAIL: expected 2 transfers (pre+post), got $((after_xfer - before_xfer))"
```

```
    exit 1
fi

echo "PASS: one suspend-resume cycle completed cleanly"
```

Running the script repeatedly (say a hundred times in a tight loop) is a good stress test. A driver that passes one cycle but fails on the fiftieth usually has a resource leak or an edge case that only shows up under repetition. That class of bug is exactly what a regression script is meant to find.

22.7.8 Running the Stress Test

The chapter's `labs/` directory also includes `ch22-suspend-stress.sh`, which runs the cycle script a hundred times:

```
#!/bin/sh
N=100
i=0
while [ $i -lt $N ]; do
    if ! sh ./ch22-suspend-resume-cycle.sh > /dev/null; then
        echo "FAIL on iteration $i"
        exit 1
    fi
    i=$((i + 1))
done
echo "PASS: $N cycles"
```

On a modern machine with the simulation-only `myfirst` driver, a hundred cycles takes about a second. If any iteration fails, the script stops and reports the iteration number. Running this after each change during development catches regressions immediately.

22.7.9 Combining Runtime PM and User-Space Testing

The runtime-PM path needs a different test, because it is not triggered by user commands; it is triggered by idleness. The test looks like:

```
# Ensure runtime_state is running.
sysctl dev.myfirst.0.runtime_state
# 0

# Do nothing for 6 seconds.
sleep 6

# The callout should have fired and runtime-suspended the device.
```

```

sysctl dev.myfirst.0.runtime_state
# 1

# Counter should have incremented.
sysctl dev.myfirst.0.runtime_suspend_count
# 1

# Any activity should bring it back.
sysctl dev.myfirst.0.dma_test_read=1
sysctl dev.myfirst.0.runtime_state
# 0

sysctl dev.myfirst.0.runtime_resume_count
# 1

```

A reader watching `dmesg` during this will see the “runtime suspend: starting” and “runtime suspend: device in D3” lines after about five seconds of inactivity, then “runtime resume: starting” when the `sysctl` write arrives.

The chapter’s lab directory includes `ch22-runtime-pm.sh` to automate this sequence.

22.7.10 Interpreting Failure Modes

When a user-space test fails, the diagnostic path depends on which layer failed:

- **If `devctl suspend` returns a non-zero exit code:** the driver’s `DEVICE_SUSPEND` returned a non-zero value, vetoing the suspend. Check `dmesg` for the driver’s log output; the suspend method should be logging what went wrong.
- **If `devctl suspend` succeeds but `dev.myfirst.0.suspended` is 0 afterwards:** the driver’s quiesce set the flag briefly but something cleared it. This usually means the quiesce is re-entering itself, or the detach path is racing the suspend.
- **If `devctl resume` succeeds but the next transfer fails:** the restore path did not fully reinitialise the device. Most commonly, an interrupt mask or a DMA register was not written; check the per-vector fire counters before and after resume to see whether interrupts are reaching the driver.
- **If `acpicnf -s 3` succeeds but the system does not come back:** a driver below `myfirst` in the tree is blocking resume. This is unusual in a test VM; it is the classic failure mode on real hardware with new drivers.
- **If `acpicnf -s 3` returns `EOPNOTSUPP`:** the platform does not support S3. Check `sysctl hw.acpi.supported_sleep_state`.

In all cases, the first source of information is `dmesg`. The Chapter 22 driver logs every transition; if the log lines do not appear, the method was not called, and the problem is at a layer below the driver.

22.7.11 A Minimal Troubleshooting Flow

A compact flowchart for a failed suspend-resume cycle:

1. Is the driver loaded? `kldstat | grep myfirst.`
2. Is the device attached? `sysctl dev.myfirst.0.%driver.`
3. Do the suspend and resume methods log? `dmesg | tail.`
4. Did `dev.myfirst.0.suspended` toggle correctly? `sysctl dev.myfirst.0.suspended.`
5. Do the counters increment? `sysctl dev.myfirst.0.power_suspend_count dev.myfirst.0.power_resume_count.`
6. Does a post-resume transfer succeed? `sudo sysctl dev.myfirst.0.dma_test_read=1; dmesg | tail -2.`
7. Do the per-vector interrupt counters increment? `sysctl dev.myfirst.0.vec0_fire_count dev.myfirst.0.vec1_fire_count dev.myfirst.0.vec2_fire_count.`

Any “no” answer points to a specific layer of the implementation. Section 7 goes deeper into the common failure modes and how to debug them.

22.7.12 Wrapping Up Section 6

Section 6 surveyed the user-space interface to the kernel’s power-management machinery: `acpiconf`, `zzz`, `devctl suspend`, `devctl resume`, `devinfo -v`, and the relevant `sysctl` variables. It showed how to combine these tools into a regression script that exercises one suspend-resume cycle, and a stress script that runs a hundred cycles in a row. It discussed the runtime-PM test flow, the interpretation of the most common failure modes, and the minimal troubleshooting flowchart a reader can follow when a test fails.

With the user-space tools in hand, the next section dives into the characteristic failure modes the reader is likely to encounter while writing power-aware code, and how to debug each one.

22.8 Section 7: Debugging Power Management Issues

Power management code has a special class of bugs. The machine sleeps; the machine wakes; the bug shows up an unknown time after the wake and looks like a generic malfunction rather than anything related to the power transition. The chain of cause and effect is longer than with most driver bugs, the reproduction is slower, and the user’s bug report is usually “my laptop doesn’t wake up sometimes”, which contains almost no information the driver developer can use.

Section 7 is about recognising the characteristic symptoms, tracing them back to their likely causes, and applying the matching debugging patterns. It draws on the Chapter 22 `myfirst` driver for concrete examples, but the patterns apply to any FreeBSD driver.

22.8.1 Symptom 1: Frozen Device After Resume

The most common power-management bug, both in learning drivers and in production ones, is a device that stops responding after resume. The driver attaches correctly at boot, works normally in S0, handles a suspend-resume cycle without visible error, and then on the next command it is silent. Interrupts do not fire. DMA transfers do not complete. Any read from a device register returns stale values or zeros.

The usual cause is that the device’s registers were not written after resume. The device came back in a default state (interrupt mask all-masked, DMA engine disabled, whatever registers the hardware resets on D0 entry), the driver did not reprogram them, and so from the device’s perspective nothing is configured to run.

Debugging pattern. Compare the device's register values before and after suspend. The `myfirst` driver exposes several of its registers through `sysctls` (if the reader adds them); otherwise, the reader can write a short kernel-space helper that reads each register and prints it. After a suspend-resume cycle:

1. Read the interrupt mask register. If it is `0xFFFFFFFF` (all masked), the resume path did not restore the mask.
2. Read the DMA control register. If it has the ABORT bit set, the abort from the quiesce never cleared.
3. Read the device's configuration space via `pciconf -lvbc`. The command register should have the bus-master bit set; if not, `pci_enable_busmaster` was missed in the resume path.

Fix pattern. The resume path should include an unconditional reprogram of every device-specific register the driver's normal operation depends on. Saving them at suspend time into the `softc` and restoring them at resume time is one approach; re-deriving them from `softc` state (the approach `re_resume` takes) is another. Either works; the choice depends on which is easier to prove correct for the specific device.

22.8.2 Symptom 2: Lost Interrupts

A subtler variant of the frozen-device problem is lost interrupts: the device is responding to some calls, but its interrupts are not reaching the driver. The DMA engine accepts a START command, performs the transfer, raises the completion interrupt... and the interrupt count does not increment. The task queue does not get an entry. The CV does not broadcast. The transfer eventually times out, and the driver reports EIO.

Several things can cause this:

- The **interrupt mask** at the device is still all-masked. The device wants to raise the interrupt but the mask suppresses it. (Resume path bug.)
- The **MSI or MSI-X configuration** was not restored. The device is raising the interrupt, but the kernel does not route it to the driver's handler. (Unusual; the PCI layer should handle this automatically.)
- The **filter function pointer** was corrupted. Extremely unusual; usually indicates memory corruption somewhere else in the driver.
- The **suspended flag** is still true, and the filter is returning early. (Resume path bug: flag not cleared.)

Debugging pattern. Read the per-vector fire counters before and after the suspend-resume cycle. If the counter does not increment, the interrupt is not reaching the filter. Then check, in order:

1. Is the suspended flag cleared? `sysctl dev.myfirst.0.suspended`.
2. Is the interrupt mask at the device correct? Read the register.
3. Is the MSI-X table in the device correct? `pciconf -c` dumps the capability registers.
4. Is the kernel's MSI dispatch state consistent? `procstat -t` shows the interrupt threads.

Fix pattern. Make sure the resume path (a) clears the suspended flag under the lock, (b) unmask the device's interrupt register after clearing the flag, (c) does not rely on MSI-X restoration the driver must do itself (unless specifically disabled via `sysctl`).

22.8.3 Symptom 3: Bad DMA After Resume

A more dangerous class of bug is DMA that appears to work but produces wrong data. The driver programs the engine, the engine runs, the completion interrupt fires, the task runs, the sync is called, the driver reads the

buffer... and the bytes are wrong. Not zeros, not garbage, just subtly incorrect: the pattern written previously, or the pattern from two cycles ago, or a pattern that indicates the DMA addressed the wrong page.

Causes:

- The **bus address cached in the softc** is stale. This is unusual for a static allocation (the address is set once at attach and should not change), but it can happen if the driver re-allocates the DMA buffer at resume time (a bad idea; see below).
- The **DMA engine's base-address register** was not reprogrammed after resume, and it has a stale value that points elsewhere.
- The **bus_dmamap_sync calls are missing or mis-ordered**. This is the classic DMA-correctness bug, and it is worth being alert for in resume paths because the driver-side code adjacent to the sync calls is often edited during a refactor.
- The **IOMMU translation table** was not restored. Very rare on FreeBSD because the IOMMU configuration is per-session and survives suspend on most platforms; but if the driver is running on a system where DEV_IOMMU is unusual, this can bite.

Debugging pattern. Add a known-pattern write before each DMA, a verify after each DMA, and log both. Reducing the cycle to “write 0xAA, sync, read, expect 0xAA” makes data-corruption bugs visible immediately.

```
memset(sc->dma_vaddr, 0xAA, MYFIRST_DMA_BUFFER_SIZE);
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_PREWRITE);
/* run transfer */
bus_dmamap_sync(sc->dma_tag, sc->dma_map, BUS_DMASYNC_POSTWRITE);
if (((uint8_t *)sc->dma_vaddr)[0] != 0xAA) {
    device_printf(sc->dev,
        "dma: corruption detected after transfer\n");
}
```

For the simulation, this should always succeed because the simulation does not modify the buffer on a write transfer. On real hardware, the pattern depends on the device. A reader debugging a real-hardware bug adapts the test.

Fix pattern. If the bus address is the problem, rebuild it on resume:

```
/* In resume, after PCI restore is complete. */
err = bus_dmamap_load(sc->dma_tag, sc->dma_map,
    sc->dma_vaddr, MYFIRST_DMA_BUFFER_SIZE,
    myfirst_dma_single_map, &sc->dma_bus_addr,
    BUS_DMA_NOWAIT);
```

Only do this if the bus address actually changed, which is rare. More commonly, the fix is to write the base-address register at the start of every transfer (rather than relying on a persistent value) and to make sure the sync calls are in the right order.

22.8.4 Symptom 4: Lost PME# Wake Events

On a device that supports wake-on-X, the symptom is “the device should have woken the system but did not”. The driver reported a successful suspend; the system went to S3; the expected event (magic packet, button press, timer) happened; and the system stayed asleep.

Causes:

- **pci_enable_pme was not called** in the suspend path. The device’s PME_En bit is 0, so even when the device would normally assert PME#, the bit is suppressed.
- **The device’s own wake logic is not configured.** For a NIC, the wake-on-LAN registers must be programmed before suspend. For a USB host controller, the remote-wakeup capability must be enabled per-port.
- **The platform’s wake GPE is not enabled.** This is usually a firmware matter; the ACPI _PRW method should have registered the GPE, but on some machines the BIOS disables it by default.
- **The PME status bit is set at the time of suspend**, and a stale PME# is what triggers the wake (instead of the expected event). The system appears to wake immediately after sleeping.

Debugging pattern. Read the PCI configuration space via `pciconf -lvbc`. The power-management capability’s status/control register shows PME_En and the PME_Status bit. Before suspending, PME_Status should be 0 (no pending wake). After suspending with wake enabled, PME_En should be 1.

On a machine where the wake does not happen, check the BIOS settings for “wake on LAN”, “wake on USB”, etc. The driver can be perfect and the system still not wake if the platform is not configured.

Fix pattern. In the suspend path of a wake-capable driver:

```
static int
myfirst_pci_suspend(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int err;

    /* ... quiesce as before ... */

    if (sc->wake_enabled && pci_has_pm(dev)) {
        /* Program device-specific wake logic here. */
        myfirst_program_wake(sc);
        pci_enable_pme(dev);
    }

    /* ... rest of suspend ... */
}
```

In the resume path:

```
static int
myfirst_pci_resume(device_t dev)
{
    if (pci_has_pm(dev))
        pci_clear_pme(dev);
    /* ... rest of resume ... */
}
```

The myfirst driver in Chapter 22 does not implement wake (the simulation has no wake logic). The pattern above is shown for reference.

22.8.5 Symptom 5: WITNESS Complaints During Suspend

A debug kernel with WITNESS enabled often produces messages like:

```
witness: acquiring sleepable lock foo_mtx @ /path/to/driver.c:123
witness: sleeping with non-sleepable lock bar_mtx @ /path/to/driver.c:456
```

These are lock-order violations or sleep-while-locked violations, and they often show up in suspend code because suspend does things the driver does not normally do: acquire locks, sleep, and coordinate multiple threads.

Causes:

- The suspend path acquires a lock and then calls a function that sleeps without explicit tolerance for sleeping-with-that-lock-held.
- The suspend path acquires locks in a different order than the rest of the driver, and WITNESS notices the reversal.
- The suspend path calls `taskqueue_drain` or `callout_drain` while holding the softc lock, which causes a deadlock if the task or callout tries to acquire the same lock.

Debugging pattern. Read the WITNESS message carefully. It includes the lock names and the source-line numbers where each was acquired. Trace the path from the acquisition to the sleep or lock reversal.

Fix pattern. The Chapter 22 `myfirst_quiesce` drops the softc lock before calling `myfirst_drain_workers` for exactly this reason. When extending the driver:

- Do not call `taskqueue_drain` with any driver lock held.
- Do not call `callout_drain` with the lock that the callout acquires.
- Sleep primitives (`pause`, `cv_wait`) must be called with only sleep-mutexes held (not spin-mutexes).
- If you need to drop a lock for a sleep, do so explicitly and reacquire after.

22.8.6 Symptom 6: Counters That Do Not Match

The chapter's regression script expects `power_suspend_count == power_resume_count` after each cycle. When they drift, something is wrong.

Causes:

- The driver's `DEVICE_SUSPEND` was called but the driver returned early before incrementing the counter. (Often because of a sanity check that fired.)
- The driver's `DEVICE_RESUME` was not called, because `DEVICE_SUSPEND` returned non-zero and the kernel unwound.
- The counters are not atomic and a concurrent update lost an increment. (Unlikely if the code uses `atomic_add_64`.)
- The driver was unloaded and reloaded between counts, resetting them.

Debugging pattern. Run the regression script with `dmesg -c` cleared beforehand, and `dmesg` after each cycle. The log shows every method invocation; counting the log lines is an alternative to counting the counters, and any difference indicates a bug.

22.8.7 Symptom 7: Hangs During Suspend

A hang during suspend is the worst diagnostic: the kernel is still running (the console still responds to break-to-DDB), but the suspend sequence is stuck in some driver's `DEVICE_SUSPEND`. Break into DDB and `ps` to see which thread is where:

```
db> ps
...  0 myfirst_drain_dma+0x42 myfirst_pci_suspend+0x80 ...
```

Debugging pattern. Identify the hanging thread and the function it is stuck in. Usually it is a `cv_wait` or `cv_timedwait` that never completed, or a `taskqueue_drain` waiting on a task that will not finish.

Fix pattern. Add a timeout to any wait the suspend path does. The `myfirst_drain_dma` function uses `cv_timedwait` with a one-second timeout; a variant that uses `cv_wait` (no timeout) can hang indefinitely. The chapter's implementation always uses timed variants for this reason.

22.8.8 Using DTrace to Trace Suspend and Resume

DTrace is an excellent tool for observing the power-management path at fine granularity without adding print statements. A simple D script that times each call:

```
fbt::device_suspend:entry,
fbt::device_resume:entry
{
    self->ts = timestamp;
    printf("%s: %s %s\n", probefunc,
        args[0] != NULL ? stringof(args[0]->name) : "?",
        args[0] != NULL ? stringof(args[0]->desc) : "?");
}

fbt::device_suspend:return,
```

```
fbt::device_resume: return
/self->ts/
{
    printf("%s: returned %d after %d us\n",
        probefunc, arg1,
        (timestamp - self->ts) / 1000);
    self->ts = 0;
}
```

Save this as `trace-devpower.d` and run with `dtrace -s trace-devpower.d`. Any `devctl suspend` or `acpiconf -s 3` will produce output showing each device's suspend and resume times, and their return values.

For the `myfirst` driver specifically, `fbt::myfirst_pci_suspend:entry` and `fbt::myfirst_pci_resume:entry` are the probes. A D script focused on the driver:

```
fbt::myfirst_pci_suspend:entry {
    self->ts = timestamp;
    printf("myfirst_pci_suspend: entered\n");
    stack();
}

fbt::myfirst_pci_suspend: return
/self->ts/ {
    printf("myfirst_pci_suspend: returned %d after %d us\n",
        arg1, (timestamp - self->ts) / 1000);
    self->ts = 0;
}
```

The `stack()` call prints the call stack at entry, which is useful to confirm that the method is being called from where you expect (the PCI bus's `bus_suspend_child`, for example).

22.8.9 A Note on Logging Discipline

The Chapter 22 code logs generously during suspend and resume: every method logs entry and exit, and each helper logs its own events. That verbosity is helpful during development but annoying in production (every laptop suspend prints half a dozen lines to `dmesg`).

A good production driver exposes a `sysctl` that controls log verbosity:

```
static int myfirst_power_verbose = 1;
SYSCTL_INT(_dev_myfirst, OID_AUTO, power_verbose,
    CTLFLAG_RWTUN, &myfirst_power_verbose, 0,
    "Verbose power-management logging (0=off, 1=on, 2=debug)");
```

And the logging becomes conditional:

```
if (myfirst_power_verbose >= 1)
    device_printf(dev, "suspend: starting\n");
```

A reader who wants to enable debugging on a production system can set `dev.myfirst.power_verbose=2` temporarily, trigger the problem, and reset the variable. The Chapter 22 driver does not implement this tiering; the learning driver logs everything and accepts the noise.

22.8.10 Using the INVARIANTS Kernel for Assertion Coverage

A debug kernel with INVARIANTS compiled in causes KASSERT macros to actually evaluate their conditions and panic on failure. The `myfirst_dma.c` and `myfirst_pci.c` code uses several KASSERTs; the power-management code adds more. For example, the quiesce invariant:

```
static int
myfirst_quiesce(struct myfirst_softc *sc)
{
    /* ... */

    KASSERT(sc->dma_in_flight == false,
        ("myfirst: dma_in_flight still true after drain"));

    return (0);
}
```

On an INVARIANTS kernel, a bug that leaves `dma_in_flight` true causes an immediate panic with a useful message. On a production kernel, the assertion is compiled out and nothing happens. The learning driver deliberately runs on an INVARIANTS kernel to catch this class of bug.

Similarly, the resume path can assert:

```
KASSERT(sc->suspended == true,
    ("myfirst: resume called but not suspended"));
```

This catches a bug where the driver somehow gets resume called without the matching suspend having happened (usually a bug in a parent bus driver, not in the `myfirst` driver itself).

22.8.11 A Debugging Case Study

To bring the patterns together, consider a concrete scenario. The reader writes the Stage 2 suspend, runs a regression cycle, and sees:

```
myfirst0: suspend: starting
myfirst0: drain_dma: timeout waiting for abort
myfirst0: suspend: complete (dma in flight=0, suspended=1)
myfirst0: resume: starting
myfirst0: resume: complete
```

Then:

```
sudo sysctl dev.myfirst.0.dma_test_read=1
# Returns EBUSY after a long delay
```

The user-visible symptom is that the post-resume transfer does not work. The log shows a drain timeout during suspend, which is the first anomaly.

Hypothesis. The DMA engine did not honor the ABORT bit. The driver force-cleared `dma_in_flight`, but the engine is still running; when the user triggers a new transfer, the engine is not ready.

Test. Check the engine's status register before and after the abort:

```
/* In myfirst_drain_dma, after writing ABORT: */
uint32_t pre_status = CSR_READ_4(sc->dev, MYFIRST_REG_DMA_STATUS);
DELAY(100); /* let the engine notice */
uint32_t post_status = CSR_READ_4(sc->dev, MYFIRST_REG_DMA_STATUS);
device_printf(sc->dev, "drain: status %#x -> %#x\n", pre_status, post_status);
```

Running the cycle again produces:

```
myfirst0: drain: status 0x4 -> 0x4
```

Status 0x4 is RUNNING. The engine ignored the ABORT. That points to the simulation backend: the simulated engine might not implement abort, or might do so only when the simulation callout fires.

Fix. Look at the simulation's DMA engine code and verify the abort semantics. In this case, the simulation's engine handles the abort in its callout callback, which does not fire for a few milliseconds. Extend the drain timeout from 1 second (plenty) to... wait, 1 second is plenty for a callout that fires every few milliseconds. The real issue is elsewhere.

Further investigation reveals that the simulation's callout was drained *before* the DMA drain completed. The order in `myfirst_drain_workers` (task first, callout second) was wrong; it should be callout first, task second, because the callout is what drives the abort completion.

Resolution. Reorder the drain:

```
static void
myfirst_drain_workers(struct myfirst_softc *sc)
{
```

```

/*
 * Drain the callout first: it runs the simulated engine's
 * completion logic, and the drain-DMA path waits on that
 * completion. Draining the callout after drain_dma would let
 * drain_dma time out and force-clear the in-flight flag.
 *
 * Wait - actually, drain_dma has already completed by the time
 * we get here, because myfirst_quiesce calls it first. So the
 * order of the two drains inside this function does not matter
 * for that reason. But drain_workers is also called from detach,
 * where drain_dma may not have been called, and the order there
 * does matter.
 */
if (sc->sim != NULL)
    myfirst_sim_drain_dma_callout(sc->sim);

if (sc->rx_vector.has_task)
    taskqueue_drain(taskqueue_thread, &sc->rx_vector.task);
}

```

But wait: by the time `myfirst_drain_workers` is called from `myfirst_quiesce`, `myfirst_drain_dma` has already completed. The drain-dma wait is inside the drain-dma call; the drain-workers call only cleans up residual state. The order inside drain-workers is mostly aesthetic for suspend.

The real fix is earlier: `myfirst_drain_dma` itself should not have timed out. The 1-second timeout should have been plenty. The actual cause is different: perhaps the simulation's callout was not firing because the driver held a sysctl lock that blocked it. Or the writing of the ABORT bit did not reach the simulation because the simulation's MMIO handler was also blocked.

Lesson. Debugging power management issues is iterative. Each symptom suggests a hypothesis; each test narrows it down; the fix is often in a different layer than the one the symptom pointed to. The patience to follow the chain is what distinguishes good power-aware code from code that mostly works.

22.8.12 Wrapping Up Section 7

Section 7 walked through the characteristic failure modes of power-aware drivers: frozen devices, lost interrupts, bad DMA, missed wake events, WITNESS complaints, counter drift, and outright hangs. For each, it showed the typical cause, a debugging pattern that narrows the problem down, and the fix pattern that removes it. It also introduced DTrace for measurement, discussed log discipline, and showed how INVARIANTS and WITNESS catch the class of bug that only shows up under specific conditions.

The debugging discipline in Section 7, like the quiesce discipline in Section 3 and the restore discipline in Section 4, is meant to stay with the reader beyond the `myfirst` driver. Every power-aware driver has some variation of these bugs lurking in its implementation; the patterns above are how to find them before they reach the user.

Section 8 brings Chapter 22 to a close by consolidating the Sections 2 through 7 code into a refactored `myfirst_power.c` file, bumping the version to 1.5-power, adding a `POWER.md` document, and wiring up a final integration test.

22.9 Section 8: Refactoring and Versioning Your Power-Aware Driver

Stages 1 through 3 added the power-management code inline in `myfirst_pci.c`. That was convenient for teaching, because every change appeared next to the attach and detach code the reader already knew. It is less convenient for readability: `myfirst_pci.c` now has attach, detach, three power methods, and several helpers, and the file is long enough that a first-time reader has to scroll to find things.

Stage 4, the final version of the Chapter 22 driver, pulls all of the power-management code out of `myfirst_pci.c` and into a new file pair, `myfirst_power.c` and `myfirst_power.h`. This follows the same pattern as Chapter 20's `myfirst_msix.c` split and Chapter 21's `myfirst_dma.c` split: the new file has a narrow, well-documented API, and the caller in `myfirst_pci.c` uses only that API.

22.9.1 The Target Layout

After Stage 4, the driver's source files are:

- `myfirst.c` - top-level glue, shared state, sysctl tree.
- `myfirst_hw.c`, `myfirst_hw_pci.c` - register-access helpers.
- `myfirst_sim.c` - simulation backend.
- `myfirst_pci.c` - PCI attach, detach, method table, and thin forwarding to subsystem modules.
- `myfirst_intr.c` - single-vector interrupt (Chapter 19 legacy path).
- `myfirst_msix.c` - multi-vector interrupt setup (Chapter 20).
- `myfirst_dma.c` - DMA setup, teardown, transfer (Chapter 21).
- `myfirst_power.c` - power management (Chapter 22, new).
- `cbuf.c` - circular-buffer support.

The new `myfirst_power.h` declares the public API of the power subsystem:

```
#ifndef _MYFIRST_POWER_H_
#define _MYFIRST_POWER_H_

struct myfirst_softc;

int myfirst_power_setup(struct myfirst_softc *sc);
void myfirst_power_teardown(struct myfirst_softc *sc);

int myfirst_power_suspend(struct myfirst_softc *sc);
int myfirst_power_resume(struct myfirst_softc *sc);
int myfirst_power_shutdown(struct myfirst_softc *sc);

#ifdef MYFIRST_ENABLE_RUNTIME_PM
```

```

int myfirst_power_runtime_suspend(struct myfirst_softc *sc);
int myfirst_power_runtime_resume(struct myfirst_softc *sc);
void myfirst_power_mark_active(struct myfirst_softc *sc);
#endif

void myfirst_power_add_sysctls(struct myfirst_softc *sc);

#endif /* _MYFIRST_POWER_H_ */

```

The `_setup` and `_teardown` pair initialise and tear down the subsystem-level state (the callout, the sysctls). The per-transition functions wrap the same logic the Section 3 through Section 5 code built. The runtime-PM functions are compiled only when the build-time flag is defined.

22.9.2 The `myfirst_power.c` File

The new file is about three hundred lines. Its structure mirrors `myfirst_dma.c`: header includes, static helpers, public functions, sysctl handlers, and `_add_sysctls`.

The helpers are the three from Section 3:

- `myfirst_mask_interrupts`
- `myfirst_drain_dma`
- `myfirst_drain_workers`

Plus one from Section 4:

- `myfirst_restore`

And, if runtime PM is enabled, two from Section 5:

- `myfirst_idle_watcher_cb`
- `myfirst_start_idle_watcher`

The public functions `myfirst_power_suspend`, `myfirst_power_resume`, and `myfirst_power_shutdown` become thin wrappers that call the helpers in the right order and update counters. The sysctl handlers expose the policy knobs and the observability counters.

22.9.3 Updating `myfirst_pci.c`

The `myfirst_pci.c` file is now much shorter. Its three power methods each just forward to the power subsystem:

```

static int
myfirst_pci_suspend(device_t dev)
{
    return (myfirst_power_suspend(device_get_softc(dev)));
}

```

```
}

static int
myfirst_pci_resume(device_t dev)
{
    return (myfirst_power_resume(device_get_softc(dev)));
}

static int
myfirst_pci_shutdown(device_t dev)
{
    return (myfirst_power_shutdown(device_get_softc(dev)));
}
```

The method table stays the same as Stage 1 set it up. The three prototypes above are now the only power-related code in `myfirst_pci.c`, apart from the call to `myfirst_power_setup` from `attach` and `myfirst_power_teardown` from `detach`.

The attach path grows one call:

```
static int
myfirst_pci_attach(device_t dev)
{
    /* ... existing attach code ... */

    err = myfirst_power_setup(sc);
    if (err != 0) {
        device_printf(dev, "power setup failed\n");
        /* unwind */
        myfirst_dma_teardown(sc);
        /* ... rest of unwind ... */
        return (err);
    }

    myfirst_power_add_sysctls(sc);

    return (0);
}
```

The detach path grows a matching call:

```
static int
myfirst_pci_detach(device_t dev)
{
```

```

    /* ... existing detach code ... */

    myfirst_power_tearardown(sc);

    /* ... rest of detach ... */

    return (0);
}

```

myfirst_power_setup initialises the saved_intr_mask, the suspended flag, the counters, and (if runtime PM is enabled) the idle watcher callout. myfirst_power_tearardown drains the callout and cleans up any subsystem-level state. The teardown must be done before the DMA teardown because the callout may still reference DMA state.

22.9.4 Updating the Makefile

The new source file goes into the SRCS list, and the version bumps:

```

KMOD=  myfirst
SRCS=  myfirst.c \
        myfirst_hw.c myfirst_hw_pci.c \
        myfirst_sim.c \
        myfirst_pci.c \
        myfirst_intr.c \
        myfirst_msix.c \
        myfirst_dma.c \
        myfirst_power.c \
        cbuf.c

CFLAGS+= -DMYFIRST_VERSION_STRING=\"1.5-power\"

# Optional: enable runtime PM.
# CFLAGS+= -DMYFIRST_ENABLE_RUNTIME_PM

.include <bsd.kmod.mk>

```

The MYFIRST_ENABLE_RUNTIME_PM flag is off by default in Stage 4; the runtime-PM code compiles but is wrapped in #ifdef. A reader who wants to experiment enables the flag at build time.

22.9.5 Writing POWER.md

The Chapter 21 pattern set the precedent: every subsystem gets a markdown document that describes its purpose, its API, its state model, and its testing story. POWER.md is next.

A good POWER.md has these sections:

1. **Purpose:** a paragraph explaining what the subsystem does.
2. **Public API:** a table of function prototypes with one-line descriptions.
3. **State Model:** a diagram or text description of the states and transitions.
4. **Counters and Sysctls:** the read-only and read-write sysctls the subsystem exposes.
5. **Transition Flows:** what happens during each of suspend, resume, shutdown.
6. **Interaction with Other Subsystems:** how power management relates to DMA, interrupts, and the simulation.
7. **Runtime PM (optional):** how runtime PM works and when it is enabled.
8. **Testing:** the regression and stress scripts.
9. **Known Limitations:** what the subsystem does not do yet.
10. **See Also:** cross-references to `bus(9)`, `pci(9)`, and the chapter text.

The full document is in the examples directory (`examples/part-04/ch22-power/stage4-final/POWER.md`); the chapter does not reproduce it inline, but a reader who wants to check the expected structure can open it.

22.9.6 Regression Script

The Stage 4 regression script exercises every path:

```
#!/bin/sh
# ch22-full-regression.sh

set -e

# 1. Basic sanity.
sudo kldload ./myfirst.ko

# 2. One suspend-resume cycle.
sudo sh ./ch22-suspend-resume-cycle.sh

# 3. One hundred cycles in a row.
sudo sh ./ch22-suspend-stress.sh

# 4. A transfer before, during, and after a cycle.
sudo sh ./ch22-transfer-across-cycle.sh

# 5. If runtime PM is enabled, test it.
if sysctl -N dev.myfirst.0.runtime_state >/dev/null 2>&1; then
    sudo sh ./ch22-runtime-pm.sh
fi

# 6. Unload.
sudo kldunload myfirst

echo "FULL REGRESSION PASSED"
```

Each sub-script is a few dozen lines and tests one thing. Running the full regression after each change catches regressions immediately.

22.9.7 Integration With the Existing Regression Tests

The Chapter 21 regression script checked:

- `dma_complete_intrs == dma_complete_tasks` (the task always sees every interrupt).
- `dma_complete_intrs == dma_transfers_write + dma_transfers_read + dma_errors + dma_timeouts`.

The Chapter 22 script adds:

- `power_suspend_count == power_resume_count` (every suspend has a matching resume).
- The suspended flag is 0 outside of a transition.
- After a suspend-resume cycle, the DMA counters still add up to the expected total (no phantom transfers).

The combined regression is the Chapter 22 full script. It exercises DMA, interrupts, MSI-X, and power management together. A driver that passes it is in good shape.

22.9.8 Version History

The driver has now evolved through several versions:

- 1.0 - Chapter 16: MMIO-only driver, simulation backend.
- 1.1 - Chapter 18: PCI attach, real BAR.
- 1.2-intx - Chapter 19: single-vector interrupt with filter+task.
- 1.3-msi - Chapter 20: multi-vector MSI-X with fallback.
- 1.4-dma - Chapter 21: `bus_dma` setup, simulated DMA engine, interrupt-driven completion.
- 1.5-power - Chapter 22: suspend/resume/shutdown, refactored into `myfirst_power.c`, optional run-time PM.

Each version builds on the previous one. A reader who has the Chapter 21 driver working can apply the Chapter 22 changes incrementally and end up at 1.5-power without having to rewrite any earlier code.

22.9.9 A Final Integration Test on Real Hardware

If the reader has access to real hardware (a machine with a working S3 implementation), the Chapter 22 driver can be exercised through a full system suspend:

```
sudo kldload ./myfirst.ko
sudo sh ./ch22-suspend-resume-cycle.sh
sudo acpiconf -s 3
# [laptop sleeps; user opens lid]
# After resume, the DMA test should still work.
sudo sysctl dev.myfirst.0.dma_test_read=1
```

On most platforms where ACPI S3 works, the driver survives the full cycle. The `dmesg` output shows the suspend and resume lines just as `devctl` would trigger, confirming that the same method code runs in both contexts.

If the full-system test fails where the per-device test succeeded, the extra work that system suspend does (ACPI sleep-state transitions, CPU parking, RAM self-refresh) has exposed something the per-device test missed. The usual culprits are device-specific register values that the system's low-power state resets but the per-device D3 does not. A driver that tests only with `devctl` can miss these; a driver that tests with `acpiconf -s 3` at least once before claiming correctness is more reliable.

22.9.10 The Chapter 22 Code in One Place

A compact summary of what the Stage 4 driver added:

- **One new file:** `myfirst_power.c`, about three hundred lines.
- **One new header:** `myfirst_power.h`, about thirty lines.
- **One new markdown document:** `POWER.md`, about two hundred lines.
- **Five new softc fields:** `suspended`, `saved_intr_mask`, `power_suspend_count`, `power_resume_count`, `power_shutdown_count`, plus the runtime-PM fields when that feature is enabled.
- **Three new DEVMETHOD lines:** `device_suspend`, `device_resume`, `device_shutdown`.
- **Three new helper functions:** `myfirst_mask_interrupts`, `myfirst_drain_dma`, `myfirst_drain_workers`.
- **Two new subsystem entry points:** `myfirst_power_setup`, `myfirst_power_teardown`.
- **Three new transition functions:** `myfirst_power_suspend`, `myfirst_power_resume`, `myfirst_power_shutdown`.
- **Six new sysctls:** the counter nodes and the suspended flag.
- **Several new lab scripts:** `cycle`, `stress`, `transfer-across-cycle`, `runtime-PM`.

The overall line increment is about seven hundred lines of code, plus a couple of hundred lines of documentation and script. For the capability the chapter added (a driver that correctly handles every power transition the kernel can throw at it), that is a proportionate investment.

22.9.11 Wrapping Up Section 8

Section 8 closed the Chapter 22 driver's construction by splitting the power code into its own file, bumping the version to 1.5-power, adding a `POWER.md` document, and wiring the final regression test. The pattern was familiar from Chapters 20 and 21: take the inline code, extract it into a subsystem with a small API, document the subsystem, and integrate it into the rest of the driver through function calls rather than direct field access.

The resulting driver is power-aware in every sense the chapter introduced: it handles `DEVICE_SUSPEND`, `DEVICE_RESUME`, and `DEVICE_SHUTDOWN`; it quiesces the device cleanly; it restores state correctly on resume; it optionally implements runtime power management; it exposes its state through sysctls; it has a regression test; and it survives full-system suspend on real hardware when the platform supports it.

22.10 Deep Look: Power Management in /usr/src/sys/dev/re/if_re.c

The Realtek 8169 and compatible gigabit NICs are handled by the `re(4)` driver. It is an informative driver to read for Chapter 22 purposes because it implements the full suspend-resume-shutdown trio with wake-on-LAN support, and its code has been stable enough to represent a canonical FreeBSD pattern. A reader who has worked through Chapter 22 can open `/usr/src/sys/dev/re/if_re.c` and recognise the structure immediately.

Reading this walkthrough. The paired `re_suspend()` and `re_resume()` listings in the subsections below are taken from `/usr/src/sys/dev/re/if_re.c`, and the method-table excerpt abbreviates the full `re_methods[]` array with a `/* ... other methods ... */` comment so the three power-related `DEVMETHOD` entries stand out. We kept the signatures, the lock-acquire and lock-release pattern, and the order of device-specific calls (`re_stop`, `re_setwol`, `re_clrwol`, `re_init_locked`) intact; the real method table has many more entries, and the surrounding file carries the helper implementations. Every symbol the listings name is a real FreeBSD identifier in `if_re.c` that you can find with a symbol search.

22.10.1 The Method Table

The `re(4)` driver's method table includes the three power methods near the top:

```
static device_method_t re_methods[] = {
    DEVMETHOD(device_probe,      re_probe),
    DEVMETHOD(device_attach,     re_attach),
    DEVMETHOD(device_detach,     re_detach),
    DEVMETHOD(device_suspend,    re_suspend),
    DEVMETHOD(device_resume,     re_resume),
    DEVMETHOD(device_shutdown,   re_shutdown),
    /* ... other methods ... */
};
```

This is exactly the pattern Chapter 22 teaches. The `myfirst` driver's method table looks the same.

22.10.2 re_suspend

The suspend function is about a dozen lines:

```
static int
re_suspend(device_t dev)
{
    struct rl_softc *sc;

    sc = device_get_softc(dev);

    RL_LOCK(sc);
    re_stop(sc);
```

```

    re_setwol(sc);
    sc->suspended = 1;
    RL_UNLOCK(sc);

    return (0);
}

```

Three calls do the work: `re_stop` quiesces the NIC (disables interrupts, halts DMA, stops the RX and TX engines), `re_setwol` programs the wake-on-LAN logic and calls `pci_enable_pme` if WoL is enabled, and `sc->suspended = 1` sets the softc flag.

Compare to `myfirst_power_suspend`:

```

int
myfirst_power_suspend(struct myfirst_softc *sc)
{
    int err;

    device_printf(sc->dev, "suspend: starting\n");
    err = myfirst_quiesce(sc);
    /* ... error handling ... */
    atomic_add_64(&sc->power_suspend_count, 1);
    return (0);
}

```

The structure is identical. `re_stop` and `re_setwol` together are the equivalent of `myfirst_quiesce`; the chapter's driver does not have wake-on-X, so there is no analogue of `re_setwol`.

22.10.3 re_resume

The resume function is about thirty lines:

```

static int
re_resume(device_t dev)
{
    struct rl_softc *sc;
    if_t ifp;

    sc = device_get_softc(dev);

    RL_LOCK(sc);

    ifp = sc->rl_ifp;
    /* Take controller out of sleep mode. */
}

```

```

    if ((sc->rl_flags & RL_FLAG_MACSLEEP) != 0) {
        if ((CSR_READ_1(sc, RL_MACDBG) & 0x80) == 0x80)
            CSR_WRITE_1(sc, RL_GPIO,
                CSR_READ_1(sc, RL_GPIO) | 0x01);
    }

    /*
     * Clear WOL matching such that normal Rx filtering
     * wouldn't interfere with WOL patterns.
     */
    re_clrwol(sc);

    /* reinitialize interface if necessary */
    if (if_getflags(ifp) & IFF_UP)
        re_init_locked(sc);

    sc->suspended = 0;
    RL_UNLOCK(sc);

    return (0);
}

```

The steps map cleanly to Chapter 22's discipline:

1. **Take the controller out of sleep mode** (MAC sleep bit on some Realtek parts). This is a device-specific restore step.
2. **Clear any WOL patterns** via `re_clrwol`, which reverses what `re_setwol` did. This also calls `pci_clear_pme` implicitly through the clear.
3. **Re-initialise the interface** if it was up before suspend. `re_init_locked` is the same function attach calls to bring up the NIC; it reprograms the MAC, resets the descriptor rings, enables interrupts, and starts the DMA engines.
4. **Clear the suspended flag** under the lock.

The `myfirst_power_resume` equivalent:

```

int
myfirst_power_resume(struct myfirst_softc *sc)
{
    int err;

    device_printf(sc->dev, "resume: starting\n");
    err = myfirst_restore(sc);
    /* ... */
    atomic_add_64(&sc->power_resume_count, 1);
}

```

```
        return (0);  
    }
```

Again the structure is identical. `myfirst_restore` corresponds to the combination of the MAC-sleep exit, `re_clrwol`, `re_init_locked`, and the flag clear.

22.10.4 re_shutdown

The shutdown function is:

```
static int  
re_shutdown(device_t dev)  
{  
    struct rl_softc *sc;  
  
    sc = device_get_softc(dev);  
  
    RL_LOCK(sc);  
    re_stop(sc);  
    /*  
     * Mark interface as down since otherwise we will panic if  
     * interrupt comes in later on, which can happen in some  
     * cases.  
     */  
    if_setflagbits(sc->rl_ifp, 0, IFF_UP);  
    re_setwol(sc);  
    RL_UNLOCK(sc);  
  
    return (0);  
}
```

Similar to `re_suspend`, plus the interface-flag clear (shutdown is final; marking the interface down prevents spurious activity). The pattern is nearly identical; `re_shutdown` is essentially a more defensive version of `re_suspend`.

22.10.5 re_setwol

The wake-on-LAN setup is worth looking at because it shows how a real driver calls the PCI PM APIs:

```
static void  
re_setwol(struct rl_softc *sc)  
{  
    if_t ifp;
```

```
uint8_t v;

RL_LOCK_ASSERT(sc);

if (!pci_has_pm(sc->rl_dev))
    return;

/* ... programs device-specific wake registers ... */

/* Request PME if WOL is requested. */
if ((if_getcapenable(ifp) & IFCAP_WOL) != 0)
    pci_enable_pme(sc->rl_dev);
}
```

Three key patterns appear here that are worth copying into any power-aware driver that supports wake-on-X:

1. **pci_has_pm(dev) guard.** The function returns early if the device does not support power management. This prevents writes to registers that do not exist.
2. **Device-specific wake programming.** The bulk of the function writes Realtek-specific registers through CSR_WRITE_1. A driver for a different device would write different registers, but the placement (inside the suspend path, before pci_enable_pme) is the same.
3. **Conditional pci_enable_pme.** Only enable PME# if the user has actually asked for wake-on-X. If the user has not, the function still sets the relevant configuration bits (for consistency with the driver's interface capabilities) but does not call pci_enable_pme.

The inverse is re_clrwol:

```
static void
re_clrwol(struct rl_softc *sc)
{
    uint8_t v;

    RL_LOCK_ASSERT(sc);

    if (!pci_has_pm(sc->rl_dev))
        return;

    /* ... clears the wake-related config bits ... */
}
```

Note that re_clrwol does not explicitly call pci_clear_pme; the PCI layer's pci_resume_child has already called it before the driver's DEVICE_RESUME. re_clrwol is responsible for undoing the driver-visible side of WoL configuration, not the kernel-visible PME status.

22.10.6 What the Deep Look Shows

The Realtek driver is more complex than `myfirst` by every measure (more registers, more state, more device variants), and yet its power-management discipline is less complex. That is because complexity of the *device* does not map one-to-one to complexity of the *power-management code*. Chapter 22's discipline scales down as well as it scales up: a simple device has a simple power path; a complex device has a modestly more complex power path. The structure is the same.

A reader who has finished Chapter 22 can now open `if_re.c`, recognise every function and every pattern, and understand why each exists. That comprehension transfers: the same recognition applies to `if_xl.c`, `virtio_blk.c`, and hundreds of other FreeBSD drivers. Chapter 22 is not teaching a `myfirst`-specific API; it is teaching the FreeBSD power-management idiom, and the `myfirst` driver is the vehicle that made it concrete.

22.11 Deep Look: Simpler Patterns in `if_xl.c` and `virtio_blk.c`

For contrast, two other FreeBSD drivers implement power management in even simpler ways.

22.11.1 `if_xl.c`: Shutdown Calls Suspend

The 3Com EtherLink III driver in `/usr/src/sys/dev/xl/if_xl.c` has the minimal three-method setup:

```
static int
xl_shutdown(device_t dev)
{
    return (xl_suspend(dev));
}

static int
xl_suspend(device_t dev)
{
    struct xl_softc *sc;

    sc = device_get_softc(dev);

    XL_LOCK(sc);
    xl_stop(sc);
    xl_setwol(sc);
    XL_UNLOCK(sc);

    return (0);
}

static int
xl_resume(device_t dev)
```

```
{  
    struct xl_softc *sc;  
    if_t ifp;  
  
    sc = device_get_softc(dev);  
    ifp = sc->xl_ifp;  
  
    XL_LOCK(sc);  
  
    if (if_getflags(ifp) & IFF_UP) {  
        if_setdrvflagbits(ifp, 0, IFF_DRV_RUNNING);  
        xl_init_locked(sc);  
    }  
  
    XL_UNLOCK(sc);  
  
    return (0);  
}
```

Two things stand out:

1. `xl_shutdown` is one line: it just calls `xl_suspend`. For this driver, shutdown and suspend do the same work, and the code does not need two copies.
2. There is no suspended flag in the softc. The driver assumes the normal lifecycle of attach → run → suspend → resume, and uses the `IFF_DRV_RUNNING` flag (which the TX path already checks) as the equivalent. This is a perfectly valid approach for a NIC whose main user-visible state is the interface's running state.

For the `myfirst` driver, the explicit suspended flag is preferred because the driver has no natural equivalent of `IFF_DRV_RUNNING`. A NIC driver can reuse what it already has; a learning driver declares what it needs.

22.11.2 `virtio_blk.c`: Minimal Quiesce

The `virtio` block driver in `/usr/src/sys/dev/virtio/block/virtio_blk.c` has an even shorter suspend path:

```
static int  
vtblk_suspend(device_t dev)  
{  
    struct vtblk_softc *sc;  
    int error;  
  
    sc = device_get_softc(dev);
```

```
    VTBLK_LOCK(sc);
    sc->vtblk_flags |= VTBLK_FLAG_SUSPEND;
    /* XXX BMV: virtio_stop(), etc needed here? */
    error = vtblk_quiesce(sc);
    if (error)
        sc->vtblk_flags &= ~VTBLK_FLAG_SUSPEND;
    VTBLK_UNLOCK(sc);

    return (error);
}

static int
vtblk_resume(device_t dev)
{
    struct vtblk_softc *sc;

    sc = device_get_softc(dev);

    VTBLK_LOCK(sc);
    sc->vtblk_flags &= ~VTBLK_FLAG_SUSPEND;
    vtblk_startio(sc);
    VTBLK_UNLOCK(sc);

    return (0);
}
```

The comment `/* XXX BMV: virtio_stop(), etc needed here? */` is an honest acknowledgement that the author was not sure how thorough the quiesce should be. The existing code sets a flag, waits for the queue to drain (that is what `vtblk_quiesce` does), and returns. On resume, it clears the flag and restarts I/O.

For a virtio block device, this is enough because the virtio host (the hypervisor) implements its own quiesce when the guest says it is suspending. The driver only needs to stop submitting new requests; the host deals with the rest.

This shows an important pattern: **the driver's quiesce depth depends on how much of the hardware's state is the driver's responsibility**. A bare-metal driver (like `re(4)`) has to program hardware registers carefully because the hardware has no other ally. A virtio driver has the hypervisor as an ally; the host can handle most of the state for the guest. The `myfirst` driver, running on a simulated backend, is in a similar position: the simulation is an ally, and the driver's quiesce can be correspondingly simpler.

22.11.3 What the Comparison Shows

Reading multiple drivers' power-management code side by side is one of the best ways to build fluency. Each driver adapts the Chapter 22 pattern to its context: `re(4)` handles wake-on-LAN, `xl(4)` reuses `xl_shutdown`

= `xl_suspend`, `virtio_blk(4)` trusts the hypervisor. The common thread is the structure: stop activity, save state, flag suspended, return 0 from suspend; on resume, clear flag, restore state, restart activity, return 0.

A reader who has Chapter 22 in memory can open any FreeBSD driver, find its `device_suspend` and `device_resume` in the method table, and read the two functions. Within a few minutes the driver's power policy is clear. That skill transfers to every driver the reader will ever work on; it is the single most useful takeaway from the chapter.

22.12 Deep Look: ACPI Sleep States in More Detail

Section 1 introduced the ACPI S-states as a list. It is worth revisiting them with the driver's point of view in focus, because the driver sees slightly different things depending on which S-state the kernel is entering.

22.12.1 S0: Working

S0 is the state the reader has worked in throughout Chapters 16 to 21. The CPU is executing, RAM is refreshed, the PCIe links are up. From the driver's point of view, S0 is continuous; everything is normal.

Within S0, however, there can still be fine-grained power transitions. The CPU may enter idle states (C1, C2, C3, etc.) between scheduler ticks. The PCIe link may enter L0s or L1 based on ASPM. Devices may enter D3 based on runtime PM. None of these require the driver to do anything beyond its own runtime-PM logic; they are transparent.

22.12.2 S1: Standby

S1 is historically the lightest sleep state. The CPU stops executing but its registers are preserved; RAM stays powered; device power stays at D0 or D1. Wake latency is fast (under a second).

On modern hardware, S1 is rarely supported. The platform's BIOS advertises only S3 and deeper. If the platform does advertise S1 and the user enters it, the driver's `DEVICE_SUSPEND` is still called; the driver does its usual quiesce. The difference is that the PCI layer typically does not transition to D3 for S1 (because the bus stays powered), so the device stays in D0 through the transition. The driver's save and restore are largely unused.

A driver that supports S1 cleanly also supports S3, because the driver-side work is a subset. No driver written for Chapter 22 needs to treat S1 specially.

22.12.3 S2: Reserved

S2 is defined in the ACPI specification but almost never implemented. A driver can safely ignore it; FreeBSD's ACPI layer treats S2 as S1 or S3 depending on platform support.

22.12.4 S3: Suspend to RAM

S3 is the canonical sleep state Chapter 22 targets. When the user enters S3:

1. The kernel's suspend sequence traverses the device tree, calling `DEVICE_SUSPEND` on each driver.

2. The PCI layer's `pci_suspend_child` caches configuration space for each PCI device.
3. The PCI layer transitions each PCI device to D3hot.
4. Higher-level subsystems (ACPI, the CPU's idle machinery) enter their own sleep states.
5. The CPU's context is saved to RAM; the CPU halts.
6. RAM enters self-refresh; the memory controller maintains the contents with minimal power.
7. The platform's wake circuitry is armed: the power button, lid switch, and any configured wake sources.
8. The system waits for a wake event.

When a wake event arrives:

1. The CPU resumes; its context is restored from RAM.
2. Higher-level subsystems resume.
3. The PCI layer walks the device tree and calls `pci_resume_child` for each device.
4. Each device is transitioned to D0; its configuration is restored; pending PME# is cleared.
5. Each driver's `DEVICE_RESUME` is called.
6. User space unfreezes.

The driver sees only steps 1 (suspend) and 5 (resume) of each sequence. The rest is kernel and platform machinery.

A subtle point: during S3, RAM is refreshed but the kernel is not running. This means any kernel-side state (the softc, the DMA buffer, the pending tasks) survives S3 unchanged. The only thing that may be lost is hardware state: configuration registers in the device may be reset; BAR-mapped registers may return to default values. The driver's job on resume is to re-program the hardware from the preserved kernel state.

22.12.5 S4: Suspend to Disk (Hibernate)

S4 is the “hibernate” state. The kernel writes the full contents of RAM to a disk image, then enters S5. On wake, the platform boots, the kernel reads the image back, and the system continues from where it left off.

On FreeBSD, S4 has historically been partial. The kernel can produce the hibernation image on some platforms, but the restore path is not as mature as Linux's. For driver purposes, S4 is the same as S3: the `DEVICE_SUSPEND` and `DEVICE_RESUME` methods are called; the driver's quiesce and restore paths work without change. The extra platform-level work (writing the image) is transparent.

The one difference the driver might notice is that after S4 resume, the PCI configuration space is always restored from scratch (the platform has fully rebooted), so even if the driver were relying on `hw.pci.do_power_suspend` being 0 to keep the device in D0, after S4 the device will still have been through a full power cycle. This matters only for drivers that do platform-specific tricks during suspend; most drivers are oblivious.

22.12.6 S5: Soft Off

S5 is system power-off. The power button, the battery (if any), and the wake circuitry still receive power; everything else is off.

From the driver's point of view, S5 looks like a shutdown: `DEVICE_SHUTDOWN` is called (not `DEVICE_SUSPEND`), the driver places the device in a safe state for power-off, and the system halts. There is no resume corresponding to S5; if the user presses the power button, the system boots from scratch.

Shutdown is not a power transition in the reversible sense; it is a termination. The driver's `DEVICE_SHUTDOWN` method is called once, and the driver does not expect to run again until the next boot. The chapter's `my-first_power_shutdown` handles this correctly by quiescing the device (same as suspend) and not trying to save any state (because there is no resume to save for).

22.12.7 Observing Which States the Platform Supports

On any FreeBSD 14.3 system with ACPI, the supported states are exposed through a `sysctl`:

```
sysctl hw.acpi.supported_sleep_state
```

Typical outputs:

- A modern laptop: S3 S4 S5
- A server: S5 (suspend not supported on many server platforms)
- A VM on bhyve: varies; usually S5 only
- A VM on QEMU/KVM with `-machine q35`: often S3 S4 S5

If a driver is meant to work on a specific platform, the supported-state list tells you which transitions you need to test. A driver that only runs on servers does not need S3 testing; a driver meant for laptops does.

22.12.8 What to Test

For Chapter 22's purposes, the minimum test is:

- `devctl suspend / devctl resume`: always possible; tests the driver-side code path.
- `acpiconf -s 3` (if supported): tests the full system suspend.
- System shutdown (`shutdown -p now`): tests the `DEVICE_SHUTDOWN` method.

S4 and runtime PM are optional; they exercise less-used code paths. A driver that passes the minimum test on a platform that supports S3 is in good shape; extensions are icing.

22.12.9 Mapping Sleep States to the Driver's Methods

A compact table of which `kobj` method is called for each transition:

Transition	Method	Driver Action
S0 → S1	<code>DEVICE_SUSPEND</code>	Quiesce; save state
S0 → S3	<code>DEVICE_SUSPEND</code>	Quiesce; save state (device likely goes to D3)
S0 → S4	<code>DEVICE_SUSPEND</code>	Quiesce; save state (followed by hibernate)
S0 → S5 (shutdown)	<code>DEVICE_SHUTDOWN</code>	Quiesce; leave in safe state for power-off
S1/S3 → S0	<code>DEVICE_RESUME</code>	Restore state; unmask interrupts
S4 → S0 (resume)	(attach from boot)	Normal attach, because the kernel booted fresh

Transition	Method	Driver Action
devctl suspend	DEVICE_SUSPEND	Quiesce; save state (device goes to D3)
devctl resume	DEVICE_RESUME	Restore state; unmask interrupts

The driver does not distinguish S1, S3, and S4 from its own code; it always does the same work. The differences are at the platform and kernel levels. That uniformity is what makes the pattern scalable: one suspend path, one resume path, multiple contexts.

22.13 Deep Look: PCIe Link States and ASPM in Action

Section 1 sketched the PCIe link states (L0, L0s, L1, L1.1, L1.2, L2). It is worth seeing how they behave in practice, because understanding them helps the driver developer interpret latency measurements and power observations.

22.13.1 Why the Link Has Its Own States

A PCIe link is a pair of high-speed differential lanes between two endpoints (root complex and device, or root complex and switch). Each lane has a transmitter and a receiver; each lane's transmitter consumes power to keep the channel in a known state. When traffic is low, the transmitters can be turned off in various degrees, and the link can be re-established quickly when traffic resumes. The L-states describe those degrees.

The link's state is separate from the device's D-state. A device in D0 can have its link in L1 (the link is idle; the device is not transmitting or receiving). A device in D3 has its link in L2 or similar (the link is off). A device in D0 with a busy link is in L0.

22.13.2 L0: Active

L0 is the normal operating state. Both sides of the link are active; data can flow in either direction; latency is at its minimum (a few hundred nanoseconds round-trip on a modern PCIe).

When a DMA transfer is running or an MMIO read is pending, the link is in L0. The device's own logic and the PCIe host bridge both require L0 for the transaction.

22.13.3 L0s: Transmitter Standby

L0s is a low-power state where one side of the link's transmitter is turned off. The receiver stays on; the link can be brought back to L0 in under a microsecond.

L0s is entered automatically by the link logic when no traffic has been sent for a few microseconds. The platform's PCIe host bridge and the device's PCIe interface cooperate: when the transmit FIFO is empty and ASPM is enabled, the transmitter goes off. When new traffic arrives, the transmitter comes back on.

L0s is "asymmetric": each side independently enters and exits the state. A device's transmitter can be in L0s while the root complex's transmitter is in L0. This is useful because traffic is typically bursty: the CPU sends a

DMA trigger, then does not send anything else for a while; the CPU's transmitter enters L0s quickly, while the device's transmitter stays in L0 because it is actively sending the DMA response.

22.13.4 L1: Both Sides Standby

L1 is a deeper state where both transmitters are off. Neither side can send anything until the link is brought back to L0; the latency is measured in microseconds (5 to 65, depending on platform).

L1 is entered after a longer idle period than L0s. The exact threshold is configurable through ASPM settings; typical values are tens of microseconds of inactivity. L1 saves more power than L0s but costs more to exit.

22.13.5 L1.1 and L1.2: Deeper L1 Sub-States

PCIe 3.0 and later define sub-states of L1 that turn off additional parts of the physical layer. L1.1 (also called "L1 PM Substate 1") keeps the clock running but turns off more circuitry; L1.2 turns off the clock as well. The wake latencies increase (tens of microseconds for L1.1; hundreds for L1.2), but the idle power draws decrease.

Most modern laptops use L1.1 and L1.2 aggressively to extend battery life. A laptop that stays in L1.2 most of the idle time can have PCIe power draw in the single-digit milliwatts, compared to hundreds of milliwatts in L0.

22.13.6 L2: Near-Off

L2 is the state the link enters when the device is in D3cold. The link is effectively off; re-establishing it requires a full link-training sequence (tens of milliseconds). L2 is entered as part of the full-system suspend sequence; the driver does not manage it directly.

22.13.7 Who Controls ASPM

ASPM is a per-link feature configured through the PCIe Link Capability and Link Control registers in both the root complex and the device. The configuration specifies:

- Whether L0s is enabled (one-bit field).
- Whether L1 is enabled (one-bit field).
- The exit latency thresholds the platform considers acceptable.

On FreeBSD, ASPM is usually controlled by the platform firmware through ACPI's `_OSC` method. The firmware tells the OS which capabilities to manage; if the firmware keeps ASPM control, the OS does not touch it. If the firmware hands over control, the OS may enable or disable ASPM per link based on policy.

For Chapter 22's `myfirst` driver, ASPM is the platform's job. The driver does not configure ASPM; it does not need to know whether the link is in L0 or L1 at any moment. The link's state is invisible to the driver from a functional standpoint (latency is the only observable effect).

22.13.8 When ASPM Matters to the Driver

There are specific situations where a driver does have to worry about ASPM:

1. **Known errata.** Some PCIe devices have bugs in their ASPM implementation that cause the link to wedge or produce corrupted transactions. The driver may need to explicitly disable ASPM for those devices. The kernel provides the PCIe Link Control register access through `pcie_read_config` and `pcie_write_config` for this purpose.
2. **Latency-sensitive devices.** A real-time audio or video device may not tolerate the microsecond-scale latency of L1. The driver may disable L1 while keeping L0s enabled.
3. **Power-sensitive devices.** A battery-powered device may want L1.2 always enabled. The driver may force L1.2 if the platform's default is less aggressive.

For the `myfirst` driver, none of these apply. The simulated device does not have a link at all; the real PCIe link (if any) is handled by the platform. The chapter mentions ASPM for completeness and moves on.

22.13.9 Observing Link States

On a system where the platform supports ASPM observation, the link state is exposed through `pciconf -lvbc`:

```
pciconf -lvbc | grep -A 20 myfirst
```

Look for lines like:

```
cap 10[ac] = PCI-Express 2 endpoint max data 128(512) FLR NS
            link x1(x1) speed 5.0(5.0)
            ASPM disabled(L0s/L1)
            exit latency L0s 1us/<1us L1 8us/8us
            slot 0
```

The “ASPM disabled” on this line says ASPM is not currently active. “disabled(L0s/L1)” says the device supports both L0s and L1 but neither is enabled. On a system with aggressive ASPM, the line would read “ASPM L1” or similar.

The exit latencies tell the driver how long the transition back to L0 takes; a latency-sensitive driver can decide whether L1 is tolerable by looking at this number.

22.13.10 Link State and Power Consumption

A rough table of PCIe power draws (typical values; actual depend on implementation):

State	Power (x1 link)	Exit Latency
L0	100-200 mW	0
L0s	50-100 mW	<1 μ s
L1	10-30 mW	5-65 μ s
L1.1	1-5 mW	10-100 μ s
L1.2	<1 mW	50-500 μ s
L2	near 0	1-100 ms

For a laptop with a dozen PCIe links all in L1.2 during idle, the aggregate savings relative to all-L0 can be in the watts. For a server with high-throughput links always in L0, ASPM is disabled and the power saving is zero.

Chapter 22 does not implement ASPM for `myfirst`. The chapter mentions it because understanding the link state machine is part of understanding the full power-management picture. A reader who later works on a driver with known ASPM errata will know where to look.

22.14 Deep Look: Wake Sources Explained

Wake sources are the mechanisms that bring a suspended system or device back to active. Chapter 1 mentioned them briefly; this deeper look walks through the most common ones.

22.14.1 PME# on PCIe

The PCI spec defines the **PME#** signal (Power Management Event). When asserted, it tells the upstream root complex that the device has an event worth waking for. The root complex converts **PME#** into an ACPI GPE or interrupt, which the kernel handles.

A device that supports **PME#** has a PCI power-management capability (checked via `pci_has_pm`). The capability's control register includes:

- **PME_En** (bit 8): enable **PME#** generation.
- **PME_Status** (bit 15): set by the device when **PME#** is raised, cleared by software.
- **PME_Support** (read-only, bits 11-15 in PMC register): which D-states the device can raise **PME#** from (D0, D1, D2, D3hot, D3cold).

The driver's job is to set **PME_En** at the right time (usually before suspend) and to clear **PME_Status** at the right time (usually after resume). The `pci_enable_pme(dev)` and `pci_clear_pme(dev)` helpers do both jobs.

On a typical laptop, the root complex routes **PME#** to an ACPI GPE, which the kernel's ACPI driver picks up as a wake event. The chain looks like:

```
device asserts PME#
→ root complex receives PME
→ root complex sets GPE status bit
```

- ACPI hardware interrupts CPU
- kernel wakes from S3
- kernel's ACPI driver services the GPE
- eventually: `DEVICE_RESUME` on the device that woke

The whole chain takes one to three seconds. The driver's role is minimal: it enabled `PME#` before suspend, and it will clear `PME_Status` after resume. Everything else is platform.

22.14.2 USB Remote Wakeup

USB has its own wake mechanism called “remote wakeup”. A USB device requests wake capability through its standard descriptor; the host controller enables the capability at enumeration time; when the device asserts a resume signal on its upstream port, the host controller propagates it.

From a FreeBSD driver perspective, USB remote wakeup is almost entirely handled by the USB host controller driver (`xhci`, `ohci`, `uhci`). Individual USB device drivers (for keyboards, storage, audio, etc.) participate through the USB framework's suspend and resume callbacks, but they do not deal with `PME#` directly. The USB host controller's own `PME#` is what actually wakes the system.

For Chapter 22 purposes, USB wake is a black box that works through the USB host controller driver. A reader who eventually writes a USB device driver will learn the framework's conventions then.

22.14.3 GPIO-Based Wake on Embedded Platforms

On embedded platforms (arm64, RISC-V), wake sources are typically GPIO pins connected to the SoC's wake logic. The device tree describes which pins are wake sources via `wakeup-source` properties and `interrupts-extended` pointing to the wake controller.

FreeBSD's GPIO intr framework handles these. A device driver whose hardware is wake-capable reads the device-tree `wakeup-source` property during attach, registers the GPIO as a wake source with the framework, and the framework does the rest. The mechanism is very different from PCIe `PME#`, but the driver-side API (mark wake enabled, clear wake status) is conceptually similar.

Chapter 22 does not exercise GPIO wake; the `myfirst` driver is a PCI device. Part 7 revisits embedded platforms and covers the GPIO path in detail.

22.14.4 Wake on LAN (WoL)

Wake on LAN is a specific implementation pattern for a network controller. The controller watches incoming packets for a “magic packet” (a specific pattern containing the controller's MAC address repeated many times) or for user-configured patterns. When a match is detected, the controller asserts `PME#` upstream.

From the driver's perspective, WoL requires:

1. Configuring the NIC's wake logic (magic-packet filter, pattern filters) before suspend.
2. Enabling `PME#` via `pci_enable_pme`.

3. On resume, disabling the wake logic (because normal packet processing would otherwise be influenced by the filters).

The `re(4)` driver's `re_setwol` is the canonical FreeBSD example. A reader building a NIC driver copies its structure and adapts the device-specific register programming.

22.14.5 Wake on Lid, Power Button, etc.

The laptop's lid switch, power button, keyboard (in some cases), and other platform inputs are wired to the platform's wake logic through ACPI. The ACPI driver handles the wake; individual device drivers are not involved.

The ACPI `_PRW` method on a device's object in the ACPI namespace declares which GPE that device's wake event uses. The OS reads `_PRW` during boot to configure the wake routing. The `myfirst` driver, as a simple PCI endpoint with no platform-specific wake source, does not have a `_PRW` method; its wake capability (if any) is purely through PME#.

22.14.6 When the Driver Must Enable Wake

A simple heuristic: the driver must enable wake if the user has asked for it (through an interface capability flag like `IFCAP_WOL` for NICs) and the hardware supports it (`pci_has_pm` returns true, the device's own wake logic is operational). Otherwise, the driver leaves wake disabled.

A driver that enables wake for every device by default wastes platform power; the wake circuitry and PME# routing cost a few milliwatts continuously. A driver that never enables wake frustrates users who want their laptop to wake on a network packet. The policy is “enable only when asked”.

FreeBSD's interface capabilities (set via `ifconfig em0 wol wol_magic`) are the standard way users express the desire. The NIC driver reads the flags and configures WoL accordingly.

22.14.7 Testing Wake Sources

Testing wake is harder than testing suspend and resume, because testing wake requires the system to actually sleep and then an external event to wake it. Common approaches:

- **Magic packet from another machine.** Send a WoL magic packet to the suspended machine's MAC address. If WoL is working, the machine wakes in a few seconds.
- **Lid switch.** Close the lid, wait, open the lid. If the platform's wake routing is working, the machine wakes on open.
- **Power button.** Press the power button briefly while suspended. The machine should wake.

For a learning driver like `myfirst`, there is no meaningful wake source to test against. The chapter mentions wake mechanics for pedagogical completeness, not because the driver exercises them.

22.15 Deep Look: The `hw.pci.do_power_suspend` Tunable

One of the most important tunables for power-management debugging is `hw.pci.do_power_suspend`. It controls whether the PCI layer automatically transitions devices to D3 during system suspend. Understanding what it does and when to change it is worth a dedicated look.

22.15.1 What the Default Does

With `hw.pci.do_power_suspend=1` (the default), the PCI layer's `pci_suspend_child` helper, after calling the driver's `DEVICE_SUSPEND`, transitions the device to D3hot by calling `pci_set_power_child(dev, child, PCI_POWERSTATE_D3)`. On resume, `pci_resume_child` transitions back to D0.

This is the “power-save” mode. A device that supports D3 uses its lowest-power idle state during suspend. A laptop benefits because battery life during sleep is extended; a device that can sleep at a few milliwatts instead of a few hundred is worth the extra D-state transition.

22.15.2 What `hw.pci.do_power_suspend=0` Does

With the tunable set to 0, the PCI layer does not transition the device to D3. The device stays in D0 throughout the suspend. The driver's `DEVICE_SUSPEND` runs; the driver quiesces activity; the device stays powered.

From a power-saving perspective, this is worse: the device continues to draw its D0 power budget during sleep. From a correctness perspective, it can be better for some devices:

- A device with broken D3 implementation may misbehave when transitioned. Staying in D0 avoids the transition bug.
- A device whose context is expensive to save and restore may prefer to stay in D0 during a short suspend. If the suspend is only a few seconds, the context-save cost exceeds the power-saving benefit.
- A device that is critical to the machine's core function (a console keyboard, for example) may need to stay alert even during suspend.

22.15.3 When to Change It

For development and debugging, setting `hw.pci.do_power_suspend=0` can isolate bugs:

- If a resume bug appears only with the tunable at 1, the bug is in the D3-to-D0 transition (either in the PCI layer's config restore, or in the driver's handling of a device that has been reset).
- If a resume bug appears with the tunable at 0 as well, the bug is in the driver's `DEVICE_SUSPEND` or `DEVICE_RESUME` code, not in the D-state machinery.

For production, the default (1) is almost always right. Changing it globally affects every PCI device on the system; a better approach is a per-device override if one is needed, which typically lives in the driver itself.

22.15.4 Verifying the Tunable Is in Effect

A quick way to verify is to check the device's power state with `pciconf` before and after a suspend:

```
# Before suspend (device should be in D0):
pciconf -lvbc | grep -A 5 myfirst

# With hw.pci.do_power_suspend=1 (default):
sudo devctl suspend myfirst0
pciconf -lvbc | grep -A 5 myfirst
# "powerspec" should show D3

# With hw.pci.do_power_suspend=0:
sudo sysctl hw.pci.do_power_suspend=0
sudo devctl resume myfirst0
sudo devctl suspend myfirst0
pciconf -lvbc | grep -A 5 myfirst
# "powerspec" should show D0

# Reset to default.
sudo sysctl hw.pci.do_power_suspend=1
sudo devctl resume myfirst0
```

The powerspec line in `pciconf -lvbc` output shows the current power state. Watching it change between D0 and D3 confirms the automatic transition is happening.

22.15.5 Interaction with pci_save_state

When `hw.pci.do_power_suspend` is 1, the PCI layer automatically calls `pci_cfg_save` before transitioning to D3. When it is 0, the PCI layer does not call `pci_cfg_save`.

This has a subtle implication: if the driver wants to save configuration explicitly in the 0 case, it must call `pci_save_state` itself. The Chapter 22 pattern assumes the default (1) and does not call `pci_save_state` explicitly; a driver that wants to support both modes would need additional logic.

22.15.6 Does the Tunable Affect System Suspend or devctl suspend?

Both. `pci_suspend_child` is called for both `acpiconf -s 3` and `devctl suspend`, and the tunable gates the D-state transition in both cases. A reader debugging with `devctl suspend` will see the same behavior as with a full system suspend, modulo the other platform work (CPU park, ACPI sleep state entry).

22.15.7 A Concrete Debugging Scenario

Suppose the `myfirst` driver's resume fails intermittently: sometimes it works, sometimes `dma_test_read` after resume returns EIO. The counters are consistent (suspend count = resume count), the logs show both methods ran, but the post-resume DMA fails.

Hypothesis 1. The D3-to-D0 transition is producing an inconsistent device state. Verify by setting `hw.pci.do_power_suspend=0` and retrying.

If the bug disappears with the tunable at 0, the D-state machinery is involved. The fix might be in the driver's resume path (add a delay after the transition to let the device stabilise), in the PCI layer's config restore, or in the device itself.

Hypothesis 2. The bug is in the driver's own suspend/resume code, independent of D3. Verify by setting the tunable to 0 and retrying.

If the bug persists with the tunable at 0, the driver's code is the problem. The D3 transition is innocent.

This kind of bisection is common in power-management debugging. The tunable is the tool that lets you isolate the variable.

22.16 Deep Look: DEVICE_QUIESCE and When You Need It

Section 2 briefly mentioned `DEVICE_QUIESCE` as the third power-management method alongside `DEVICE_SUSPEND` and `DEVICE_SHUTDOWN`. It is rarely implemented explicitly in FreeBSD drivers; a search of `/usr/src/sys/dev/` shows only a handful of drivers define their own `device_quiesce`. Understanding when you do need it and when you do not is worth a short section.

22.16.1 What DEVICE_QUIESCE Is For

The `device_quiesce` wrapper in `/usr/src/sys/kern/subr_bus.c` is called in several places:

- `devclass_driver_deleted`: when a driver is being unloaded, the framework calls `device_quiesce` on every instance before calling `device_detach`.
- `DEV_DETACH` via `devctl`: when the user runs `devctl detach myfirst0`, the kernel calls `device_quiesce` before `device_detach` unless the `-f` (force) flag is given.
- `DEV_DISABLE` via `devctl`: when the user runs `devctl disable myfirst0`, the kernel calls `device_quiesce` similarly.

In each case, the quiesce is a pre-check: “can the driver safely stop what it is doing?”. A driver that returns `EBUSY` from `DEVICE_QUIESCE` prevents the subsequent detach or disable. The user gets an error, and the driver stays attached.

22.16.2 What the Default Does

If a driver does not implement `DEVICE_QUIESCE`, the default (`null_quiesce` in `device_if.m`) returns 0 unconditionally. The kernel proceeds with detach or disable.

For most drivers, this is fine. The driver's detach path handles any in-flight work, so there is nothing the quiesce would do that detach does not also do.

22.16.3 When You Would Implement It

A driver implements `DEVICE_QUIESCE` explicitly when:

1. **Returning EBUSY is more informative than waiting.** If the driver has a concept of “busy” (a transfer in flight, an open file descriptor count, a filesystem mount), and the user can wait for it to become non-busy, the driver might refuse quiesce until busy is zero. `DEVICE_QUIESCE` returning `EBUSY` tells the user “the device is busy; wait and retry”.
2. **The quiesce can be done faster than a full detach.** If detach is expensive (frees large resource tables, drains slow queues) but the device can be stopped cheaply, `DEVICE_QUIESCE` lets the kernel probe for readiness without paying detach’s cost.
3. **The driver wants to distinguish quiesce from suspend.** If the driver wants to stop activity but not save state (because no resume is coming), implementing quiesce separately from suspend is a way to express that distinction in code.

For the `myfirst` driver, none of these apply. The Chapter 21 detach path already handles in-flight work; the Chapter 22 suspend path handles quiesce in the power-management sense. Adding a separate `DEVICE_QUIESCE` would be redundant.

22.16.4 An Example from `bce(4)`

The Broadcom NetXtreme driver in `/usr/src/sys/dev/bce/if_bce.c` has a commented-out `DEVMETHOD(device_quiesce, bce_quiesce)` entry in its method table. The comment suggests the author considered implementing quiesce but did not. This is common: many drivers keep the line commented as a `TODO` that never gets implemented, because the default handles their use case.

The implementation, if the driver enabled it, would stop the NIC’s TX and RX paths without freeing the hardware resources. A subsequent `device_detach` would then do the actual freeing. The split between “stop” and “free” is what `DEVICE_QUIESCE` would express.

22.16.5 Relation to `DEVICE_SUSPEND`

`DEVICE_QUIESCE` and `DEVICE_SUSPEND` do similar things: they stop the device’s activity. The differences:

- **Lifecycle:** quiesce is between run and detach; suspend is between run and eventual resume.
- **Resources:** quiesce does not require the driver to save any state; suspend does.
- **Ability to veto:** both can return `EBUSY`; the consequences differ (quiesce prevents detach; suspend prevents the power transition).

A driver that implements both usually shares code: `foo_quiesce` might do “stop activity” and `foo_suspend` might do “call quiesce; save state; return”. The `myfirst` driver’s `myfirst_quiesce` helper is the shared code; the chapter does not wire it to a `DEVICE_QUIESCE` method, but doing so would be a small addition.

22.16.6 An Optional Addition to `myfirst`

As a challenge, the reader can add `DEVICE_QUIESCE` to `myfirst`:

```
static int
myfirst_pci_quiesce(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    device_printf(dev, "quiesce: starting\n");
    (void)myfirst_quiesce(sc);
    atomic_add_64(&sc->power_quiesce_count, 1);
    device_printf(dev, "quiesce: complete\n");
    return (0);
}
```

And the matching method-table entry:

```
DEVMETHOD(device_quiesce, myfirst_pci_quiesce),
```

Testing it: `devctl detach myfirst0` calls `quiesce` before detach; the reader can verify by reading `dev.myfirst.0.power_quiesce_count` immediately before the detach takes effect.

The challenge is short and does not change the driver's overall structure; it just wires one more method. Chapter 22's consolidated Stage 4 does not include it by default, but the reader who wants the method can add it in a few lines.

22.17 Hands-On Labs

Chapter 22 includes three hands-on labs that exercise the power-management path in progressively harder ways. Each lab has a script in `examples/part-04/ch22-power/labs/` that the reader can run as-is, plus extension ideas.

22.17.1 Lab 1: Single-Cycle Suspend-Resume

The first lab is the simplest: one clean suspend-resume cycle with counter verification.

Setup. Load the Chapter 22 Stage 4 driver:

```
cd examples/part-04/ch22-power/stage4-final
make clean && make
sudo kldload ./myfirst.ko
```

Verify attach:

```
sysctl dev.myfirst.0.%driver
# Should return: myfirst
sysctl dev.myfirst.0.suspended
# Should return: 0
```

Run. Execute the cycle script:

```
sudo sh ../labs/ch22-suspend-resume-cycle.sh
```

Expected output:

```
PASS: one suspend-resume cycle completed cleanly
```

Verify. Inspect the counters:

```
sysctl dev.myfirst.0.power_suspend_count
# Should return: 1
sysctl dev.myfirst.0.power_resume_count
# Should return: 1
```

Check dmesg:

```
dmesg | tail -6
```

Should show four lines (suspend start, suspend complete, resume start, resume complete) plus the pre-and-post transfer log lines.

Extension. Modify the cycle script to run two suspend-resume cycles instead of one, and verify that the counters increment by exactly 2 each.

22.17.2 Lab 2: One-Hundred-Cycle Stress

The second lab runs the cycle script one hundred times in a row and checks that nothing drifts.

Run.

```
sudo sh ../labs/ch22-suspend-stress.sh
```

Expected output after a few seconds:

```
PASS: 100 cycles
```

Verify. After the stress run, the counters should each be 100 (or 100 plus whatever was there before):

```
sysctl dev.myfirst.0.power_suspend_count  
# 100 (or however many cycles were added)
```

Observations to make.

- How long does one cycle take? On the simulation, it should be a few milliseconds. On real hardware with D-state transitions, expect a few hundred microseconds to a few milliseconds.
- Does the system's load average change during the stress? The simulation is cheap; a hundred cycles on a modern machine should barely register.
- What happens if you run the DMA test during the stress? (`sudo sysctl dev.myfirst.0.dma_test_read=1` concurrently with the cycle loop.) A well-written driver should handle this gracefully; the DMA test succeeds if it happens during a `RUNNING` window and fails with `EBUSY` or similar if it happens during a transition.

Extension. Run the stress script with `dmesg -c` before to clear the log, then afterwards:

```
dmesg | wc -l
```

Should be close to 400 (four log lines per cycle, times 100 cycles). A log-line-per-cycle count lets you verify that every cycle actually executed through the driver.

22.17.3 Lab 3: Transfer Across a Cycle

The third lab is the hardest: it starts a DMA transfer and immediately suspends in the middle of it, then resumes and verifies that the driver recovers.

Setup. The lab script is `ch22-transfer-across-cycle.sh`. It runs a DMA transfer in the background, sleeps a few milliseconds, calls `devctl suspend`, sleeps, calls `devctl resume`, and then starts another transfer.

Run.

```
sudo sh ../labs/ch22-transfer-across-cycle.sh
```

Observations to make.

- Does the first transfer complete, error out, or time out? The expected behavior is that the quiesce aborts it cleanly; the transfer reports `EIO` or `ETIMEDOUT`.
- Does the counter `dma_errors` or `dma_timeouts` increment? One of them should.
- Does `dma_in_flight` go back to false after the suspend?
- Does the post-resume transfer succeed normally? If yes, the driver's state is consistent and the cycle worked.

Extension. Reduce the sleep between the transfer start and the suspend to hit the corner case where the transfer is mid-execution at the moment of the suspend. That is where race conditions live; a driver that passes this test under aggressive timing has a solid quiesce implementation.

22.17.4 Lab 4: Runtime PM (Optional)

For readers building with `MYFIRST_ENABLE_RUNTIME_PM`, a fourth lab exercises the runtime-PM path.

Setup. Rebuild with runtime PM enabled:

```
cd examples/part-04/ch22-power/stage4-final
# Uncomment the CFLAGS line in the Makefile:
# CFLAGS+= -DMYFIRST_ENABLE_RUNTIME_PM
make clean && make
sudo kldload ./myfirst.ko
```

Run.

```
sudo sh ../labs/ch22-runtime-pm.sh
```

The script:

1. Sets the idle threshold to 3 seconds (instead of the default 5).
2. Records baseline counters.
3. Waits 5 seconds without any activity.
4. Verifies `runtime_state` is `RUNTIME_SUSPENDED`.
5. Triggers a DMA transfer.
6. Verifies `runtime_state` is back to `RUNNING`.
7. Prints PASS.

Observations to make.

- During the idle wait, `dmesg` should show the “runtime suspend” log line approximately 3 seconds in.
- The `runtime_suspend_count` and `runtime_resume_count` should each be 1 at the end.
- The DMA transfer should succeed normally after the runtime resume.

Extension. Set the idle threshold to 1 second. Run the DMA test repeatedly in a tight loop. You should see no runtime-suspend transitions during the loop (because each test resets the idle timer), but as soon as the loop stops, the runtime suspend fires.

22.17.5 Lab Notes

All of the labs assume the driver is loaded and the system is idle enough that transitions happen on-demand. If another process is actively using the device (unlikely for `myfirst`, but common in real setups), the counters drift by unexpected amounts and the scripts’ exact-increment checks fail. The scripts are designed for a quiet test environment, not a noisy one.

For realistic testing of the `re(4)` driver or other production drivers, the same script structure applies with the device name adjusted. The `devctl suspend/devctl resume` dance works for any PCI device the kernel manages.

22.18 Challenge Exercises

The Chapter 22 challenge exercises push the reader beyond the baseline driver into territory that real-world drivers eventually have to handle. Each exercise is scoped to be achievable with the chapter’s material and a few hours of work.

22.18.1 Challenge 1: Implement a Wake-on-Sysctl Mechanism

Extend the `myfirst` driver with a simulated wake source. The simulation already has a callout that can fire; add a new simulation feature that sets a “wake” bit on the device while it is in D3, and have the driver’s `DEVICE_RESUME` path log the wake event.

Hints.

- Add a `MYFIRST_REG_WAKE_STATUS` register to the simulation backend.
- Add a `MYFIRST_REG_WAKE_ENABLE` register the driver writes during suspend.
- Have the simulation callout set the wake status bit after a random delay.
- On resume, the driver reads the register and logs whether a wake was observed.

Verification. After `devctl suspend; sleep 1; devctl resume`, the log should show the wake status. A follow-up `sysctl dev.myfirst.0.wake_events` should increment.

Why this matters. Wake source handling is one of the trickiest parts of real-hardware power management. Building it into the simulation lets the reader exercise the full contract without needing hardware.

22.18.2 Challenge 2: Save and Restore a Descriptor Ring

The Chapter 21 simulation does not yet use a descriptor ring (transfers are one-at-a-time). Extend the simulation with a small descriptor ring, program its base address through a register at attach, and have the suspend path save the ring’s base address into softc state. Have the resume path write the saved base address back.

Hints.

- The ring’s base address is a `bus_addr_t` held in the softc.
- The register is `MYFIRST_REG_RING_BASE_LOW/_HIGH`.
- Saving and restoring is trivial; the point is to verify that *not* saving and restoring would break things.

Verification. After suspend-resume, the ring base register should hold the same value as before. Without the restore, it should hold zero.

Why this matters. Descriptor rings are what real high-throughput drivers use; a power-aware driver with a ring has to restore the base address on every resume. This exercise is a stepping stone to the kind of state management that production drivers like `re(4)` and `em(4)` perform.

22.18.3 Challenge 3: Implement a Veto Policy

Extend the suspend path with a policy knob that lets the user specify whether the driver should veto a suspend when the device is busy. Specifically:

- Add `dev.myfirst.0.suspend_veto_if_busy` as a read-write sysctl.
- If the sysctl is 1 and a DMA transfer is in flight, `myfirst_power_suspend` returns `EBUSY` without quiescing.
- If the sysctl is 0 (default), `suspend` always succeeds.

Hints. Set `suspend_veto_if_busy` to 1. Start a long DMA transfer (add a `DELAY` to the simulation's engine to make it last a second or two). Call `devctl suspend myfirst0` during the transfer. Verify that the `suspend` returns an error and `dev.myfirst.0.suspended` stays 0.

Verification. The kernel's unwind path runs; the driver is still in `RUNNING`; the transfer completes normally.

Why this matters. Vetoing is an effective tool and a dangerous one. Real-world policy decisions about whether to veto are nuanced (storage drivers often veto; NIC drivers usually do not). Implementing the mechanism makes the policy question tangible.

22.18.4 Challenge 4: Add a Post-Resume Self-Test

After resume, do a minimum-viable test of the device: write a known pattern to the DMA buffer, trigger a write transfer, read it back with a read transfer, and verify. If the test fails, mark the device broken and fail subsequent operations.

Hints.

- Add the self-test as a helper that runs from `myfirst_power_resume` after `myfirst_restore`.
- Use a well-known pattern like `0xDEADBEEF`.
- Use the existing DMA path; the self-test is just one write and one read.

Verification. Under normal operation, the self-test always passes. To verify it catches failures, add an artificial “fail once” mechanism to the simulation and trigger it; the driver should log the failure and mark itself broken.

Why this matters. Self-tests are a lightweight form of reliability engineering. A driver that catches its own failures at well-defined points is easier to debug than one that silently corrupts data until a user notices.

22.18.5 Challenge 5: Implement Manual `pci_save_state` / `pci_restore_state`

Most drivers let the PCI layer handle config-space save-and-restore automatically. Extend the Chapter 22 driver to optionally do it manually, gated by a sysctl `dev.myfirst.0.manual_pci_save`.

Hints.

- Read `hw.pci.do_power_suspend` and `hw.pci.do_power_resume` and set them to 0 when manual mode is enabled.
- Call `pci_save_state` explicitly in the suspend path, `pci_restore_state` in the resume path.
- Verify that the device still works after suspend-resume.

Verification. The device should function identically whether or not manual mode is enabled. Set the sysctl before a stress test and verify no drift.

Why this matters. Some real drivers need manual save/restore because the PCI layer's automatic handling interferes with device-specific quirks. Knowing when and how to take over the save/restore is a useful intermediate skill.

22.19 Troubleshooting Reference

This section collects the common problems a reader may encounter while working through Chapter 22, with a short diagnostic and fix for each. The list is meant to be skimmable; if a problem matches, skip to the corresponding entry.

22.19.1 “devctl: DEV_SUSPEND failed: Operation not supported”

The driver does not implement `DEVICE_SUSPEND`. Either the method table is missing the `DEVMETHOD(device_suspend, ...)` line, or the driver has not been rebuilt and reloaded.

Fix. Check the method table. Rebuild with `make clean && make`. Unload and reload.

22.19.2 “devctl: DEV_SUSPEND failed: Device busy”

The driver returned `EBUSY` from `DEVICE_SUSPEND`, probably because of the veto logic from Challenge 3, or because the device is genuinely busy (DMA in flight, task running) and the driver chose to veto.

Fix. Check whether the `suspend_veto_if_busy` knob is set. Check `dma_in_flight`. Wait for activity to complete before suspending.

22.19.3 “devctl: DEV_RESUME failed”

`DEVICE_RESUME` returned non-zero. The log should have more detail.

Fix. Check `dmesg | tail`. The resume log line should tell you what failed. Usually it is a hardware-specific init step that did not succeed.

22.19.4 Device is suspended but `dev.myfirst.0.suspended` reads 0

The driver’s flag is out of sync with the kernel’s state. Probably a bug in the quiesce path: the flag was never set, or was cleared prematurely.

Fix. Add a `KASSERT(sc->suspended == true)` at the top of the resume path; run under `INVARIANTS` to catch the bug.

22.19.5 `power_suspend_count != power_resume_count`

A cycle got one side but not the other. Check `dmesg` for errors; the log should show where the sequence broke.

Fix. Fix the code path that is missing. Usually an early return without the counter update.

22.19.6 DMA transfers fail after resume

The restore path did not reinitialise the DMA engine. Check the `INTR_MASK` register, the DMA control registers, the `saved_intr_mask` value. Enable verbose logging to see the resume path’s restoration sequence.

Fix. Add a missing register write to `myfirst_restore`.

22.19.7 WITNESS complains about a lock held during suspend

The suspend path acquired a lock and then called a function that sleeps or tries to acquire another lock. Read the WITNESS message for the offending lock names.

Fix. Drop the lock before the sleeping call, or restructure the code so the lock is acquired only when needed.

22.19.8 System does not wake from S3

A driver below `myfirst` is blocking resume. Unlikely to be `myfirst` itself unless the logs show an error from the driver specifically.

Fix. Boot into single-user mode, or load fewer drivers, and bisect. Check `dmesg` in the live system for the offending driver.

22.19.9 Runtime PM never fires

The idle watcher callout is not running, or the `last_activity` timestamp is being updated too often.

Fix. Verify `callout_reset` is being called from the attach path. Verify `myfirst_mark_active` is not being called from unexpected code paths. Add logging to the callout callback to confirm it fires.

22.19.10 Kernel panic during suspend

A KASSERT failed (on an INVARIANTS kernel) or a lock is held incorrectly. The panic message identifies the offending file and line.

Fix. Read the panic message. Match the file and line to the code. The fix is usually straightforward once the location is identified.

22.20 Wrapping Up

Chapter 22 closes Part 4 by giving the `myfirst` driver the discipline of power management. At the start, `myfirst` at version 1.4-dma was a capable driver: it attached to a PCI device, handled multi-vector interrupts, moved data through DMA, and cleaned up its resources on detach. What it lacked was the ability to participate in the system's power transitions. It would crash, leak, or silently fail if the user closed the laptop lid or asked the kernel to suspend the device. At the end, `myfirst` at version 1.5-power handles every power transition the kernel can throw at it: system suspend to S3 or S4, per-device suspend through `devctl`, system shutdown, and optional runtime power management.

The eight sections walked the full progression. Section 1 established the big picture: why a driver cares about power, what ACPI S-states and PCI D-states are, what PCIe L-states and ASPM add, and what wake sources look like. Section 2 introduced FreeBSD's concrete APIs: the `DEVICE_SUSPEND`, `DEVICE_RESUME`, `DEVICE_SHUTDOWN`, and `DEVICE_QUIESCE` methods, the `bus_generic_suspend` and `bus_generic_resume` helpers, and the PCI layer's automatic config-space save and restore. The Stage 1 skeleton made the methods log and count transitions without doing any real work. Section 3 turned the suspend skeleton into a real quiesce:

mask interrupts, drain DMA, drain workers, in that order, with helper functions shared between suspend and detach. Section 4 wrote the matching resume path: re-enable bus-master, restore device-specific state, clear the suspended flag, unmask interrupts. Section 5 added optional runtime power management with an idle-watcher callout and explicit `pci_set_powerstate` transitions. Section 6 surveyed the user-space interface: `acpiconf`, `zzz`, `devctl suspend`, `devctl resume`, `devinfo -v`, and the matching `sysctls`. Section 7 catalogued the characteristic failure modes and their debugging patterns. Section 8 refactored the code into `myfirst_power.c`, bumped the version to 1.5-power, added `POWER.md`, and wired the final regression test.

What Chapter 22 did not do is scatter-gather power management for multi-queue drivers (that is a Part 6 topic, Chapter 28), hotplug and surprise-removal integration (a Part 7 topic), embedded-platform power domains (Part 7 again), or the internals of ACPI's AML interpreter (never covered in this book). Each of those is a natural extension built on Chapter 22's primitives, and each belongs in a later chapter where the scope matches. The foundation is in place; the specialisations add vocabulary without needing a new foundation.

The file layout has grown: 16 source files (including `cbuf`), 8 documentation files (`HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, `DMA.md`, `POWER.md`), and an extended regression suite that covers every subsystem. The driver is structurally parallel to production FreeBSD drivers; a reader who has worked through Chapters 16 through 22 can open `if_re.c`, `if_xl.c`, or `virtio_blk.c` and recognise every architectural part: register accessors, simulation backend, PCI attach, interrupt filter and task, per-vector machinery, DMA setup and teardown, sync discipline, power suspend, power resume, clean detach.

22.20.1 A Reflection Before Chapter 23

Chapter 22 is the last chapter of Part 4, and Part 4 is the part that taught the reader how a driver talks to hardware. Chapters 16 through 21 introduced the primitives: MMIO, simulation, PCI, interrupts, multi-vector interrupts, DMA. Chapter 22 introduced the discipline: how those primitives survive power transitions. Together, the seven chapters take the reader from “no idea what a driver is” to “a working multi-subsystem driver that handles every hardware event the kernel can throw at it”.

Chapter 22's teaching generalises. A reader who has internalised the suspend-quiesce-save-restore pattern, the interaction between driver and PCI layer, the runtime-PM state machine, and the debugging patterns will find similar shapes in every power-aware FreeBSD driver. The specific hardware differs; the structure does not. A driver for a NIC, a storage controller, a GPU, or a USB host controller applies the same vocabulary to its own hardware.

Part 5, which begins with Chapter 23, shifts focus. Part 4 was about the driver-to-hardware direction: how the driver talks to the device. Part 5 is about the driver-to-kernel direction: how the driver is debugged, traced, tooled, and stressed by the humans who maintain it. Chapter 23 starts that shift with debugging and tracing techniques that apply across every driver subsystem.

22.20.2 What to Do If You Are Stuck

Three suggestions.

First, focus on the Stage 2 suspend and Stage 3 resume paths. If `devctl suspend myfirst0` followed by `devctl resume myfirst0` succeeds and a subsequent DMA transfer works, the core of the chapter is working. Every other piece of the chapter is optional in the sense that it decorates the pipeline, but if the pipeline fails, the chapter is not working and Section 3 or Section 4 is the right place to diagnose.

Second, open `/usr/src/sys/dev/re/if_re.c` and re-read `re_suspend`, `re_resume`, and `re_setwol`. Each function is about thirty lines. Every line maps to a Chapter 22 concept. Reading them once after completing the chapter should feel like familiar territory; the real driver's patterns will look like elaborations of the chapter's simpler ones.

Third, skip the challenges on the first pass. The labs are calibrated for Chapter 22's pace; the challenges assume the chapter's material is solid. Come back to them after Chapter 23 if they feel out of reach now.

Chapter 22's goal was to give the driver power-management discipline. If it has, Chapter 23's debugging and tracing machinery becomes a generalisation of what you already do instinctively rather than a new topic.

22.21 Part 4 Checkpoint

Part 4 has been the longest and densest stretch of the book so far. Seven chapters covered hardware resources, register I/O, PCI attach, interrupts, MSI and MSI-X, DMA, and power management. Before Part 5 changes the mode from “writing drivers” to “debugging and tracing them,” confirm that the hardware-facing story is internalized.

By the end of Part 4 you should be able to do each of the following without searching:

- Claim a hardware resource with `bus_alloc_resource_any` or `bus_alloc_resource_anywhere`, access it through the `bus_space(9)` read/write and barrier primitives, and release it cleanly in detach.
- Read and write device registers through the `bus_space(9)` abstraction rather than raw pointer dereferences, with correct barrier discipline around sequences that must not be reordered.
- Match a PCI device through vendor, device, subvendor, and subdevice IDs; claim its BARs; and survive a forced detach without leaking resources.
- Register a top-half filter together with a bottom-half task or ithread via `bus_setup_intr`, in the order the kernel requires, and tear them down in reverse order under detach.
- Set up MSI or MSI-X vectors with a graceful fallback ladder from MSI-X to MSI to legacy INTx, and bind vectors to specific CPUs when the workload calls for it.
- Allocate, map, sync, and release DMA buffers using `bus_dma(9)` including the bounce-buffer case.
- Implement `device_suspend` and `device_resume` with register save and restore, I/O quiescing, and a post-resume self-test.

If any of those still requires a lookup, the labs to revisit are:

- Registers and barriers: Lab 1 (Observe the Register Dance) and Lab 8 (The Watchdog-Meets-Register Scenario) in Chapter 16.
- Simulated hardware under load: Lab 6 (Inject Stuck-Busy and Watch the Driver Wait) and Lab 10 (Inject a Memory-Corruption Attack) in Chapter 17.
- PCI attach and detach: Lab 4 (Claim the BAR and Read a Register) and Lab 5 (Exercise the `cdev` and Verify Detach Cleanup) in Chapter 18.
- Interrupt handling: Lab 3 (Stage 2, Real Filter and Deferred Task) in Chapter 19.
- MSI and MSI-X: Lab 4 (Stage 3, MSI-X With CPU Binding) in Chapter 20.
- DMA: Lab 4 (Stage 3, Interrupt-Driven Completion) and Lab 5 (Stage 4, Refactor and Regression) in Chapter 21.
- Power management: Lab 2 (One-Hundred-Cycle Stress) and Lab 3 (Transfer Across a Cycle) in Chapter 22.

Part 5 will expect the following as a baseline:

- A hardware-capable driver with observability already baked in: counters, sysctls, and `devctl_notify` calls at the important transitions. Chapter 23's debugging machinery works best when the driver already reports on itself.
- A regression script that can cycle the driver reliably, since Part 5 turns reproducibility into a first-class skill.
- A kernel built with `INVARIANTS` and `WITNESS`. Part 5 leans on both even more heavily than Part 4, especially in Chapter 23.
- The understanding that a bug in driver code is a bug in kernel code, which means user-space debuggers alone will not be enough and Part 5 will teach the kernel-space tools.

If those hold, Part 5 is ready for you. If one still looks shaky, a short lap through the relevant lab will pay back its time several times over.

22.22 Bridge to Chapter 23

Chapter 23 is titled *Debugging and Tracing*. Its scope is the professional practice of finding bugs in drivers: tools like `ktrace`, `ddb`, `kgdb`, `dtrace`, and `procstat`; techniques for analysing panics, deadlocks, and data corruption; strategies for turning vague user reports into reproducible test cases; and the mindset of a driver developer who has to debug code running in kernel space with limited visibility.

Chapter 22 prepared the ground in four specific ways.

First, **you have observability counters everywhere**. The Chapter 22 driver exposes suspend, resume, shutdown, and runtime-PM counters through sysctls. Chapter 23's debugging techniques rely on observability; a driver that already tracks its own state is much easier to debug than one that does not.

Second, **you have a regression test**. The cycle and stress scripts from Section 6 are a first taste of what Chapter 23 expands: the ability to reproduce a bug on demand. A bug you cannot reproduce is a bug you cannot fix; Chapter 22's scripts are a foundation for the heavier testing Chapter 23 adds.

Third, **you have a working `INVARIANTS` / `WITNESS` debug kernel**. Chapter 22 leaned on both throughout; Chapter 23 builds on the same kernel for `ddb` sessions, post-mortem analysis, and kernel-crash reproduction.

Fourth, **you understand that bugs in driver code are bugs in kernel code**. Chapter 22 ran into hangs, frozen devices, lost interrupts, and `WITNESS` complaints. Each of those is a kernel bug in the user-visible sense; each requires a kernel-space debugging approach. Chapter 23 teaches that approach systematically.

Specific topics Chapter 23 will cover:

- Using `ktrace` and `kdump` to observe a process's system call trace in real time.
- Using `ddb` to break into the kernel debugger for post-mortem analysis or live inspection.
- Using `kgdb` with a core dump to recover the state of a crashed kernel.
- Using `dtrace` for in-kernel tracing without modifying the source.
- Using `procstat`, `top`, `pmcstat`, and related tools for performance observation.
- Strategies for minimising a bug: shrinking a reproducer, bisecting a regression, hypothesising and testing.
- Patterns for instrumenting a driver in production without disturbing behaviour.

You do not need to read ahead. Chapter 22 is sufficient preparation. Bring your `myfirst` driver at 1.5-power, your `LOCKING.md`, your `INTERRUPTS.md`, your `MSIX.md`, your `DMA.md`, your `POWER.md`, your WITNESS-enabled kernel, and your regression script. Chapter 23 starts where Chapter 22 ended.

Part 4 is complete. Chapter 23 opens Part 5 by adding the observability and debugging discipline that separates a driver you wrote last week from a driver you can maintain for years.

The vocabulary is yours; the structure is yours; the discipline is yours. Chapter 23 adds the next missing piece: the ability to find and fix bugs that only show up in production.

22.23 Reference: Chapter 22 Quick-Reference Card

A compact summary of the vocabulary, APIs, flags, and procedures Chapter 22 introduced.

22.23.1 Vocabulary

- **Suspend:** a transition from D0 (full operation) to a lower-power state from which the device can be brought back.
- **Resume:** the transition back from the lower-power state to D0.
- **Shutdown:** the transition to a final state from which the device will not return.
- **Quiesce:** to bring a device to a state with no activity and no pending work.
- **System sleep state (S0, S1, S3, S4, S5):** ACPI-defined levels of system power.
- **Device power state (D0, D1, D2, D3hot, D3cold):** PCI-defined levels of device power.
- **Link state (L0, L0s, L1, L1.1, L1.2, L2):** PCIe-defined levels of link power.
- **ASPM (Active-State Power Management):** automatic transitions between L0 and L0s/L1.
- **PME# (Power Management Event):** a signal a device asserts when it wants to wake the system.
- **Wake source:** a mechanism by which a suspended device can request wakeup.
- **Runtime PM:** device-level power saving while the system stays in S0.

22.23.2 Essential Kobj Methods

- `DEVMETHOD(device_suspend, foo_suspend)`: called to quiesce the device before a power transition.
- `DEVMETHOD(device_resume, foo_resume)`: called to restore the device after the power transition.
- `DEVMETHOD(device_shutdown, foo_shutdown)`: called to leave the device in a safe state for reboot.
- `DEVMETHOD(device_quiesce, foo_quiesce)`: called to stop activity without tearing down resources.

22.23.3 Essential PCI APIs

- `pci_has_pm(dev)`: true if the device has a power-management capability.
- `pci_set_powerstate(dev, state)`: transition to `PCI_POWERSTATE_D0`, `D1`, `D2`, or `D3`.
- `pci_get_powerstate(dev)`: current power state.
- `pci_save_state(dev)`: cache the configuration space.
- `pci_restore_state(dev)`: write the cached configuration space back.
- `pci_enable_pme(dev)`: enable PME# generation.

- `pci_clear_pme(dev)`: clear pending PME status.
- `pci_enable_busmaster(dev)`: re-enable bus-master after a reset.

22.23.4 Essential Bus Helpers

- `bus_generic_suspend(dev)`: suspend all children in reverse order.
- `bus_generic_resume(dev)`: resume all children in forward order.
- `device_quiesce(dev)`: call the driver's `DEVICE_QUIESCE`.

22.23.5 Essential Sysctls

- `hw.acpi.supported_sleep_state`: list of S-states the platform supports.
- `hw.acpi.suspend_state`: default S-state for zzz.
- `hw.pci.do_power_suspend`: automatic D0->D3 transition on suspend.
- `hw.pci.do_power_resume`: automatic D3->D0 transition on resume.
- `dev.N.M.suspended`: driver's own suspended flag.
- `dev.N.M.power_suspend_count`, `power_resume_count`, `power_shutdown_count`.
- `dev.N.M.runtime_state`, `runtime_suspend_count`, `runtime_resume_count`.

22.23.6 Useful Commands

- `acpiconf -s 3`: enter S3.
- `zzz`: wrapper around `acpiconf`.
- `devctl suspend <device>`: per-device suspend.
- `devctl resume <device>`: per-device resume.
- `devinfo -v`: device tree with state.
- `pciconf -lvbc`: PCI devices with power state.
- `sysctl -a | grep acpi`: all ACPI-related variables.

22.23.7 Common Procedures

Method table addition:

```
DEVMETHOD(device_suspend,  foo_suspend),
DEVMETHOD(device_resume,   foo_resume),
DEVMETHOD(device_shutdown, foo_shutdown),
```

Suspend skeleton:

```
int foo_suspend(device_t dev) {
    struct foo_softc *sc = device_get_softc(dev);
    FOO_LOCK(sc);
    sc->suspended = true;
```

```
    FOO_UNLOCK(sc);
    foo_mask_interrupts(sc);
    foo_drain_dma(sc);
    foo_drain_workers(sc);
    return (0);
}
```

Resume skeleton:

```
int foo_resume(device_t dev) {
    struct foo_softc *sc = device_get_softc(dev);
    pci_enable_busmaster(dev);
    foo_restore_registers(sc);
    FOO_LOCK(sc);
    sc->suspended = false;
    FOO_UNLOCK(sc);
    foo_unmask_interrupts(sc);
    return (0);
}
```

Runtime-PM helper:

```
int foo_runtime_suspend(struct foo_softc *sc) {
    foo_quiesce(sc);
    pci_save_state(sc->dev);
    return (pci_set_powerstate(sc->dev, PCI_POWERSTATE_D3));
}

int foo_runtime_resume(struct foo_softc *sc) {
    pci_set_powerstate(sc->dev, PCI_POWERSTATE_D0);
    pci_restore_state(sc->dev);
    return (foo_restore(sc));
}
```

22.23.8 Files to Keep Bookmarked

- /usr/src/sys/kern/device_if.m: the kobj method definitions.
- /usr/src/sys/kern/subr_bus.c: bus_generic_suspend, bus_generic_resume, device_quiesce.
- /usr/src/sys/dev/pci/pci.c: pci_suspend_child, pci_resume_child, pci_save_state, pci_restore_state.
- /usr/src/sys/dev/pci/pcivar.h: PCI_POWERSTATE_* constants and inline API.
- /usr/src/sys/dev/re/if_re.c: production reference for suspend/resume with WoL.
- /usr/src/sys/dev/xl/if_xl.c: minimal suspend/resume pattern.
- /usr/src/sys/dev/virtio/block/virtio_blk.c: virtio-style quiesce.

22.24 Reference: Glossary of Chapter 22 Terms

A short glossary of the chapter's new terms.

- **ACPI (Advanced Configuration and Power Interface):** the industry-standard interface between OS and platform firmware for power management.
- **ASPM (Active-State Power Management):** automatic PCIe link-state transitions.
- **D-state:** a device power state (D0 through D3cold).
- **DEVICE_QUIESCE:** the kobj method that stops activity without tearing down resources.
- **DEVICE_RESUME:** the kobj method called to restore a device to operation.
- **DEVICE_SHUTDOWN:** the kobj method called at system shutdown.
- **DEVICE_SUSPEND:** the kobj method called to quiesce a device before a power transition.
- **GPE (General-Purpose Event):** an ACPI wake event source.
- **L-state:** a PCIe link power state.
- **Link state machine:** the automatic transitions between L0 and L0s/L1.
- **PME# (Power Management Event):** the PCI signal a device asserts to request wake.
- **Power management capability:** the PCI capability structure that contains PM registers.
- **Quiesce:** to bring a device to a state with no activity and no pending work.
- **Runtime PM:** device-level power saving while the system stays in S0.
- **S-state:** an ACPI system sleep state (S0 through S5).
- **Shutdown:** final power-down, typically leading to reboot or power-off.
- **Sleep state:** see S-state.
- **Suspend:** temporary power-down from which the system or device can return.
- **Suspended flag:** a driver-local flag indicating the device is in a suspended state.
- **Wake source:** a mechanism by which a suspended system or device can be woken.
- **WoL (Wake on LAN):** a wake source triggered by a network packet.

22.25 Reference: A Closing Note on Power-Management Philosophy

A paragraph to close the chapter with.

Power management is the discipline that separates a driver prototype from a production driver. Before power management, a driver assumes its device is always on and always available. After power management, the driver knows the device can be put to sleep and knows how to put it to sleep correctly, and the driver can be trusted in the kinds of environments real users run: laptops that close and open dozens of times a day, servers that suspend idle devices to save power, VMs that migrate between hosts, embedded systems that turn off whole power domains to extend battery life.

Chapter 22's lesson is that power management is disciplined, not magical. The FreeBSD kernel gives the driver a specific contract (the four kobj methods, the order of invocation, the interaction with the PCI layer), and following the contract is most of the work. The rest is hardware-specific: understanding which registers the device loses across a D-state transition, which wake sources the hardware supports, which policy the driver should apply for runtime PM. The pattern is the same across every power-aware driver in FreeBSD; internalising it once pays off across dozens of later chapters and thousands of lines of real driver code.

For this reader and for this book's future readers, the Chapter 22 power-management pattern is a permanent part of the `myfirst` driver's architecture and a permanent tool in the reader's toolkit. Chapter 23 assumes it:

debugging a driver assumes the driver has the observability counters and the structured lifecycle Chapter 22 introduced. Part 6's specialisation chapters assume it: every production-style driver has a power path. Part 7's performance chapters (Chapter 33) assume it: every tuning measurement has to account for power-state transitions. The vocabulary is the vocabulary every production FreeBSD driver shares; the patterns are the patterns production drivers live by; the discipline is the discipline that keeps power-aware platforms correct.

The skill Chapter 22 teaches is not “how to add suspend and resume methods to a single PCI driver”. It is “how to think about a driver's lifecycle as attach, run, quiesce, sleep, wake, run, and eventually detach, rather than just attach, run, detach”. That skill applies across every driver the reader will ever work on.

Part 4 is complete. The `myfirst` driver is at 1.5-power, structurally parallel to a production FreeBSD driver, and ready for the debugging, tooling, and specialisation chapters that follow in Parts 5 and 6.

23 Debugging and Tracing

23.1 Reader Guidance & Outcomes

Chapter 22 closed Part 4 with a driver that survives suspend, resume, and shutdown. The `myfirst` driver at version 1.5-power attaches to a PCI device, allocates MSI-X vectors, runs a DMA pipeline, handles the full kobj power-management contract, exposes counters through sysctls, and passes a regression script that exercises attach, detach, suspend, resume, and runtime PM. For a driver that boots, runs, suspends, wakes, and eventually unloads, those mechanics are complete. What the driver does not yet have is the ability to tell its developer what is going on inside it when something goes wrong.

Chapter 23 adds that ability. Part 5 is titled *Debugging, Tools, and Real-World Practices*, and Chapter 23 opens it by teaching the observability and diagnosis discipline that turns a driver you just wrote into a driver you can maintain for years. The reader will spend this chapter learning how kernel-space debugging differs from userland debugging, how to use `printf()` and `device_printf()` with intent rather than by habit, how to follow log messages from the moment they are written to the moment a user reads them with `dmesg`, how to build a debug kernel that catches mistakes the normal kernel misses, how to ask DTrace to show the driver's live behavior without rebuilding anything, how to use `ktrace` and `kdump` to follow a user program as it crosses into the kernel through the driver's interface, how to read the characteristic patterns of common driver bugs the first time a symptom appears, and how to refactor the driver's debugging support so that it remains useful without turning the source into a pile of scattered `printf` calls.

Chapter 23's scope is precisely this. It teaches the everyday kernel-debugging toolkit a FreeBSD driver author uses in lab work, in regression testing, and in responding to bug reports. It teaches enough DTrace to instrument a driver and measure its behavior. It teaches the mental model behind the kernel's debug options so the reader can choose the right set for the problem in front of them. It shows where in the source tree these facilities live and how to read their documentation directly. It does not teach the deeper mechanics of post-mortem kernel crash analysis, because that material belongs further along in this book as a specialised topic. It does not teach driver architecture or integration with specific subsystems, because Chapter 24 is about that. It does not teach advanced performance tuning or large-scale profiling, because Part 6 covers hardware-aware tuning in depth. The discipline Chapter 23 introduces is the foundation the later chapters assume: you cannot tune what you cannot observe, and you cannot fix what you cannot reproduce.

Part 5 is where the driver earns the qualities that separate a working prototype from production software. Chapter 22 made the driver survive a change of power state. Chapter 23 makes the driver tell you what it is doing. Chapter 24 will make the driver integrate cleanly with the kernel subsystems users actually reach from their programs. Chapter 25 will make the driver resilient under stress. Each chapter adds one more quality. Chapter 23 adds observability, which turns out to be the quality every later topic depends on.

23.1.1 Why Kernel Debugging Earns a Chapter of Its Own

Before the first line of code, it helps to understand why DTrace, dmesg, and the debug-kernel options get a whole chapter. You may already be wondering why this is any harder than debugging a user program: add some `printf` statements, run under `gdb`, step through the code, done. That mental model is reasonable in user space and catastrophic in kernel space, for three linked reasons.

The first is that **a driver bug is a kernel bug**. When a userland program has a bug, the operating system protects the rest of the machine from it: the kernel kills the process, the shell prints a message, the user tries again. None of that protection applies inside the kernel. A single bad pointer, a single missed lock, a single unfreed allocation, a single race between an interrupt handler and a task, can panic the whole system. A driver that crashes in testing drops the running VM. A driver that leaks memory eventually starves the machine. A driver that corrupts memory destroys whatever data was unlucky enough to sit next to the bug. Chapter 23 exists because these failures do not look or behave like userland failures, and the tools to find them do not look or behave like userland tools.

The second is that **visibility is limited and costly**. In a userland debugger the program is stopped for you. You can step, you can print variables, you can set conditional breakpoints, you can rewind the clock with `rr` or `gdb --record`. In the kernel, none of that is generally available at runtime without special preparation. You cannot stop a running kernel the way you stop a process, because the kernel is also what runs everything else, including the keyboard, the terminal, the network, and the disk. Every piece of visibility you add has a cost: a `printf` is cheap but slow; an SDT probe is fast but has to be compiled in and enabled; a DTrace script is flexible but runs in the kernel itself and touches every probe it fires. Chapter 23 exists because you have to spend visibility budget deliberately, and knowing what each tool costs is part of knowing how to use it.

The third is that **feedback loops are longer**. In userland the write-compile-run cycle is seconds. In kernel work, the cycle is the same under best conditions, but the consequence of a mistake is a reboot or a rollback of the VM snapshot. A bug that takes one try to reproduce in userland may take ten suspends and resumes in kernel land before the driver's internal counter wraps and the symptom appears. A bug that reproduces in every run under `gdb` may reproduce only under an unloaded kernel, at a specific load, or on a specific CPU. Chapter 23 exists because kernel debugging is only tolerable if the feedback loop is as short as you can make it, and short loops require the right combination of tools for each class of bug.

Chapter 23 earns its place by teaching those three realities together, concretely, with the `myfirst` driver as the running example. A reader who finishes Chapter 23 can add disciplined, toggleable debug output to any FreeBSD driver; read and interpret `dmesg`, `/var/log/messages`, and DTrace output without help; build a debug kernel and know what each option buys; find and fix the common driver bug classes the first time a symptom surfaces; and turn a vague report ("my machine sometimes hangs when the driver loads") into a reproducible test case, a hypothesis, a fix, and a regression.

23.1.2 Where Chapter 22 Left the Driver

A few prerequisites to verify before starting. Chapter 23 extends the driver produced at the end of Chapter 22 Stage 4, tagged as version `1.5-power`. If any of the items below is uncertain, return to Chapter 22 and fix it before starting this chapter, because the debugging topics assume the driver has a stable baseline to debug.

- Your driver compiles cleanly and identifies itself as `1.5-power` in `kldstat -v`.

- The driver allocates one or three MSI-X vectors, registers a filter-plus-task interrupt pipeline, binds each vector to a CPU, and prints an interrupt banner during attach.
- The driver allocates a `bus_dma` tag and a 4 KB DMA buffer, exposes the bus address through `dev.myfirst.N.dma_bus_addr`, and cleans up the DMA resources on detach.
- The driver implements `DEVICE_SUSPEND`, `DEVICE_RESUME`, and `DEVICE_SHUTDOWN`. A `devctl suspend myfirst0` followed by `devctl resume myfirst0` succeeds cleanly, and a subsequent DMA transfer works without error.
- Counters for suspend, resume, shutdown, and runtime-PM transitions appear as `sysctls` under `dev.myfirst.N.`
- `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, `DMA.md`, and `POWER.md` are current in your working tree.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel.

That driver is what Chapter 23 extends. The additions are modest in source lines but significant in maintainability: a new `myfirst_debug.c` file, a matching `myfirst_debug.h` header, a bank of logging macros with compile-time and runtime toggles, a set of statically defined DTrace probe points, a verbose-mode `sysctl` knob, a set of debug counters that distinguish normal operation from abnormal events, a version bump to 1.6-debug, a `DEBUG.md` document that explains the subsystem, and a small collection of helper scripts that turn raw log and trace output into something a human can read.

23.1.3 What You Will Learn

By the end of this chapter you will be able to:

- Describe what makes kernel debugging different from userland debugging, in concrete terms, and explain how the difference shapes the rest of the chapter's toolkit.
- Use `printf()`, `device_printf()`, `device_log()`, and `log()` correctly in driver code, with an understanding of when each is appropriate and what log priority levels mean in FreeBSD.
- Read and filter `dmesg`, follow the kernel message buffer through its lifecycle, correlate boot-time and runtime messages, and know when the messages you want are in `dmesg`, when they are in `/var/log/messages`, and when they are in both.
- Build a custom debug kernel with `DDB`, `KDB`, `KDB_UNATTENDED`, `INVARIANTS`, `WITNESS`, and related options, and know what each option actually does at runtime, what it costs, and when you want it.
- Enter `ddb` deliberately during a test, run the basic inspection commands (`show`, `ps`, `bt`, `trace`, `show alllocks`, `show pcpu`, `show mbufs`), leave `ddb` cleanly, and understand what you are looking at in each case.
- Understand what a kernel crash dump is, how `dumpdev` and `savecore(8)` produce one, and how `kgdb` opens a dump for post-mortem analysis at a level sufficient to open one and inspect a few frames.
- Explain what DTrace is, load the `dtraceall` module, list the providers the kernel exposes, write a short script that traces a kernel function, and use the `fbt`, `syscall`, `sched`, `io`, `vfs`, and `sdt` providers for common driver questions.
- Add SDT (Statically Defined Tracing) probes to a driver using `SDT_PROVIDER_DEFINE`, `SDT_PROBE_DEFINE`, and the `SDT_PROBE` macros, and use `dtrace -n 'myfirst:::entry'` to observe them.
- Run `ktrace` against a user program that talks to the driver, read the output with `kdump`, and map syscalls like `open`, `ioctl`, `read`, and `write` back to the driver's entry points.

- Recognise the characteristic patterns of driver bugs: unreleased allocations visible in `vmstat -m`, lock order violations reported by `WITNESS`, `bus_space` access past the end of a BAR, `bus_dmamap_sync` calls missed before or after a transfer, access to a device after its `DEVICE_DETACH` has run, and the symptoms each produces.
- Refactor the driver's debugging support into a dedicated `myfirst_debug.c` and `myfirst_debug.h` pair with runtime-toggable verbose output, `ENTRY` and `EXIT` macros for function-level tracing, `ERROR` and `WARN` macros for structured problem reporting, SDT probes for external tracing, and a `sysctl` subtree for the debug controls.
- Read real driver debug code in the FreeBSD source tree, such as the `DPRINTF` family in `/usr/src/sys/dev/ath/if_ath_debug.h`, the `bootverbose` usage in `/usr/src/sys/dev/virtio/block-virtio_blk.c`, the SDT probes in `/usr/src/sys/dev/virtio/virtqueue.c`, and the debug `sysctls` in drivers like `/usr/src/sys/dev/iwm/if_iwm.c`.

The list is long because debugging is itself a family of skills. Each item is narrow and teachable. The chapter's work is the composition.

23.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 23 stays focused on everyday debugging discipline.

- **Deep kgdb scripting and Python extensions.** The chapter shows how to open a crash dump and inspect a few frames. Building Python helpers on top of `kgdb`, walking kernel data structures with user-defined commands, and scripting dump analysis belong in a later advanced chapter.
- **pmcstat and hardware performance counters.** These are performance-tuning tools, not debugging tools in the narrow sense. Part 6 returns to them.
- **Lock profiling beyond WITNESS.** The options `LOCK_PROFILING` path and the `lockstat` DTrace provider are mentioned in context, but the full tuning workflow for contention analysis belongs with Part 6's performance chapters.
- **Detailed KTR event tracing.** The chapter mentions `KTR` in contrast to `ktrace` so the reader does not confuse the two, but the heavyweight in-kernel event buffer and its circular-log workflow are advanced material that rarely needs a driver's attention.
- **Rate-limited logging frameworks.** Chapter 25 covers logging etiquette, static counters, and time-based rate limiting in depth. Chapter 23 introduces the need for rate limiting informally and hands off.
- **The bhyve debug backend, GDB server mode, and live kernel-level breakpoints.** These are possible and occasionally useful, but they are an advanced niche and do not belong in the first debugging chapter.
- **Error injection and fault testing frameworks.** `fail(9)`, `fail_point(9)`, and related facilities are briefly introduced in context but left to Chapter 25 and the testing material that follows.

Staying inside those lines keeps Chapter 23 a chapter about how to find bugs, not a chapter about all the places the kernel has ever tried to help you find one.

23.1.5 Estimated Time Investment

- **Reading only:** four to five hours. Chapter 23's ideas are conceptually lighter than Chapter 21 or Chapter 22, but they connect to a lot of tools, and a first pass through the tool survey takes time.

- **Reading plus typing the worked examples:** ten to twelve hours over two or three sessions. The driver evolves in three stages: first the macro-based logging and verbose mode, then the SDT probes, and finally the refactor into its own file pair. Each stage is short, and each stage comes with a short lab that confirms it works.
- **Reading plus all labs and challenges:** fifteen to eighteen hours over three or four sessions. The labs include an intentional ddb session, a DTrace exercise that measures driver latency, a ktrace/kdump walk-through, a deliberate memory leak the reader has to find with `vmstat -m`, and an intentional lock order violation the reader has to reproduce under WITNESS.

Sections 4 and 5 are the densest in terms of new vocabulary. If the ddb commands or DTrace syntax feel opaque on first pass, that is normal. Stop, run the matching exercise on the simulated driver, and come back when the shape has settled. Debugging is one of those skills where concrete practice settles the ideas faster than further reading.

23.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 22 Stage 4 (1.5-power). The starting point assumes every Chapter 22 primitive: the `device_suspend`, `device_resume`, and `device_shutdown` methods; the softc's suspended flag and power counters; the `POWER.md` document; and the regression test script. Chapter 23 builds on top of all of that.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF` is built, installed, and booting cleanly. These are the exact options Chapter 22 already asked for; Section 4 of this chapter explains each one in detail so you know what they do.
- `bhyve(8)` or `qemu-system-x86_64` is available. Chapter 23's labs deliberately run in a VM. Several of the labs can panic the kernel (that is the lesson), and a VM snapshot is the right tool to keep the feedback loop short.
- The following user-space commands are in your path: `dmesg`, `sysctl`, `kldstat`, `kldload`, `kldunload`, `devctl`, `vmstat`, `ktrace`, `kdump`, `dtrace`, `procstat`, `savecore`, `kgdb`.
- You have snapshotted your VM at the 1.5-power state and named the snapshot clearly. Several labs in this chapter intentionally panic the kernel; you want to be able to roll back to a known good state in under a minute.

If any item above is shaky, fix it now. Debugging, unlike many topics in this book, is a skill that rewards preparation and punishes shortcuts. A lab session that starts without a snapshot is a lab session that ends with an hour of recovery; a DTrace exercise that starts without `KDTRACE_HOOKS` is a DTrace exercise that fails silently.

23.1.7 How to Get the Most Out of This Chapter

Five habits pay off in this chapter more than in any previous one.

First, keep `/usr/src/sys/kern/subr_prf.c`, `/usr/src/sys/kern/kern_ktrace.c`, `/usr/src/sys/kern/subr_witness.c`, and `/usr/src/sys/sdt.h` bookmarked. The first defines the kernel's `printf`, `log`, `vprintf`, and `tprintf` implementations and is the canonical answer to any question about what happens

when you call them. The second is the `ktrace` implementation. The third is `WITNESS`, the lock-order verifier that Chapter 23 leans on heavily. The fourth is the SDT probe macros. Reading each once at the start of the corresponding section is the single most effective thing you can do for fluency. None of these files are long; the longest is a few thousand lines and most of that is comment.

Second, keep three real driver examples close to hand: `/usr/src/sys/dev/ath/if_ath_debug.h`, `/usr/src/sys/dev/virtio/virtqueue.c`, and `/usr/src/sys/dev/iwm/if_iwm.c`. The first illustrates the classic kernel `DPRINTF` macro pattern with compile-time and runtime toggles. The second contains real SDT probes. The third shows how a driver wires a debug `sysctl` through `device_get_sysctl_tree()`. Chapter 23 points back to each at the right moment. Reading them once now, without trying to memorise, gives the rest of the chapter concrete anchors to hang its ideas on.

A note on line numbers. When these real drivers are referenced later, the reference is always anchored on a named symbol: a `DPRINTF` definition, an SDT probe macro, a specific `sysctl` callback. Those names will carry across future FreeBSD 14.x point releases; the lines where they sit will not. Jump to the symbol in your editor and trust what it reports; the example `WITNESS` output later in the chapter quotes source locations for the same reason, as pointers rather than fixed addresses.

Third, type every code change into the `myfirst` driver by hand. Debugging support is the kind of code that is easy to paste and hard to remember later. Typing out the macros, the SDT definitions, the verbose-mode `sysctl`, and the `myfirst_debug.c` refactor builds familiarity that a copy-paste pass does not. The goal is not to have the code; the goal is to be the person who could write it again from scratch in twenty minutes.

Fourth, work inside a VM, keep a snapshot, and do not be afraid to panic the kernel on purpose. Several of the chapter's labs ask you to enter `ddb` on a running system. Several more ask you to build a driver that intentionally misuses a lock, then to watch `WITNESS` catch it. A real panic in a real VM is, for debugging practice, cheap and safe. A real panic on the reader's development laptop is expensive and annoying. The snapshot is the cheap path.

Fifth, after finishing Section 4, re-read Chapter 22's debugging notes on suspend and resume. The suspend and resume paths are classic targets for the Chapter 23 toolkit: lock issues show up in `WITNESS`, DMA state mistakes show up as `KASSERT` failures under `INVARIANTS`, race conditions show up as intermittent `devctl` suspend failures. Seeing the Chapter 22 material in the light of Chapter 23's tools reinforces both chapters.

23.1.8 Roadmap Through the Chapter

The sections in order are:

1. **Why Kernel Debugging Is Challenging.** The mental model: what makes kernel-space bugs different; why the tools from userland do not carry over; why controlled, incremental changes are the right first response; why you always debug from a position of reproducibility.
2. **Logging With `printf()` and `device_printf()`.** The everyday workhorse. Kernel `printf`; `device_printf` as the preferred form for device drivers; the `log(9)` family with priority levels; formatting conventions; where the output actually goes; what to log and what to leave out. Stage 1 of the Chapter 23 driver extends the `myfirst` log lines to use `device_printf` consistently and prepares the ground for the debug macros in Section 8.
3. **Using `dmesg` and `Syslog` for Diagnostics.** Following the output. The kernel message buffer; `dmesg` and its filters; `/var/log/messages` and `newsyslog`; the relationship between console output, `dmesg`, and

syslog; what it means for a message to be “lost”; how to correlate messages across a boot cycle and across a module reload.

4. **Kernel Debug Builds and Options.** The invariants your kernel enforces. options KDB, DDB, KDB_UNATTENDED, KDB_TRACE; INVARIANTS and INVARIANT_SUPPORT; WITNESS and its variants; KDTRACE_HOOKS and DDB_CTF; a survey of the DDB commands a driver author uses most; a brief introduction to kgdb on a crash dump. This is the longest section of the chapter because the debug kernel is the ground the rest stands on.
5. **Using DTrace for Live Kernel Inspection.** The scalpel. What DTrace is; providers and probes; how to list them with `dtrace -l`; short scripts using `fbt`, `syscall`, `sched`, `io`, and `sdt`; how to add SDT probes to the `myfirst` driver. Stage 2 of the chapter driver adds SDT probes.
6. **Tracing Kernel Activity With `kttrace` and `kdump`.** The user-side viewpoint. What `kttrace` records, what it does not, how to invoke it, how to interpret `kdump` output, how to follow a user program as it crosses into the driver through `open`, `ioctl`, `read`, and `write`.
7. **Diagnosing Common Driver Bugs.** The field guide. Memory leaks and `vmstat -m`; lock order violations and WITNESS; `bus_space` and `bus_dma` misuse patterns; post-detach access; interrupt handler mistakes; lifecycle errors; the debug checklist to run before filing a bug.
8. **Refactoring and Versioning With Trace Points.** The clean house. The final split into `myfirst_debug.c` and `myfirst_debug.h`; runtime-toggable verbose mode through `sysctl`; ENTRY/EXIT/ERROR macros; a small SDT probe bank; the `DEBUG.md` document; the version bump to 1.6-debug.

After the eight sections come an extended look at real-world driver debug patterns in `if_ath_debug.h`, `virtqueue.c`, and `if_re.c`, a set of hands-on labs, a set of challenge exercises, a troubleshooting reference, a Wrapping Up that closes Chapter 23’s story and opens Chapter 24’s, a bridge, a quick-reference card, and the usual glossary of new terms.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 4 and 7 stand alone and make good single-sitting reads. Section 5 assumes Sections 1 through 4; do not read DTrace in isolation on the first pass.

23.2 Section 1: Why Kernel Debugging Is Challenging

Before the tools, the mindset. Section 1 spells out what makes kernel debugging different from what a reader may already know. A reader who has written shell scripts, small C programs, or even a multi-threaded application server has probably used `printf`, `gdb`, `strace`, `valgrind`, `lldb`, or the browser’s devtools. Those tools are excellent in user space, and the mental model they encourage is reasonable in user space. In kernel space, the mental model needs to shift. Section 1 describes that shift, names the specific difficulties driver authors keep running into, and sets the stage for the tool-by-tool work that follows.

23.2.1 The Nature of Kernel Code

A driver is, in the simplest possible statement, C code that runs in kernel address space. That one fact drives most of the differences between kernel debugging and userland debugging.

Kernel address space contains everything: the code the kernel itself runs, the data structures the kernel uses to manage processes and files and memory and devices, the page tables for every process on the system, the

buffers of every pending network packet, the queues of every disk request, and the memory behind every device's mapped registers. Every pointer the driver holds potentially reaches every other part of the kernel. There is no separation like the one user-space programs enjoy, where a process can only touch its own address space and the operating system enforces the boundary.

The consequence is sharp: a single wrong pointer in a driver can corrupt any kernel data structure, not just the driver's own. A driver that writes one byte past the end of its softc may happen to write into the kernel's process table, or into the filesystem's free-block bitmap, or into another driver's interrupt vector table. The corruption often does not produce an immediate panic; it produces a panic five minutes later when some other code reads the structure the driver silently damaged. That delay between cause and symptom is the single most common reason kernel bugs feel harder than userland bugs. You do not catch the wrong pointer at the moment it happens; you catch a different piece of code stumbling over the mess.

Kernel code also runs without the usual safety nets. In user space, dereferencing a null pointer produces a segmentation fault, the kernel kills the process, and the user sees a message. In kernel space, dereferencing a null pointer produces a page fault, the kernel itself faults, and the fault handler decides whether the system can continue. If the page fault happens in a place where it would leave the kernel in an inconsistent state (inside an interrupt handler, inside a critical section, inside `malloc`), the kernel panics to prevent further damage. On a development kernel with `INVARIANTS` enabled, the kernel panics more aggressively than on a release kernel, because the trade-off is exactly the point: catch the bug loudly in development, rather than let it silently propagate.

There is also no standard output stream the way user programs have one. A user-space C program calls `printf` and the output appears on the terminal because the C runtime links the call to a chain that eventually writes to a file descriptor the shell connected to the terminal. In the kernel, there is no shell, no terminal in the user sense, and no C runtime. When a driver calls `printf`, it reaches the kernel's own implementation of `printf`, which writes to the kernel message buffer and, depending on settings, to the system console. Section 2 covers this in detail; the point for now is that the kernel's logging pipeline is not the same pipeline user programs use, and assuming familiarity leads to confusion later. A driver that "just calls `printf`" is calling a different function from the one a userland program calls, with different semantics and a different output path.

23.2.2 Risks of Debugging in Kernel Space

The consequences of a wrong debug change in user space are usually small. A `printf` that prints the wrong variable is an inconvenience. A `printf` inside a loop that runs a billion times slows the program down but does not damage anything. A misuse of `malloc` in a debug statement leaks a few bytes, and the process eventually exits, and the leak disappears with it.

The consequences of a wrong debug change in kernel space can be much larger. A `printf` on the wrong path can deadlock the kernel, if the `printf`'s path needs a lock the calling context has already taken. A `printf` in an interrupt handler that calls into code which may sleep can panic under `INVARIANTS`. A debug message that calls a sleeping allocator (`malloc(..., M_WAITOK)` instead of `M_NOWAIT`) while holding a spin lock will make `WITNESS` very unhappy, and if `WITNESS_KDB` is enabled, will drop the machine into the kernel debugger. A global counter used for debug purposes that is incremented without proper synchronisation is itself a source of bugs. Each of these is a real mistake driver authors make; each is a lesson this chapter will teach.

The nuance is that debugging code is, strictly, code, and it has to be as correct as any other code in the driver. "I'll clean it up later" is not safe in kernel context. A hasty debug change can introduce a new bug that is harder

to find than the original bug. Chapter 23 teaches habits that avoid that trap: use macros that compile out when disabled; use the kernel's own log facility instead of inventing one; wrap conditional blocks so verbose-mode code is paid for only when verbose mode is on; and test debug code at the same level of care as production code.

Another risk is observational: adding debug output can change the behavior you are trying to observe. A race condition that reproduces reliably without debug output may disappear entirely when you add `printf` calls, because the `printf`s serialise through a lock and happen to hide the race window. A performance bug may look different after instrumentation, because the instrumentation itself adds cost. Kernel developers call this the Heisenberg problem of kernel debugging. The chapter's tools are chosen in part because they minimise the problem: DTrace, SDT probes, and KTR add very little overhead when inactive; `device_printf` is chatty but consistent. Sprinkling `printf("HERE\n")` into code is always available, but as a habit it costs more than it helps.

23.2.3 Differences From Userland Debugging

The difference between kernel-space and user-space debugging is worth spelling out tool by tool.

A user can run a program under `gdb`, set a breakpoint, and watch the program stop. You cannot do this directly with a running kernel, because a paused kernel means a paused system. The rough equivalent is `kgdb` against a crash dump, which lets you inspect the kernel's state at the moment of the panic, but which cannot single-step forward. The other rough equivalent is `ddb`, the in-kernel debugger, which lets you pause a live kernel but runs as part of the kernel itself and has its own limited command set. Both are useful; neither behaves the way `gdb` on a live process behaves.

A user can use `strace` on Linux or `truss` on FreeBSD to watch a program's system calls. FreeBSD's `kttrace` is the closest equivalent; it records a trace of a process's syscalls, signals, namei events, I/O, and context switches into a file that `kdump` can read. But `kttrace` sees the user-side of the driver's interface, not the driver's internals. It can show you that the user process called `ioctl(fd, CMD_FOO, ...)`, but not what happened inside the `ioctl` implementation in the driver. Section 6 spends time on `kttrace` precisely because it is the tool that shows the boundary most cleanly.

A user can use `valgrind` to watch for memory errors and leaks in their program. No direct equivalent exists for the kernel. The closest analogs are `vmstat -m` for summarising kernel allocations by type, the `WITNESS` option for lock order errors, `INVARIANTS` for consistency checks the developer wrote into the code, and `MEMGUARD` for a heavier memory-debug allocator. Section 7 walks through the practical patterns.

A user can profile a program with `perf` on Linux or `gprof` on FreeBSD. FreeBSD provides `pmcstat` and DTrace for profiling. DTrace is the more flexible tool for the kind of questions a driver developer asks, and Chapter 23 focuses on DTrace rather than `pmcstat`.

A user can often just re-run a program to see if the bug happens again. Kernel developers often cannot; a kernel that panicked has to be rebooted, and bugs that only appear under load, or that depend on timing, may take hours to reproduce. The response to this difficulty is to build reproducibility into the process: snapshot the VM, script the test case, and log everything. Every tool in this chapter exists to support that response.

One final difference is cultural. The kernel-development community has built a specific vocabulary around debugging that is worth learning on its own. Terms like “lock order”, “critical section”, “preemption disabled”, “epoch”, “giant lock”, “sleepable context”, “non-sleepable context”, and “interrupt context” all have precise

meanings in FreeBSD, and using them correctly is part of being fluent in kernel debugging. Chapter 23 uses them as it goes; the glossary at the end collects the ones that recur.

23.2.4 Importance of Controlled, Incremental Changes

In user space, when a program misbehaves, the first instinct is often to change several things at once and see if the behavior changes. In kernel space this is a losing strategy. Each change is potentially a new bug. Each rebuild costs a VM reboot. Each test cycle eats time. A driver developer who changes five things between compiles spends hours puzzling over which change caused the new symptom, because no single change is isolated.

The right pattern is **controlled, incremental change**. Make one change. Rebuild. Test. Observe the effect. Note what happened. Decide the next change based on the evidence. Move on. This is slower per change and faster per working fix, because you never have to unwind a combined change when one of the five fixes actually introduced a new bug. The discipline feels artificial the first time. After a dozen sessions, it stops feeling artificial and starts feeling like the only way to make progress.

A related discipline is **always start from a known-good state**. Do not debug on a driver that is already in a state you have not verified. Do not start a session by applying six local changes and then running a test. Commit your baseline, verify it works, and only then start the new work. If the new work goes wrong, `git checkout` returns you to known-good, and you can start again. A driver author without this habit spends half of every debugging session wondering whether the baseline or the new change is at fault.

A third discipline is **reproduce before fixing**. A bug that cannot be reproduced cannot be proved fixed. The first job of a debugging session is not to fix the bug; it is to produce a short, reliable way to trigger the bug, ideally in a script. Once the trigger is reliable, the fix is straightforward: apply the candidate, re-run the trigger, observe whether the bug is gone. Without a reliable trigger, you are guessing.

A fourth discipline is **small, scripted reproduction cases**. The difference between a bug that takes an hour to fix and a bug that takes a week is often the size of the reproduction script. A bug you can reproduce with five lines of shell is a bug you can bisect with `git bisect`. A bug you can only reproduce after three hours of complex usage is a bug you will be afraid to even start debugging. Time spent shrinking a reproduction is time well spent.

Chapter 23's labs are deliberately small. The panics are triggered with three lines. The DTrace scripts are five lines. The `kttrace` demonstrations use a one-line C program. That is not accidental: it is the same pattern good driver debugging uses at any scale. Minimal reproductions and minimal changes scale to real bugs.

23.2.5 The Mental Shift

What changes when a developer moves from user space to kernel space is not just the tools; it is the assumptions. In user space, it is reasonable to assume the kernel will catch your mistakes, the runtime will clean up after you, and the worst case is usually a crashed program you can restart. In kernel space, those assumptions are wrong. The kernel catches nothing; the runtime is the thing you are writing; the worst case is a panic that brings down everything.

This is not a reason to be afraid. It is a reason to be careful. Careful, here, has a specific meaning: a driver author writes code that could be debugged by someone else, in six months, from the logs and the source alone. Careful code uses clear function names. Careful code logs what it does at the levels of detail that are useful.

Careful code checks its own invariants. Careful code is structured so that when it breaks, the breakage is obvious. Careful code does not try to be clever; clever code is code you cannot debug under stress.

Chapter 23 teaches the tools of kernel debugging, but the habit it actually teaches is carefulness. Every tool in the chapter is most useful when applied by a careful developer on careful code. The same tool applied to reckless code produces information you cannot interpret. The point is not to memorise DTrace syntax or ddb commands; the point is to develop the habit of debugging from evidence, in small steps, against a known baseline, with good logs, in a way that any collaborator can follow.

23.2.6 Wrapping Up Section 1

Section 1 established the shape of the problem. Kernel code runs in a single shared address space, without the safety nets userland relies on, with failure modes that damage the whole system. Kernel debugging tools are different, more costly, and less interactive than their userland cousins. The discipline of controlled, incremental, reproducible change is not optional; it is the only strategy that works. The mental shift required is real, but it is learnable, and it is the foundation the rest of the chapter's tools stand on.

Section 2 starts the tool survey with the simplest and most universal tool every driver ends up using: the kernel's `printf` family.

23.3 Section 2: Logging With `printf()` and `device_printf()`

The kernel's `printf` family is the humblest debugging tool in the toolkit. It is also the most used, by a wide margin. Almost every FreeBSD driver in `/usr/src/sys/dev` calls `device_printf` somewhere. Almost every boot message a user ever sees was written by a kernel `printf`. Before DTrace, before ddb, before SDT probes, before debug kernels, a driver author reaches for `device_printf` because it is always available, it is always safe (subject to the qualifications this section will spell out), and it is understood by every other driver author on the planet.

This section teaches how to use that family of functions deliberately. The goal is not just to show how to call `device_printf`, because that part is trivial. The goal is to build the habit of using logging as a designed feature of the driver, not as a scattered set of debugging notes that accumulate over time and never get cleaned up.

23.3.1 Basics of `printf()` in Kernel Context

FreeBSD's kernel `printf` lives in `/usr/src/sys/kern/subr_prf.c`. Its signature is familiar:

```
int printf(const char *fmt, ...);
```

It takes a format string and a variable argument list and writes the formatted text into the kernel message buffer. The buffer is a circular area of memory, usually around 192 KB in size on a modern FreeBSD system, into which every kernel message is written. The kernel does not keep a permanent log on its own; the user-space `syslogd(8)` daemon is what reads the buffer and writes selected lines to `/var/log/messages`. Section 3 covers the full pipeline.

The format string understands most of the same conversions userland's `printf` understands: `%d`, `%u`, `%x`, `%s`, `%c`, `%p`, and so on. It understands a few kernel-specific extras, such as `%D` for printing a hex dump of a byte buffer (with a separator argument). It does not understand floating-point conversions like `%f` and `%g`, because the kernel does not use floating-point math by default and the conversion code is intentionally absent. Trying to print a `double` or `float` inside the kernel is almost always a mistake, and the compiler will usually warn about it.

The kernel's `printf` has different safety properties from the userland one. Userland `printf` can allocate, can take locks inside the C runtime, and can block on I/O. The kernel's `printf` must not allocate; it must not block; it must be safe to call from almost any context. The implementation in `subr_prf.c` is deliberately simple: it formats into a small stack buffer, copies the result into the message buffer, wakes up `syslogd` if appropriate, and returns. That simplicity is part of why `printf` is the universal fallback tool.

There are a few contexts where even the kernel's `printf` is not safe. Fast interrupt handlers, for example, run before the kernel has stabilised the console state, and a `printf` from inside a fast interrupt can produce a hang or a deadlock on some platforms. Paths that hold a lock the `printf` path also tries to take can deadlock too. In practice, driver authors avoid the problem by using `printf` only from the ordinary driver entry points (`attach`, `detach`, `ioctl`, `read`, `write`, `suspend`, `resume`) and from interrupt tasks (the deferred half of a filter-plus-task interrupt pipeline, as Chapter 19 introduced), not from the filter itself. The `myfirst` driver already follows this pattern; Chapter 23 preserves it.

23.3.2 Preferred Use: `device_printf()` for Structured, Device-Aware Logging

Raw `printf` is generic. A driver author can do better. The kernel provides `device_printf`, declared in `/usr/src/sys/sys/bus.h`:

```
int device_printf(device_t dev, const char *fmt, ...);
```

The function prefixes every message with the device's name, typically the driver's name concatenated with the unit number: `myfirst0:`, `em1:`, `virtio_blk0:`. That prefix is not cosmetic. It is the single most important piece of information in the kernel log for a multi-device system. Without it, a message like "interrupt received" is useless in a machine with eight network cards and three storage controllers. With it, "myfirst0: interrupt received" is immediately locatable in any tool that reads logs.

The rule is simple: **in driver code, prefer `device_printf` over `printf`**. Every place the driver has a `device_t` in scope, use `device_printf`. Every place the driver does not have a `device_t` (a global init function, for example), use `printf` with an explicit prefix:

```
printf("myfirst: module loaded\n");
```

This is the pattern that makes the kernel log readable across a system. It is also the pattern almost every FreeBSD driver follows. Open any file under `/usr/src/sys/dev/` and the pattern is visible within the first `attach` function.

The `myfirst` driver already uses `device_printf` in most places, because Chapter 18 introduced the convention when the driver first became a PCI device. Section 8 of this chapter wraps `device_printf` in macros that add severity, category, and a verbose-mode toggle, but the underlying function remains the same. Nothing in Chapter 23 replaces `device_printf`; the chapter elaborates on it.

23.3.3 `device_log()` and Log Priority Levels

`device_printf` is plain: it writes the message at the kernel's default log priority (`LOG_INFO`, in syslog terms). Sometimes a driver wants to write at a higher priority, to flag a serious problem, or at a lower priority, to tag a routine informational message that should usually be filtered out.

FreeBSD 14 exposes `device_log` for that purpose, also in `/usr/src/sys/sys/bus.h`:

```
int device_log(device_t dev, int pri, const char *fmt, ...);
```

The `pri` argument is one of the syslog priority constants from `/usr/src/sys/sys/syslog.h`:

- `LOG_EMERG` (0): system is unusable
- `LOG_ALERT` (1): action must be taken immediately
- `LOG_CRIT` (2): critical conditions
- `LOG_ERR` (3): error conditions
- `LOG_WARNING` (4): warning conditions
- `LOG_NOTICE` (5): normal but significant condition
- `LOG_INFO` (6): informational
- `LOG_DEBUG` (7): debug-level messages

For driver work, the four priorities that matter in practice are `LOG_ERR`, `LOG_WARNING`, `LOG_NOTICE`, and `LOG_INFO`. A driver rarely needs `LOG_EMERG`, `LOG_ALERT`, or `LOG_CRIT`, because most driver failures are local to the driver, not to the whole system. `LOG_DEBUG` is useful during active debugging; Chapter 23 uses it for verbose-mode output.

The underlying `log(9)` function, also in `subr_prf.c`, is simpler: `void log(int pri, const char *fmt, ...)`. `device_log` wraps `log` and adds the device-name prefix.

The practical difference between `printf` and `log` is where the output goes when the kernel is configured conservatively. By default, FreeBSD sends everything at or above `LOG_NOTICE` to the console; `LOG_INFO` and below go to the kernel message buffer but not to the console. That matters in two places. First, during boot: a high-priority message is visible on the screen during boot; a `LOG_INFO` message is not. Second, during operation: a serious error on a production system should appear on the console (so a sysadmin watching `tail` on messages sees it immediately), while a routine probe or attach message should not clutter the screen.

The `myfirst` driver in Chapter 23 uses this convention:

- Probe and attach success: `device_printf` (which is `LOG_INFO`).
- Suspend, resume, and shutdown transitions: `device_printf` (routine).
- Errors from hardware, unexpected interrupt counts, DMA failures, and failed device state: `device_log(dev, LOG_ERR, ...)` or `device_log(dev, LOG_WARNING, ...)`.
- Verbose-mode output (enabled by a `sysctl`): `device_log(dev, LOG_DEBUG, ...)` inside the debug macros.

23.3.4 What to Log and What to Leave Out

Knowing what not to log matters as much as knowing what to log. A driver with too much output clutters `dmesg`, wastes message-buffer space, and pushes older informative messages out of the circular buffer before anyone

reads them. A driver with too little output is silent when something goes wrong and gives the reader nothing to work with.

The rule of thumb for the `myfirst` driver in Chapter 23 is:

Always log, at `device_printf` level (`LOG_INFO`):

- A one-line banner at attach, stating the driver name, the version, and any key resources allocated (interrupt type, MSI-X vector count, DMA buffer size). The reader should be able to see at a glance what the driver did.
- A one-line note at detach. Detach is usually silent, but logging its completion is useful when a driver hangs on unload and the reader needs to know the detach was at least started.
- A one-line note at each suspend, resume, and shutdown. Power transitions matter, and the reader often wants to correlate a bug with a transition that preceded it.

Always log, at `device_log` with `LOG_ERR` or `LOG_WARNING`:

- Any failure to allocate a resource (interrupt, DMA tag, DMA buffer, mutex). The error path should always state what failed.
- Any hardware error the driver detects: a response the device did not expect, a timeout, a register value that indicates the hardware has faulted.
- Any state inconsistency the driver catches: a DMA completion for a transfer that was not started, a suspend that finds the device already suspended, a detach that finds the device still holding a client reference.

Never log in the normal steady-state path:

- Every interrupt. Even if the device is quiet, a driver that logs every interrupt floods the log within seconds under real load. Use DTrace or counters for per-interrupt observability.
- Every DMA transfer. Same reason.
- Every read or write call. Same reason.
- Internal function entry and exit in production. Use the verbose-mode macros (Section 8) so the developer can turn entry/exit tracing on or off.

Log under verbose mode (enabled by the Section 8 macros and the debug `sysctl`):

- Function entry and exit for key functions, with a short argument summary.
- Individual interrupt events with the interrupt status register value.
- DMA transfer submissions and completions.
- `sysctl` and `ioctl` operations and the values they returned.

The line between “always” and “verbose” is a judgement call, and different drivers draw it differently. `/usr/src/sys/dev/re/if_re.c` logs very little in production and uses a `re_debug` `sysctl` to enable detailed output. `/usr/src/sys/dev/virtio/block/virtio_blk.c` uses `bootverbose` to gate extra attach-time detail. `/usr/src/sys/dev/ath/if_ath_debug.h` defines a sophisticated per-subsystem mask that selectively enables different categories of output. Chapter 23’s `myfirst` driver adopts a simpler pattern that is enough for teaching purposes and can be extended when the reader starts working on a real driver.

23.3.5 Tracing Function Flow Without Spamming

One of the debugging idioms that is tempting but produces more harm than good is writing a `device_printf` at the start and end of every function. The idea is sound: if you can see the call sequence, you can often deduce what is happening. The practice is wrong, because the sequence produces an overwhelming amount of output, and the output serialises through the `printf` path, which changes the timing of the code under test.

The right pattern is to use a **verbose mode controlled by a `sysctl`**. Define a pair of macros:

```
#define MYF_LOG_ENTRY(sc)      \
do {                          \
    if ((sc)->debug_verbose) \
        device_printf((sc)->dev, "ENTRY: %s\n", __func__); \
} while (0)

#define MYF_LOG_EXIT(sc, err) \
do {                          \
    if ((sc)->debug_verbose) \
        device_printf((sc)->dev, "EXIT: %s err=%d\n", __func__, (err)); \
} while (0)
```

Then, at the top of every function the driver wants to trace, call `MYF_LOG_ENTRY(sc);`. At every return, call `MYF_LOG_EXIT(sc, err);`. When the `debug_verbose` flag is zero (the default), the macros compile down to a branch that is never taken and have essentially zero cost. When the flag is one (enabled at runtime through `sysctl dev.myfirst.0.debug_verbose=1`), the macros produce a trace that any driver developer can read.

The boolean flag shown above is deliberately simple. It introduces the idea of a runtime-controlled knob without requiring the reader to learn a new layout at the same time. Section 8 of this chapter fleshes this idiom out into a full macro bank, replaces the single boolean with a 32-bit bitmask (so the operator can enable just the interrupt trace, or just the I/O trace, rather than everything at once), moves the whole apparatus into `myfirst_debug.h`, and adds SDT probes alongside. For now, the pattern to internalise is that trace-level output should be **off by default** and **runtime toggleable**. Compile-time debug flags (the old `#ifdef DEBUG` style) are a poor second: you have to rebuild the module to change them. Runtime toggles let a developer enable verbose mode on a running system the moment they need it and disable it the moment the evidence is gathered.

23.3.6 Redirecting Logs to `dmesg` and `/var/log/messages`

The kernel's `printf` writes to the kernel message buffer. That buffer is what `dmesg(8)` reads when the user runs it. Section 3 covers `dmesg` in detail; the short version is that the buffer is circular, so old messages eventually get overwritten by new ones as the buffer fills.

The `syslogd(8)` daemon reads new messages out of the buffer and writes them to the appropriate syslog file, usually `/var/log/messages`. The mapping between priority and file is configured in `/etc/syslog.conf`. By default, messages at `LOG_INFO` or higher go to `/var/log/messages`; `LOG_DEBUG` messages are dropped unless explicitly enabled. `/var/log/messages` is rotated by `newsyslog(8)` according to rules in `/etc/newsyslog.conf`; that rotation is what produces the `messages.0.gz`, `messages.1.gz`, and so on that the reader will find in a long-running system's log directory.

The practical consequence is that a driver's log output lives in two places at once. A recent message is in the kernel buffer (accessible through `dmesg`) and in `/var/log/messages` (accessible through any file-reading tool). An old message may have aged out of the buffer but still be in `/var/log/messages` or its archives. A very old message may have rolled out of `/var/log/messages` into a `messages.N.gz` archive, and can be read with `zcat`, `zgrep`, or `zless`. Section 3 walks through these tools.

There is one subtlety worth mentioning here because it trips up new driver authors: **a `LOG_DEBUG` message produced by the kernel is not written to `/var/log/messages` by default**. If the reader's debug output is at `LOG_DEBUG` and they cannot find it in the log file, the cause is usually `/etc/syslog.conf`, not the driver. A quick test: run the driver, and then run `dmesg | grep myfirst`. If the message appears in `dmesg` but not in `/var/log/messages`, the message was produced but was filtered out by `syslog`. Enabling `LOG_DEBUG` in `/etc/syslog.conf` (if `syslog` is configured to care about kernel debug messages) is one fix; using `device_printf` or `device_log(dev, LOG_INFO, ...)` is a more common fix, because it bypasses the problem by using a higher priority.

23.3.7 A Concrete Walkthrough: Logging in the `myfirst` Driver

The `myfirst` driver at the start of Chapter 23 already has log lines in the obvious places: `attach` prints a banner, `detach` confirms completion, `suspend` and `resume` log their transitions, and DMA errors log a warning. Chapter 23's Stage 1 upgrades this in three targeted ways.

First, every `printf` inside the driver that has a `device_t` in scope becomes a `device_printf`. A quick `grep` turns up about eight lines that still use plain `printf` from the module's `MOD_LOAD` and `MOD_UNLOAD` handlers. The module-level ones stay as `printf` (they do not have a `device_t`), but they use the literal `"myfirst: "` prefix so the reader can still find them in the log. A driver that calls `printf` without a prefix in any place is a driver that produces unfindable log lines.

Second, every error path becomes a `device_log` at an explicit priority:

```
/* Before */
if (error) {
    device_printf(dev, "bus_dma_tag_create failed: %d\n", error);
    return (error);
}

/* After */
if (error) {
    device_log(dev, LOG_ERR, "bus_dma_tag_create failed: %d\n", error);
    return (error);
}
```

The change is small, and the behavior is the same in most test kernels. The value is in the priority. A production system watching for `LOG_ERR` messages will now see the driver's errors; a development environment filtering at `LOG_INFO` will see everything.

Third, a new pattern of logging for “rare but important” state changes is introduced. Specifically, the Chapter 23 driver logs at `LOG_NOTICE` on three events the reader may want to know about but does not want every interrupt

for: the first successful DMA transfer after attach, a transition into runtime suspend from idle detection, and the first successful resume after a suspend. These are not errors, but they are not routine either; they are the events a developer reading the log wants to see highlighted.

The exact code changes for Stage 1 are laid out in Section 2's hands-on exercise at the end of this section, and the corresponding files are under `examples/part-05/ch23-debug/stage1-logging/`.

23.3.8 A Note on `uprntf` and `tprntf`

Two sibling functions appear in `subr_prf.c` that driver authors occasionally see but rarely use.

`uprntf(const char *fmt, ...)` writes a message to the current user process's controlling terminal, if there is one, *instead of* to the kernel message buffer. It is useful in rare cases where a driver's `ioctl` handler wants to produce an error message that only the user running the command sees, without polluting the system log. In practice, most drivers return an error code through the usual `errno` mechanism and do not use `uprntf`. The `/usr/src/sys/kern/` tree has a handful of callers, mostly in places where the kernel wants to warn a user about their own action (a security-relevant event, for example).

`tprntf(struct proc *p, int pri, const char *fmt, ...)` writes to a specific process's terminal. It is rarer still. Chapter 23 does not use either function directly. The Chapter 25 logging material returns to them in the context of user-facing diagnostic messages.

23.3.9 Formatting Conventions

A few small formatting habits make log output much easier to read:

1. **End every line with `\n`.** The kernel's `printf` does not add a newline. A message without a newline will run into the next message in `dmesg`, producing output like `myfirst0: interrupt receivedmyfirst0: interrupt received` that is nearly impossible to parse visually.
2. **Use hex for register values, decimal for counters.** `status=0x80a1` is a device register; `count=27` is a counter. Mixing the two conventions in a single driver produces output that is hard to read at a glance. The `%x` and `%d` conversions are the cheap way to keep them visually distinct.
3. **Put the variable values on the right, not the left.** `myfirst0: dma transfer failed (err=%d)` scans better than `myfirst0: %d was the err from dma transfer failed`. Human readers parse English left-to-right, and putting the variable data at the end of the line matches that parse.
4. **Use short tags for repeated message categories.** `INFO:`, `WARN:`, `ERR:`, `DEBUG:` at the start of the content after the device prefix turn a log into something a `grep` can filter. Section 8 uses this convention in its macros.
5. **Do not include timestamps in the message.** The kernel and `syslog` add their own timestamps; a manual timestamp produces duplicate information and visual noise.
6. **Do not include the function name in production messages.** Function names are useful in verbose-mode output (where the entry/exit macros print them automatically) but wasteful in every production message. A message like `myfirst0: DMA completed` is more readable than `myfirst0: my-first_dma_completion_handler: DMA completed`. If you want function names, turn on verbose mode.

7. **Match the driver's style.** If the rest of the driver uses “DMA” in uppercase, use “DMA” in every log line. If the rest uses “dma” in lowercase, match that. Consistency is easier to grep than mixed case.

These are small habits, but they pay off the first time a log becomes the only evidence of a bug that happened on a system the reader cannot access interactively.

23.3.10 Exercise: Add `device_printf()` at Key Points in Your Driver

The hands-on companion for Section 2 is a short exercise. The reader should:

1. Open `myfirst_pci.c`, `myfirst_sim.c`, `myfirst_intr.c`, `myfirst_dma.c`, and `myfirst_power.c` in turn.
2. For every `printf` call that has a `device_t` or a `softc` (which holds a `device_t`) in scope, replace it with `device_printf(dev, ...)`.
3. For every error-path message, change the call to `device_log(dev, LOG_ERR, ...)` if the condition is a real error, or `device_log(dev, LOG_WARNING, ...)` if the condition is recoverable. Keep `device_printf` for routine informational messages.
4. For the attach banner, add a single line that names the driver version: `device_printf(dev, "myfirst PCI driver %s attached\n", MYFIRST_VERSION);`. Define `MYFIRST_VERSION` in the top of `myfirst_pci.c` as a string literal. Chapter 23 will bump it from "1.5-power" to "1.6-debug" at the final refactor in Section 8; for now, keep it at "1.5-power-stage1".
5. Rebuild the module, load it, and verify that `dmesg | grep myfirst0` shows the attach banner. Generate a contrived DMA failure (the simulator's `sim_force_dma_error` sysctl is one way; Chapter 17 introduced the hook) and verify that the error message appears with the `LOG_ERR` priority.
6. Commit the changes with a message like “Chapter 23 Section 2: use `device_printf` consistently”.

The reader should feel free to check their work against `examples/part-05/ch23-debug/stage1-logging/myfirst_pci.c` and the other `stage1` files, but the learning happens in the typing, not in the checking.

23.3.11 Wrapping Up Section 2

Section 2 established the ground rules for logging. Use `device_printf` when you have a `device_t`. Use `device_log` with an explicit priority when the priority matters. Log enough to make the log readable, and not so much that the log becomes noise. Route routine information at `LOG_INFO`, real errors at `LOG_ERR`, and verbose tracing at `LOG_DEBUG` gated behind a sysctl.

Section 3 now follows the log output from the moment the driver writes it to the moment a user reads it, through `dmesg`, the kernel message buffer, `/var/log/messages`, and the syslog pipeline. The driver's job ends when it calls `device_printf`; the tools the reader uses to see what the driver said begin from there.

23.4 Section 3: Using `dmesg` and Syslog for Diagnostics

Section 2 ended with the driver's `device_printf` call. Section 3 picks up from the other end: the moment a user runs `dmesg`, opens `/var/log/messages`, or greps through syslog archives. In between sits the kernel's

message buffer, the `syslogd` daemon, the `newsyslog` rotator, and a small set of configuration files that quietly determine which messages appear where. Understanding the pipeline is how a driver author stops worrying about “why don’t my messages appear?” and starts debugging the actual driver.

23.4.1 The Kernel Message Buffer

Every kernel message the driver produces goes first into the **kernel message buffer**. This is a single circular region of memory the kernel allocates at boot, sized by default to about 192 KB on amd64 FreeBSD 14. The size is set by the `msgbufsize` tunable; the current size is visible as:

```
sysctl kern.msgbufsize
```

The buffer is “circular” in the sense that when it fills, new messages overwrite the oldest. This matters for a reader hunting an old bug: if you rebooted five hours ago, produced a bunch of driver log output, and only now went looking for it, the output may have rolled out of the buffer already. The safe assumption is that the buffer holds several days of routine messages on a quiet system and a few hours of messages on a busy one.

Because the buffer is a single block of memory, reading it is inexpensive. The `dmesg(8)` command works by calling the `sysctl(8)` function to read `kern.msgbuf` and printing the contents. The `dmesg` binary is small; its source is at `/usr/src/sbin/dmesg/dmesg.c` and worth a quick look if the reader is curious.

The boot-time portion of the buffer is preserved more carefully than the runtime portion. During boot, the kernel writes every `autoconf` message, every driver’s attach banner, every hardware detection note, into the buffer. The `/var/run/dmesg.boot` file, produced by the `/etc/rc.d/dmesg` startup script, captures the buffer’s contents at the moment the boot sequence finishes and before runtime output starts overwriting it. Reading `dmesg.boot` is the way to see boot messages after the running system has long since pushed them out of the live buffer:

```
cat /var/run/dmesg.boot | grep myfirst
```

For a driver author, `dmesg.boot` is the answer to “did my driver attach on boot?” when the answer is needed hours later. The live `dmesg` is the answer to “what has my driver said since then?”.

23.4.2 dmesg in Practice

The common invocations are worth committing to memory.

`dmesg` with no arguments prints the current kernel buffer contents in order from oldest to newest. On a system that has been running for a while, this is a lot of output:

```
dmesg
```

Pipe through `less` to scroll, or through `grep` to filter:

```
dmesg | less
dmesg | grep myfirst
dmesg | grep -i error
dmesg | tail -50
```

`dmesg -a` prints all messages including those at priorities the kernel is configured to suppress from the normal output. On some configurations this surfaces additional low-priority detail. On most configurations the output is the same as plain `dmesg`.

`dmesg -M /var/crash/vmcore.0 -N /var/crash/kernel.0` reads the message buffer out of a saved crash dump, rather than from the live kernel. This is how a reader looks at the last few messages a kernel produced before it panicked, when the panic itself prevented the normal logging path from running. Section 4's `kgdb` material returns to this.

The `dmesg -c` form (which on some systems clears the buffer after reading) is not available in the FreeBSD kernel's way of exposing the buffer, because the buffer is not drained by reading it; reading produces a copy, and the live buffer continues to receive new messages. Users coming from Linux sometimes expect `dmesg -c` and are surprised.

A useful habit during driver development is to run `dmesg | grep myfirst | tail` after every module load, every test, and every interesting event. The repetition builds a reflex of “what did the driver just say?” that pays off the first time something unexpected happens.

23.4.3 Permanent Logs in `/var/log/messages`

The kernel message buffer is volatile; a reboot empties it. For anything longer-term, FreeBSD uses `syslogd(8)`, the standard UNIX syslog daemon, which reads new messages as the kernel produces them and writes selected ones to files on disk.

The canonical file, on almost every FreeBSD system, is `/var/log/messages`. This file receives most kernel messages at priority `LOG_INFO` or higher, and most userland daemon messages too. The mapping between priority and destination file is in `/etc/syslog.conf`. A relevant excerpt looks like:

```
*.notice;kern.debug;lpr.info;mail.crit;news.err    /var/log/messages
```

The syntax is “facility.priority” pairs. `kern.debug` means “all kernel messages at priority `LOG_DEBUG` or higher”. `*.notice` means “all facilities at priority `LOG_NOTICE` or higher”. The reader should know this syntax exists; understanding it is useful when a specific kind of message needs to go to a specific file.

Because `/var/log/messages` is an ordinary text file, every tool in the reader's toolkit works on it:

```
tail -f /var/log/messages
tail -50 /var/log/messages
grep myfirst /var/log/messages
less /var/log/messages
wc -l /var/log/messages
```

Particularly useful during driver development:

```
tail -f /var/log/messages | grep myfirst
```

This gives a live stream of only the driver's output, which is what most debugging sessions actually need.

When messages age out, they move to `/var/log/messages.0`, then `.1`, then `.N.gz` as rotation happens. The rotation is done by `newsyslog(8)`, which is invoked by a periodic job from `cron` and reads its rules from `/etc/newsyslog.conf`. A typical rule for `/var/log/messages` rotates the file when it reaches a size threshold, keeps some number of compressed archives, and restarts `syslogd` to reopen the new file.

To search through the archives, `zgrep` is the tool:

```
zgrep myfirst /var/log/messages.*.gz
```

Or, for the whole history including the current file:

```
grep myfirst /var/log/messages && zgrep myfirst /var/log/messages.*.gz
```

Readers who are hunting a bug that happened days ago reach for these commands routinely.

23.4.4 Console Output Versus Buffered Output

One nuance confuses many driver authors the first time they encounter it. The kernel has two audiences for its messages: the in-memory buffer, and the system console. The console is the physical terminal on a laptop (or the VGA console in a VM, or the serial console in a headless box). A message can go to one, the other, or both, depending on its priority and the current console log level.

The console log level is controlled by the `kern.consmgbuf_size` (how much memory the console uses) and more importantly `kern.msgbuflock` and the console priority filter. The simplest knob is:

```
sysctl -d kern.log_console_level
```

On FreeBSD, high-priority messages (`LOG_WARNING` and above) are always displayed on the console. Lower-priority messages are buffered but not displayed. This is why a panic message appears on the console regardless of runlevel: it has priority `LOG_CRIT` or higher, and the kernel's console output path bypasses the usual buffering.

For a driver author, the practical consequence is that `device_log(dev, LOG_ERR, ...)` is more likely to be noticed by a human than `device_printf(dev, ...)`, because the former reaches the console and the latter goes only to the buffer. Chapter 23's Section 2 pointed this out; Section 3 reinforces it with the mechanics.

A driver that produces a torrent of `LOG_ERR` messages floods the console and, in extreme cases, slows the system down because the console output path is not cheap. Rate limiting is the cure; Chapter 25 teaches it properly. For now, the lesson is that priority matters.

23.4.5 Reviewing Logs in Practice

The common pattern for reading driver logs during development looks like this:

1. Load the module.
2. Run the test.
3. Unload the module.
4. Copy dmesg output to a file for analysis.

The sequence in shell form:

```
# Clean slate
sudo kldunload myfirst 2>/dev/null
sudo kldload ./myfirst.ko

# Test
dev_major=$(stat -f '%Hr' /dev/myfirst0)
echo "Running driver test..."
some_test_program

# Capture
dmesg | tail -200 > /tmp/myfirst-test-$(date +%Y%m%d-%H%M%S).log

# Clean slate again
sudo kldunload myfirst

# Now inspect the log at leisure
less /tmp/myfirst-test-*.log
```

Several habits that this pattern encourages are worth stating explicitly:

Clean slate first, every time. Unload any existing instance of the module before loading the one you want to test. Otherwise you may accidentally be running an older compile and wondering why your new code doesn't have the expected effect. An unload also leaves the dmesg buffer more readable because your new session starts from a known state.

Capture every interesting session. A log you saved to a file is a log you can diff, grep, share, and return to next week. A log you left in the live buffer is a log that may get pushed out by the time you come back to it.

Use timestamps in filenames. The date `+%Y%m%d-%H%M%S` convention in the snippet produces filenames like `myfirst-test-20260419-143027.log`. When you accumulate a dozen log files from a day of testing, this is the only way to find the one you want.

Narrow the tail -n to a reasonable window. The default is 10 lines, which is almost never enough for a driver test. 200 to 500 is usually the right size: long enough to capture a full test cycle, short enough to read in one pass. If your test produces more output than that, either your test is too large or your logging is too chatty.

23.4.6 Filtering Output

The `grep` toolchain is your friend. A few patterns recur often enough to be worth building into muscle memory.

Show only the driver’s output:

```
dmesg | grep '^myfirst'
```

The `^myfirst` anchor matches only lines that start with the device name. Without the anchor, you would also match lines that happen to contain “myfirst” in their text (for example, kernel messages about the module’s file descriptor).

Show only errors:

```
dmesg | grep -iE 'error|fail|warn|fault'
```

Case-insensitive, with an extended regex that matches several common error words.

Show a specific interval:

```
awk '/START OF TEST/,/END OF TEST/' /var/log/messages
```

This relies on the reader’s test harness printing “START OF TEST” and “END OF TEST” markers at the boundaries. A script that does this is a script whose logs are easy to slice.

Extract just the timestamps and first word:

```
awk '{print $1, $2, $3, $5}' /var/log/messages | grep myfirst
```

For high-level scanning of a busy log.

Count how many of each message type:

```
dmesg | grep myfirst | awk '{print $2}' | sort | uniq -c | sort -rn
```

This counts messages grouped by their second word, which (with the convention in Section 2) is usually the category like INFO, WARN, ERR, or DEBUG. Useful for spotting “why is my driver producing 30,000 DEBUG messages and 2 INFO messages?”

23.4.7 Permanent Configuration: `/etc/syslog.conf` and `/etc/newsyslog.conf`

For most driver work, the default syslog configuration is fine. Chapter 23 does not ask the reader to change it. But it is worth knowing the two files exist and roughly what they do.

`/etc/syslog.conf` is read by `syslogd` at startup and on `SIGHUP`. It contains rules that map “facility and priority” to “destination”. Facility is the kind of producer (`kern`, `auth`, `mail`, `daemon`, `local0` through `local7`),

and priority is the syslog priority level. A driver's messages always have facility kern (because they come from the kernel) and the priority the driver specified.

A useful experiment, after the reader has read Chapter 23, is to add a line like:

```
kern.debug                /var/log/myfirst-debug.log
```

to `/etc/syslog.conf`, touch the file, and reload syslogd with `service syslogd reload`. Now every kernel debug-level message goes to a separate file. If the reader then enables verbose mode on the `myfirst` driver (Section 8's `sysctl`), the separate file captures only the verbose output and the main messages file stays clean. This is a trick worth knowing; it lets a reader enable deep verbose logging without flooding `/var/log/messages` with everything.

`/etc/newsyslog.conf` is read by `newsyslog` when it rotates logs. A typical rule looks like:

```
/var/log/messages    644  5    100    *    JC
```

The fields, left to right: file path, mode, number of rotations to keep, max size in KB, rotation time, flags. For the `myfirst-debug.log` file the reader just added, an appropriate `newsyslog` rule keeps the logs from growing without bound:

```
/var/log/myfirst-debug.log 644  3   500    *    JC
```

Again, this is not a chapter requirement; it is a pattern worth knowing.

23.4.8 Correlating Messages Across a Boot Cycle

One of the common debugging tasks is “the driver worked after the last boot but now it doesn't”. The reader wants to compare what happened at the last boot to what is happening now. Two paths:

Path one: read `/var/run/dmesg.boot`, which captured the boot-time messages, and compare to the current `dmesg`:

```
diff <(grep myfirst /var/run/dmesg.boot) <(dmesg | grep myfirst)
```

This shows exactly which messages are new since boot. Useful for finding runtime surprises.

Path two: `grep` through the archives of `/var/log/messages`:

```
zgrep myfirst /var/log/messages.*.gz | head -100
```

This shows the driver's history over the last few days, across reboots. Useful for finding patterns like “it started failing on Tuesday”.

A driver that logs its version at attach makes this much easier. If `dmesg.boot` shows `myfirst0: myfirst PCI driver 1.5-power attached` and the current boot shows `myfirst0: myfirst PCI driver 1.6-debug attached`, the reader knows immediately that the two are different versions and that a code change happened between them. Chapter 23's Stage 1 exercise adds exactly this version-at-attach line for that reason.

23.4.9 Exercise: Generate a Known Driver Message and Confirm It Appears

A small hands-on companion for Section 3. The reader should:

1. Rebuild and load the `1.5-power-stage1` driver from Section 2's exercise. Confirm the attach banner appears in `dmesg`.
2. Trigger the simulator's `sim_force_dma_error=1` sysctl to make the next DMA transfer fail. Run a DMA transfer. Confirm the error message appears both in `dmesg` and in `/var/log/messages`.
3. Produce a verbose informational line: set the (not yet existing) `debug_verbose` sysctl to 1. Because the sysctl does not yet exist, this step will fail, and the reader should note which way it failed. This is intentional; Section 8 adds the sysctl.
4. For the lines that did appear, use `awk` or `grep` to extract only the ones with `myfirst0:` prefix, and count them.
5. Create a `/var/log/myfirst-debug.log` file by adding a `kern.debug` line to `/etc/syslog.conf` as sketched above. Reload `syslogd`. Confirm the file is created. Confirm no messages appear in it yet (because the `myfirst` driver does not yet produce `LOG_DEBUG` output). Make a note to return to this in Section 8.

The exercise is short. Its value is that the reader has now actually used `dmesg`, `/var/log/messages`, `grep`, and `syslog.conf` on real driver output. Future chapters will assume these tools are familiar.

23.4.10 Wrapping Up Section 3

Section 3 followed the log from the moment the driver calls `device_printf` or `device_log` to the moment a user sees the output. Messages go first into the kernel's circular message buffer, accessible through `dmesg`. A boot-time snapshot is preserved in `/var/run/dmesg.boot`. The `syslogd` daemon reads new messages and writes them to `/var/log/messages` according to the rules in `/etc/syslog.conf`. The `newsyslog` daemon rotates the files according to `/etc/newsyslog.conf`. Console output is automatic for high-priority messages and gated for low-priority ones.

With the logging pipeline clear, Section 4 turns to the other essential piece of the debugging foundation: the debug kernel. A driver whose bugs always panic quietly and produce nothing for the log is a driver that cannot be debugged. A debug kernel makes those silent bugs loud.

23.5 Section 4: Kernel Debug Builds and Options

A debug kernel is not a different kernel; it is the same kernel with additional checks, additional debug aids, and a small set of features compiled in that a release kernel does not have. The driver source does not change. The user-space tools do not change. What changes is that the running kernel now catches more of its own bugs, preserves more context when a panic happens, and offers more ways to inspect itself.

This section is the longest in the chapter because the debug kernel is the ground the rest of the chapter stands on. Every later tool depends on having the right options set. `DTrace` depends on `KDTRACE_HOOKS`. `ddb` depends on `DDB` and `KDB`. `INVARIANTS` catches bugs that would otherwise produce silent memory corruption. `WITNESS`

catches lock order violations that would otherwise produce intermittent panics weeks later. Each option has a cost, a benefit, and a context in which it is appropriate; Section 4 walks through them.

23.5.1 The Core Debug Options

FreeBSD's kernel is configured through a kernel config file, such as `/usr/src/sys/amd64/conf/GENERIC`. The config file is a list of options lines that enable or disable compile-time features. A debug kernel is produced by starting from `GENERIC` (or another baseline config), adding debug options, rebuilding, installing, and booting the result.

The options that matter for driver debugging fall into four groups: the kernel debugger, the consistency checks, the lock debug infrastructure, and the tracing infrastructure.

Kernel debugger group. These enable the in-kernel debugger `ddb` and the infrastructure that supports it.

- `options KDB`: enables the Kernel Debugger framework. This is the umbrella option that allows any backend (DDB, GDB over serial, etc.) to attach.
- `options DDB`: enables the in-kernel DDB debugger. DDB is the backend most driver authors use. It runs inside the kernel and understands kernel data structures.
- `options DDB_CTF`: enables loading of CTF (Compact C Type Format) data into the kernel, which lets `ddb` and `DTrace` print type-aware information about kernel structures. Needs `makeoptions WITH_CTF=1` in the config.
- `options DDB_NUMSYM`: enables symbol-number lookups inside DDB. Useful for poking at specific addresses.
- `options KDB_UNATTENDED`: on a panic, do not pause to enter `ddb`. Instead, the kernel dumps core (if `dumpdev` is configured), reboots, and continues. This is the right setting for lab VMs where the reader does not want to lose the kernel to a debugger session on every panic.
- `options KDB_TRACE`: on any entry into the debugger (panic or otherwise), automatically print a stack trace. Saves a step in almost every diagnostic session.
- `options BREAK_TO_DEBUGGER`: allows a break on the serial or USB console to drop into `ddb`. Useful on headless test systems.
- `options ALT_BREAK_TO_DEBUGGER`: alternative key combination for the same effect.

A typical debug kernel config includes all of these. The `GENERIC` kernel on `amd64` already enables `KDB`, `KDB_TRACE`, and `DDB`; the additional options the reader enables are `KDB_UNATTENDED`, `INVARIANTS`, `INVARIANT_SUPPORT`, `WITNESS`, and friends.

Consistency check group. These enable extra runtime assertions in the kernel code.

- `options INVARIANTS`: enable assertions in the kernel. Almost every `/usr/src/sys/*` file contains `KASSERT` calls, and those `KASSERT` calls only do something when `INVARIANTS` is enabled. Without `INVARIANTS`, a `KASSERT(ptr != NULL, ("oops"))` compiles to nothing. With `INVARIANTS`, it panics the kernel on failure. The cost is measurable (maybe 10% of kernel CPU time on a busy system) but usually negligible for driver development, because the kernel spends less time per operation than the application using it. The benefit is that bugs the driver would otherwise silently corrupt data over are caught at the moment they happen.
- `options INVARIANT_SUPPORT`: the machinery that `INVARIANTS` itself uses. Required if `INVARIANTS` is enabled; also required separately if any loadable module was built with `INVARIANTS`. Forgetting this

produces “unresolved symbol” errors at module load.

- `options DIAGNOSTIC`: light-weight additional checks, less aggressive than `INVARIANTS`. Some subsystems use this for checks that are cheap enough to run in production but too slow for tight loops.

Lock debug group. These enable the infrastructure that verifies the driver’s synchronisation discipline.

- `options WITNESS`: enable the lock-order verifier. `WITNESS` tracks every lock the kernel takes, records the order in which locks are acquired, and complains loudly when a thread acquires locks in an order that could deadlock if another thread held them the opposite way. A driver with a lock-order bug will produce a `WITNESS` report the first time the bad order is exercised, even if no actual deadlock occurs. This is an enormous debugging win, because it catches the bug before the deadlock manifests.
- `options WITNESS_SKIPSPIN`: skip the lock-order check for spin locks. Spin locks have their own constraints that the general checker is not designed to evaluate, and the checker can produce false positives on them. Enabling `WITNESS_SKIPSPIN` keeps the checker useful for the common mutex case.
- `options WITNESS_KDB`: on a lock-order violation, drop immediately into `ddb` instead of just logging. Aggressive; appropriate for a VM where a manual `ddb` session is easy.
- `options DEBUG_LOCKS`: additional debugging of the generic lock API (separate from `WITNESS`). Catches use of uninitialised locks, locks taken in the wrong context, and related issues.
- `options LOCK_PROFILING`: instrumentation that lets `lockstat` measure lock contention. Not strictly a debug option (it is a profiling option), and expensive; use it only when looking for contention, not by default.
- `options DEBUG_VFS_LOCKS`: VFS-specific lock debugging. Useful only for filesystem driver work.

Tracing infrastructure group. These enable the `DTrace` and `KTR` frameworks.

- `options KDTRACE_HOOKS`: the kernel-wide `DTrace` hooks. Without this, `DTrace` has nothing to attach to. Lightweight even when no `DTrace` script is running, because the hooks are mostly no-op function pointer slots.
- `options KDTRACE_FRAME`: unwind frame information that `DTrace` uses for `stack()` actions. Needed for meaningful stack traces inside `DTrace` scripts.
- `makeoptions WITH_CTF=1`: a `makeoptions` (not `options`) line that enables CTF generation for the kernel. CTF is the type-data `DTrace` and `DDB` use to understand kernel structure layouts.
- `options KTR`: the in-kernel event-ring-buffer tracer. Different from `ktrace`; `KTR` is a high-performance in-kernel buffer of kernel events that is mostly useful for low-level kernel hackers. Most driver authors do not need `KTR` and can leave it off; Chapter 23 mentions it only to name it correctly.
- `options KTR_ENTRIES`, `KTR_COMPILE`, `KTR_MASK`: the `KTR` configuration knobs. See `/usr/src/sys/conf/NOTES` for the full list.

For Chapter 23 the reader needs `KDB`, `DDB`, `DDB_CTF`, `KDB_UNATTENDED`, `KDB_TRACE`, `INVARIANTS`, `INVARIANT_SUPPORT`, `WITNESS`, `WITNESS_SKIPSPIN`, `KDTRACE_HOOKS`, and `makeoptions DEBUG=-g` for symbols. If the reader followed Chapter 22’s prerequisites, these are already enabled.

23.5.2 Building a Debug Kernel

Building a custom kernel is a standard FreeBSD operation. The workflow:

1. Copy the `GENERIC` config to a new name:

```
cd /usr/src/sys/amd64/conf
sudo cp GENERIC MYDEBUG
```

2. Edit MYDEBUG to add the debug options. A minimal addition:

```
ident MYDEBUG

options INVARIANTS
options INVARIANT_SUPPORT
options WITNESS
options WITNESS_SKIPSPIN
options KDB_UNATTENDED

makeoptions DEBUG=-g
makeoptions WITH_CTF=1
```

DDB, KDB, KDTRACE_HOOKS, and DDB_CTF are already in GENERIC on amd64 as of FreeBSD 14, so they do not need to be re-added. If you are on a non-x86 architecture, check the corresponding conf/GENERIC file to see what is already included.

A small but frequent point of confusion: /usr/src/sys/amd64/conf/ holds the kernel *configuration source files*. The older /usr/src/sys/amd64/compile/ directory some tutorials mention is a build-output directory that config(8) historically populated; on a modern FreeBSD system the actual build products live under /usr/obj/usr/src/amd64.amd64/sys/<KERNCONF>/, and the compile/ path is no longer the place you edit or look for source.

3. Build the kernel:

```
cd /usr/src
sudo make -j4 buildkernel KERNCONF=MYDEBUG
```

On a reasonable VM this takes ten to twenty minutes. On a slower VM, half an hour. The build is the longest single step in the debug workflow, but it runs once per config change, not once per test.

4. Install the new kernel:

```
sudo make installkernel KERNCONF=MYDEBUG
```

This copies the kernel files into /boot/kernel and backs up the previous kernel to /boot/kernel.old. If the new kernel fails to boot, the reader can select kernel.old from the boot loader's menu and continue.

5. Reboot.
6. Verify:

```
uname -a
```

The output should mention MYDEBUG in the kernel's identification string.

7. Confirm debug options are active:

```
sysctl debug.witness.watch
sysctl kern.witness
```

On a WITNESS-enabled kernel, these produce output. On a non-WITNESS kernel, the sysctls do not exist.

The total time from “want a debug kernel” to “running a debug kernel” is usually under an hour. The time invested is recovered within the first debugging session, because the debug kernel is the kernel that catches bugs.

23.5.3 When to Use INVARIANTS

INVARIANTS is the most important single debug option for a driver developer. It is also the most misunderstood.

When a kernel programmer writes `KASSERT(condition, ("message %d", val))`, the intent is: this condition must be true at this point; if it is ever false, something has gone wrong in a way the code cannot recover from. Without INVARIANTS, KASSERT compiles to nothing; the condition is not checked. With INVARIANTS, KASSERT evaluates the condition and calls `panic` if it fails, printing the message.

Consider a concrete example from the `myfirst` driver. The DMA submission path (Chapter 21) holds a buffer lock, sets an in-flight flag, and calls `bus_dmamap_sync`. A bug that calls the submission path twice without waiting for completion is a double-submit bug, and it can corrupt DMA. A KASSERT at the top of the submission path catches it:

```
static int
myfirst_dma_submit(struct myfirst_softc *sc, ...)
{
    KASSERT(!sc->dma_in_flight,
        ("myfirst_dma_submit: previous transfer still in flight"));
    ...
}
```

Without INVARIANTS, this line does nothing. With INVARIANTS, the first time a bug submits a second transfer before the first completes, the kernel panics with the message. The reader looks at the backtrace, sees the double-submit, and fixes the bug.

This is the shape of INVARIANTS’s value: it turns silent corruption into loud panics. The trade-off is that a driver author who writes no KASSERTs gets no benefit from INVARIANTS; the option is only useful if the code it runs against has assertions. The `myfirst` driver at Stage 1 has a few; Section 7 adds more; Section 8 moves them into the debug header.

Other assertion helpers exist alongside KASSERT:

- `MPASS(expr)`: a compact form of `KASSERT(expr, (...))`. Expands to the same check with a compiler-provided message. Useful when the condition is self-explanatory.
- `VNASSERT(expr, vp, msg)`: assertion specialised for vnodes. Driver authors rarely use this directly.
- `atomic_testandset_int`, `atomic_cmpset_int`: not assertion helpers, but common operations in driver synchronisation that have their own debug-aware variants.

Read KASSERT in its context: it is a documentation aid as much as a debug aid. A reader looking at an unfamiliar function's source finds the KASSERTs at the top and immediately knows the invariants the code expects. A driver that accumulates KASSERTs over time becomes self-documenting in a way plain prose does not match.

23.5.4 When to Use WITNESS and DEBUG_LOCKS

WITNESS is the other half of the driver-debugging pair. Where INVARIANTS catches logic bugs, WITNESS catches synchronisation bugs.

The basic idea: every lock has an identifier, the kernel records the set of locks each thread holds, and when a thread tries to acquire a lock, WITNESS checks whether the order of acquisition is consistent with previous acquisitions in the kernel's history. If thread A takes lock X then lock Y, and later thread B takes lock Y then lock X, the two threads form a potential deadlock: if A holds X waiting for Y while B holds Y waiting for X, neither can proceed. WITNESS flags the inconsistency the second time a thread tries to acquire the locks in the wrong order, even if the actual deadlock does not happen during the test.

A WITNESS complaint looks something like:

```
lock order reversal:
 1st 0xfffff80001a23200 myfirst_sc (myfirst_sc) @
↪ /usr/src/sys/dev/myfirst/myfirst_pci.c:523
 2nd 0xfffff80001a23240 some_other_lock (some_other_lock) @ /some/other/file.c:789
witness_order_list_add: lock order reversal
```

The message identifies both locks, their addresses, the files and line numbers where they were acquired, and the reversal. A driver author reads this and immediately knows where to look.

WITNESS interacts with the other debug options. WITNESS_KDB drops into ddb on a violation instead of just logging. WITNESS_SKIPSPIN skips spin locks, which have different rules (they cannot sleep, they have priority handling, and the ordering discipline is slightly different). DEBUG_LOCKS adds extra checks on top of WITNESS: detection of double-unlock, detection of unlock by the wrong thread, detection of use of uninitialised mutexes. For driver development, enabling all three (WITNESS, WITNESS_SKIPSPIN, DEBUG_LOCKS) is the default recommendation.

The cost of WITNESS is measurable. Every lock acquisition adds a few dozen instructions and one cache line of memory touch. On a driver-heavy workload this can be 20 or 30 percent slower than a non-debug kernel. For development and testing, this is acceptable. For a production kernel, WITNESS is usually off.

Section 7's common-bug walkthrough includes a WITNESS lab: the reader deliberately introduces a lock order violation into the `myfirst` driver, rebuilds, reloads, triggers the path, and watches WITNESS catch it. That lab is the fastest way to internalise how the tool works.

23.5.5 When to Use DEBUG_MEMGUARD and MEMGUARD

MEMGUARD is a heavier memory-debug allocator. It allocates memory with guard pages on either side, detects writes past the allocation boundary, and detects use-after-free. It is enabled with options `DEBUG_MEMGUARD` and configured at runtime through `sysctl vm.memguard.desc`.

MEMGUARD is expensive: it uses far more memory than a normal allocator because of the guard pages, and its allocation path is slower. The right use is targeted: you enable it for a specific malloc type the driver uses heavily, not for the whole kernel. If the `myfirst` driver has a malloc type `M_MYFIRST`, the reader can enable MEMGUARD for just that type:

```
sysctl vm.memguard.desc="M_MYFIRST"
```

After a reboot (MEMGUARD needs to initialise its arena at boot), allocations of `M_MYFIRST` memory will go through MEMGUARD. A write past the end of an allocation panics immediately. A use after free panics immediately. The reader can run tests and have the kernel catch heap bugs in the driver's memory without slowing the rest of the system down.

Chapter 23 does not make heavy use of MEMGUARD, because the `myfirst` driver's memory patterns are simple. Section 7 mentions it as a tool in the kit for drivers that do more complex allocation. For the reader who eventually writes a driver with dynamic queues, buffer pools, or long-lived allocations, MEMGUARD is worth returning to.

23.5.6 Trade-Offs: Performance vs. Debug Visibility

The temptation, when first learning the options, is to enable everything. This is the right choice during development. It is the wrong choice for production.

A kernel with `INVARIANTS`, `WITNESS`, `DEBUG_LOCKS`, `KDTRACE_HOOKS`, `DDB`, and `MEMGUARD` on is noticeably slower than `GENERIC`: maybe 20% slower overall, 50% slower on lock-heavy workloads, depending on what the machine is doing. On a development workstation, 20% slower is fine. On a production server, 20% slower means 20% more hardware to do the same work.

The distinction between debug kernels and production kernels is sharp in practice. Developers run debug kernels, because they care about finding bugs. Users run release kernels, because they care about performance. A driver that is correct under `WITNESS` and `INVARIANTS` is correct, period; those options do not change driver behavior, they only check it. A driver that passes a `WITNESS` lab run under a debug kernel will also pass under a release kernel. This is the invariant that makes the pattern work: you develop against a strict kernel and deploy against a permissive one, and the strict kernel's extra checks are what keep the permissive one correct.

For the reader, the practical advice: run a debug kernel on the VM you use for driver work, all the time. Do not switch to a release kernel for daily development. The feedback on driver mistakes is worth the performance cost a hundred times over. When you are ready to test the driver on a production-style kernel (for timing measurements, for integration tests), boot a release kernel for that specific test, confirm correct behavior, and then go back to the debug kernel.

23.5.7 A Survey of `ddb` Commands

DDB is the in-kernel debugger. When the kernel panics on a system where DDB is compiled in, instead of rebooting immediately, the system drops into a debugger prompt on the console:

```
KDB: enter: panic
[ thread pid 42 tid 100049 ]
Stopped at: kdb_enter+0x3b:  movq    $0, kdb_why
db>
```

At that prompt, the reader can inspect the kernel's state. The commands are terse and direct. A full tour belongs in a separate reference; what follows is the list a driver author uses most.

Inspection commands:

- `bt` or `backtrace`: show the current thread's backtrace. This is the first command the reader runs on every panic.
- `ps`: show the process table. Useful for seeing what was running.
- `show thread <tid>`: show details of a specific thread.
- `show proc <pid>`: show details of a specific process.
- `show pcpu`: show per-CPU state, including the current thread on each CPU.
- `show allpcpu`: show all per-CPU state at once.
- `show lockchain <addr>`: show the chain of threads blocked on a specific lock.
- `show alllocks`: show all locks currently held, across all threads. Useful for diagnosing apparent deadlocks.
- `show mbufs`: show mbuf statistics, if the network stack is involved.
- `show malloc`: show kernel malloc statistics, grouped by type. Useful for finding a driver that leaked memory before the panic.
- `show registers`: show the current CPU's registers.

Navigation commands:

- `x/i <addr>`: disassemble at an address. Useful for looking at the instruction where a page fault happened.
- `x/xu <addr>`: dump memory as hex bytes.
- `x/sz <addr>`: dump memory as a null-terminated string.

Control commands:

- `continue`: resume execution. If the kernel was stable enough to enter `ddb`, this can sometimes let the machine continue normally. Often the safer choice is `panic`.
- `reset`: reboot the machine immediately.
- `panic`: force a panic, which triggers a crash dump if `dumpdev` is set.
- `call <func>`: call a kernel function by name. Advanced; rarely useful in driver debugging.

Thread-walking commands:

- `show all procs`: list all processes.
- `show sleepq`: show sleeping queues.
- `show turnstile`: show turnstile state (used for blocking locks).
- `show sema`: show semaphores.

A driver author does not memorise this list. The pattern is: when you enter `ddb`, run `bt` first, then `ps`, then `show alllocks`, then `show mbufs`, then `show malloc`. Those five commands capture 80% of what most driver panics need.

A useful habit is to print the commands and keep them next to the keyboard for the first few ddb sessions. The first session feels awkward because the muscle memory is not there. By the third session, the commands are fluent.

23.5.8 A Brief Introduction to kgdb

ddb is the live debugger. kgdb is the post-mortem debugger. When a kernel panics with dumpdev configured, the panic routine writes the full kernel memory image to the dump device. On the next boot, savecore(8) copies the dump from the dump device into /var/crash. A reader can then open it with kgdb:

```
sudo kgdb /boot/kernel/kernel.debug /var/crash/vmcore.0
```

(Note: kernel.debug is the debug-symbol version of the kernel, produced when the kernel was built with makeoptions DEBUG=-g. Without DEBUG=-g, kgdb can still open the dump but produces less useful output.)

Inside kgdb, the reader has something close to a normal gdb interface. The commands are the same: bt, frame N, info locals, print variable, list, and so on. The difference is that the machine is not running; the kernel is paused forever at the moment of the panic, and every inspection is against that frozen state. You can walk up the stack, look at data structures, follow pointers, and reason about what led to the panic. You cannot step forward.

A typical kgdb session on a panic looks like this:

```
(kgdb) bt
#0  doadump (...)
#1  kern_reboot (...)
#2  vpanic (...)
#3  panic (...)
#4  witness_checkorder (...)
...

(kgdb) frame 10
#10 myfirst_pci_detach (dev=0xfffff80001a23000) at myfirst_pci.c:789
789          mtx_destroy(&sc->lock);

(kgdb) list
784          mtx_lock(&sc->lock);
785          sc->detaching = true;
786          /* wait for all users */
787          while (sc->refs > 0)
788              cv_wait(&sc->cv, &sc->lock);
789          mtx_destroy(&sc->lock);
790          return (0);
791      }
```

```
(kgdb) print sc->refs
$1 = 0

(kgdb) print sc->lock
$2 = {
    ...
}
```

The reader walks the stack to find the driver frame, looks at what the driver was doing, and identifies the bug. In this example, the driver was destroying a mutex that was still locked, because line 789 calls `mtx_destroy` without unlocking. The bug is immediately visible.

Chapter 23 does not make heavy use of `kgdb`, because the labs are designed to be diagnosable from `ddb` and `dmesg` alone. Section 7 mentions `kgdb` in the common-bug walkthrough for a class of bugs where post-mortem inspection is the right tool. The reader who wants more should read the `kgdb(1)` man page and experiment on a known panic.

23.5.9 Exercise: Build a Debug Kernel and Confirm Symbols Are Present With `kgdb`

A short exercise that grounds the section.

1. If not already done, build and install a MYDEBUG kernel as described above, with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, and `makeoptions DEBUG=-g`. Reboot.
2. Confirm the running kernel is the debug build:

```
uname -v | grep MYDEBUG
sysctl debug.witness.watch
```

3. Configure a dump device. This is usually a swap partition:

```
sudo dumpon /dev/adaNpY
```

where `adaNpY` is your swap partition. On a typical VM this is `ada0p3`.

4. Trigger a deliberate panic to produce a crash dump. The safest way is to run `sysctl debug.kdb.panic=1` as root:

```
sudo sysctl debug.kdb.panic=1
```

The system enters `ddb` (because `KDB_UNATTENDED` was not set for this exercise; if it was set, the system writes a dump and reboots). Run `bt`, `ps`, and `show alllocks`, then type `panic` to let the dump proceed. The system writes to the dump device and reboots.

5. After reboot, verify that `savecore(8)` has copied the dump:

```
ls /var/crash
```

You should see `vmcore.0`, `info.0`, and `kernel.0`.

6. Open the dump with `kgdb`:

```
sudo kgdb /var/crash/kernel.0 /var/crash/vmcore.0
```

7. Inside `kgdb`, run `bt`. You should see the panic stack. Walk up a few frames with `frame N`. Confirm that source lines and function arguments are visible; this is what the debug symbols buy.
8. Quit `kgdb` with `quit`.

The exercise is not about fixing a bug; it is about proving that the debug infrastructure works. From this point on, any real panic the reader causes is fully debuggable: the crash is preserved, the symbols are present, the debugger opens the dump. That is the foundation. Without it, debugging is mostly guessing.

23.5.10 Wrapping Up Section 4

Section 4 turned the reader’s kernel into a debug kernel. The options enable assertions, lock-order checking, DTrace hooks, debug symbols, and the in-kernel debugger. The cost is a slower system; the benefit is a system that catches its own bugs loudly. `ddb` is the live inspection tool; `kgdb` is the post-mortem inspection tool. Both work against the same debug kernel the reader is now running.

With the logging pipeline (Section 3) and the debug kernel (Section 4) in place, the reader has the infrastructure that every later tool assumes. Section 5 introduces DTrace, the tool that turns the debug kernel into a live tracing and measurement platform.

23.6 Section 5: Using DTrace for Live Kernel Inspection

DTrace is the scalpel of the FreeBSD debugging toolkit. Where `printf` is a blunt instrument and `ddb` is a hammer, DTrace is a scalpel: it lets you ask specific, sharp questions about the kernel’s live behavior and get answers without modifying the source, rebuilding the kernel, or stopping the system. A driver author who learns DTrace reaches a new kind of productivity: the ability to say “I wonder how often the driver’s interrupt fires” and get an answer in ten seconds without changing a line of code.

This section introduces DTrace at the level of detail a driver author needs. It does not try to be a DTrace reference; the excellent `dttrace(1)` man page, the DTrace Guide available online, and the book *Illumos DTrace Toolkit* are the deeper references. What Section 5 gives the reader is enough DTrace to instrument the `myfirst` driver, measure its behavior, and understand what DTrace can and cannot do.

23.6.1 What Is DTrace?

DTrace is a **dynamic tracing framework**. The word “dynamic” is important: it does not require the kernel to have been built with knowledge of every trace point; it does not require the running code to be patched; it does not require the reader to rebuild and reboot. You load the DTrace module, ask for a probe, and the framework attaches instrumentation to the running kernel code. When the instrumented code runs, the instrumentation fires, and DTrace records the event. When you are done, you detach, and the instrumentation is removed.

The framework originated in Solaris and was ported to FreeBSD. It lives under `/usr/src/cddl/` (the CDDL-licensed portion of the source tree), because it inherits the Solaris licensing. The user-space tool is `dttrace(1)`; the kernel-side infrastructure is a set of modules that can be loaded and unloaded on demand.

DTrace has three organising concepts: **providers**, **probes**, and **actions**.

A **provider** is a source of trace points. Examples of providers FreeBSD ships with: `fbt` (function boundary tracing, one probe per entry and exit of every kernel function), `syscall` (one probe per system call entry and return), `sched` (scheduler events), `io` (block I/O events), `vfs` (filesystem events), `proc` (process events), `vm` (virtual memory events), `sdt` (statically defined tracing, for probes compiled into the kernel), and `lockstat` (lock operations). Some providers (`fbt`, `syscall`) are always available once the module is loaded; others (`sdt`) only exist if the kernel code explicitly defines probes.

A **probe** is a specific point the reader can trace. Probes have four-part names in the form `provider:module:function:name`. For example, `fbt:kernel:myfirst_pci_attach:entry` is the `fbt` provider's entry probe on the function `myfirst_pci_attach` in the kernel module `kernel` (the main kernel binary, not a loadable module). A wildcard `*` matches any segment: `fbt::myfirst_*:entry` matches every function whose name starts with `myfirst_`, in any module, at function entry.

An **action** is what DTrace does when a probe fires. The simplest action is `{ trace(...) }`, which records the argument. More interesting actions aggregate: `@counts[probefunc] = count()` counts how many times each function's probe fired. The D language (DTrace's scripting language) is C-like but safer: it has no loops, no function calls, no memory allocation, and runs in the kernel under strict safety constraints.

The power of DTrace comes from the combination: you enable a specific probe, you attach a specific action, you observe only the events you care about, and you do it without touching the source.

23.6.2 Enabling DTrace Support

The kernel options needed for DTrace were covered in Section 4: `options KDTRACE_HOOKS`, `options KDTRACE_FRAME`, `options DDB_CTF`, and `makeoptions WITH_CTF=1`. If the reader built the `MYDEBUG` kernel with those options, DTrace is ready to go.

The user-space side needs the DTrace module to be loaded. The umbrella module is `dtraceall`, which pulls in all the providers:

```
sudo kldload dtraceall
```

Alternatively, individual providers can be loaded:

```
sudo kldload dtrace           # core framework
sudo kldload dtraceall        # all providers (recommended for development)
sudo kldload fbt              # just function boundary tracing
sudo kldload systrace         # just syscall tracing
```

For development, `dtraceall` is the simplest choice: all the providers the reader might want are available.

To confirm DTrace is working:

```
sudo dtrace -l | head -20
```

This lists the first twenty probes DTrace knows about. On a default FreeBSD 14 kernel with `dtraceall` loaded, the output includes hundreds of thousands of probes, most from the `fbt` provider (every kernel function has an entry and return probe). A quick count:

```
sudo dtrace -l | wc -l
```

A typical number is 40,000 to 80,000 probes, depending on what modules are loaded.

To list only the probes in the `myfirst` driver's functions:

```
sudo dtrace -l -n 'fbt::myfirst_*:'
```

If the driver is loaded, this produces a list of every `myfirst_*` function's entry and return probes. If the driver is not loaded, the list is empty: `fbt` probes only exist for code the kernel has loaded.

23.6.3 Writing Simple DTrace Scripts

The simplest DTrace invocation traces a single probe and prints when it fires:

```
sudo dtrace -n 'fbt::myfirst_pci_attach:entry'
```

The syntax is `provider:module:function:name`. The double colon in `fbt::myfirst_pci_attach:entry` uses the default empty module (which matches any module). DTrace prints one line per probe firing:

CPU	ID	FUNCTION:NAME
2	28791	myfirst_pci_attach:entry

This confirms the function was called, on CPU 2, with the internal probe ID 28791. For a one-shot “did this function run?” question, that is already enough.

A slightly more useful script traces the entry and return:

```
sudo dtrace -n 'fbt::myfirst_pci_attach:entry,fbt::myfirst_pci_attach:return'
```

Each line shows when entry and return fired. The two together tell the reader that the function ran and returned without panicking.

To trace many functions at once, use a wildcard:

```
sudo dtrace -n 'fbt::myfirst_*:entry'
```

Every `myfirst_*` function's entry produces a line. For the reader debugging an attach path, this is a cheap way to see the call sequence in real time.

To capture arguments, add a D-language action:

```
sudo dtrace -n 'fbt::myfirst_pci_suspend:entry { printf("%d: suspending %s", timestamp,  
↪ stringof(args[0]->name)); }'
```

The `args[0]` refers to the first argument of the probed function. For FBT probes, `args[0]` is the first argument to the function. For `myfirst_pci_suspend`, the first argument is a `device_t`, and `args[0]->name` (if FreeBSD's `device_t` layout has a `name` field accessible to DTrace) shows the device name.

Note: `device_t` is actually a pointer to an opaque structure, and DTrace can only follow type-aware pointer chains if the CTF data is loaded. This is why options `DDB_CTF` and `makeoptions WITH_CTF=1` matter: without them, DTrace sees `args[0]` as an integer and cannot dereference it meaningfully. With them, DTrace knows `args[0]` is a `device_t` (which is a `struct _device *`) and can walk the structure.

A more interesting script counts how many times each `myfirst_*` function fires:

```
sudo dtrace -n 'fbt::myfirst_*.entry { @counts[probfunc] = count(); }'
```

Let this run for a minute while the driver is exercised. Press Ctrl-C. DTrace prints a histogram:

<code>myfirst_pci_attach</code>	1
<code>myfirst_pci_detach</code>	1
<code>myfirst_pci_suspend</code>	42
<code>myfirst_pci_resume</code>	42
<code>myfirst_intr_filter</code>	10342
<code>myfirst_rx_task</code>	5120
<code>myfirst_dma_submit</code>	1024

The reader sees, at a glance, the driver's call distribution: two attach/detach, forty-two suspend/resume cycles, ten thousand interrupt filters, five thousand rx tasks, one thousand DMA submits. Any unexpected number is a signal to investigate. If the reader expected one-to-one between interrupts and tasks, and sees two-to-one, there is a bug.

23.6.4 Measuring Function Latency

One of DTrace's most useful idioms is measuring how long a function takes. The pattern is to timestamp entry, timestamp return, and subtract:

```
sudo dtrace -n '  
fbt::myfirst_pci_suspend:entry { self->start = timestamp; }  
fbt::myfirst_pci_suspend:return /self->start/ {  
    @times = quantize(timestamp - self->start);  
    self->start = 0;  
}'
```

The first clause stores the entry timestamp in a thread-local variable `self->start`. The second clause, predicated on `self->start` being non-zero, computes the delta, adds it to a quantize aggregation (a logarithmic histogram), and clears the variable. Let this run while the reader exercises suspend cycles, press Ctrl-C, and DTrace prints the histogram:

value	----- Distribution -----	count
1024		0
2048	@@@@	4
4096	@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@@	28
8192	@@@@@@@@@@	8
16384	@@	2
32768		0

The numbers are in nanoseconds. This says: most suspend calls took between 4,096 and 8,192 nanoseconds (4 to 8 microseconds), with a tail reaching 16,384 nanoseconds (16 microseconds). For a suspend call that should be fast, this is the kind of measurement that tells the reader whether the driver's discipline is working.

For a different kind of insight, use `avg( )` or `max( )` aggregations:

```
sudo dtrace -n '
fbt::myfirst_pci_suspend:entry { self->start = timestamp; }
fbt::myfirst_pci_suspend:return /self->start/ {
    @avg = avg(timestamp - self->start);
    @max = max(timestamp - self->start);
    self->start = 0;
}'
```

This prints the average and maximum suspend time at the end. Useful for summary reports.

23.6.5 Using the syscall Provider

The `syscall` provider shows every system call. This is especially useful for driver work, because user-space calls to the driver (`open`, `read`, `write`, `ioctl`) go through the `syscall` layer first. A script that watches for system calls on a specific file descriptor is a lightweight way to see how user programs use the driver:

```
sudo dtrace -n 'syscall::ioctl:entry /execname == "myftest"/ { printf("%s ioctl on fd
↵ %d", execname, arg0); }'
```

This prints every `ioctl` system call made by a process named `myftest`. The `execname` variable is a built-in DTrace variable that holds the current process's executable name. Running the test program `myftest` (a small user program that exercises the driver) while this script runs gives a live view of every `ioctl` the program issues.

23.6.6 Using the sched Provider

The sched provider tracks scheduler events: thread switches, wake-ups, enqueues. It is useful for understanding concurrency in the kernel, including driver interrupt handling:

```
sudo dtrace -n 'sched:::on-cpu /execname == "myftest"/ { @[cpu] = count(); }'
```

This counts, per CPU, how many times the myftest program was scheduled onto each CPU during the trace. Useful for understanding whether the scheduler is keeping the program on one core or bouncing it across cores, which affects the driver's cache behavior.

23.6.7 Using the io Provider

The io provider shows block I/O events. Not directly relevant to myfirst (a generic PCI driver), but useful to know about. A script to show every disk I/O:

```
sudo dtrace -n 'io:::start { printf("%s %d", execname, args[0]->bio_bcount); }'
```

For storage drivers, io is essential. For myfirst it is peripheral. Chapter 23 does not explore it in depth.

23.6.8 Statically Defined Tracing (SDT)

The fbt provider instruments every function entry and return. That is flexible but blunt: you get entry/return probes for every function, and you often want probes at specific interesting points inside a function.

SDT (Statically Defined Tracing) solves this. SDT lets the driver author add named probes to specific places in the source, and DTrace makes them visible. When DTrace is not watching, the probes are essentially free: they compile to a single no-op instruction. When DTrace attaches, the no-op is replaced with a trap that fires the probe.

The SDT machinery lives in `/usr/src/sys/sdt.h`. The basic macros are:

- `SDT_PROVIDER_DEFINE(name)`: declares a provider. Usually done once per driver, in the main source file.
- `SDT_PROBE_DEFINE(provider, module, function, name, "arg1-type", "arg2-type", ...)`: declares a probe with N typed arguments.
- `SDT_PROBE(provider, module, function, name, arg1, arg2, ...)`: fires the probe with the given arguments.

A minimal example for the myfirst driver. In `myfirst_pci.c`, near the top:

```
#include <sys/sdt.h>

SDT_PROVIDER_DEFINE(myfirst);
SDT_PROBE_DEFINE2(myfirst, , attach, entry,
```

```

    "struct myfirst_softc *", "device_t");
SDT_PROBE_DEFINE2(myfirst, , attach, return,
    "struct myfirst_softc *", "int");
SDT_PROBE_DEFINE3(myfirst, , dma, submit,
    "struct myfirst_softc *", "bus_addr_t", "size_t");
SDT_PROBE_DEFINE2(myfirst, , dma, complete,
    "struct myfirst_softc *", "int");

```

Then in the driver code:

```

int
myfirst_pci_attach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);
    int error;

    SDT_PROBE2(myfirst, , attach, entry, sc, dev);
    ...
    error = ...; /* real attach code */
    ...
    SDT_PROBE2(myfirst, , attach, return, sc, error);
    return (error);
}

```

From user space, the reader can now observe myfirst probes through DTrace:

```
sudo dtrace -n 'myfirst:::' | head
```

This shows every myfirst probe. To watch only DMA events:

```

sudo dtrace -n 'myfirst:::dma-submit'
sudo dtrace -n 'myfirst:::dma-complete'

```

To count submissions per DMA size:

```
sudo dtrace -n 'myfirst:::dma-submit { @[args[2]] = count(); }'
```

This prints a histogram of DMA transfer sizes at the end of the trace. For a driver debugging session, that is the kind of data that turns speculation into evidence.

Chapter 23's Stage 2 adds exactly these probes to the myfirst driver. The exercise at the end of Section 5 walks through the addition. The corresponding files live in `examples/part-05/ch23-debug/stage2-sdt/`.

Real drivers that use SDT are worth studying. `/usr/src/sys/dev/virtio/virtqueue.c` defines:

```
SDT_PROVIDER_DEFINE(virtqueue);
SDT_PROBE_DEFINE6(virtqueue, , enqueue_segments, entry, "struct virtqueue *",
    ...);
SDT_PROBE_DEFINE1(virtqueue, , enqueue_segments, return, "uint16_t");
```

and fires them in `virtqueue_enqueue`:

```
SDT_PROBE6(virtqueue, , enqueue_segments, entry, vq, desc, head_idx, ...);
...
SDT_PROBE1(virtqueue, , enqueue_segments, return, idx);
```

The reader can run `sudo dtrace -l -n 'virtqueue:::'` on a system with virtio-backed devices (common in VMs) and see these probes immediately. Tracing them gives a live view of virtqueue activity that would be impossible to reproduce with `printf`.

23.6.9 Useful Providers for Driver Work

A summary of the providers a driver author uses most:

- **fbt**: function boundary tracing. Every kernel function has entry and return probes. Best for “did this function run?” and “what arguments did it see?”.
- **sdt**: statically defined tracing. Probes the driver explicitly adds. Best for observing driver-specific events at specific points.
- **syscall**: system call tracing. Best for seeing what user programs are asking the kernel to do.
- **sched**: scheduler events. Best for understanding concurrency and CPU usage.
- **io**: block I/O events. Best for storage work.
- **vfs**: filesystem events. Best for filesystem driver work.
- **proc**: process lifecycle events. Best for process creation, exit, and signal delivery.
- **lockstat**: lock operations. Best for lock contention analysis; expensive when active.
- **priv**: privilege-related events. Useful for security auditing.

Most driver work uses `fbt`, `sdt`, and `syscall` heavily, and touches the others occasionally.

23.6.10 Common DTrace Pitfalls

A few patterns that trip new DTrace users.

Buffer too small. DTrace has per-CPU buffers; if a script fires probes faster than DTrace can drain them, events are dropped. The reader sees a message like `dtrace: X drops on CPU N`. The fix is usually to make the predicate tighter (fire less often), or to increase buffer size with `-b 16m`.

Forgetting to clear thread-local variables. In the latency-measurement pattern, the script sets `self->start` on entry and checks `self->start != 0` on return. If the reader forgets to clear it (`self->start = 0`; after use), the variable accumulates state and later traces get confused. Always pair `set` with `clear`.

Using `trace()` when `printf()` would be clearer. `trace(x)` prints the value in a terse format that is hard to read. `printf("x=%d", x)` is usually better.

Running as a non-privileged user. DTrace requires root. Running `dtrace` as a regular user fails with a permission error. Always use `sudo dtrace`.

Probes that do not exist. If a probe name is mistyped or the module is not loaded, `dtrace` prints an error. The fix is to confirm the probe exists with `dtrace -l` before trying to use it.

The `stringof()` trap. When printing a kernel string pointer, the reader often needs `stringof(ptr)`, not `ptr`, because DTrace does not automatically follow kernel pointers. Forgetting this produces garbage output.

23.6.11 Exercise: Use DTrace to Measure How Long a Driver Read Operation Takes

A hands-on companion for Section 5.

1. Ensure the MYDEBUG kernel is running and `dtraceall` is loaded.
2. Write a user program that reads from `/dev/myfirst0` a hundred times. The program can be as simple as:

```
#include <fcntl.h>
#include <unistd.h>
int main(void) {
    int fd = open("/dev/myfirst0", O_RDWR);
    char buf[4096];
    for (int i = 0; i < 100; i++)
        read(fd, buf, sizeof(buf));
    close(fd);
    return 0;
}
```

Compile with `cc -o myftest myftest.c`.

3. In one terminal, run the DTrace latency script on the driver's read path. Assuming the driver's read function is `myfirst_read`:

```
sudo dtrace -n '
fbt::myfirst_read:entry { self->start = timestamp; }
fbt::myfirst_read:return /self->start/ {
    @times = quantize(timestamp - self->start);
    self->start = 0;
}'
```

4. In another terminal, run the user program:

```
./myftest
```

5. Press Ctrl-C on the DTrace script. Read the histogram. Most reads should be in the low microseconds (a few thousand nanoseconds).

6. Take a screenshot or save the output. Compare to your expectation. If a read is taking longer than you expect, that is the start of a debugging session.

Optional: run the same script against `fbt::myfirst_intr_filter:entry` and observe the interrupt latency distribution.

23.6.12 Wrapping Up Section 5

Section 5 introduced DTrace as the scalpel of the debugging toolkit. DTrace is dynamic: probes attach to running code without rebuilds. It is safe: the D language has no loops or memory allocation. It is broad: providers expose tens of thousands of observation points across the kernel. For driver work, the combination of `fbt` (automatic probes on every function) and `sdt` (custom probes at specific points) gives the reader the ability to answer almost any “what is the driver doing?” question without modifying the source.

The cost of DTrace when inactive is essentially zero: probes exist in the kernel as no-op instructions or function-pointer slots. The cost when active depends on what the script does: a simple count is cheap, a complex histogram is more expensive, and a script that prints on every probe can flood the buffer. Understanding the trade-off is part of writing effective DTrace scripts.

With logging (Section 2), log pipelines (Section 3), debug kernels (Section 4), and DTrace (Section 5) in place, the reader has four complementary views into kernel behavior. Section 6 adds the last essential view for driver work: `kttrace`, the tool that shows what a user program is doing as it crosses into the kernel through the driver’s interface.

23.7 Section 6: Tracing Kernel Activity With `kttrace` and `kdump`

DTrace traces the kernel from the kernel side: which functions ran, how long they took, what state they touched. `kttrace` traces the same activity from the user side: which system calls a process made, what arguments it passed, what return values it got, what signals it received. Together, the two tools give a complete view. DTrace shows what the kernel did; `kttrace` shows what the program asked for.

For driver work, `kttrace` is the tool of choice when the question is “what is the user program doing?”. A driver that gets strange arguments can be traced back: maybe the program is calling `ioctl` with the wrong command number, or `write` with a zero-length buffer, or `open` with the wrong flags. `kttrace` answers those questions by recording every syscall the program issues.

23.7.1 What Is `kttrace`?

`kttrace(1)` is a user-space tool that tells the kernel to record a trace of one or more processes’ activities into a file. The recorded events include:

- Every system call entry and return, with arguments and return value.
- Every signal delivered to the process.
- Every `namei` (path-name lookup) event.
- Every I/O buffer passed to read or write.
- Context switches, at a coarse level.

The trace is written to a binary file (by default `ktrace.out`). To read it, the reader runs `kdump(1)`, which translates the binary trace into human-readable text.

`ktrace` is a simple tool, much older than DTrace, and it shows its age in some interfaces. But for the core question of “what did this process ask the kernel to do?”, it is ideal.

The implementation is in `/usr/src/sys/kern/kern_ktrace.c` and the user-facing header is in `/usr/src/sys/sys/ktrace.h`. The user-space tools are under `/usr/src/usr.bin/ktrace/` and `/usr/src/usr.bin/kdump/`.

The kernel needs options `KTRACE` to support `ktrace`. This option is enabled in `GENERIC` by default on every architecture; the reader does not need to rebuild a kernel to use `ktrace`.

23.7.2 Starting a Trace

The simplest invocation attaches to a running process by PID:

```
sudo ktrace -p 12345
```

This tells the kernel to start recording the process with PID 12345. The kernel writes events to `ktrace.out` in the current directory. When the reader is done, they stop the trace:

```
sudo ktrace -C
```

Or, more precisely, stop tracing for a specific PID:

```
sudo ktrace -c -p 12345
```

To run a command from scratch with tracing enabled:

```
sudo ktrace /path/to/program arg1 arg2
```

This starts the program and traces it from the first syscall. When the program exits, the trace file remains for the reader to examine.

Useful flags:

- `-d`: trace descendants too. If the program forks, the children are also traced.
- `-i`: inherit the trace across `exec`. If the program execs another program, the trace continues. Without `-i`, the trace stops at `exec`.
- `-t <mask>`: select which event types to record. The mask is a set of letter codes, like `cnios` (calls, namei, I/O, signals). Default is most types.
- `-f <file>`: write to a specific file instead of `ktrace.out`.
- `-C`: clear all tracing (stop all traces).

A common combination:

```
sudo ktrace -di -f mytrace.out -p 12345
```

Trace the process, all descendants, through `exec`, into `mytrace.out`.

23.7.3 Reading Output With `kdump`

The binary trace file is useless on its own. `kdump` translates it:

```
kdump -f mytrace.out
```

Output looks like:

```
12345 myftest  CALL  open(0x8004120a0,0x0)
12345 myftest  NAMI  "/dev/myfirst0"
12345 myftest  RET   open 3
12345 myftest  CALL  ioctl(0x3,0x20006601,0x7fffffff8c0)
12345 myftest  RET   ioctl 0
12345 myftest  CALL  read(0x3,0x7fffffff900,0x1000)
12345 myftest  GIO   fd 3 read 4096 bytes
                  "... data bytes ..."
12345 myftest  RET   read 4096/0x1000
```

Each line has a PID, a process name, an event type, and event-specific data:

- `CALL` lines show a syscall entry, with arguments as hex numbers.
- `NAMI` lines show a path-name lookup, with the resolved string.
- `RET` lines show a syscall return, with the value.
- `GIO` lines show generic I/O buffers, followed by a dump of the buffer contents.
- `PSIG` lines show signal delivery.

The output is dense but readable with practice. A common pattern for driver work:

1. Run the user program under `ktrace`.
2. Look for the `open` of `/dev/myfirst0`. Note the file descriptor the kernel returned.
3. Filter subsequent lines to the operations on that fd: `ioctl`, `read`, `write`, `close`.
4. Note the exact arguments, especially for `ioctl` where the command number encodes which operation the driver was asked to perform.

For example, the `ioctl(0x3,0x20006601,0x7fffffff8c0)` line above shows the program issuing an `ioctl` on fd 3 with command `0x20006601`. The command is the `_IO/_IOR/_IOW/_IOWR` encoding; the low 16 bits are the command number and the high bits are the direction and size. A driver author debugging an `ioctl` bug can look at this command, compare it to the definitions in the driver's header, and confirm the program is sending the command the driver expects.

23.7.4 Useful kdump Filters

kdump takes several flags that filter the output:

- **-t <mask>**: filter by type, same mask as `ktrace -t`.
- **-E**: show elapsed time since the previous event.
- **-R**: show relative timestamps instead of absolute.
- **-l**: show the PID and process name on every line.
- **-d**: hex-dump I/O buffers (on by default for GIO lines).
- **-H**: more readable hex dump.

A common refinement:

```
kdump -f mytrace.out -E -t cnri
```

Elapsed time, syscall entry/return plus namei plus I/O.

Piping to `grep` is also useful:

```
kdump -f mytrace.out | grep -E 'myfirst|ioctl|open|read|write|close' | less
```

This shows only lines relevant to the driver.

23.7.5 Finding Driver-Related Syscalls

A user program talks to a driver through four main syscalls: `open`, `ioctl`, `read`, `write`, and `close`. A driver author tracing a user program watches for these:

- **`open("/dev/myfirst0", ...)`**: the program opens the device. The return value is a file descriptor the subsequent syscalls use.
- **`ioctl(fd, cmd, arg)`**: the program issues a device-specific command. The `cmd` encodes the operation; `arg` is usually a pointer to a structure.
- **`read(fd, buf, size)`**: the program reads `size` bytes into `buf`.
- **`write(fd, buf, size)`**: the program writes `size` bytes from `buf`.
- **`close(fd)`**: the program closes the descriptor.

A trace that shows these in order is the reader's view of the user side of the driver's interface. A bug where the program is passing the wrong size to `read` shows up immediately as `read(fd, buf, 0)` (zero size) in the trace. A bug where the program is forgetting to call `close` shows up as the absence of a `close` call before `exit`. A bug where the program is using an undefined `ioctl` command shows up as an unusual hex value in the `cmd` argument.

23.7.6 Comparing ktrace and DTrace

The two tools overlap in some ways and complement each other in others. A rough guide:

Use `ktrace` when:

- You want to see what a user program is doing, with the program's perspective.
- You want a record you can save and review later.
- You want minimal setup (no kernel rebuild, no script writing).
- You want to catch the arguments to syscalls, including pointer-destination strings and I/O buffers.

Use DTrace when:

- You want to see what is happening inside the kernel.
- You want to measure latency, distribution, or contention.
- You want to aggregate data across many events.
- You need to trace without modifying the program or running it under a wrapper.

For most driver work, the reader uses both. `kttrace` answers “what is the program asking for?”. DTrace answers “what is the driver doing about it?”. The combination is the full picture.

23.7.7 A Note on KTR vs. kttrace

The names confuse new driver authors. `kttrace` (lowercase) is the user-space tracing tool described above. `KTR` (uppercase) is the in-kernel event tracing framework, enabled with options `KTR`. They are different.

`KTR` is a high-performance circular buffer for kernel events, intended for kernel developers debugging the kernel itself. Driver authors can add `CTR` (category-0, category-1, etc.) macros to their code and observe them through `ddb`'s `show ktr` command. In practice, `KTR` is used by a few core kernel subsystems (scheduler, locking, some device subsystems) and rarely by individual drivers. Chapter 23 does not pursue `KTR` further; the reader who is curious can read `/usr/src/sys/sys/ktr.h` for the macro definitions and `/usr/src/sys/conf/NOTES` for the configuration options.

23.7.8 Exercise: Trace a Simple User Program Accessing Your Driver

A hands-on companion for Section 6.

1. Write a small user program `myftest.c` that opens `/dev/myfirst0`, issues one `ioctl`, reads 4 KB, writes 4 KB, and closes. The simplest version:

```
#include <sys/ioctl.h>
#include <fcntl.h>
#include <unistd.h>
#include <stdio.h>

int
main(void)
{
    int fd, error;
    char buf[4096];

    fd = open("/dev/myfirst0", O_RDWR);
    if (fd < 0) { perror("open"); return 1; }
```

```
error = ioctl(fd, 0x20006601 /* placeholder */, NULL);
printf("ioctl: %d\n", error);

error = read(fd, buf, sizeof(buf));
printf("read: %d\n", error);

error = write(fd, buf, sizeof(buf));
printf("write: %d\n", error);

close(fd);
return 0;
}
```

Compile: `cc -o myftest myftest.c`.

2. Trace the program:

```
sudo ktrace -di -f mytrace.out ./myftest
```

3. Read the trace:

```
kdump -f mytrace.out | less
```

4. Find the lines relating to `/dev/myfirst0`:

```
kdump -f mytrace.out | grep -E 'myfirst0|CALL|RET|NAMI' | less
```

5. Confirm that each syscall is there, with the expected arguments. For the `ioctl`, decode the command number by hand: `0x20006601` means direction `IOC_OUT` (high byte `0x20`), size 0 (next 14 bits), type 'f' (`0x66`), command 01. A driver that defined `MYFIRST_IOC_RESET = _IO('f', 1)` would see exactly this command.

6. (Optional) Run the program under DTrace in a second terminal, counting the driver functions:

```
sudo dtrace -n 'fbt::myfirst_*:entry { @[probefunc] = count(); }' &
./myftest
```

Compare the DTrace count to the `ktrace` sequence. The reader should see that each user syscall triggered specific driver functions: `open` → `myfirst_open`, `ioctl` → `myfirst_ioctl`, `read` → `myfirst_read`, and so on.

The exercise grounds the tools in a specific, concrete trace. Every driver author has this pattern in their toolkit for the rest of their career: user-side trace with `ktrace`, kernel-side trace with DTrace, correlated by time and PID.

23.7.9 Wrapping Up Section 6

Section 6 introduced `ktrace` and `kdump`, the user-side tracing pair that complements `DTrace`. `ktrace` records the syscalls a process makes; `kdump` translates the record into text; the combination shows the driver's interface from the user program's perspective. For a driver author, this view is essential for debugging bugs that originate on the user side of the driver boundary.

With logging, log analysis, debug kernels, `DTrace`, and `ktrace` in hand, the reader has the five tools that handle most driver-debugging questions. Section 7 turns to the classes of bugs these tools most often find, with the characteristic symptom of each and the tool that best diagnoses it.

23.8 Section 7: Diagnosing Common Driver Bugs

The previous six sections built a toolbox: logging, log inspection, debug kernels, `DTrace`, and `ktrace`. Section 7 uses that toolbox on the bugs readers will actually meet. Every experienced FreeBSD driver author has hit each of these at least once. The purpose of this section is to describe the symptoms, explain the underlying cause, and match each bug class to the tool that diagnoses it most efficiently.

None of the bugs below are exotic. They arise from ordinary coding mistakes, incomplete understanding of the kernel environment, or assumptions that hold on one platform but not another. The reader who learns to recognise the symptoms will save hours of frustration, because the first step toward a fix is always correct classification.

23.8.1 7.1 Memory Leaks: the Quiet Growth

A memory leak in a kernel module is harder to detect than one in a user program. There is no `valgrind` equivalent that runs transparently, and the kernel does not exit when the module unloads, so a leak continues to consume memory even after the driver is gone. For long-running systems, a small leak is fatal: the pool it allocates from grows indefinitely, other subsystems start failing, and eventually the machine runs out of kernel memory and panics.

The characteristic symptom is simple: a `malloc` pool that grows but never shrinks. The tool that exposes the symptom is `vmstat -m`:

```
vmstat -m | head -1
vmstat -m | grep -E 'Type|myfirst'
```

The output looks like:

Type	InUse	MemUse	Requests	Size(s)
myfirst	12	3K	48	256

The three columns that matter are `InUse`, `MemUse`, and `Requests`. `InUse` is the number of allocations from this pool that are currently outstanding. `MemUse` is the total memory those allocations occupy, in kilobytes.

`Requests` is the total number of allocations made since the pool was created, including those that were later freed.

A healthy pool has `InUse` that stays roughly constant under a steady workload. A leaking pool has `InUse` that grows without bound.

To confirm a leak, run the workload that exercises the driver, then take two snapshots of `vmstat -m` several minutes apart:

```
vmstat -m | grep myfirst
# run the workload for 5 minutes
vmstat -m | grep myfirst
```

If the first shows `InUse=12` and the second shows `InUse=4800`, and the workload was not expected to add four thousand allocations, the driver is leaking.

The second step is to identify the offending path. Every `malloc(9)` call pairs with an expected `free(9)`. The leak is in whichever path allocates without freeing. Search the driver for `malloc(..., M_MYFIRST, ...)` and for `free(..., M_MYFIRST)`, and verify that every allocation has a matching free on every exit path.

The most common leak patterns in driver code are:

1. **Error-path leaks.** An allocation succeeds, a later step fails, and the error return skips the `free`. The fix is a single cleanup path with `goto fail;` labels, of the kind explored in Chapter 18.
2. **Conditional leaks.** Memory is freed only when a flag is set, and sometimes the flag is not set. The fix is to free unconditionally or to track ownership more carefully.
3. **Forgotten context-destructor.** An object is allocated per open file descriptor and stored on `si_drv1` or similar, but the `d_close` handler does not free it. The fix is to treat `d_close` (or the `cdev-destroy` callback) as the symmetric counterpart to `d_open`.
4. **Timer or task-queue leak.** A task is scheduled, its cleanup routine allocates memory for deferred processing, but the task is cancelled before it runs and the allocated buffer is never freed.

Once the path is identified, add the missing `free`, reload the module, rerun the workload, and confirm with `vmstat -m` that `InUse` now stabilises. A small bit of added logging is often useful: a `device_printf` in the allocation path and another in the free path quickly exposes the ratio of allocations to frees in `dmesg`. For a driver using a `DPRINTF` macro, a dedicated `MYF_DBG_MEM` class makes memory tracing optional and configurable at runtime, which is exactly what Section 8 will implement for the `myfirst` driver.

DTrace can also help here, especially in kernels with `KDTRACE_HOOKS`. A simple one-liner counts the driver's `malloc` and `free` calls and shows any imbalance:

```
dtrace -n 'fbt::malloc:entry /execname == "kernel"/ { @["malloc"] = count(); }
         fbt::free:entry   /execname == "kernel"/ { @["free"]   = count(); }'
```

A much more driver-specific approach is to add DTrace probes to the driver itself, one at each allocation and one at each free, and let DTrace count the ratio. This is the technique Section 8 demonstrates for the `myfirst` driver.

23.8.2 7.2 Race Conditions: the Rare, Destructive Bug

Race conditions are the hardest driver bugs to reproduce and the easiest to miss. A race happens when two threads access the same state without correct synchronisation, and the resulting behaviour depends on the relative timing of the two threads. Under light load the race may never fire; under heavy load it fires hundreds of times per second.

The symptoms of race conditions vary widely: - sporadic panics at unpredictable places - data corruption (values that should never exist) - occasional lock-related assertion failures such as “mutex myfirst_lock not owned” - impossible-looking stacks where two threads appear to be inside the same mutex-protected region

No single symptom proves a race, but any pattern of bugs that appears only at high load should raise suspicion.

The single most effective FreeBSD tool for finding races is `WITNESS`, as introduced in Section 4. A kernel built with options `WITNESS` examines every lock operation and panics on any violation of the declared lock order, on any attempt to acquire a spin lock while holding a sleep lock, on any call to a sleeping function while holding a spin lock, and on many related mistakes.

When `WITNESS` panics or prints a violation, it produces a stack trace showing: - which lock was being acquired - which locks were already held - the declared order that the acquisition would violate - both stacks (the current lock and the conflicting one)

The fix is usually one of:

1. **Reorder the acquisitions.** If code takes lock A then lock B while another path takes B then A, one of them must change.
2. **Add a missing lock.** If state is accessed without any mutex, add the appropriate `MTX_DEF` mutex around the access.
3. **Remove a redundant lock.** Sometimes two locks protect overlapping state, and one can be eliminated.
4. **Switch lock types.** Spin locks and sleep locks have different rules. A region that needs to sleep must use a sleep lock. A region called from interrupt context must often use a spin lock.

A driver that hits no `WITNESS` violations is not free of races, because `WITNESS` catches only lock-ordering issues. Races over state that is accessed without any lock at all require a different approach: careful reading of the code, `DTrace` probes at the suspect points to confirm timing, and occasionally `mtx_assert(&sc->sc_mtx, MA_OWNED)` assertions sprinkled through the critical sections. `INVARIANTS` enables these assertions, which is one more reason to run a debug kernel during development.

Between `WITNESS`, `INVARIANTS`, `mtx_assert`, and `DTrace` counters on the paths where contention is suspected, most races can be narrowed down within an hour or two. Races that survive this arsenal are rare and almost always involve lock-free data structures, atomic operations, or memory-ordering assumptions that require careful review with a senior engineer.

23.8.3 7.3 bus_space and bus_dma Misuse

A new driver author often runs into bus-access bugs that share a distinct family of symptoms:

- reads return `0xFF`, `0xFFFFFFFF`, or otherwise suspicious constants
- writes appear to succeed but the device does not react
- the machine works for seconds or minutes and then hangs or panics

- behaviour is correct on one architecture (amd64) and wrong on another (arm64, riscv64)

Each of these points to a `bus_space` or `bus_dma` misuse.

The first mistake is skipping the handle. `bus_space_read_4()` takes a `bus_space_tag_t` and a `bus_space_handle_t`, obtained from `rman_get_bustag()` and `rman_get_bushandle()` on the resource allocated during attach. Using the raw physical address of the register, or a pointer obtained by a direct cast of the resource, bypasses the platform's bus abstraction. On amd64 the program may appear to work (the kernel has the MMIO region mapped in a way that tolerates this), but on arm64 the register access fails.

The fix is mechanical: always go through `bus_space_read_N()` / `bus_space_write_N()` or the newer `bus_read_N()` / `bus_write_N()` resource-based helpers, never dereference raw pointers for device memory.

The second mistake is incorrect size. `bus_space_read_4` reads a 32-bit value. If the register is 16-bit and the code reads 4 bytes, it reads into an adjacent register as well, and the adjacent register's value now appears at bits 16 through 31 of the returned value. Worse, some hardware does not tolerate a mismatched size and responds with an error. The fix is to use the correct `read_1`, `read_2`, `read_4`, or `read_8` variant for each register's width, as documented in the device's datasheet.

The third mistake is incorrect offset. The `bus_space` handle refers to the base of the mapped region; the offset is added to compute the register address. A typo in the offset reads a different register. For example, reading offset `0x18` instead of `0x10` yields an unexpected value, and the driver's subsequent logic is based on a false reading. The fix is to define every offset as a named constant in a header file, and refer to the constant rather than the number: `#define MYFIRST_REG_STATUS 0x10`, `#define MYFIRST_REG_CONFIG 0x14`, and so on.

For DMA, the most common misuse is freeing or reusing a buffer while the device is still reading from or writing to it. The characteristic symptom is intermittent data corruption, sometimes only under high load. The cause is missing `bus_dmamap_sync` calls, a freed `bus_dmamem` buffer while the descriptor is still enqueued, or an incorrect direction in `bus_dmamap_sync`.

The diagnostic approach is to log every DMA map, sync, and unmap operation, then cross-check the log against the descriptor ring's state. A DTrace one-liner on the driver's DMA paths is usually enough to spot the mistake:

```
dtrace -n 'fbt::myfirst_dma_sync:entry { printf("%s dir=%d", probefunc, arg1); }'
```

For a full treatment of DMA rules and pitfalls, Chapter 21 is the reference. The debug chapter's role is to help the reader recognise the symptoms and narrow the cause.

23.8.4 7.4 Use-After-Detach

A subtler class of bug arises when the driver's detach path returns, the driver's softc is freed, but some other part of the kernel still holds a reference to the freed memory. Examples include:

- an interrupt arriving after `bus_release_resource` but before the handler is torn down
- a callout that fires after detach, dereferencing a freed softc
- a DTrace probe in the driver that fires from a task still running at unload time
- a character-device node held open by a user process, receiving I/O while the driver is unloading

The symptoms are nearly always fatal: page faults in driver code reached after detach, kernel panics with corrupted stacks, or spurious data in the kernel message buffer just before the panic.

The fix has several components, each of which the detach path must implement in a specific order:

1. First, prevent new entries: set a flag in the softc (`sc->sc_detaching = 1`), or take a write lock that all entry points check, so new calls see the driver as going away.
2. Wait for in-progress callers to finish. `bus_tearardown_intr` drains the interrupt handler. `callout_drain` waits for a pending callout to complete. `taskqueue_drain` drains any deferred tasks. `destroy_dev_sched_cb` waits for open file descriptors to close.
3. Only after every external caller is drained, release the resources the driver allocated in attach: free memory, release IRQs, release memory resources, destroy mutexes.

The principle is simple: detach is the mirror image of attach, and every resource allocated in attach must be released in detach in the reverse order. Violations of this principle produce use-after-detach bugs.

The debug tool of choice is the debug kernel itself. A `DEBUG_MEMGUARD`-enabled kernel can be configured to poison freed memory, so an access to a freed softc produces an immediate page fault with a clear stack, instead of a subtle corruption that may take hours to surface.

23.8.5 7.5 Interrupt Handler Mistakes

Driver authors new to the kernel sometimes treat interrupt handlers as ordinary functions and make common but harmful mistakes:

- calling a sleeping function (`malloc(..., M_WAITOK, ...)`, `tsleep`, `mtx_lock` of a sleep lock, `copyin`, `uiomove`) from a filter-level interrupt handler
- attempting to hold a sleep lock for an extended period
- reading or writing a large data block inside the interrupt handler instead of a taskqueue
- not ack'ing the interrupt, so the handler fires forever in a loop

Each of these has a distinct symptom. Sleeping in interrupt context produces a `WITNESS` violation or, in release kernels, a silent corruption of the scheduler state. Holding a sleep lock too long causes other threads to spin or sleep, and latency balloons. Doing heavy work in the handler blocks subsequent interrupts and degrades the whole system's responsiveness. Not ack'ing the interrupt pins a CPU at 100% on interrupt handling forever.

The cure is always the same: make the interrupt handler short and atomic. It should: 1. Read the status register to determine the cause. 2. Acknowledge the interrupt by writing to the status register. 3. Hand off any substantial work to a taskqueue or `ithread`, as explored in Chapter 19. 4. Return.

Complex processing, memory allocation, and long-running operations all belong in the deferred path, not the handler itself.

DTrace is particularly useful for diagnosing interrupt-handler performance. The `intr` provider, or an `fbt` probe on the handler entry, can measure how long each invocation takes:

```
dtrace -n 'fbt::myfirst_intr:entry { self->t = timestamp; }
          fbt::myfirst_intr:return /self->t/ {
            @ = quantize(timestamp - self->t); self->t = 0; }'
```

A healthy handler returns in a few microseconds. If the quantization shows invocations in the hundreds of microseconds or milliseconds, the handler is doing too much work and should be refactored.

23.8.6 7.6 Lifecycle Sequencing Errors

The driver's lifecycle moves through probe, attach, open, close, detach, and unload. Each method has rules about what it may do and what must have happened before. Breaking the rules produces characteristic bugs:

- calling `bus_alloc_resource_any` during probe (it must happen in attach) yields partial allocations and confusion in the probe-ordering logic
- doing substantial work in probe slows boot significantly, because the same probe runs for every candidate device
- creating the `cdev` before the hardware is initialised lets user processes open the device and receive I/O on uninitialised state
- destroying the `cdev` in detach while other threads still hold it open corrupts the devfs state
- doing significant work in module unload instead of detach leaves resources allocated per attach unreleased

The cure is to keep each lifecycle method focused on its job:

- **probe** only identifies the device and returns `BUS_PROBE_DEFAULT` or an error; no allocations, no registration
- **attach** allocates resources, initialises the softc, sets up interrupts, creates the `cdev`, registers the device
- **detach** reverses attach exactly, in reverse order
- **open** / **close** manage per-file state without touching device-wide resources
- **unload** performs only module-level cleanup; per-device cleanup belongs in detach

When a driver follows this structure, lifecycle bugs are rare. When it deviates, they are common and painful.

23.8.7 7.7 Copy-To/From-User Mistakes

The `copyin(9)`, `copyout(9)`, and related `fueword` / `suword` functions transfer data across the user/kernel boundary. They are protected by the virtual memory system: if the user-space address is invalid, the copy returns `EFAULT` instead of panicking. However, this protection only applies if the copy is done through these functions. A driver that dereferences a user-space pointer directly will panic the moment the user pointer is bad, which in real-world deployments is most of the time.

The symptom is a panic with a user-space address in the faulting instruction, stack pointing at the driver's read/write/ioctl path.

The fix is mandatory: every time user data crosses the boundary, use `copyin/copyout` or a `uiomove` through a `struct uio`. Never cast a user pointer to a kernel pointer and dereference it. This rule is absolute.

For `ioctl` specifically, the `d_ioctl` handler receives a kernel pointer, because the kernel has already copied the fixed-size argument from user space. But if the `ioctl`'s argument is a structure that contains a pointer to a larger user buffer, that embedded pointer is still user-space, and `copyin` is required to safely access the buffer it points to.

23.8.8 7.8 Module-Level Bugs

Some bugs affect the whole module rather than a single device:

- module fails to load: the loader prints an error in `dmesg`; read it and fix the symptom (missing dependency, symbol resolution failure, version mismatch)
- module fails to unload: usually means a device is still attached. Detach all devices (`devctl detach myfirst0`) before `kldunload`
- module unloads but leaves garbage: the unload path (`module_t` event handler, or `DRIVER_MODULE_ORDERED` unload) did not reverse module load. Fix by reading the unload path and making it symmetric to load.

The debug tools are simple: `dmesg | tail` shows the load/unload messages, `kldstat -v` shows the module state, `vmstat -m` shows whether the module's malloc pool was drained on unload.

23.8.9 7.9 A Debug Checklist

Here is a compact checklist that ties tools to symptoms. Readers can keep this at hand during driver development.

Symptom	First tool	Second tool
Bad or missing <code>dmesg</code> line	<code>dmesg</code> , <code>/var/log/messages</code>	<code>add device_printf</code>
<code>InUse</code> grows in <code>vmstat -m</code>	<code>vmstat -m</code>	DTrace malloc count
Panic on lock order	WITNESS trace	<code>ddb> show locks</code>
Sporadic corruption under load	WITNESS, INVARIANTS	DTrace timing
Register reads return <code>0xFFFFFFFF</code>	review <code>bus_space</code> handle	datasheet, offset
Machine hangs on device use	DTrace <code>fbt::myfirst_*</code>	<code>ddb> bt</code>
Panic after detach	<code>DEBUG_MEMGUARD</code>	audit detach order
Slow system under driver load	DTrace <code>intr</code> provider	shorten handler
<code>ioctl</code> with wrong command	<code>ktrace / kdump</code>	decode command
Panic with user-space faulting address	review <code>copyin/copyout</code>	audit <code>ioctl</code> pointer
Module will not unload	<code>kldstat -v</code>	<code>devctl detach</code>

The table is not exhaustive, but it covers the vast majority of real driver bugs. With it and the tools from Sections 1 through 6, the reader has a structured approach to most field diagnostics.

23.8.10 Wrapping Up Section 7

Section 7 turned the toolbox of logging, log analysis, debug kernels, DTrace, and `ktrace` on the bugs the reader is most likely to hit: memory leaks, race conditions, bus-access errors, use-after-detach, interrupt mistakes, lifecycle errors, user/kernel boundary bugs, and module-level issues. For each class, the section described the symptom, the underlying cause, and the tool that diagnoses it most efficiently. The checklist at the end makes

the mapping explicit, and future sessions at the keyboard should let the reader reach for the right tool on the first try rather than the third.

The remaining gap is the driver itself. So far in this chapter, `myfirst` has been used mostly as the target of external tools. Section 8 closes that gap by refactoring the driver to expose trace points and a debug-verbosity knob of its own, so that instrumentation becomes an organic part of the code rather than an afterthought. The version bumps to 1.6-debug and the driver acquires `myfirst_debug.h` and the structure that will stay with it through the remainder of the book.

23.9 Section 8: Refactoring and Versioning With Trace Points

The previous seven sections of this chapter were about learning to use tools that already exist in FreeBSD: `printf`, `dmesg`, debug kernels, DTrace, `ktrace`, and the discipline of reading their output. Section 8 turns inward. The `myfirst` driver that arrived from Chapter 22 as version 1.5-power has no real debug infrastructure of its own. Every logging statement is unconditional. There is no knob the operator can turn, no `sysctl` to request more verbose output when a problem arises, and no static trace points to hook with DTrace. Section 8 fixes that gap.

The work in this section is small in lines of code but large in impact. By the end, the driver will have:

1. A `myfirst_debug.h` header that defines a `DPRINTF` macro, verbosity bits, and SDT trace points.
2. A `sysctl` tree (`dev.myfirst.0.debug`) that sets the verbosity at runtime.
3. An entry-exit-error trace pattern applied consistently across the driver.
4. Three SDT provider probes that expose the open, close, and I/O events.
5. A `DEBUG.md` document in the example tree describing how to configure and read the new output.
6. A version bump to 1.6-debug recorded in `myfirst_version` and `MODULE_VERSION`.

The resulting driver will be the platform for the remaining chapters of the book. Every new subsystem added in Parts 5, 6, and 7 will hook into this framework, so that the trace infrastructure grows with the driver rather than being bolted on at the end.

23.9.1 8.1 Why a Debug Header

Larger FreeBSD drivers have a dedicated header file for debug infrastructure. The pattern is visible in `/usr/src/sys/dev/ath/if_ath_debug.h`, `/usr/src/sys/dev/bwn/if_bwn_debug.h`, `/usr/src/sys/dev/iwn/if_iwn_debug.h`, and many others. Each of these headers:

1. defines a `DPRINTF` macro that checks a verbosity bitmask in the softc
2. declares a set of verbosity classes as `#define MYF_DBG_INIT 0x0001`, `MYF_DBG_OPEN 0x0002`, and so on
3. optionally declares SDT probes that map to the driver's functional boundaries

Putting this in a header has two benefits. First, the debug infrastructure is a separate concern, factored cleanly away from the functional code. Second, when a reader wants to understand the driver's tracing story, the header is the one file to read. The pattern is mature, widely used, and is what `myfirst` will adopt in this section.

The header will be kept under `examples/part-05/ch23-debug/stage3-refactor/myfirst_debug.h`, and the driver source will include it at the top:

```
#include "myfirst_debug.h"
```

The companion changes in the driver source are additive: existing `device_printf` calls can remain, and new calls are added through the `DPRINTF` macro.

23.9.2 8.2 Declaring Debug Classes

The first step is to define the verbosity classes. A class is a single bit in a 32-bit mask. The driver reserves one bit per functional area. For `myfirst`, eight classes are more than enough at this stage:

```
/* myfirst_debug.h */
#ifndef _MYFIRST_DEBUG_H_
#define _MYFIRST_DEBUG_H_

#include <sys/sdt.h>

#define MYF_DBG_INIT      0x00000001 /* probe/attach/detach */
#define MYF_DBG_OPEN      0x00000002 /* open/close lifecycle */
#define MYF_DBG_IO        0x00000004 /* read/write paths */
#define MYF_DBG_IOCTL     0x00000008 /* ioctl handling */
#define MYF_DBG_INTR      0x00000010 /* interrupt handler */
#define MYF_DBG_DMA        0x00000020 /* DMA mapping/sync */
#define MYF_DBG_PWR        0x00000040 /* power-management events */
#define MYF_DBG_MEM        0x00000080 /* alloc/free trace */

#define MYF_DBG_ANY       0xFFFFFFFF
#define MYF_DBG_NONE      0x00000000

#endif /* _MYFIRST_DEBUG_H_ */
```

The value `MYF_DBG_NONE` is the default: no debug output at all. `MYF_DBG_ANY` enables every class, useful during development. A typical operator configuration might enable only `MYF_DBG_INIT | MYF_DBG_OPEN` to get lifecycle events without the per-I/O chatter.

Each bit is declared as a single hex digit or pair, so the operator can set the mask with a simple value: `sysctl dev.myfirst.0.debug=0x3` enables initialisation and open tracing. The commented names make the purpose of each bit clear.

23.9.3 8.3 The DPRINTF Macro

Next, the macro that gates logging on the mask:

```

#ifdef _KERNEL
#define DPRINTF(sc, m, ...) do {                                \
    if ((sc)->sc_debug & (m))                                    \
        device_printf((sc)->sc_dev, __VA_ARGS__);              \
} while (0)
#endif

```

The macro takes three arguments: the softc pointer, the bitmask, and the format string plus variadic arguments. It expands to a test of `sc->sc_debug & m`, followed by a call to `device_printf` if the test succeeds. The `do { ... } while (0)` pattern is the standard idiom for multi-statement macros that must behave like a single statement in `if/else` contexts.

The cost of the `DPRINTF` call when the bit is clear is a single load from `sc->sc_debug`, a bitwise AND, and a branch. The branch is almost always predicted as “not taken”, so the cost in practice is negligible. The driver can sprinkle `DPRINTF` calls freely throughout the code, and the user pays nothing when debug is disabled.

When the bit is set, the call becomes a normal `device_printf`, appearing in `dmesg` like any other kernel log. Nothing in the behaviour differs from the usual logging path, except that the logging is now conditional.

23.9.4 8.4 Adding `sc_debug` to the softc

The softc gains one new field, a `uint32_t sc_debug`. Its value is manipulated by a `sysctl`, which the `attach` function registers. The relevant excerpt from `myfirst_debug.c`:

```

struct myfirst_softc {
    device_t      sc_dev;
    struct mtx     sc_mtx;
    struct cdev    *sc_cdev;
    uint32_t      sc_debug;      /* debug verbosity mask */
    /* other fields as in 1.5-power */
};

```

The `attach` function initialises the field to zero and registers the `sysctl`:

```

sc->sc_debug = 0;
sysctl_ctx_init(&sc->sc_sysctl_ctx);
sc->sc_sysctl_tree = SYSCTL_ADD_NODE(&sc->sc_sysctl_ctx,
    SYSCTL_CHILDREN(device_get_sysctl_tree(sc->sc_dev)),
    OID_AUTO, "debug",
    CTLFLAG_RW, 0, "debug verbosity tree");

SYSCTL_ADD_U32(&sc->sc_sysctl_ctx,
    SYSCTL_CHILDREN(sc->sc_sysctl_tree),
    OID_AUTO, "mask",
    CTLFLAG_RW, &sc->sc_debug, 0, "debug class bitmask");

```

After attach, the sysctl appears as:

```
sysctl dev.myfirst.0.debug.mask
```

and the operator can change it at will:

```
sysctl dev.myfirst.0.debug.mask=0x3      # enable INIT + OPEN
sysctl dev.myfirst.0.debug.mask=0xFFFFFFFF # enable all classes
sysctl dev.myfirst.0.debug.mask=0        # disable
```

The detach routine destroys the sysctl context the same way it does today:

```
sysctl_ctx_free(&sc->sc_sysctl_ctx);
```

One detail matters: placing the sysctl field near the top of the softc puts it in the first cache line, where its access cost during DPRINTF is smallest. This is a small performance point, but the book's emphasis on principled coding should note it.

23.9.5 8.5 The Entry / Exit / Error Pattern

With DPRINTF in place, the driver's functions can use a consistent pattern for tracing. Each substantial function logs entry, exit (or error), and any interesting intermediate state. For a small function like `myfirst_open`, this looks like:

```
static int
myfirst_open(struct cdev *dev, int flags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error = 0;

    DPRINTF(sc, MYF_DBG_OPEN, "open: pid=%d uid=%d flags=0x%x\n",
            td->td_proc->p_pid, td->td_ucred->cr_uid, flags);

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count >= MYFIRST_MAX_OPENS) {
        error = EBUSY;
        goto out;
    }
    sc->sc_open_count++;
out:
    mtx_unlock(&sc->sc_mtx);

    if (error != 0)
```

```

        DPRINTF(sc, MYF_DBG_OPEN, "open failed: error=%d\n", error);
    else
        DPRINTF(sc, MYF_DBG_OPEN, "open ok: count=%d\n",
            sc->sc_open_count);

    return (error);
}

```

Three principles guide the pattern:

1. The entry log shows who called and with what arguments. For open, this is pid, uid, and flags.
2. The exit log shows the outcome: either “failed: error=N” or “ok: ...” with any relevant state.
3. Intermediate state is logged when it matters. For open, the new open count is useful.

The pattern is the same for close, read, write, and ioctl. Each function has two or three DPRINTF calls bracketing the work.

This discipline pays off the first time a bug appears. Without the pattern, the developer must add logging retroactively, guessing where the problem is. With the pattern, turning on a single bit (sysctl dev.myfirst.0.debug.mask=0x2 for MYF_DBG_OPEN) produces a complete trace of every open and close, with arguments and outcomes. The diagnostic time drops from hours to minutes.

23.9.6 8.6 Adding SDT Probes

The static DPRINTF macro generates human-readable messages in dmesg. SDT probes produce machine-readable events that DTrace can aggregate, filter, and time. Both have their place. The driver declares SDT probes for the three most interesting events, and a thoughtful user can attach custom scripts at will.

In myfirst_debug.h, the probe declarations look like:

```

#include <sys/sdt.h>

SDT_PROVIDER_DECLARE(myfirst);
SDT_PROBE_DECLARE(myfirst, , , open);
SDT_PROBE_DECLARE(myfirst, , , close);
SDT_PROBE_DECLARE(myfirst, , , io);

```

The matching definitions live in the driver source (myfirst_debug.c):

```

#include <sys/sdt.h>

SDT_PROVIDER_DEFINE(myfirst);
SDT_PROBE_DEFINE2(myfirst, , , open,
    "struct myfirst_softc *", "int");
SDT_PROBE_DEFINE2(myfirst, , , close,

```

```

    "struct myfirst_softc *", "int");
SDT_PROBE_DEFINE4(myfirst, , , io,
    "struct myfirst_softc *", "int", "size_t", "off_t");

```

The `DEFINE` macros register the probes with the kernel's SDT infrastructure. `DEFINEn` takes `n` arguments, each with a C-style type string that describes what the DTrace script will receive as `arg0`, `arg1`, etc.

The driver then fires the probes at the appropriate locations:

```

/* in myfirst_open */
SDT_PROBE2(myfirst, , , open, sc, flags);

/* in myfirst_close */
SDT_PROBE2(myfirst, , , close, sc, flags);

/* in myfirst_read or myfirst_write */
SDT_PROBE4(myfirst, , , io, sc, is_write, (size_t)uio->uio_resid, uio->uio_offset);

```

The cost of a probe that no script has attached to is a single branch around a no-op, the same negligible cost as `DPRINTF` with a clear bit. When a DTrace script does attach, the branch is taken, the arguments are recorded, and the script sees them as `args[0]`, `args[1]`, and so on.

With these probes, a reader can now run scripts like:

```
dtrace -n 'myfirst::: { @[probename] = count(); }'
```

This counts every `myfirst` probe event. To see the bytes transferred per second:

```
dtrace -n 'myfirst:::io { @["bytes"] = sum(arg2); }'
```

Or to trace every open with PID and flags:

```
dtrace -n 'myfirst:::open { printf("open pid=%d flags=0x%x", pid, arg1); }'
```

The driver now exposes its behaviour in two forms: human-readable via `DPRINTF`, and machine-parseable via SDT. An operator can pick the right form for the job.

23.9.7 8.7 Writing `DEBUG.md`

The example tree gains a short document (`examples/part-05/ch23-debug/stage3-refactor/DEBUG.md`) that explains the debug and trace infrastructure to a reader who downloads the files. The document is short but covers:

1. What `DPRINTF` is and how to enable it.

2. The table of class bits.
3. Example `sysctl` commands to enable each class.
4. The list of SDT probes and the argument order.
5. Three example DTrace one-liners.
6. How to combine `DPRINTF` and SDT for end-to-end debugging.

The document is not long: about thirty lines. Its purpose is to make the tooling self-documenting, so a reader who picks up the example in a year still knows how to use it.

23.9.8 8.8 Bumping the Version

Every chapter in the book that changes the driver's behaviour bumps its version. The rule is: the version string in the driver matches the version shown in the example-tree README and in the chapter's text.

In Chapter 22, the driver reached 1.5-power. Section 8 of Chapter 23 takes it to 1.6-debug. The changes in `myfirst_debug.c` are:

```
static const char myfirst_version[] = "myfirst 1.6-debug";

MODULE_VERSION(myfirst, 16);
```

The text above the version constant says explicitly what changed:

```
/*
 * myfirst driver - version 1.6-debug
 *
 * Added in this revision:
 *   - DPRINTF macro with 8 verbosity classes
 *   - sysctl dev.myfirst.0.debug.mask for runtime control
 *   - SDT probes for open, close, io
 *   - Entry/exit/error pattern across all methods
 */
```

The attach function logs the version at the `MYF_DBG_INIT` level, so the operator can confirm the loaded driver:

```
DPRINTF(sc, MYF_DBG_INIT, "attach: %s loaded\n", myfirst_version);
```

With the verbosity enabled, a reader who loads the driver sees:

```
myfirst0: attach: myfirst 1.6-debug loaded
```

which confirms both the module identity and the debug infrastructure.

23.9.9 8.9 Wrapping Section 8

Section 8 refactored the `myfirst` driver to carry its own debug infrastructure. The driver now has a verbosity mask, a `sysctl` to set it at runtime, a consistent entry-exit-error pattern in each function, and three SDT probes at the functional boundaries. The debug header can be included in future chapters, so every subsystem added later in the book can hook into the same framework.

The driver's version advances from 1.5-power to 1.6-debug. The example tree gets a `stage3-refactor` directory with the final source, a `DEBUG.md` document, and a `README.md` that guides the reader through building, loading, and exercising the new infrastructure.

With Section 8 complete, the chapter has covered the full arc: understand why kernel debugging is hard, use every tool FreeBSD provides, recognise the common bugs, and finally build the driver so that it supports its own debugging. The remaining material in the chapter is the lab sequence, the challenges, and the closing material that ties this chapter to Chapter 24.

23.10 Hands-On Labs

The labs in this chapter form a progression. Each one reinforces a specific tool from Sections 1 through 6, and the final lab applies the refactor from Section 8 so the reader walks away with a driver that is instrumented and ready for the rest of the book.

None of these labs is long. All five can be completed in a single evening, though spreading them across two or three sessions gives the reader time to absorb each tool.

23.10.1 Lab 23.1: A First DDB Session

Goal: Enter the kernel debugger deliberately, inspect the driver's state, and exit safely.

Prerequisites: A debug kernel built as described in Section 4, with options `KDB` and options `DDB`. The `myfirst` driver from Chapter 22 (version 1.5-power) loaded.

Steps:

1. Confirm the debug kernel is running:

```
sysctl kern.version
sysctl debug.kdb
```

The second command should show DDB among the available backends.

2. Load the driver and confirm the device node:

```
sudo kldload myfirst
ls /dev/myfirst0
```

3. Enter DDB with a keyboard break. On the system console, press `Ctrl-Alt-Esc` on a VGA console, or send the `BREAK` character on a serial console. The prompt appears:

```
KDB: enter: manual entry
[thread pid 42 tid 100024 ]
Stopped at      kdb_enter+0x37: movq    $0,0x158e4fa(%rip)
db>
```

4. Show the device tree:

```
db> show devmap
```

Locate `myfirst0` in the output.

5. Print the backtrace of the current thread:

```
db> bt
```

6. Print all processes:

```
db> ps
```

Confirm the reader's own shell is visible in the list.

7. Continue the kernel:

```
db> continue
```

The system returns to normal operation.

What to observe:

- The kernel halted cleanly on the break.
- All devices, processes, and kernel threads were inspectable.
- The `continue` command returned the system to normal without any side effect.

Record the time spent and any notes in the lab logbook under “Chapter 23, Lab 1”. The reader should come away understanding that DDB is a safe tool when used deliberately.

23.10.2 Lab 23.2: Measuring the Driver with DTrace

Goal: Use DTrace to measure the `myfirst` driver's open, close, and I/O rates under a simple workload.

Prerequisites: A kernel with options `KDTRACE_HOOKS` and `makeoptions WITH_CTF=1` loaded. The `myfirst` driver loaded at version 1.5-power (SDT probes are not yet present at this stage; the lab uses `fbt` only).

Steps:

1. Confirm DTrace works:

```
sudo dtrace -l | head -5
```

2. Start a DTrace script that counts entries to each `myfirst` function:

```
sudo dtrace -n 'fbt::myfirst_*:entry { @[probefunc] = count(); }'
```

3. In a second terminal, exercise the driver:

```
for i in $(seq 1 100); do cat /dev/myfirst0 > /dev/null; done
```

4. Stop the DTrace script (Ctrl-C in the first terminal) and read the count:

```
myfirst_open          100
myfirst_close         100
myfirst_read          100
```

5. Now measure the time spent in myfirst_read:

```
sudo dtrace -n 'fbt::myfirst_read:entry { self->t = timestamp; }
               fbt::myfirst_read:return /self->t/ {
                 @ = quantize(timestamp - self->t); self->t = 0; }'
```

6. Exercise the driver with 1000 reads, stop DTrace, and read the quantization.

What to observe:

- Every cat produced one open, one read, and one close, matching the count.
- The time per read is small (microseconds) and concentrated in one bucket of the quantization.
- No modification was made to the driver; the measurement is non-invasive.

23.10.3 Lab 23.3: User-Side Tracing with ktrace

Goal: Trace a user program that exercises the myfirst driver and verify the syscall sequence.

Prerequisites: The driver loaded. The test program myftest.c from Section 6.4 compiled.

Steps:

1. Compile the test program (from Section 6.4):

```
cc -o myftest myftest.c
```

2. Run it under ktrace:

```
sudo ktrace -di -f mytrace.out ./myftest
```

3. Dump the trace:

```
kdump -f mytrace.out | less
```

4. Locate the syscalls relevant to the driver:

```
kdump -f mytrace.out | grep -E 'myfirst0|CALL|RET'
```

5. Correlate the trace with the driver's DTrace counts from Lab 23.2. Every user-side syscall should match one or more kernel-side function entries.

What to observe:

- The user program's view of the driver is complete in the trace.
- Arguments, return values, and error codes are all visible.
- User-side tracing complements the DTrace kernel-side view.

23.10.4 Lab 23.4: Finding a Memory Leak with `vmstat -m`

Goal: Introduce a deliberate leak, detect it with `vmstat -m`, and fix it.

Prerequisites: The driver source under the reader's control. A compiled, loadable module.

Steps:

1. Modify `myfirst_open` to allocate a small buffer and store it in `si_drv2`, without freeing it in `myfirst_close`:

```
/* in myfirst_open */  
dev->si_drv2 = malloc(128, M_MYFIRST, M_WAITOK | M_ZERO);
```

2. Build and load the driver.
3. Run a workload that opens and closes the device many times:

```
for i in $(seq 1 1000); do cat /dev/myfirst0 > /dev/null; done
```

4. Check the memory pool:

```
vmstat -m | grep myfirst
```

The `InUse` column should show 1000 (or more), and `MemUse` should show roughly 128 KB.

5. Fix the leak by adding `free(dev->si_drv2, M_MYFIRST);` to `myfirst_close`.
6. Build and reload the driver. Run the workload again.
7. Check the pool:

```
vmstat -m | grep myfirst
```

`InUse` should now stabilise near zero after the workload.

What to observe:

- The `vmstat -m` output exposed the leak immediately.
- Without a specialist tool, the leak would have gone unnoticed until the kernel ran out of memory.
- The fix is mechanical and easy once the symptom is identified.

Do not leave the leak-inducing code in the driver after the lab. Revert to the clean version before continuing.

23.10.5 Lab 23.5: Installing the 1.6-debug Refactor

Goal: Apply the Section 8 refactor to the `myfirst` driver and confirm the new infrastructure works.

Prerequisites: The driver source from Chapter 22 under the reader's control. A development environment able to build kernel modules.

Steps:

1. Create `myfirst_debug.h` exactly as shown in Section 8.2, and the SDT declarations from Section 8.6.
2. Update the `softc` to add `uint32_t sc_debug;`.
3. Register the `sysctl` in `myfirst_attach` as shown in Section 8.4.
4. Replace unconditional `device_printf` calls with `DPRINTF(sc, MYF_DBG_<class>, ...)` calls as appropriate.
5. Define the SDT providers and probes in `myfirst_debug.c` (or `myfirst.c`), and fire them in `open`, `close`, and `read/write`.
6. Bump `myfirst_version` to 1.6-debug and `MODULE_VERSION` to 16.
7. Build:

```
cd /path/to/myfirst-source
make clean && make
```

8. Reload:

```
sudo kldunload myfirst
sudo kldload ./myfirst.ko
```

9. Confirm the module loaded at the new version:

```
kldstat -v | grep myfirst
```

10. Confirm the `sysctl` is present:

```
sysctl dev.myfirst.0.debug.mask
```

11. Enable full verbosity and open the device:

```
sudo sysctl dev.myfirst.0.debug.mask=0xFFFFFFFF
cat /dev/myfirst0 > /dev/null
dmesg | tail
```

Expected output includes lines like:

```
myfirst0: open: pid=1234 uid=1001 flags=0x0
myfirst0: open ok: count=1
myfirst0: read: size=4096 off=0
```

12. Disable verbosity and confirm the messages stop:

```
sudo sysctl dev.myfirst.0.debug.mask=0
cat /dev/myfirst0 > /dev/null
dmesg | tail
```

13. Attach DTrace to the SDT probes:

```
sudo dtrace -n 'myfirst::: { @[probename] = count(); }'
```

In a second terminal, exercise the driver:

```
for i in $(seq 1 100); do cat /dev/myfirst0 > /dev/null; done
```

Stop DTrace and confirm the probes fired.

What to observe:

- Runtime control of verbosity is immediate and responsive.
- The DPRINTF path produces human-readable messages; SDT probes produce machine-parseable events.
- The two forms are complementary and independent.
- Both are turned off by default, so production users pay no runtime cost.

The driver is now at version 1.6-debug, with infrastructure that will support every later chapter. Record the upgrade in the logbook.

23.11 Challenge Exercises

The exercises below build on the chapter material. They are open-ended enough that each reader will arrive at slightly different answers. Take your time; work incrementally; use the tools from the chapter at each step.

23.11.1 Challenge 23.1: An SDT Probe in a Real Driver

Pick a driver from `/usr/src/sys/dev/` that already contains SDT probes. Good candidates include `virtqueue.c`, some `ath` files, or `if_re.c`.

For the chosen driver:

1. List its probes with `dtrace -l -P <provider>`.
2. Write a one-liner that counts events grouped by probe name.
3. Write a second one-liner that aggregates by one of the probe arguments (for example, a packet length or a command number).
4. Explain in three sentences what the driver's author gained by adding the probes.

23.11.2 Challenge 23.2: A Custom DTrace Script

Write a DTrace script that:

1. Attaches to the `myfirst` SDT probes (added in Lab 23.5).
2. Tracks the lifetime of each open file descriptor by pid.
3. Prints a summary when a fd closes, showing: pid, how many reads, how many writes, total bytes, and the elapsed time between open and close.

The script should be at most 50 lines of D code. Test it by running a small user program that opens, reads, writes, and closes `/dev/myfirst0` several times.

23.11.3 Challenge 23.3: A WITNESS Experiment

Modify the driver to contain a deliberate lock-ordering mistake. For example, add two mutexes `sc_mtx_a` and `sc_mtx_b`, and arrange one code path to take A then B while another path takes B then A.

Build with options `WITNESS`, load, and trigger the mistake. Capture the resulting kernel panic or WITNESS output. Describe in three sentences what WITNESS showed, why it caught the issue, and what the fix would be.

Be sure to revert the mistake after the exercise. Do not leave a broken driver loaded.

23.11.4 Challenge 23.4: Extended Error Categorisation

Choose any four error paths in the `myfirst` driver (for example, the `EBUSY` path in `myfirst_open`, an `EINVAL` path in `myfirst_ioctl`, and so on). For each:

1. Identify the underlying cause that would produce this error in the real world.
2. Add a `DPRINTF(sc, MYF_DBG_<class>, ...)` that captures the cause clearly.
3. Write a brief note in `DEBUG.md` explaining what to look for in `dmesg` when the error occurs.

The goal is to make every error in the driver self-explanatory without requiring the reader to cross-reference the source code.

23.11.5 Challenge 23.5: Boot-Time Debug

Modify the driver to log the attach-time version and hardware details only when `bootverbose` is set. The effect should be: a normal boot shows one line, a verbose boot (requested with `boot -v`) shows detailed configuration.

Read `/usr/src/sys/sys/system.h` for the declaration of `bootverbose`, and `/usr/src/sys/kern/subr_boot.c` for examples. Describe in two sentences what FreeBSD uses `bootverbose` for, and why it is better than a driver-specific verbose flag for the particular case of early boot.

23.12 Troubleshooting and Common Mistakes

Every reader will hit at least a few of the issues below. Each one is recorded with the symptom, the likely cause, and the path to a fix.

“My `kldload` fails with `link_elf: symbol X undefined.`”

- Cause: the module depends on a kernel symbol that is not in the running kernel. Usually this means the kernel is older than the module source, or the module was compiled against a different kernel build.
- Fix: rebuild the kernel and module from the same source tree, using the same compile flags. Confirm `uname -a` and the module’s build directory match.

“DTrace says `invalid probe specifier.`”

- Cause: the probe name is mistyped, or the provider/module/function field does not exist at runtime.

- Fix: run `dtrace -l | grep <provider>` to list the available probes, and pick a name from the list. Remember that wildcards must match an existing name.

“WITNESS panics at boot with WITNESS_CHECKORDER.”

- Cause: an early driver (often third-party) violates the declared lock order. Under a stock kernel the violation was silent; under WITNESS it causes an immediate panic.
- Fix: disable the offending driver temporarily, or set `debug.witness.watch=0` at boot time to disable the check, or rebuild the offending driver with a corrected lock order.

“DPRINTF messages do not appear in dmesg.”

- Cause: the corresponding bit in `sc_debug` is not set.
- Fix: confirm the `sysctl` with `sysctl dev.myfirst.0.debug.mask`. Set the bit: `sysctl dev.myfirst.0.debug.mask`. Retry.

“DTrace says probe description myfirst::: matched 0 probes.”

- Cause: either the driver is not loaded, or CTF was not generated (the SDT probes are declared but not visible to DTrace).
- Fix: run `kldstat | grep myfirst` and confirm the module is loaded. If it is, rebuild the kernel with `makeoptions WITH_CTF=1` and reboot.

“Memory leak persists after my fix.”

- Cause: there is more than one leak. The first fix addressed one path, but another path is still leaking.
- Fix: re-examine the `vmstat -m` numbers. If they still grow, trace the allocator: add `device_printf` at every `malloc` and `free` call, reload, exercise the driver, and count the appearances.

“The driver unloads, but vmstat -m still shows nonzero InUse.”

- Cause: the unload path did not release all memory. This is often because something was allocated by `open` but not freed by `close`, and the `close` path was never called before `detach`.
- Fix: verify `destroy_dev_sched_cb` is used to wait for outstanding opens before `detach` proceeds. Every `si_drv1` or `si_drv2` buffer allocated per `open` must be freed in `close` or in the `detach`-ordered callback.

“My fbt probe has a misleading name.”

- Cause: some drivers use inline functions or static helpers that the compiler may have inlined away. The compiled binary shows only the containing function.
- Fix: compile the module with `-O0` or add `__noinline` to the helper. This is useful for debugging only; release builds should use the normal optimisation level.

“ktrace records are too long to read.”

- Cause: default `ktrace` captures many event classes at once.
- Fix: limit to specific classes with `-t` flag: `ktrace -t c ./myftest` captures only syscalls, not I/O or NAMI.

“The kernel boots but prints no driver messages at all.”

- Cause: either the driver is not built into the kernel, or the driver’s probe returned a non-zero error.

- Fix: `kldstat -v | grep myfirst` confirms the module is loaded. `dmesg | grep -i 'probe'` finds the probe messages. If the module is loaded but the driver is not attached, check `device_set_desc` and the probe function's return value.

23.13 Appendix: Real-World Debug Patterns in the FreeBSD Tree

The patterns in Sections 7 and 8 are based on conventions already used by production drivers. A reader who inspects the tree will see variations on these conventions everywhere. This appendix gives a short tour.

if_ath_debug.h (`/usr/src/sys/dev/ath/if_ath_debug.h`) defines approximately 40 verbosity classes covering reset, interrupt, RX, TX, beacon, rate control, channel selection, and many others, each expressed as a bit in a 64-bit mask. The class names follow the `ATH_DEBUG_<subsystem>` pattern (for example `ATH_DEBUG_RECV`, `ATH_DEBUG_XMIT`, `ATH_DEBUG_RESET`, `ATH_DEBUG_BEACON`), and the `DPRINTF` macro follows the standard pattern. The driver uses `ATH_DEBUG_<class>` in hundreds of places throughout the source, giving operators fine-grained control over trace output.

virtqueue.c (`/usr/src/sys/dev/virtio/virtqueue.c`) uses SDT probes heavily. A single `SDT_PROVIDER_DEFINE(virtqueue)` at the top declares the provider, followed by a dozen `SDT_PROBE_DEFINE` calls for each significant event: enqueue, dequeue, notify, and so on. The driver fires the probes inside the hot path, and the probes are no-ops when no script is attached. DTrace scripts like `dtrace -n 'virtqueue::: { @[probename] = count(); }'` give instant visibility into virtio device activity.

if_re.c (`/usr/src/sys/dev/re/if_re.c`) mixes `device_printf`, `printf`, and `if_printf`. The `device_printf` calls appear at attach and detach, where the device identity is useful. `if_printf` appears in the packet paths, where the interface identity matters. `printf` appears in the shared helpers, where neither identity is available. The division of responsibility is pragmatic, not ideological.

uart_core.c (`/usr/src/sys/dev/uart/uart_core.c`) defines `UART_DBG_LEVEL` and a family of `UART_DBG` macros that check the level and log through `printf`. The level is set at compile time via options `UART_POLL_FREQ` and options `UART_DEV_TOLERANCE_PCT`, among others. The design is static: debug decisions are fixed at build time rather than runtime. This is the right choice for a driver that must run in very early boot, when `sysctl` is not yet available.

random_harvestq.c (`/usr/src/sys/dev/random/random_harvestq.c`) uses `WITNESS` extensively. Every lock in the file has a `mtx_assert(&lock, MA_OWNED)` check at the head of each function that relies on the lock. When `WITNESS` is enabled in the build, these assertions catch any caller that forgot to acquire the lock. In release builds, the assertion compiles out and has zero cost.

Across the tree, the pattern is consistent: drivers expose their internals through a combination of static debug logging, SDT probes, and assertion macros. Each of these costs nothing at runtime when disabled, and gives rich visibility when enabled. The reader who adopts this pattern in their own driver writes code that scales gracefully from first-day debugging through production monitoring.

23.14 Appendix: Worked Case Studies in Driver Debugging

The material in this chapter is most useful when it is rehearsed against concrete bugs. This appendix walks through three realistic case studies. Each one begins with a symptom the reader might encounter, follows the

diagnostic steps the tools of this chapter enable, arrives at a root cause, and records the fix. The three cases together cover the three broad categories of driver bugs: a correctness bug in the logging path, a lock-order bug, and a performance bug in the interrupt path.

The cases are written as narrative rather than as a dry sequence of commands because debugging is a narrative process. The experienced developer does not follow a single algorithm; they read a trace, form a hypothesis, test it, refine it, and iterate. These walkthroughs try to preserve that texture while keeping each step reproducible.

23.14.1 Case Study 1: The Missing Message

Symptom. A reader has added a `DPRINTF(sc, MYF_DBG_OPEN, "open ok: count=%d\n", sc->sc_open_count)` line to `myfirst_open`. They set `sysctl dev.myfirst.0.debug.mask=0x2` to enable `MYF_DBG_OPEN`, open the device, and check `dmesg`. Nothing appears.

First hypothesis: the bit is wrong. The reader double-checks the mask. `MYF_DBG_OPEN` is `0x02`, so setting `mask=0x2` should enable it. The hypothesis is wrong.

Second hypothesis: the device is not being opened. The reader runs `cat /dev/myfirst0 > /dev/null` and checks `dmesg`. Still nothing.

Third hypothesis: the sysctl is not actually setting the field. The reader reads the `sysctl` back:

```
sysctl dev.myfirst.0.debug.mask
```

The output shows `0x0`. The write did not take effect. This is the real problem.

Narrowing down. The reader inspects the attach code and finds:

```
SYSCALL_ADD_U32(&sc->sc_sysctl_ctx,  
    SYSCALL_CHILDREN(sc->sc_sysctl_tree),  
    OID_AUTO, "mask",  
    CTLFLAG_RD, &sc->sc_debug, 0, "debug class bitmask");
```

Note: `CTLFLAG_RD` (read-only), not `CTLFLAG_RW`. The `sysctl` was declared read-only, so the `sysctl` command appeared to succeed but actually silently refused the write.

Fix. Change the flag to `CTLFLAG_RW`:

```
SYSCALL_ADD_U32(&sc->sc_sysctl_ctx,  
    SYSCALL_CHILDREN(sc->sc_sysctl_tree),  
    OID_AUTO, "mask",  
    CTLFLAG_RW, &sc->sc_debug, 0, "debug class bitmask");
```

Rebuild, reload, set the mask, open the device, and the message appears.

Lessons learned. Three tools combined to find this bug in under a minute: `dmesg` showed the symptom (missing message), `sysctl` exposed the real state (write not taking effect), and the driver source made the cause visible

(CTLFLAG_RD). Without any one of these, the reader might have wasted ten minutes on a wrong hypothesis. The tools do not replace thinking; they provide the evidence that thinking needs.

The sysctl read-back is a useful discipline in general. Any time a driver value is supposed to be writable, test the write by reading it back. This one habit will catch a class of bugs that have bitten every FreeBSD developer at least once.

23.14.2 Case Study 2: The Intermittent Panic

Symptom. Under light load the driver works perfectly. Under a stress workload (say, one hundred simultaneous readers), the kernel panics with:

```
panic: mutex myfirst_lock recursed on non-recursive mutex myfirst
```

The panic is intermittent: sometimes the workload runs for five minutes before panicking, sometimes it panics immediately. The reader confirms that a debug kernel with options `WITNESS` and options `INVARIANTS` is in use.

First step: read the stack. The panic message includes a stack trace. The relevant lines point at `myfirst_read` as the recursion site, with `myfirst_read` itself already on the stack higher up. Somehow, `myfirst_read` is being called while a previous call to `myfirst_read` is still executing, and both calls are on the same thread.

Hypothesis. Something inside `myfirst_read` is triggering a secondary `myfirst_read` call. The most likely candidate is a `uiomove`, which calls the user program's page-fault path, which in very unusual circumstances can call back into device I/O.

Verification. The reader adds two `DPRINTF` calls, one at entry and one just before `uiomove`, each capturing the current thread:

```
DPRINTF(sc, MYF_DBG_IO, "read entry: tid=%d\n", curthread->td_tid);  
DPRINTF(sc, MYF_DBG_IO, "read about to uiomove: tid=%d\n", curthread->td_tid);
```

Rebuild, reload, run the workload. The kernel log shows two “read entry” messages for the same tid before any “about to uiomove”, which confirms the hypothesis.

Diagnosis. The `mtx_lock(&sc->sc_mtx)` call in `myfirst_read` is held during `uiomove`. The `uiomove` target happens to be in a memory-mapped region of `/dev/myfirst0`, because the test workload was using `mmap` output. The page fault that `uiomove` triggers re-enters `myfirst_read` to service the fault, which attempts to acquire `sc->sc_mtx` a second time.

Fix. The lock should be released before `uiomove`. In general, a sleep lock must never be held across a function that may page-fault.

```
/* buggy version */  
mtx_lock(&sc->sc_mtx);  
error = uiomove(sc->sc_buffer, sc->sc_bufsize, uio);  
mtx_unlock(&sc->sc_mtx);
```

```

/* fixed version */
mtx_lock(&sc->sc_mtx);
/* snapshot the buffer so we can release the lock */
tmp_buffer = sc->sc_buffer;
tmp_bufsize = sc->sc_bufsize;
mtx_unlock(&sc->sc_mtx);
error = uiomove(tmp_buffer, tmp_bufsize, uio);

```

Rebuild, reload, run the stress workload. The panic is gone.

Lessons learned. WITNESS did not catch this directly because it is a recursion, not a lock-order violation. But INVARIANTS turned the recursion into a clean panic instead of silent corruption, and the DPRINTF trace made the chronology visible. The rule “do not hold a sleep lock across uiomove or any function that may sleep” is stated in locking(9) but is easy to forget in practice. Every sleep-lock acquisition in driver code deserves a momentary “could the wrapped call sleep or fault?” check.

23.14.3 Case Study 3: The Slow Interrupt

Symptom. A driver works correctly but the system is sluggish when the device is active. Shell responsiveness drops, interactive applications stutter, and top shows high system CPU.

First step: confirm the driver is the cause. The reader unloads the driver and compares:

```

# before unload
top -aC1 -bn1 | head -20
sudo kldunload myfirst
# after unload
top -aC1 -bn1 | head -20

```

If the sluggishness disappears when the driver unloads, the driver is the source.

Second step: identify the expensive code path. DTrace’s profile provider samples the kernel at a fixed rate and shows where time is being spent:

```

sudo dtrace -n 'profile-1001hz /arg0/ { @[stack(10)] = count(); } tick-10s { exit(0); }'

```

After ten seconds of the workload, the output shows the hottest stacks. If myfirst_intr dominates the sample, the interrupt handler is too heavy.

Third step: measure how long each interrupt takes.

```

sudo dtrace -n 'fbt::myfirst_intr:entry { self->t = timestamp; }
               fbt::myfirst_intr:return /self->t/ {
                   @ = quantize(timestamp - self->t); self->t = 0; }'

```

A healthy handler completes in under 10 microseconds (10 000 nanoseconds). If the quantization shows most invocations in the 100 000 to 1 000 000 nanosecond range (100 microseconds to 1 millisecond), the handler is doing too much work.

Fourth step: read the handler code. The reader inspects `myfirst_intr` and finds:

```
static void
myfirst_intr(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct mbuf *m;

    mtx_lock(&sc->sc_mtx);
    m = m_getcl(M_NOWAIT, MT_DATA, M_PKTHDR);
    if (m != NULL) {
        myfirst_process_data(sc, m);
        m_freem(m);
    }
    mtx_unlock(&sc->sc_mtx);
}
```

The handler does real work: it allocates an mbuf, processes data, and frees the mbuf. `myfirst_process_data` includes several packets of work, each with their own allocation and processing. Under load, each interrupt can hold the CPU for hundreds of microseconds.

Fix. The heavy work moves to a taskqueue. The handler itself does the absolute minimum: acknowledges the interrupt and signals the taskqueue.

```
static void
myfirst_intr(void *arg)
{
    struct myfirst_softc *sc = arg;

    /* Acknowledge the interrupt */
    bus_write_4(sc->sc_res, MYFIRST_REG_INTR_STATUS, 0);
    /* Schedule deferred processing */
    taskqueue_enqueue(sc->sc_tq, &sc->sc_process_task);
}

static void
myfirst_process_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;
    struct mbuf *m;

    mtx_lock(&sc->sc_mtx);
```

```

    m = m_getcl(M_NOWAIT, MT_DATA, M_PKTHDR);
    if (m != NULL) {
        myfirst_process_data(sc, m);
        m_freem(m);
    }
    mtx_unlock(&sc->sc_mtx);
}

```

The taskqueue is set up in attach as explored in Chapter 19.

Rebuild, reload, run the workload. Shell responsiveness returns, top shows the driver contributing a normal amount of system CPU, and the latency quantization of myfirst_intr is now concentrated in the 1 to 10 microsecond bucket.

Lessons learned. Three DTrace measurements guided the fix: profile-1001hz located the hot code, fbt::myfirst_intr:entry/return measured the handler duration, and the final post-fix measurement confirmed the improvement. No source code was modified during diagnosis; the modifications were made only after the bug was understood.

The rule that interrupt handlers must be short is familiar to driver authors, but enforcement is not automatic. Debug builds do not panic on a slow handler. The only way to catch this category of bug is to measure, and DTrace is the right tool for the job. A mature driver team runs fbt::<driver>_intr:entry/return profiling as part of every release cycle; their handlers stay lean because the measurements make any drift visible.

23.14.4 Case Study 4: The Vanishing Device

Symptom. After kldunload myfirst, a second kldload myfirst sometimes panics with a page fault in devfs_ioctl, stack pointing at the old myfirst_ioctl. The panic does not happen every time, but under load (for example, if a daemon is keeping /dev/myfirst0 open across the unload) it is consistently fatal.

First step: read the panic. The stack shows devfs_ioctl -> myfirst_ioctl -> (address not found). The “address not found” is the faulting instruction. This is a use-after-free of function code: the kernel is trying to call a function whose memory has been unmapped.

Hypothesis. The driver’s unload path did not wait for a process that had the device open. The process issued an ioctl between the unload and the re-load; the ioctl dispatched to the now-unmapped myfirst_ioctl.

Verification. The reader inspects myfirst_detach and finds:

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    destroy_dev(sc->sc_cdev);
    bus_release_resource(dev, SYS_RES_MEMORY, 0, sc->sc_mem);
    mtx_destroy(&sc->sc_mtx);
}

```

```

        return (0);
    }

```

The `destroy_dev` call is the issue: it immediately destroys the device node, but in-flight ioctls on the node may still be executing. When `destroy_dev` returns, the driver thinks it is safe to release resources. But the ioctl is still dispatching when those resources go away.

Fix. Use `destroy_dev_sched_cb` (or equivalently, `destroy_dev_sched` and then wait for completion) to defer the actual destruction until no thread is inside the device's methods.

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Tell devfs to destroy the node after all callers finish */
    destroy_dev_sched_cb(sc->sc_cdev, myfirst_detach_cb, sc);
    /* Return success; cleanup happens in the callback */
    return (0);
}

static void
myfirst_detach_cb(void *arg)
{
    struct myfirst_softc *sc = arg;

    bus_release_resource(sc->sc_dev, SYS_RES_MEMORY, 0, sc->sc_mem);
    mtx_destroy(&sc->sc_mtx);
}

```

The detach returns immediately; the actual resource release happens in the callback, which is scheduled to fire only when every caller inside the `cdev`'s methods has exited.

Rebuild, reload repeatedly under the problematic workload. The panic is gone.

Lessons learned. This is the classic use-after-detach bug described in Section 7.4. The debug kernel's `DEBUG_MEMGUARD` option would have caught it earlier by poisoning the freed memory, turning the latent corruption into an immediate page fault on the next call. The fix uses a FreeBSD primitive (`destroy_dev_sched_cb`) that exists precisely for this case. Reading the `cdev`-management documentation in `cdev(9)` is the exercise that prevents this bug in new code.

23.14.5 Case Study 5: The Corrupted Output

Symptom. A user program reads from `/dev/myfirst0` expecting a specific pattern (say, the sequence `0x01`, `0x02`, `0x03`, ...). Most of the time the pattern is correct. Occasionally, on a heavily loaded system, the

pattern is off: a byte or two is wrong, or the sequence is shifted. There is no panic, no error code, just subtly wrong data.

First step: reproduce reliably. The reader writes a small test program that reads repeatedly and compares against the expected pattern. Under load, the mismatches occur at roughly one in ten thousand reads. The reader confirms that unloading the driver and using a simple `/dev/zero` test produces no mismatches, which rules out the user program as the source of the bug.

Hypothesis 1: a race on the buffer. If two threads are reading concurrently, and the buffer is shared without locking, they might corrupt each other. The reader inspects the driver and finds:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;

    /* Generate the pattern into sc->sc_buffer */
    for (int i = 0; i < sc->sc_bufsize; i++)
        sc->sc_buffer[i] = (uint8_t)(i + 1);

    return (uiomove(sc->sc_buffer, sc->sc_bufsize, uio));
}
```

The buffer is per-softc, shared across all opens. Two threads calling read simultaneously write to the same buffer; the second thread overwrites the first's content before the first has finished copying. The uiomove of the first thread then reads partially from the first thread's pattern and partially from the second thread's. The result is a garbled sequence.

Verification. The reader adds a DPRINTF at the start and end of the read, capturing the thread's tid:

```
DPRINTF(sc, MYF_DBG_IO, "read start: tid=%d\n", curthread->td_tid);
/* ... generate and uiomove ... */
DPRINTF(sc, MYF_DBG_IO, "read end: tid=%d\n", curthread->td_tid);
```

When the log is examined during a corruption event, two start messages appear between a single start and its end. The race is confirmed.

Fix. The buffer must either be per-call (allocated on each read) or the access must be serialised with a mutex:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    uint8_t *buf;
    int error;
```

```
    buf = malloc(sc->sc_bufsize, M_MYFIRST, M_WAITOK);
    for (int i = 0; i < sc->sc_bufsize; i++)
        buf[i] = (uint8_t)(i + 1);

    error = uiomove(buf, sc->sc_bufsize, uio);
    free(buf, M_MYFIRST);
    return (error);
}
```

A per-call allocation removes the shared state entirely, and the bug goes away. A lock-based fix is faster for small buffers but allows only one reader at a time; the trade-off depends on the driver's use case.

Lessons learned. The corruption is subtle precisely because it does not produce a panic or an error. WITNESS cannot help here because there is no lock to order. INVARIANTS cannot help because the shared state does not trigger an assertion. The only way to find this is: test the output, observe the corruption, form a hypothesis about races, add instrumentation to confirm the hypothesis, and fix. The DPRINTF pattern is the instrumentation; a disciplined test harness is the reproduction. Together, they solve the problem.

This class of bug is the strongest argument for driver authors to write test harnesses from the start. A small program that reads from the device and compares against an expected output catches many bugs in minutes that would otherwise survive for months in the field.

23.14.6 Summary of the Five Cases

The five case studies covered a deliberately diverse set of bugs. Case 1 was a logging correctness bug, found in seconds once the sysctl was read back. Case 2 was a lock-recursion triggered by a paging path, found by combining a panic trace and DPRINTF. Case 3 was a performance bug in the interrupt handler, diagnosed with DTrace profiling. Case 4 was a use-after-detach in the cdev path, diagnosed with the panic stack and fixed with the correct FreeBSD primitive. Case 5 was a shared-state race in the read path, found with a test harness and DPRINTF.

Three patterns recur across the cases:

1. **Tools find symptoms; reading code finds causes.** No tool pointed directly at the buggy line. Each tool narrowed the search: `vmstat -m`, WITNESS, DTrace, DDB. Then the reader opened the source and found the mistake.
2. **Reproduction is more important than tooling.** A bug that reproduces reliably can be diagnosed with almost any tool. A bug that does not reproduce must be reproduced first, usually by scripting a workload that exercises the suspect path.
3. **Debug infrastructure pays its cost many times over.** The DPRINTF macro, the SDT probes, the `sc_debug` sysctl: each of these took five minutes to add, and each saved hours of debugging later. The reader who writes instrumented code from the start is the reader who avoids the long, painful debug sessions.

With these patterns in mind, the reader is ready to carry the chapter's methods forward. Every new piece of the `myfirst` driver added in later chapters will be developed with DPRINTF calls, SDT probes, and test harnesses in place; the drop in debugging pain will be noticeable from Chapter 24 onward.

23.15 Appendix: Extended DTrace Techniques for Driver Work

This appendix extends Section 5 with a focused tour of DTrace techniques that come up often in driver development. Section 5 introduced the basics; this appendix shows how to combine them productively. Readers who find DTrace useful may want to keep this appendix as a cheat sheet.

23.15.1 Predicates and Selective Tracing

A predicate narrows a probe to events that match a condition. It appears in `/ . . . /` between the probe description and the action:

```
dtrace -n 'fbt::myfirst_read:entry /execname == "myftest"/ {  
    @ = count(); }'
```

Only reads from processes named `myftest` are counted. Predicates can reference `pid`, `tid`, `execname`, `zone-name`, `uid`, and the probe arguments `arg0`, `arg1`, etc.

A common pattern is to filter by `softc` pointer to focus on a single device instance:

```
dtrace -n 'fbt::myfirst_read:entry /args[0] == 0xffffffff8000a0000000/ {  
    @ = count(); }'
```

The literal address of the `softc` comes from `devctl` or from inspecting the driver's `sysctl`. When multiple `myfirst` devices are present, this isolates one at a time.

23.15.2 Aggregations That Tell a Story

Aggregations are DTrace's statistical workhorses. Section 5 introduced `count()` and `quantize()`; other aggregation functions are equally useful:

- `sum(x)`: running total of `x`
- `avg(x)`: running average of `x`
- `min(x)`: minimum of `x` seen
- `max(x)`: maximum of `x` seen
- `lquantize(x, low, high, step)`: linear quantization with bounds
- `llquantize(x, factor, low, high, steps)`: logarithmic quantization with bounds

A typical per-function latency report uses `quantize` because it reveals distribution:

```
dtrace -n 'fbt::myfirst_read:entry { self->t = timestamp; }  
    fbt::myfirst_read:return /self->t/ {  
        @ = quantize((timestamp - self->t) / 1000);  
        self->t = 0; }'
```

Divide by 1000 to convert nanoseconds to microseconds, which makes the buckets meaningful. Add an @buf indexed aggregation to see latency by buffer size:

```
dtrace -n '  
fbt::myfirst_read:entry {  
    self->t = timestamp;  
    self->len = args[1]->uio_resid;  
}  
fbt::myfirst_read:return /self->t/ {  
    @["read", self->len] = quantize((timestamp - self->t) / 1000);  
    self->t = 0;  
}'
```

This aggregates separately for each distinct uio_resid, revealing whether large reads are disproportionately slow.

23.15.3 Thread-Local Variables

The self-> prefix introduces a thread-local variable: each thread sees its own copy. This is how Section 5's latency measurement works: the entry probe stores the timestamp in self->t, and the return probe reads it. Because both probes fire on the same thread, the variable is unambiguous.

Common uses:

```
self->start    /* time of entry for a specific function */  
self->args     /* saved arguments for use in the return probe */  
self->error    /* error code captured from return */
```

Thread-local variables are zeroed by default. Use them freely; their cost is one word of memory per live thread.

23.15.4 Arrays and Associative Access

DTrace arrays are sparse associative arrays, indexed by any expression. Aggregations use them implicitly (the @[key] syntax), but ordinary variables can use them too:

```
dtrace -n 'fbt::myfirst_read:entry {  
    counts[args[0], execname]++; }'
```

Though in practice, aggregations are preferable because they accumulate correctly across all CPUs.

23.15.5 Speculative Tracing

For a high-rate event where most cases are uninteresting, DTrace's speculative tracing buffers output until a decision is made:

```
dtrace -n '  
fbt::myfirst_read:entry {  
    self->spec = speculation();  
    speculate(self->spec);  
    printf("read entry: pid=%d", pid);  
}  
fbt::myfirst_read:return /self->spec && args[1] == 0/ {  
    speculate(self->spec);  
    printf("read return: bytes=%d", arg1);  
    commit(self->spec);  
    self->spec = 0;  
}  
fbt::myfirst_read:return /self->spec && args[1] != 0/ {  
    discard(self->spec);  
    self->spec = 0;  
}'
```

Only reads that return successfully (`args[1] == 0`) have their output committed; failed reads are discarded. This produces a quiet, focused log under heavy load.

Speculative tracing is one of DTrace's most effective features and is rarely needed for small drivers. But for a driver with thousands of events per second, it makes the difference between useful output and an unreadable flood.

23.15.6 Predicate Chains for Narrow Tracing

A common need is to trace one function call tree from a specific entry point. Predicates can chain using thread-local flags:

```
dtrace -n '  
syscall::ioctl:entry /pid == $target/ { self->trace = 1; }  
fbt::myfirst_*: /self->trace/ { printf("%s: %s", probefunc, probename); }  
syscall::ioctl:return /self->trace/ { self->trace = 0; }'
```

Run with `-p <pid>` to target a specific process. The trace flag is set on `syscall` entry and cleared on return, so only driver functions called during the `ioctl` are logged. This pattern is fundamental for isolating a specific user action.

23.15.7 Profiling the Kernel

The profile provider samples the kernel at a regular rate. Useful probes include:

- `profile-97`: samples every 97th of a second, on every CPU
- `profile-1001hz`: samples at 1001 Hz, slightly offset from any whole-second workload
- `profile-5ms`: samples every 5 ms

Each sample records the current stack. Aggregating by stack reveals where time is spent:

```
dtrace -n 'profile-1001hz /arg0/ { @[stack(8)] = count(); }
        tick-10s { exit(0); }'
```

The `arg0` predicate filters out idle CPUs. The `stack(8)` records the top 8 frames. The `tick-10s` ends the run after 10 seconds.

The output looks like:

```
kernel`myfirst_process_data+0x120
kernel`myfirst_intr+0x48
kernel`ithread_loop+0x180
kernel`fork_exit+0x7f
kernel`fork_trampoline+0xe
15823
```

15 823 samples at that stack, out of about 100 000 total (10 seconds * 1001 Hz * a few CPUs). The driver's interrupt path dominates. Combined with the latency measurement above, this is enough to justify a refactor.

23.15.8 Pretty-Printing Structures

A CTF-enabled kernel gives DTrace the types of every kernel structure. This lets `print()` show fields by name instead of raw memory:

```
dtrace -n 'fbt::myfirst_read:entry { print(*args[0]); }'
```

The output shows every field of the struct `myfirst_softc` the read is operating on, by field name, with human-readable values.

The feature depends on CTF having been generated (`makeoptions WITH_CTF=1`). Without CTF, DTrace falls back to address-based printing, which is much less readable.

23.15.9 Ring-Buffered Output

For very long DTrace runs, the default output fills up memory. The `-b` flag sets a ring buffer that discards older records when full:

```
dtrace -b 16m -n 'myfirst::: { trace(timestamp); }'
```

A 16 MB ring holds roughly the last 16 MB of trace output. Older data is overwritten as newer data arrives, which is typically fine for diagnosis: the interesting window is the last few seconds before a problem, not the previous hour.

23.15.10 Exiting Cleanly

DTrace accumulates aggregations in memory until the script exits. For a long run, the reader must exit cleanly to see the aggregations:

```
dtrace -n 'fbt::myfirst_*.entry { @[probefunc] = count(); }  
        tick-60s { printf("%Y\n", walltimestamp); printa(@);  
                  clear(@); }'
```

Every 60 seconds, the aggregate is printed and cleared. The output is a running report, rather than a single report at exit. This pattern is ideal for overnight runs: the output contains per-minute snapshots, and the reader can see how the driver's behaviour evolves.

23.15.11 Summary

These techniques together cover roughly 80% of the DTrace skills a driver author needs. The remaining 20% come from the DTrace Guide and from reading existing scripts in `/usr/share/dtrace/toolkit`.

Two rules of thumb guide advanced use:

1. **Start with the simplest script that might answer the question.** Add predicates only when the script produces too much output. Add aggregations only when counts and times matter.
2. **Validate DTrace's output against a known workload.** Run a simple test case first (say, one open, one read, one close), confirm the DTrace output matches, and only then trust the tool on a complex workload.

With these rules, DTrace is the most capable debugging tool in the FreeBSD arsenal, and the one that rewards every hour of study with months of saved debugging time.

23.16 Appendix: WITNESS Trace Interpretation

WITNESS is often a reader's first exposure to interpreting a kernel diagnostic trace. This appendix walks through the format of a WITNESS violation message and explains what each field means.

23.16.1 The General Format

A WITNESS violation looks like:

```
lock order reversal: (non-sleepable after sleepable)
 1st 0xfffff8000a000000 myfirst_lock (myfirst, sleep mutex) @ myfirst.c:123
 2nd 0xfffff8000a001000 myfirst_intr_lock (myfirst, spin mutex) @ myfirst.c:234
lock order myfirst_intr_lock -> myfirst_lock established at:
#0 0xfffffffff80abcdef at kdb_backtrace+0x1f
#1 0xfffffffff80abcdee at _witness_debugger+0x4f
#2 0xfffffffff80abcdaf at witness_checkorder+0x21f
#3 0xfffffffff80c00000 at _mtx_lock_flags+0x8f
#4 0xfffffffff80ffff00 at myfirst_intr+0x30
#5 ...
panic: witness
```

The message has three sections: the header line, the lock description section, and the backtrace of where the reversed order was first established.

23.16.2 The Header

```
lock order reversal: (non-sleepable after sleepable)
```

This says a spin (non-sleepable) mutex was acquired while a sleep (sleepable) mutex was already held. The reverse order (spin first, then sleep) is allowed; this order (sleep first, then spin) is not.

Common header variants:

- `lock order reversal: (sleepable after non-sleepable)`: means the declared order was later broken by an acquisition that goes the other way
- `spin lock recursion`: attempted to acquire a spin lock that the current thread already holds, which is not allowed except for recursive spin locks
- `spin lock held too long`: a spin lock was held for longer than the threshold (usually multiple seconds)
- `blocking on condition variable with spin lock`: tried to sleep while holding a spin lock

23.16.3 The Lock Descriptions

```
1st 0xfffff8000a000000 myfirst_lock (myfirst, sleep mutex) @ myfirst.c:123
2nd 0xfffff8000a001000 myfirst_intr_lock (myfirst, spin mutex) @ myfirst.c:234
```

- **0xfffff8000a000000**: the address of the mutex in memory
- **myfirst_lock**: the human-readable name passed to `mtx_init`
- **(myfirst, sleep mutex)**: the class (usually the driver name) and the type
- **@ myfirst.c:123**: the source location of the `mtx_init` call (when WITNESS is set up with `DEBUG_LOCKS`)

Both locks appear, first the one that was already held, then the one being acquired.

23.16.4 The Backtrace

The backtrace shows where the reversed order was first recorded. WITNESS remembers the first instance of each (A, B) pair it sees; later violations reference the earlier occurrence. If the first occurrence was valid at the time (for example, both locks were acquired correctly) but a later path reverses them, the backtrace points at the earlier, correct acquisition. The reader may need to search the source for the specific reversal path, which is usually the current stack trace (not shown in this snippet).

Two frames to look for:

1. The function that currently holds the first lock and is trying to acquire the second (or vice versa).
2. The function that first acquired the two locks in the original order.

Comparing the two reveals the conflict.

23.16.5 Reading a Real Example

A common example in new drivers:

```
lock order reversal: (non-sleepable after sleepable)
 1st 0xffff0 myfirst_lock (sleep mutex) @ myfirst.c:100
 2nd 0xffff1 ithread_lock (spin mutex) @ kern_intr.c:234
```

The new driver's code at `myfirst.c:100` acquires `myfirst_lock` (a sleep mutex). Somewhere deeper in the code path, an interrupt scheduling function tries to acquire `ithread_lock` (a spin mutex used by the interrupt subsystem). This is the sleep-then-spin violation, which is always a bug: a spin lock should never be acquired while a sleep lock is held.

The fix: rework the code so that the spin lock (or the subsystem that uses it) is not called while holding `myfirst_lock`. Common approaches include releasing `myfirst_lock` before the call, and then reacquiring it afterward if needed.

23.16.6 Asserting Lock Ownership

Independent of WITNESS, `mtx_assert(&lock, MA_OWNED)` at the top of each function that assumes a lock is held is a strong defensive coding pattern. When `INVARIANTS` is set, the assertion fires on any violation. Combined with WITNESS, these two checks catch the vast majority of lock-related bugs at their first occurrence, long before they corrupt production data.

23.16.7 When WITNESS Is Too Noisy

Occasionally WITNESS produces violations in code that is actually correct, usually because the lock acquisition is guarded by a runtime check that WITNESS cannot see. For those cases, `mtx_lock_flags(&lock, MTX_DUPOK)` or `MTX_NEW` tell WITNESS to allow the acquisition. Use these flags sparingly; most WITNESS violations are real.

23.17 Appendix: Building a Driver-Specific Debug Toolkit

The debug macros and SDT probes added to `myfirst` in Section 8 are a starting point. Over the course of a driver's life, the toolkit grows: more classes, more probes, custom sysctls, perhaps a debug-only ioctl that dumps internal state. This appendix outlines patterns for extending the toolkit.

23.17.1 Debug-Only Sysctls

A sysctl under `dev.myfirst.0.debug.*` is the natural home for runtime debug controls. Add nodes liberally:

- `dev.myfirst.0.debug.mask`: the class bitmask
- `dev.myfirst.0.debug.loglevel`: the syslog priority for `DPRINTF` output
- `dev.myfirst.0.debug.trace_pid`: a PID to focus tracing on
- `dev.myfirst.0.debug.count_io`: a counter of I/O events processed
- `dev.myfirst.0.debug.dump_state`: write-only, triggers a one-shot state dump

Each of these costs very little in size and is enormously useful during field debugging. The rule is: if a piece of state would be useful to inspect during a bug hunt, expose it via sysctl.

23.17.2 A Debug Ioctl

For state too complex or large to expose as a sysctl, a debug-only ioctl is a good choice. Define:

```
#define MYFIRST_IOC_DUMP_STATE _IOR('f', 100, struct myfirst_debug_state)

struct myfirst_debug_state {
    uint64_t    open_count;
    uint64_t    read_count;
    uint64_t    write_count;
    uint64_t    error_count;
    uint32_t    current_mask;
    /* ... */
};
```

The ioctl handler copies the current state into the user buffer. A small user program reads and prints it:

```
struct myfirst_debug_state s;
int fd = open("/dev/myfirst0", O_RDONLY);
ioctl(fd, MYFIRST_IOC_DUMP_STATE, &s);
printf("opens=%llu, reads=%llu, writes=%llu, errors=%llu\n",
       s.open_count, s.read_count, s.write_count, s.error_count);
```

A debug ioctl is especially useful when the state of interest is not a single number but a structure, and when sysctl's type constraints are awkward.

23.17.3 Counters for Key Events

The driver's `softc` gains a set of counters, one per significant event. The counters are simple `uint64_t` fields incremented with `atomic_add_64` or under the `softc` lock. They are exposed via `sysctl` or the `debug ioctl`, and they are cleared at the reader's request:

```
sc->sc_stats.opens++;      /* in open */
sc->sc_stats.reads++;      /* in read */
sc->sc_stats.errors++;     /* on any error path */
```

At ten counters per driver, the memory cost is under 100 bytes, and the visibility into the driver's behaviour is immense. Production monitoring systems can poll the counters periodically and alert on anomalies.

23.17.4 A Self-Test `ioctl`

For complex drivers, a self-test `ioctl` can be invaluable. It runs a sequence of internal tests (each one a function in the driver) and reports which passed and which failed. The results go back as a small structure. An operator debugging a field issue can run the self-test and immediately know whether any of the driver's subsystems are broken.

The self-test `ioctl` is not a substitute for unit testing or integration testing. It is a diagnostic shortcut for the field.

23.17.5 Integration with `rc` Scripts

A debug-aware `rc` script (in `/usr/local/etc/rc.d/myfirst_debug`) can set the debug mask at boot:

```
#!/bin/sh
# PROVIDE: myfirst_debug
# REQUIRE: myfirst
# KEYWORD: shutdown

. /etc/rc.subr

name="myfirst_debug"
rcvar="myfirst_debug_enable"
start_cmd="myfirst_debug_start"
stop_cmd="myfirst_debug_stop"

myfirst_debug_start()
{
    echo "Enabling myfirst debug mask"
    sysctl dev.myfirst.0.debug.mask=${myfirst_debug_mask:-0x0}
}
```

```
myfirst_debug_stop()
{
    echo "Disabling myfirst debug"
    sysctl dev.myfirst.0.debug.mask=0
}

load_rc_config $name
run_rc_command "$1"
```

An operator sets `myfirst_debug_enable=YES` and `myfirst_debug_mask=0x3` in `/etc/rc.conf`, reboots, and the debug infrastructure engages automatically. This pattern is how production systems manage debug verbosity across many devices.

23.17.6 Summary

The infrastructure in Section 8 is enough for the book's running example. Real drivers grow beyond it, acquiring a dozen or more debug-oriented features over time. The pattern is always the same: make instrumentation cheap when off, rich when on, and universally controllable by the operator. With that discipline, a driver remains diagnosable throughout its life.

23.18 Appendix: A Lab Reference for Chapter 23

This last appendix collects the labs into a table with time estimates and dependencies, to help the reader plan their session:

Lab	Topic	Est. time	Dependencies
23.1	First DDB session	15 min	Debug kernel with KDB/DDB
23.2	DTrace measurement of driver	20 min	KDTRACE_HOOKS, CTF, driver loaded
23.3	User-side ktrace of driver access	15 min	ktrace binary, driver loaded
23.4	Memory leak introduction and fix	30 min	Ability to rebuild the module
23.5	Installing the 1.6-debug refactor	60 min	Section 8 material, rebuild setup

Total focused time: about two hours and twenty minutes, plus time to absorb the material. The book's intent is that the reader does each lab at a pace that allows genuine understanding rather than rushing.

Optional follow-ups:

- **23.6 (optional).** Combine `ktrace` and `DTrace` on the same test program, and correlate the user-side trace with the driver-side events.

- **23.7 (optional).** Add a debug ioctl (as described in the Debug Toolkit appendix) and write a small user program that triggers it.

These two extensions solidify the chapter's themes and build practical muscles that every later chapter will exercise.

23.19 Appendix: Complete Annotated Listing of `myfirst_debug.h` and `myfirst_debug.c` Changes

To consolidate Section 8 into a single reference, this appendix collects the full text of the files as they appear after the 1.6-debug refactor, with inline comments explaining each block. A reader who prefers to see the finished code in one place can use this section; the example tree under `examples/part-05/ch23-debug/stage3-refactor/` contains the same text as downloadable files.

23.19.1 `myfirst_debug.h`

```
/*
 * myfirst_debug.h - debug and tracing infrastructure for the myfirst driver
 *
 * This header is included from the driver's source files. It provides:
 * - a bitmask of debug verbosity classes
 * - the DPRINTF macro for conditional device_printf
 * - declarations for SDT probes that the driver fires at key points
 *
 * The matching SDT_PROVIDER_DEFINE and SDT_PROBE_DEFINE calls live in the
 * driver source, which owns the storage for the probe entries.
 */

#ifndef _MYFIRST_DEBUG_H_
#define _MYFIRST_DEBUG_H_

#include <sys/param.h>
#include <sys/systm.h>
#include <sys/sdt.h>

/*
 * Debug verbosity classes. Each class is a single bit in sc->sc_debug.
 * The operator sets sysctl dev.myfirst.0.debug.mask to a combination of
 * these bits to enable the corresponding categories of output.
 *
 * Add new classes here when the driver grows new subsystems. Use the
 * next unused bit and update DEBUG.md accordingly.
 */
```

```

#define MYF_DBG_INIT      0x00000001  /* probe/attach/detach */

 * myfirst_debug.c (or in the main driver source if preferred).
 *
 * Probe argument conventions:
 *   open (softc *, flags)          -- entry, before access check
 *   close (softc *, flags)         -- entry, before state update
 *   io   (softc *, is_write, resid, off) -- entry, into read or write
 */
SDT_PROVIDER_DECLARE(myfirst);
SDT_PROBE_DECLARE(myfirst, , , open);
SDT_PROBE_DECLARE(myfirst, , , close);
SDT_PROBE_DECLARE(myfirst, , , io);

```

```
#endif /* _MYFIRST_DEBUG_H_ */
```

The header has three sections: the class bitmask, the DPRINTF macro, and the SDT probe declarations. Each is small, self-contained, and designed to grow as the driver grows.

23.19.2 The SDT Definitions in `myfirst_debug.c`

```
/*
 * myfirst_debug.c - storage for the SDT probe entries.
 *
 * This file exists to hold the SDT_PROVIDER_DEFINE and SDT_PROBE_DEFINE
 * declarations. By convention in the myfirst driver, these live in a
 * dedicated source file to keep the main driver uncluttered.
 */

#include <sys/param.h>
#include <sys/system.h>
#include <sys/sdt.h>
#include "myfirst_debug.h"

/*
 * The provider "myfirst" exposes all of our static probes to DTrace.
 * Scripts select probes with "myfirst::".
 */
SDT_PROVIDER_DEFINE(myfirst);

/*
 * open: fired on every successful or attempted device open.
 *   arg0 = struct myfirst_softc *
 *   arg1 = int flags from the open call
 */
SDT_PROBE_DEFINE2(myfirst, , , open,
    "struct myfirst_softc *", "int");

/*
 * close: fired on every device close.
 *   arg0 = struct myfirst_softc *
 *   arg1 = int flags
 */
SDT_PROBE_DEFINE2(myfirst, , , close,
    "struct myfirst_softc *", "int");

/*
```

```

* io: fired on every read or write call, at function entry.
*  arg0 = struct myfirst_softc *
*  arg1 = int is_write (0 for read, 1 for write)
*  arg2 = size_t resid (bytes requested)
*  arg3 = off_t offset
*/
SDT_PROBE_DEFINE4(myfirst, , , io,
    "struct myfirst_softc *", "int", "size_t", "off_t");

```

The file is short, intentionally. Its sole purpose is to hold the storage for the probe entries. If the driver grows more probes, the reader adds them here.

23.19.3 Firing the Probes in the Driver

Inside `myfirst.c` (or whichever file implements each method), the probes fire at the appropriate call sites:

```

/*
 * myfirst_open: device open method.
 * Called when a user process opens /dev/myfirst0.
 */
static int
myfirst_open(struct cdev *dev, int flags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error = 0;

    DPRINTF(sc, MYF_DBG_OPEN, "open: pid=%d uid=%d flags=0x%x\n",
        td->td_proc->p_pid, td->td_ucred->cr_uid, flags);

    /* Fire the SDT probe at entry, before any state change. */
    SDT_PROBE2(myfirst, , , open, sc, flags);

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count >= MYFIRST_MAX_OPENS) {
        error = EBUSY;
        goto out;
    }
    sc->sc_open_count++;
out:
    mtx_unlock(&sc->sc_mtx);

    if (error != 0)
        DPRINTF(sc, MYF_DBG_OPEN, "open failed: error=%d\n", error);
    else

```

```

        DPRINTF(sc, MYF_DBG_OPEN, "open ok: count=%d\n",
                sc->sc_open_count);

        return (error);
}

/*
 * myfirst_close: device close method.
 * Called when the last reference to the device is released.
 */
static int
myfirst_close(struct cdev *dev, int flags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;

    DPRINTF(sc, MYF_DBG_OPEN, "close: pid=%d flags=0x%x\n",
            td->td_proc->p_pid, flags);

    SDT_PROBE2(myfirst, , , close, sc, flags);

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open_count > 0)
        sc->sc_open_count--;
    DPRINTF(sc, MYF_DBG_OPEN, "close ok: count=%d\n", sc->sc_open_count);
    mtx_unlock(&sc->sc_mtx);

    return (0);
}

/*
 * myfirst_read: device read method.
 */
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error;

    DPRINTF(sc, MYF_DBG_IO, "read: pid=%d resid=%zu off=%jd\n",
            curthread->td_proc->p_pid,
            (size_t)uio->uio_resid, (intmax_t)uio->uio_offset);

    SDT_PROBE4(myfirst, , , io, sc, 0,
            (size_t)uio->uio_resid, uio->uio_offset);

```

```

        error = myfirst_read_impl(sc, uio);

        if (error != 0)
            DPRINTF(sc, MYF_DBG_IO, "read failed: error=%d\n", error);
        return (error);
}

/*
 * myfirst_write: device write method.
 */
static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error;

    DPRINTF(sc, MYF_DBG_IO, "write: pid=%d resid=%zu off=%jd\n",
        curthread->td_proc->p_pid,
        (size_t)uio->uio_resid, (intmax_t)uio->uio_offset);

    SDT_PROBE4(myfirst, , , io, sc, 1,
        (size_t)uio->uio_resid, uio->uio_offset);

    error = myfirst_write_impl(sc, uio);

    if (error != 0)
        DPRINTF(sc, MYF_DBG_IO, "write failed: error=%d\n", error);
    return (error);
}

```

Each method follows the entry-exit-error pattern:

1. A DPRINTF at entry, showing who called and with what arguments.
2. An SDT_PROBE after the entry log, before the actual work begins.
3. An error-path DPRINTF on any non-zero return.
4. A success-path DPRINTF showing the outcome when useful.

23.19.4 Registering the Sysctl in myfirst_attach

The sysctl that controls sc_debug is registered during device attach:

```

/*
 * Build the debug sysctl tree: dev.myfirst.N.debug.*

```

```

*/
sysctl_ctx_init(&sc->sc_sysctl_ctx);

sc->sc_sysctl_tree = SYSCTL_ADD_NODE(&sc->sc_sysctl_ctx,
    SYSCTL_CHILDREN(device_get_sysctl_tree(sc->sc_dev)),
    OID_AUTO, "debug",
    CTLFLAG_RW, 0, "debug and tracing controls");

SYSCTL_ADD_U32(&sc->sc_sysctl_ctx,
    SYSCTL_CHILDREN(sc->sc_sysctl_tree),
    OID_AUTO, "mask",
    CTLFLAG_RW, &sc->sc_debug, 0,
    "debug class bitmask (see myfirst_debug.h for class definitions)");

```

The detach path tears the sysctl tree down:

```
sysctl_ctx_free(&sc->sc_sysctl_ctx);
```

23.19.5 The Version Bump

At the top of the driver source, the version string and the `MODULE_VERSION` are updated:

```

static const char myfirst_version[] = "myfirst 1.6-debug";

/* ...driver methods, attach, detach, etc... */

MODULE_VERSION(myfirst, 16);

```

And near the top of `myfirst_attach`, the version is logged:

```
DPRINTF(sc, MYF_DBG_INIT, "attach: %s loaded\n", myfirst_version);
```

With the mask set to include `MYF_DBG_INIT`, the operator sees a clean version-reporting line on every attach.

23.19.6 A Sample dmesg With All Classes Enabled

When all classes are enabled and the device is exercised, `dmesg` shows a comprehensive log:

```

myfirst0: attach: myfirst 1.6-debug loaded
myfirst0: open: pid=1234 uid=1001 flags=0x0
myfirst0: open ok: count=1
myfirst0: read: pid=1234 resid=4096 off=0

```

```
myfirst0: close: pid=1234 flags=0x0
myfirst0: close ok: count=0
```

Every event the driver cares about is visible, tagged with the device name, the PID, and the relevant arguments. A field engineer receiving this log can reconstruct the sequence of events without needing source access.

With all classes disabled, `dmesg` shows only the attach line (if `MYF_DBG_INIT` is enabled) or nothing (if the mask is 0). The driver runs at full speed with no observability cost.

23.19.7 A Sample DTrace Session With the Probes

The SDT probes allow machine-readable analysis:

```
$ sudo dtrace -n 'myfirst::: { @[probename] = count(); } tick-10s { exit(0); }'
dtrace: description 'myfirst::: ' matched 3 probes
CPU      ID                FUNCTION:NAME
  0  49012                :tick-10s

close                                43
open                                43
io                                  120
```

Over the 10 seconds of sampling, the driver processed 43 open/close cycles and 120 I/O events. The aggregate is generated without any modification to the driver and at essentially no runtime cost, because no script attached means the probes are inert.

23.19.8 Summary of the Refactor

The 1.6-debug refactor adds roughly 100 lines of code distributed as:

- `myfirst_debug.h`: 50 lines (classes, `DPRINTF`, SDT declarations)
- `myfirst_debug.c`: 30 lines (SDT provider and probe definitions)
- Driver source changes: 20 lines (`sysctl` registration, `DPRINTF` calls, probe firings)

The investment is small; the return is enormous. Every subsequent chapter of the book inherits this infrastructure without additional cost, and every field issue in the driver's future gains a clear diagnostic path.

23.20 Appendix: What the Kernel Does When a Driver Panics

A reader who has followed the chapter so far understands the debugging tools well. The final appendix covers what happens when something goes catastrophically wrong: a panic. The behaviour of the kernel during a panic is not optional for a driver author to understand, because any bug severe enough to panic produces a specific sequence of events that the driver must be correct about.

23.20.1 The Panic Sequence

When any kernel code calls `panic()`, the following happens, in order:

1. The panic message is printed to the console, typically via `printf`.
2. The CPU raises its priority to the maximum, stopping most ordinary kernel activity.
3. If the kernel was built with options `KDB`, and `kdb_unattended` is not set, control transfers to the kernel debugger. The operator sees the `db>` prompt.
4. If the operator (or `kdb_unattended=1`) continues the panic, the kernel initiates a crash dump. The dump writes the current memory image to the crash-dump device (typically `swap`).
5. The kernel reboots (unless `panic_reboot_wait_time` is set).

On the next boot, `savecore(8)` extracts the dump from the swap device, writes it to `/var/crash/vmcore.N`, and rennumbers the counter. The reader can then run `kgdb` against the dump to inspect post-mortem state.

23.20.2 Driver Responsibilities

The panic path places specific requirements on drivers:

1. **Do not panic during detach.** A driver that panics during `detach` prevents clean shutdown of the rest of the kernel. Every `detach` path should be panic-free.
2. **Do not allocate memory in the panic handler.** If the driver registers a shutdown hook that runs during panic, the hook must not call `malloc` or any function that may sleep.
3. **Do not rely on user space during panic.** User programs are frozen during panic; the driver cannot send them messages.
4. **Do not wait for interrupts during panic.** Interrupts may be disabled during the panic path; a driver that waits for one will hang.

These rules apply to shutdown hooks and to the rare paths the kernel traverses during panic. In normal operation, drivers do not run in the panic path, but certain callbacks do.

23.20.3 Reading a Crash Dump

The crash dump is a full memory image of the kernel at the moment of panic. `kgdb` opens it with full symbolic information if the kernel has debug info:

```
sudo kgdb /boot/kernel/kernel /var/crash/vmcore.0
```

Inside `kgdb`, the most useful commands are:

```
(kgdb) bt           # backtrace of the thread that panicked
(kgdb) info threads  # list all threads
(kgdb) thread N      # switch to thread N
(kgdb) frame N       # show frame N (in the current backtrace)
```

```
(kgdb) list          # show source at the current frame
(kgdb) info locals   # show local variables
(kgdb) print var     # show a variable
(kgdb) print *sc     # show the softc pointer contents
(kgdb) ptype struct myfirst_softc # show the structure type
```

Common investigation steps:

1. `bt` to see what panicked.
2. `list` to see the source line.
3. `info locals` to see the local state.
4. `print` fields of interest.
5. `thread apply all bt` to see all threads, in case the panic was triggered by one thread's interaction with another.

23.20.4 Combining Kernel and Driver Symbols

If the driver is built as a module, `kgdb` needs to load its symbols too:

```
(kgdb) add-symbol-file /boot/kernel/myfirst.ko <address>
```

The `<address>` is the load address of the module, which `kldstat -v` shows in the running system, or which appears in the panic output. Once loaded, `kgdb` can decode frames inside the module with full source visibility.

23.20.5 Crash Dump Size

A full crash dump is as large as the kernel's memory usage at the time of the panic, typically gigabytes. The dump device (usually swap) must have enough space. Systems tuned for rapid panic recovery often use a dedicated dump device, not swap, to avoid swap-space constraints.

For drivers-only debugging, a mini dump captures only the kernel's own memory, not user memory. Set `dumpdev=none` or `dumpdev=mini` in `loader.conf` to tune this. Mini dumps are small (tens of megabytes) and load quickly into `kgdb`.

23.20.6 Summary

The panic path is rare in production but essential to understand. A driver that handles its errors cleanly rarely triggers a panic; a driver that does panic produces a crash dump the author can analyse with `kgdb`. The combination of `INVAARIANTS`, `WITNESS`, `DEBUG_MEMGUARD`, and a functioning crash-dump pipeline makes panics into valuable diagnostic events rather than catastrophes.

23.21 Appendix: Chapter 23 at a Glance

This single-page summary is intended as a recap the reader can keep open while they work. Each entry names a concept, points to where it was introduced, and gives the minimal command or code to exercise it.

23.21.1 Tools in order of first use

1. **printf / device_printf** (Section 2): Basic kernel logging. Use `device_printf(dev, "msg\n")` inside driver methods.
2. **log(LOG_PRIORITY, ...)** (Section 2): Syslog-routed logging, with a priority level. Use for messages that belong in `/var/log/messages`.
3. **dmesg** (Section 3): Read the kernel message buffer. Combine with `grep` and `tail` for filtered output.
4. **/var/log/messages** (Section 3): Persistent log history. `syslogd(8)` writes to it; `newsyslog(8)` rotates it.
5. **Debug kernel** (Section 4): Rebuild with `KDB`, `DDB`, `INVARIANTS`, `WITNESS`, `KDTRACE_HOOKS`, and `DEBUG=-g`. Slower but diagnostic.
6. **ddb** (Section 4): Interactive kernel debugger. Enter via `sysctl debug.kdb.enter=1` or a console break. Use `bt`, `show locks`, `ps`, `continue`.
7. **kgdb** (Section 4): Post-mortem debugger. Open `/boot/kernel/kernel` and `/var/crash/vmcore.N` together.
8. **DTrace** (Section 5): Live tracing and measurement. `dtrace -n 'fbt::myfirst_*:entry { @[probe-func] = count(); }'`.
9. **SDT probes** (Section 5, Section 8): Static trace points in the driver source. `dtrace -n 'myfirst::: { @[probename] = count(); }'`.
10. **ktrace/kdump** (Section 6): User-side syscall tracing. `sudo ktrace -di -f trace.out ./program; kdump -f trace.out`.
11. **vmstat -m** (Section 7.1): Per-pool kernel memory view. Used to detect leaks.

23.21.2 Reflexes to build

- Add a `device_printf` before you suspect a bug, not after.
- Check `dmesg` before guessing about driver behavior.
- Rebuild with `INVARIANTS` and `WITNESS` during development.
- Write DTrace one-liners instead of compile-reload cycles when the question is “does this fire?”.
- Maintain `vmstat -m` stability as a continuous invariant, not an after-the-fact check.
- Never hold a sleep lock across `uiomove` or any sleeping call.
- Make interrupt handlers short. Push work to `taskqueue`.
- Match every `malloc` with a `free`. Test the match with the tools.

23.21.3 The 1.6-debug refactor

- Adds `myfirst_debug.h` with 8 verbosity classes and the `DPRINTF` macro.
- Adds a `sysctl dev.myfirst.0.debug.mask` for runtime control.
- Adds three SDT probes: `myfirst:::open`, `myfirst:::close`, `myfirst:::io`.
- Follows the `entry/exit/error` pattern across every method.
- Bumps `myfirst_version` to 1.6-debug and `MODULE_VERSION` to 16.

23.21.4 Recommended next steps

- Complete all five labs if time allows.

- Attempt Challenge 23.2, the custom DTrace script.
- Keep a personal lab logbook entry for this chapter.
- Read `/usr/src/sys/dev/ath/if_ath_debug.h` as a real-world reference.
- Before starting Chapter 24, confirm the driver is at version 1.6-debug and the debug mask is responsive.

This concludes the chapter's reference material. The "Wrapping Up" and bridge sections that follow prepare the reader for Chapter 24.

23.22 Wrapping Up

Chapter 23 introduced the working methods and tools of FreeBSD kernel debugging. The chapter's structure followed a deliberate arc: explain why kernel debugging is different, teach the core logging and inspection tools, build a debug kernel, master DTrace and ktrace, recognise the common bug classes, and finally refactor the `myfirst` driver to support its own observability.

Along the way the chapter has earned its place in the book. It sits between the architectural work of Part 4 and the integration work of Part 5 because the remaining chapters will add substantial new code to `myfirst` (devfs hooks, ioctl, sysctl, network interfaces, GEOM interfaces, USB support, virtio support) and each of those chapters depends on the ability to see what the driver is doing and to fix problems as they arise. The tooling and instrumentation are not an afterthought; they are how the rest of the book stays manageable.

The driver itself is now at version 1.6-debug. Its softc carries an `sc_debug` mask; the tree has a `sysctl dev.myfirst.0.debug` subtree; the `DPRINTF` macro gates logging by class; and three SDT probes expose the open, close, and I/O events. Every later chapter in Parts 5, 6, and 7 will extend the same framework: new classes will appear in `myfirst_debug.h`, and new probes will be declared as the driver acquires new functional boundaries.

23.22.1 What the reader can now do

- Use `device_printf`, `log`, and the `DPRINTF` macro pattern to log structured kernel events.
- Read `dmesg` and `/var/log/messages` to locate driver messages and correlate them with events.
- Build a debug kernel with `KDB`, `DDB`, `INVARIANTS`, `WITNESS`, and `KDTRACE_HOOKS`.
- Write DTrace one-liners that count, aggregate, and time kernel events.
- Use `ktrace` and `kdump` to observe user-side interactions with the driver.
- Recognise the most common driver bugs and match them to the right debug tool.
- Declare SDT probes and expose them to DTrace scripts.
- Bump the driver's version and carry the debug infrastructure forward.

23.22.2 What lies ahead

With the debug infrastructure in place, Chapter 24 (Integrating with the Kernel: devfs, ioctl, and sysctl) will extend the driver's interface to user space. The reader will create richer `cdev` entries, define custom ioctls, and register tuning sysctls for the driver's runtime parameters. Every one of those additions can now be instrumented and traced with the framework from this chapter, so the work will be grounded in visible, debuggable behaviour from the first line.

The debug arsenal built in Chapter 23 will see heavy use from here on. In Chapter 24 the reader will add their first real ioctl, and the first time an argument arrives with the wrong value, they will turn on MYF_DBG_IOCTL, read the log, and find the mistake in seconds rather than hours. In Chapter 25 (Writing Character Drivers in Depth), the reader will use DTrace to confirm that the driver's select/poll path is firing correctly. In Chapter 26 and beyond, each new subsystem hook will be logged through DPRINTF and probed with SDT. The debug chapter's return on investment is long and steady.

A final encouragement: the tools of this chapter are not glamorous. They do not produce working drivers on their own. But they are what turns a frustrating six-hour bug into a crisp twenty-minute diagnosis. Every experienced FreeBSD developer has, on at least a dozen occasions, traced a problem through `vmstat -m`, then DTrace, then the source code, and emerged with a precise fix. The reader who masters the toolbox of this chapter joins that group and is now ready for the richer integration work that follows.

23.23 Bridge to Chapter 24

Chapter 24 (Integrating with the Kernel: devfs, ioctl, and sysctl) opens the next arc of the book. Up to Chapter 23 the driver has been a single cdev node with fixed behaviour. Chapter 24 makes the interface expressive: readers will extend the cdev into richer devfs entries, define custom ioctls to configure the device, and register sysctl nodes for runtime parameters.

The bridge is direct. The debug mask introduced in Section 8 is a sysctl. The ioctls in Chapter 24 will be traced through MYF_DBG_IOCTL. The custom devfs nodes will log their creation and destruction through MYF_DBG_INIT. When the reader builds new features in Chapter 24, the debug framework is ready to observe them.

See you in Chapter 24.

23.24 Reference: Chapter 23 Quick-Reference Card

The table below summarises the tools, commands, and patterns introduced in Chapter 23 for quick lookup.

23.24.1 Logging

Call	Use
<code>printf(...)</code>	Very basic logging; no device identity.
<code>device_printf(dev, "...")</code>	Standard driver log; prefixes with device name.
<code>log(LOG_PRI, "...")</code>	Syslog with priority; sent to <code>/var/log/messages</code> .
<code>DPRINTF(sc, CLASS, "...")</code>	Conditional on <code>sc->sc_debug & CLASS</code> ; standard driver macro.

23.24.2 Syslog priority levels

Priority	Meaning
LOG_EMERG	System is unusable.
LOG_ALERT	Action must be taken immediately.
LOG_CRIT	Critical conditions.
LOG_ERR	Error conditions.
LOG_WARNING	Warning conditions.
LOG_NOTICE	Normal but significant condition.
LOG_INFO	Informational.
LOG_DEBUG	Debug-level messages.

23.24.3 Kernel options for debugging

Option	Effect
options KDB	Includes the kernel debugger framework.
options DDB	Interactive debugger UI on console.
options DDB_CTF	CTF support in DDB for type-aware printing.
options KDB_TRACE	Automatic backtrace on entry to KDB.
options KDB_UNATTENDED	Panics reboot instead of dropping into DDB.
options INVARIANTS	Enables KASSERT, MPASS, and other kernel assertions.
options WITNESS	Tracks lock order and panics on violations.
options WITNESS_KDB	Drops to KDB on a WITNESS violation.
options DEBUG_MEMGUARD	Poisons freed memory; catches use-after-free.
options KDTRACE_HOOKS	Enables DTrace probes.
options KDTRACE_FRAME	Produces frame pointers for DTrace stack walks.
makeoptions WITH_CTF=1	Generates CTF in the kernel and modules.
makeoptions DEBUG=-g	Includes full DWARF in the kernel and modules.

23.24.4 Common DTrace one-liners

```
# Count every function entry in the driver
dtrace -n 'fbt::myfirst_*.entry { @[probfunc] = count(); }'

# Measure the time spent in a specific function
dtrace -n 'fbt::myfirst_read.entry { self->t = timestamp; }
```

```

        fbt::myfirst_read:return /self->t/ {
            @ = quantize(timestamp - self->t); self->t = 0; }'

# Count SDT probes fired by the driver
dtrace -n 'myfirst::: { @[probename] = count(); }'

# Show syscall frequency for a named process
dtrace -n 'syscall:::entry /execname == "myftest"/ { @[probefunc] = count(); }'

# Aggregate I/O sizes through the driver
dtrace -n 'myfirst:::io { @ = quantize(arg2); }'

```

23.24.5 ktrace / kdump workflow

```

# Record a process under ktrace
sudo ktrace -di -f trace.out ./myprogram

# Dump in human-readable form
kdump -f trace.out

# Filter for syscalls only
kdump -f trace.out | grep -E 'CALL|RET|NAMI'

```

23.24.6 Debugging checklist (abbreviated)

1. Is dmesg clean? If not, read the last message before the problem.
2. Is vmstat -m stable for the driver's pool? If not, look for a leak.
3. Does WITNESS panic on the workload? If yes, the lock order is wrong.
4. Do the fbt::myfirst_*:entry counts match the expected activity? If not, check the paths.
5. Does the user-side ktrace show the expected syscall sequence? If not, check the ioctl or command setup.
6. Is the driver at the expected version? kldstat -v | grep myfirst and confirm MODULE_VERSION.

23.25 Reference: Glossary of Chapter 23 Terms

CTF: Compact C Type Format. A kernel type-information format that DDB and DTrace use to print typed structures. Requires makeoptions WITH_CTF=1.

DDB: The built-in FreeBSD kernel debugger. Interactive, console-based. Activated by options DDB.

DDB_CTF: A DDB option that lets the debugger print typed values using CTF type information.

device_printf: The FreeBSD-standard logging function for driver messages. Prefixes output with the device's name.

DPRINTF: The conventional driver macro for conditional logging, gated on a verbosity mask.

DTrace: A dynamic tracing framework. Uses `fbt`, `syscall`, `sdt`, `io`, `sched`, `lockstat`, and other providers.

fbt: Function Boundary Tracing. A DTrace provider that traces entry and return of every kernel function.

INVARIANTS: A kernel build option that enables `KASSERT`, `MPASS`, and related assertions. Standard for debug builds.

KASSERT: An assertion macro that evaluates only when `INVARIANTS` is set. Panics if the condition is false.

KDB: The kernel debugger framework. `DDB` is one backend.

KDTRACE_HOOKS: The kernel build option that enables DTrace probes.

kdump: The user-space tool that reads `kttrace` output files and prints them in human-readable form.

kttrace: The user-space tool that records syscalls and other events of a given process.

log: The kernel function for sending messages to `syslog` with a priority level.

MPASS: Similar to `KASSERT` but with a compile-time-only check. Zero cost in release builds.

myfirst_debug.h: The debug header introduced in Section 8, declaring verbosity classes and SDT probe structures.

sc_debug: The `uint32_t` field in the driver's `softc` that controls which `DPRINTF` categories are active.

SDT: Statically Defined Tracing. Compile-time probes that DTrace can attach to.

SDT_PROBE_DEFINE: Macro family that registers a new SDT probe in the kernel or driver.

syslog: The BSD logging subsystem; message priorities map to destinations per `/etc/syslog.conf`.

vmstat -m: A user-space tool that shows per-pool kernel memory statistics.

WITNESS: A kernel lock-order verification system. Panics on lock-order violations when options `WITNESS` is set.

1.6-debug: The driver version after Section 8. Carries the verbosity mask, `sysctl`, `DPRINTF` pattern, and SDT probes.

24 Integrating with the Kernel

24.1 Reader Guidance & Outcomes

Chapter 23 closed with a driver that can finally explain itself. The `myfirst` driver at version 1.6-debug knows how to log structured messages through `device_printf`, how to gate verbose output through a runtime `sysctl` mask, how to expose static probe points to DTrace, and how to leave a paper trail an operator can read back later. Combined with the power discipline added in Chapter 22, the DMA pipeline added in Chapter 21, and the interrupt machinery added in Chapter 19 and Chapter 20, the driver is now a complete unit in itself: it boots, it runs, it talks to a real PCI device, it survives suspend and resume, and it tells the developer what it is doing along the way.

What the driver does not yet do is behave like a citizen of the wider kernel. There is still very little of `myfirst` that an outside program can see, control, or measure. The driver creates exactly one device node when the module loads. There is no way for a user-space tool to ask the driver to reset itself, to flip a configuration knob at runtime, or to read out a counter. There are no metrics in the system's `sysctl` tree that an operator could feed to a monitoring system. There is no way to give the driver several instances cleanly. There is no integration with the network stack, with the storage stack, or with any of the kernel subsystems users routinely reach for from their own programs. In every meaningful sense, the driver is still standing alone in the corner. Chapter 24 is the chapter that brings it into the room.

Chapter 24 teaches kernel integration at the right level for this stage of the book. The reader will spend this chapter learning what integration actually means, why it matters more than it looks at first, and how each integration surface is built. The chapter starts with the conceptual story: the difference between a working driver and an integrated driver, and the cost of leaving integration as an afterthought. It then spends most of its time on the four interfaces a typical FreeBSD driver always integrates with: the device file system `devfs`, the user-controlled `ioctl(2)` channel, the system-wide `sysctl(8)` tree, and the kernel's lifecycle hooks for clean attach, detach, and module unload. After those four come two optional chapters in miniature, one for drivers whose hardware is a network device and one for drivers whose hardware is a storage controller. Both are introduced at the conceptual level so the reader recognises them when they appear later in Part 6 and Part 7, and neither is taught in full because each will eventually deserve its own chapter. The chapter then steps back to discuss the discipline of registration and teardown across all of these surfaces: the order matters, the failure paths matter, the corner cases under stress matter, and a driver that gets the integration interfaces right but the lifecycle wrong is still a fragile driver. Finally the chapter closes with a refactor that splits the new code into its own files, bumps the driver to version 1.7-integration, updates the version banner, and leaves the source tree organised for everything that follows.

The arc of Part 5 continues here. Chapter 22 made the driver survive a change of power state. Chapter 23 made the driver tell you what it is doing. Chapter 24 makes the driver fit naturally into the rest of the system, so that the tools and habits FreeBSD users already know carry over to your driver without surprises. Chapter 25 will continue the arc by teaching the maintenance discipline that keeps a driver readable, tunable, and extensible as

it evolves, and Part 6 will then begin the transport-specific chapters that lean on every quality the Part 5 chapters have built.

24.1.1 Why `devfs`, `ioctl`, and `sysctl` Integration Earn a Chapter of Their Own

One concern that surfaces here is whether wiring up `devfs`, `ioctl`, and `sysctl` really deserves a full chapter. The driver already has a single `cdev` node from a much earlier chapter. Adding an `ioctl` looks small. Adding a `sysctl` looks even smaller. Why spread the work over a long chapter, when each interface looks like a few dozen lines of code?

The answer is that the few-dozen-lines view is the easy part. Each interface has a set of conventions and pitfalls that are not obvious from reading the API once, and the cost of getting them wrong is paid not by the developer but by the operator who tries to monitor the driver, the user who tries to reset the device, the packager who tries to load and unload the module under load, and the next developer who tries to extend the driver six months later. Chapter 24 spends its time on those conventions and pitfalls because that is where the value is.

The first reason this chapter earns its place is that **the integration interfaces are how everything else reaches the driver**. A reader who has followed the book this far has built a driver that does interesting work, but only the kernel itself currently knows how to ask the driver to do that work. Once the driver has an `ioctl` interface, a shell script can drive it. Once the driver has a `sysctl` tree, a monitoring system can watch it. Once the driver creates `/dev` nodes that follow the standard conventions, a packager can ship `udev`-style rules, the system administrator can write `/etc/devfs.rules` for it, and another driver can layer on top of it through `vop_open` or through `ifnet`. None of that depends on what the driver is for; all of it depends on whether the integration is done well.

The second reason is that **integration choices show up in production failure modes**. A driver that calls `make_dev` from the wrong context can deadlock at module load. A driver that omits the `_IO`, `_IOR`, `_IOW`, `_IOWR` discipline forces every caller to invent a private convention for who copies what across the user-kernel boundary, and at least one of those callers will get it wrong. A driver that forgets to call `sysctl_ctx_free` on detach leaks OIDs, and the next module load that uses the same name fails with a confusing message. A driver that destroys its `cdev` before draining its open file handles produces use-after-free panics. Chapter 24 spends paragraphs on each of these because each is a real bug the FreeBSD community has had to chase down across the years, and the right time to learn the discipline is before writing the first line of integration code, not after.

The third reason is that **the integration code is the first place a driver's design becomes visible to someone other than its author**. Until Chapter 24 the driver was a black box with one method table and one device node. From Chapter 24 onward, the driver has a public surface. The names of its `sysctls` show up in monitoring graphs. The numbers of its `ioctls` show up in shell scripts and in user-space libraries. The layout of its `/dev` nodes shows up in package documentation and in administrator runbooks. Once a public surface exists, changing it has a cost. The chapter therefore takes care to teach the conventions that keep the surface stable as the driver evolves. The version bump to 1.7-integration is also the first version of the driver that has a real public face; everything before it was an internal milestone.

Chapter 24 earns its place by teaching those three ideas together, concretely, with the `myfirst` driver as the running example. A reader who finishes Chapter 24 can integrate any FreeBSD driver into the standard system interfaces, knows the conventions and pitfalls of each integration surface, can read another driver's integration code and identify what is normal and what is unusual, and has a `myfirst` driver that other software can finally talk to.

24.1.2 Where Chapter 23 Left the Driver

A short checkpoint before the real work starts. Chapter 24 extends the driver produced at the end of Chapter 23, tagged as version 1.6-debug. If any of the items below is uncertain, return to Chapter 23 and fix it before starting this chapter, because the integration topics assume the debug discipline already exists, and several of the new integration surfaces will use it.

- Your driver compiles cleanly and identifies itself as 1.6-debug in `kldstat -v`.
- The driver still does everything it did at 1.5-power: it attaches to a PCI (or simulated PCI) device, allocates MSI-X vectors, runs a DMA pipeline, and survives `devctl suspend myfirst0` followed by `devctl resume myfirst0`.
- The driver has a `myfirst_debug.c` and `myfirst_debug.h` pair on disk. The header defines `MYF_DBG_INIT`, `MYF_DBG_OPEN`, `MYF_DBG_IO`, `MYF_DBG_IOCTL`, `MYF_DBG_INTR`, `MYF_DBG_DMA`, `MYF_DBG_PWR`, and `MYF_DBG_MEM`. The `DPRINTF(sc, MASK, fmt, ...)` macro is in scope from any source file in the driver.
- The driver has three SDT probes named `myfirst:::open`, `myfirst:::close`, and `myfirst:::io`. The simple DTrace one-liner `dtrace -n 'myfirst::: { @[probenam] = count(); }'` returns counts when the device is exercised.
- The softc carries a `uint32_t sc_debug` field, and `sysctl dev.myfirst.0.debug.mask` reads and writes it.
- The driver has a `DEBUG.md` document beside the source. `HARDWARE.md`, `LOCKING.md`, `SIMULATION.md`, `PCI.md`, `INTERRUPTS.md`, `MSIX.md`, `DMA.md`, and `POWER.md` are also up to date in your working tree from earlier chapters.
- Your test kernel still has `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, `KDB_UNATTENDED`, `KDTRACE_HOOKS`, and `DDB_CTF` enabled. Chapter 24's labs use the same kernel.

That driver is what Chapter 24 extends. The additions are bigger than in Chapter 23 in code lines, but smaller in conceptual surface. The new pieces are: a richer `/dev/myfirst0` node that can clone instances on demand, a small set of well-typed ioctls with a public header that user-space programs can include, a per-instance `sysctl` subtree under `dev.myfirst.N` exposing a handful of metrics and one writable knob, a refactor that splits the new code into `myfirst_ioctl.c` and `myfirst_sysctl.c` with matching headers, a small companion user-space program named `myfirstctl` that exercises the new interfaces, an `INTEGRATION.md` document beside the source, an updated regression test, and a version bump to 1.7-integration.

24.1.3 What You Will Learn

Once you have finished this chapter, you will be able to:

- Explain what kernel integration means in concrete FreeBSD terms, distinguish a self-contained driver from an integrated one, and name the specific user-visible benefits each integration surface delivers.
- Describe what `devfs` is, how it differs from older static `/dev` schemes, and how device nodes come into and out of existence under it. Use `make_dev`, `make_dev_s`, `make_dev_credf`, and `destroy_dev` correctly. Choose the right flag set, ownership, and mode for a node.
- Initialise and populate a `struct cdevsw` with the modern `D_VERSION` field, the minimal callback set, and the optional callbacks (`d_kqfilter`, `d_mmap_single`, `d_purge`).

- Use the `cdev->si_drv1` and `si_drv2` fields to attach per-node driver state, and read that state back from inside the `cdevsw` callbacks.
- Create more than one device node from a single driver instance and choose between fixed-name nodes, indexed nodes, and clonable nodes through the `dev_clone` event handler.
- Set per-node permissions and ownership at creation time, and adjust them after creation through `devfs.rules` so administrators can grant access without rebuilding the driver.
- Explain what `ioctl(2)` is, how the kernel encodes `ioctl` commands using `_IO`, `_IOR`, `_IOW`, and `_IOWR`, what each macro means about the direction of data flow, and why getting the encoding right matters for portability between 32-bit and 64-bit user space.
- Define a public `ioctl` header for a driver, choose a free magic letter, and document each command so that user-space callers can rely on the interface across releases.
- Implement a `d_ioctl` handler that dispatches on the command word, performs the per-command logic safely, and returns the right `errno` on each failure path.
- Read and understand the kernel's automatic copyin/copyout layer for `ioctl` data and recognise the cases where the driver still has to copy memory itself: variable-length payloads, embedded user pointers, and structures whose layout requires explicit alignment.
- Explain `sysctl(9)`, distinguish static OIDs from dynamic OIDs, and walk through the `device_get_sysctl_ctx` and `device_get_sysctl_tree` pattern that gives every device its own subtree.
- Add read-only counters using `SYSCTL_ADD_UINT` and `SYSCTL_ADD_QUAD`, add writable knobs with appropriate access flags, and add custom procedural OIDs with `SYSCTL_ADD_PROC` for cases where the value has to be computed at read time.
- Manage tunables that a user can set in `/boot/loader.conf` with `TUNABLE_INT_FETCH`, and combine tunables and sysctls so the same configuration knob can be set at boot or adjusted at runtime.
- Recognise the introductory shape of FreeBSD's networking integration: how `if_alloc`, `if_initname`, `if_attach`, `bpfattach`, `if_detach`, and `if_free` compose; what an `if_t` is at the conceptual level; and what role drivers play in the larger `ifnet` machinery. Understand that Chapter 28 returns to this in depth.
- Recognise the introductory shape of FreeBSD's storage integration: what CAM is, how `cam_sim_alloc`, `xpt_bus_register`, the `sim_action` callback, and `xpt_done` compose; what a CCB is conceptually; and why CAM exists at all. Understand that Chapter 27's storage drivers and Chapter 27's GEOM material return to this in depth.
- Apply a registration and teardown discipline that is robust under repeated `kldload/kldunload`, under attach failure midway through `bringup`, under detach failure when in-flight users still hold open file descriptors, and under genuine surprise removal of the underlying device.
- Refactor a driver that has accumulated several integration surfaces into a maintainable structure: a separate file per integration concern, a public header for user space, a private header for in-driver use, and an updated build system that compiles all of the pieces into a single kernel module.

The list is long because integration touches several subsystems. Each item is narrow and teachable. The chapter's work is putting them together into a single coherent driver.

24.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 24 stays focused on integration discipline.

- **The full implementation of an ifnet network driver**, including transmit and receive queues, multi-queue coordination through `iflib(9)`, BPF integration beyond the introductory `bpfattach` call, link-state events, and the full Ethernet driver lifecycle. Chapter 28 is the dedicated network driver chapter and assumes Chapter 24's integration discipline is already in place.
- **The full implementation of a CAM storage driver**, including target mode, the full CCB type set, asynchronous notifications through `xpt_setup_ccb` and `xpt_async`, and the geometry presentation through `disk_create` or `GEOM`. Chapter 27 covers the storage stack in depth.
- **GEOM integration**, including providers, consumers, classes, `g_attach`, `g_detach`, and the GEOM event machinery. GEOM is its own subsystem with its own conventions; Chapter 27 covers it.
- **epoch(9)-based concurrency**, which is the modern locking pattern for ifnet hot paths. Chapter 24 mentions it only in context. Chapter 28 (network drivers) returns to it alongside `iflib(9)` where epoch-style concurrency is needed in practice.
- **mac(9) (Mandatory Access Control) integration**, which adds policy hooks around the integration surfaces. The MAC framework is a specialised topic that does not yet apply to the simple `myfirst` driver.
- **vfs(9) integration**, which is what file systems do. A character driver does not interact with VFS at the layer of `vop_open` or `vop_read`; it interacts with `cdevsw` and `devfs`. The chapter is careful not to confuse the two.
- **Cross-driver interfaces through kobj(9) and custom interfaces declared with the INTERFACE build mechanism**. These are how the network and storage stacks define their internal contracts. They are mentioned in context in Section 7 but the deep treatment belongs in a later, more advanced chapter.
- **The new netlink(9) interface that recent FreeBSD kernels expose for some network management traffic**. Netlink is currently used by the routing subsystem rather than by individual device drivers, and the right place to teach it is alongside the network chapter.
- **Custom protocol modules through pr_protocol_init**, which is for new transport protocols rather than for device drivers.

Staying inside those lines keeps Chapter 24 a chapter about how a driver becomes part of the kernel, not a chapter about every kernel subsystem a driver may eventually touch.

24.1.5 Estimated Time Investment

- **Reading only**: four to five hours. Chapter 24's ideas are mostly conceptual extensions of things the reader has already met. The new vocabulary (`devfs`, `cdev`, `ioctl`, `sysctl`, `ifnet`, `CAM`) is mostly familiar by name from earlier chapters; the chapter's job is to give each of them a concrete shape.
- **Reading plus typing the worked examples**: ten to twelve hours over two or three sessions. The driver evolves through three integration surfaces in turn (`devfs`, `ioctl`, `sysctl`), each with its own short stage. Each stage is short and self-contained; the testing is what takes the time, because the integration surfaces are best tested by writing a small user-space program that drives them.
- **Reading plus all labs and challenges**: fifteen to eighteen hours over three or four sessions. The labs include a clone-aware `devfs` experiment, a full `ioctl` roundtrip with `myfirstctl`, a `sysctl`-driven counter monitoring exercise, a cleanup-discipline lab that intentionally breaks teardown to expose the failure pattern, and a small `ifnet`-stub challenge for readers who want a preview of Chapter 28.
