The `virtqueue_disable_intr` call tells the device not to interrupt again until re-enabled. The driver then drains the ring. The `virtqueue_enable_intr` call arms interrupts, but only if no new buffer has arrived in the meantime; if one has, it returns nonzero and the loop continues. This is a standard pattern that minimises interrupt rate without ever missing a completion.

30.12.9 Putting the Pieces Together

Time, memory, and interrupts are not glamorous topics, but they are where the rubber meets the road for drivers that want to be correct under virtualisation. The guidelines distil to a small set of disciplines:

- Use the kernel's time APIs rather than rolling your own.
- Treat the device's state as a thing that can disappear on resume; write `device_resume` correctly.
- Do not pin more memory than necessary, and go through `bus_dma(9)` for every DMA address.
- Prefer MSI-X over INTx.
- Use the virtqueue event-index mechanism where appropriate to reduce interrupt rate.

These are the disciplines of any well-written driver; under virtualisation they are not optional. A driver that follows them will work in a VM. A driver that violates them will work on bare metal and fail in the field on a customer's VM, sometimes in ways that are difficult to reproduce.

With that grounding in place, we can zoom out one more time and look at how these ideas travel to architectures other than amd64.

30.13 Section 10: Virtualisation on Other Architectures

FreeBSD runs well on amd64, arm64, and riscv64. The virtualisation story on amd64 is the one we have been telling: `bhyve(8)` uses Intel VT-x or AMD-V, guests see PCI-based VirtIO devices, the IOMMU is VT-d or

AMD-Vi, and the general flow is familiar. On the other architectures, the pieces are similar but the specifics differ. For a driver author, most of this is invisible, because FreeBSD's virtualisation APIs are architecture-independent. But a few practical points are worth knowing, and a few drivers have architecture-specific behaviour that only surfaces under virtualisation.

30.13.1 arm64 Virtualisation

On arm64, the hypervisor mode is called *EL2* (Exception Level 2), and the virtualisation extensions are part of the architecture's standard specification (ARMv8-A virtualisation). A guest runs in EL1 under the hypervisor in EL2. There is no direct amd64-style INTx; the interrupt controller is the *GICv3* (Generic Interrupt Controller version 3), and interrupt virtualisation is provided by the GIC's *virtual CPU interface*.

FreeBSD has an arm64 bhyve(8) host-side port under development that targets a future release; as of FreeBSD 14.3 the vmm implementation ships only for amd64, so arm64 hosts do not yet run guests natively. The guest side of FreeBSD, however, already uses the same `virtio_mmio` and `virtio_pci` transports that amd64 does, so a FreeBSD guest running on an arm64 hypervisor (for example, KVM or a future arm64 bhyve) does not know or care that the host is arm64.

For VirtIO specifically, arm64 guests more often use the MMIO transport. This is a practical consequence of how the virtual platforms are typically configured: arm64 hypervisors often expose VirtIO devices as MMIO regions rather than as emulated PCI buses. FreeBSD's `virtio_mmio.c` (in `/usr/src/sys/dev/virtio/mmio/`) provides the transport. A driver that uses `VIRTIO_DRIVER_MODULE` is automatically compatible with both transports, because the macro registers the driver with both `virtio_mmio` and `virtio_pci`.

This is one of the quiet wins of the `virtio_bus` design. A VirtIO driver written once runs across every VirtIO transport on every architecture that FreeBSD supports. No `#ifdef __amd64__` clauses, no per-architecture translation layer. The `virtio_bus` abstracts the transport; the driver talks to the abstraction.

30.13.2 riscv64 Virtualisation

On riscv64, virtualisation is provided by the *H extension* (Hypervisor extension). FreeBSD has a bhyve port for riscv64 as well, though it is less mature than the amd64 and arm64 ports as of FreeBSD 14.3. The VirtIO transports work the same way: drivers use `VIRTIO_DRIVER_MODULE` and the kernel's `virtio_bus` handles the transport specifics.

For driver authors working on riscv64, the most important thing to know is that the architecture-independent APIs all apply. `bus_dma(9)`, `callout(9)`, `mtx(9)`, `sx(9)`, and the VirtIO framework all work on riscv64. Code that is correct on amd64 usually runs unchanged on riscv64. The differences are in lower-level details (memory ordering, cache flushing, interrupt routing) that the kernel handles under the hood.

30.13.3 Cross-Architecture Considerations for Driver Authors

If you are writing a driver that should work on multiple architectures, the guidelines from Chapter 29 apply directly. Use the architecture-independent APIs. Avoid inline assembly except where strictly necessary (and then isolate it behind a portable wrapper). Do not assume a specific cache-line size or a specific page size. Do not assume an architecture's endianness unless you have explicitly used a conversion macro.

For virtualisation specifically, the main cross-architecture concern is *which VirtIO transports are present*. On amd64, VirtIO is almost always PCI. On arm64 with QEMU or Ampere hypervisors, VirtIO is often MMIO. On riscv64 with QEMU, VirtIO is often MMIO. A driver that only handles PCI VirtIO will not work in MMIO environments. The fix is to use `VIRTIO_DRIVER_MODULE`, which registers the driver with both transports, and to avoid assuming that the device's parent bus is PCI.

A concrete test: on your target architecture, run `pciconf -l` inside a guest and see whether VirtIO devices appear. If they do, the transport is PCI. If they do not (but the devices work), the transport is MMIO. On arm64 guests, you can also check `sysctl dev.virtio_mmio` to see MMIO VirtIO devices. A driver that works with both transports will not produce different output in these checks, because the `virtio_bus` API is what it interacts with.

30.13.4 When Architecture Matters for Real

Most drivers are architecture-independent if written in the FreeBSD idiom. The exceptions are:

- Drivers that deal with hardware-specific features: for example, ARM's SMMU is architecturally different from Intel's VT-d, and a driver that manipulates the IOMMU directly (rare) must handle both.
- Drivers that perform byte-order conversion: network drivers do this routinely, but they use portable helpers (`htonl`, `ntohs`, etc.) rather than architecture-specific code.
- Drivers that need specific CPU instructions: for example, cryptographic drivers that use AES-NI on amd64 or the AES extensions on arm64 need per-architecture code paths. These are rare and are already isolated by the kernel's crypto framework.

For most driver work on most architectures, the right mental model is “FreeBSD is FreeBSD”. The APIs are the same. The idioms are the same. The virtualisation framework is the same. The architecture is a detail the kernel manages for you.

With architecture considerations covered, we have the complete picture of virtualisation and containerisation as it affects a FreeBSD driver author. The remaining sections of the chapter turn to hands-on practice.

30.14 Hands-on Labs

The labs below walk you through four small exercises that put the chapter's ideas into practice. Each lab has a clear goal, a set of prerequisites, and a series of steps. Companion files are available under `examples/part-07/ch30-virtualisation/` for the ones that need more than a handful of lines of code.

Work through them in order. The first lab gets you comfortable inspecting a VirtIO guest from inside a VM. The second gets you writing a tiny VirtIO-adjacent driver. The third and fourth move into jails and VNET. Allow a couple of hours of hands-on time for the whole set; longer if the `bhyve(8)` or QEMU setup is new to you.

30.14.1 Lab 1: Exploring a VirtIO Guest

Goal: Confirm that you can start a FreeBSD 14.3 guest under `bhyve(8)`, log in, and observe the VirtIO devices it has attached. This establishes the development environment you will use for later labs.

Prerequisites: A FreeBSD 14.3 host (bare metal or nested in another hypervisor, provided the outer hypervisor supports nested virtualisation). Enough memory for a small guest (2 GB is plenty). The `vmm.ko` module loadable on the host, which it is on any standard FreeBSD 14.3 kernel.

Steps:

1. Fetch a FreeBSD 14.3 VM image. The base project provides prebuilt VM images at <https://download.freebsd.org>. Choose a bhyve-friendly image (typically the “BASIC-CI” or “VM-IMAGE” variants in the amd64 directory).
2. Install the `vm-bhyve` port or package: `pkg install vm-bhyve`. This wraps `bhyve(8)` in a friendlier management interface.
3. Configure a VM directory: `zfs create -o mountpoint=/vm zroot/vm` (or `mkdir /vm` if you are not using ZFS). In `/etc/rc.conf`, add `vm_enable="YES"` and `vm_dir="zfs:zroot/vm"` (or `vm_dir="/vm"`).
4. Initialise the directory: `vm init`. Copy a default template: `cp /usr/local/share/examples/vm-bhyve/default.conf /vm/.templates/default.conf`.
5. Create a VM: `vm create -t default -s 10G guest0`. Attach the downloaded image: `vm install guest0 /path/to/FreeBSD-14.3-RELEASE-amd64.iso`.
6. Log in once the installer finishes and reboots. The login prompt comes up on `vm console guest0`.
7. Inside the guest, run `pciconf -lvBb | head -40`. You will see `virtio-blk`, `virtio-net`, and possibly `virtio-random` devices, depending on the template. Note the driver each device is bound to.
8. Run `sysctl kern.vm_guest`. The output should be `bhyve`.
9. Run `dmesg | grep -i virtio`. Observe the attach messages for each VirtIO device.
10. Record your observations in a text file. You will refer to them in Labs 2 and 4.

Expected outcome: A running VM, a clear listing of attached VirtIO devices, and a confirmed `kern.vm_guest = bhyve` reading.

Common pitfalls: Not enabling VT-x or AMD-V in the host’s BIOS. Not having enough memory for the guest. Misconfigured network bridge preventing the guest from reaching the network (which is harmless for this lab but will matter later).

30.14.2 Lab 2: Using Hypervisor Detection in a Kernel Module

Goal: Write a small kernel module that reads `vm_guest` and logs the environment at load time. This is the smallest possible example of environment-aware driver behaviour.

Prerequisites: A working FreeBSD 14.3 guest from Lab 1. Kernel build tools installed (they come with the base system on the development kit). The `bsd.kmod.mk` build system, accessed via a simple `Makefile`.

Steps:

1. Under `/home/ebrandi/FDD-book/examples/part-07/ch30-virtualisation/lab02-detect/` in the companion examples tree, you will find a starter `detectmod.c` and `Makefile`. If you are not using the companion tree, create these files by hand.
2. The source file should define a kernel module that, on load, prints which environment it is in based on `vm_guest`.
3. Build the module: `make clean && make`.
4. Load it: `sudo kldload ./detectmod.ko`.
5. Check the `dmesg` output: `dmesg | tail`. You should see a line like `detectmod: running on bhyve`.

6. Unload: `sudo kldunload detectmod`.
7. Reboot the guest on a different hypervisor if possible (QEMU/KVM, for example) and re-run. The output should now reflect the new environment.

Expected outcome: A module that correctly identifies the hypervisor it is running on, using `vm_guest`.

Common pitfalls: Forgetting to include `<sys/systm.h>` for the `vm_guest` declaration. Linking errors from mistyped macros. Forgetting to set `KMOD=` and `SRCS=` in the Makefile.

30.14.3 Lab 3: A Minimal Character Device Driver Inside a Jail

Goal: Write a small character device driver, expose it from the host, create a jail with a custom devfs ruleset that makes the device visible inside, and verify that the jail's processes can use it while the host's privilege checks are still enforced.

Prerequisites: A FreeBSD 14.3 host. A working jail setup directory (typically `/jails/`). Basic familiarity with `make_dev(9)`, `d_read`, and `d_write`.

Steps:

1. Under `examples/part-07/ch30-virtualisation/lab03-jaildev/`, you will find `jaildev.c` and `Makefile`. The driver creates a `/dev/jaildev` character device whose read returns a fixed greeting.
2. Build and load the module on the host: `make && sudo kldload ./jaildev.ko`.
3. Verify `/dev/jaildev` exists and is readable: `cat /dev/jaildev`.
4. Create a jail root: `mkdir -p /jails/test && cp /bin/sh /jails/test/` (this is a minimal jail; for a real setup, use a proper filesystem layout).
5. Add a devfs ruleset to `/etc/devfs.rules`:

```
[devfsrules_jaildev=100]
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
add path 'jaildev' unhide
```

6. Reload the rules: `sudo service devfs restart`.
7. Start the jail: `sudo jail -c path=/jails/test devfs_ruleset=100 persist command=/bin/sh`.
8. In another terminal, enter the jail: `sudo jexec test /bin/sh`.
9. Inside the jail, run `cat /dev/jaildev`. The greeting should appear. Try `ls /dev/`: only the allowed devices (including `jaildev`) are visible.
10. Test the privilege boundary: modify the driver to require `PRIV_DRIVER` for an `ioctl`, rebuild, reload, and verify that the jail's root cannot run the `ioctl` while the host's root can.

Expected outcome: A driver visible in the jail only because the ruleset allows it, with privilege checks that behave differently for host root and jail root.

Common pitfalls: Forgetting to restart devfs after editing the rules. Not setting `persist` on the jail (without it, the jail dies as soon as the initial process exits). Misreading the ruleset syntax (whitespace is significant).

30.14.4 Lab 4: A Network Driver Inside a VNET Jail

Goal: Create a VNET jail, move one end of an `epair(4)` into it, and verify that network traffic flows between the host and the jail using only the jail's VNET. This exercises `if_vmove()` and the VNET lifecycle.

Prerequisites: A FreeBSD 14.3 host with `if_epair.ko` loadable. Root privileges.

Steps:

1. Load the `if_epair` module: `sudo kldload if_epair`.
2. Create an `epair`: `sudo ifconfig epair create`. You will get a device pair `epair0a` and `epair0b`.
3. Assign an IP to `epair0a` on the host: `sudo ifconfig epair0a 10.100.0.1/24 up`.
4. Create a jail root directory: `mkdir -p /jails/vnet-test`. Place a minimal shell and `ifconfig` binary inside (or bind-mount `/bin`, `/sbin`, `/usr/bin` for testing).
5. Create the jail with VNET enabled:

```
sudo jail -c \  
    name=vnet-test \  
    path=/jails/vnet-test \  
    host.hostname=vnet-test \  
    vnet \  
    vnet.interface=epair0b \  
    persist \  
    command=/bin/sh
```

The `vnet.interface=epair0b` parameter triggers the `if_vmove()` that moves the interface into the jail.

6. Enter the jail: `sudo jexec vnet-test /bin/sh`.
7. Inside the jail, configure the interface: `ifconfig epair0b 10.100.0.2/24 up`.
8. Still inside the jail, ping the host: `ping -c 3 10.100.0.1`. It should succeed.
9. From the host, ping the jail: `ping -c 3 10.100.0.2`. It should succeed.
10. Stop the jail: `sudo jail -r vnet-test`. The `epair0b` interface is moved back to the host (because it was moved with `vnet.interface`, which uses `if_vmove_loan()` under the hood in recent FreeBSD releases).
11. Verify the interface is back on the host: `ifconfig epair0b`. It should still exist but belong to the host's VNET again.

Expected outcome: A jail with its own network stack, moving an interface cleanly in and out.

Common pitfalls: Forgetting to enable VNET in the kernel (`options VIMAGE` is enabled in `GENERIC`, so this should be fine, but custom kernels might not have it). Trying to use a physical interface instead of `epair(4)` for the first attempt (this works but causes the host to lose that interface while the jail has it). Not giving the jail enough binaries to run a shell (the simplest workaround is a `nullfs` mount of the host's `/rescue` or a minimal bind-mount setup).

30.14.5 Lab 5: PCI Passthrough Simulation (Optional)

Goal: Observe how PCI passthrough changes a device's ownership, using a non-critical device as the target. This lab is marked optional because it requires a spare PCI device and an IOMMU-capable host. If those are not available, read through the steps; they illustrate the workflow even without running them.

Prerequisites: A FreeBSD 14.3 host with VT-d or AMD-Vi enabled in firmware. A spare PCI device that is safe to remove from the host (an unused NIC is a common choice). A bhyve(8) guest configuration.

Steps:

1. Identify the target device: `pciconf -lvBb | grep -B 1 -A 10 'Ethernet'` (or whatever type the spare device is). Note its bus, slot, and function (e.g., `pci0:5:0:0`).
2. Edit `/boot/loader.conf` and add the device to the passthrough list:

```
pptdevs="5/0/0"
```

3. Reboot the host. The device should now be bound to `ppt(4)` rather than its native driver. Confirm with `pciconf -l` (look for `ppt0`).
4. Configure a guest to pass the device through:

```
passthru0="5/0/0"
```

(Using the `vm-bhyve` configuration; the raw `bhyve` command is more verbose.)

5. Boot the guest. Inside the guest, run `pciconf -lvBb`. The device now appears in the guest with its real vendor and device IDs, attached to its native driver.
6. Exercise the device inside the guest: configure the NIC, send traffic, verify it works.
7. Shut down the guest. Edit `/boot/loader.conf` to remove the `pptdevs` line, reboot, and verify that the device returns to the host with its native driver attached.

Expected outcome: A clean round trip of a PCI device from host to guest and back, exercising the detach and reattach paths of the native driver.

Common pitfalls: The host firmware does not have VT-d or AMD-Vi enabled (look for it in the BIOS/UEFI setup). The chosen device is in the same IOMMU group as a device the host needs, forcing a multi-device passthrough. The device is attached to its native driver at boot before `ppt(4)` can claim it (usually this is fine if `pptdevs` is set early enough).

30.14.6 Lab 6: Building and Loading the vtdu Driver

Goal: Build the pedagogical `vtdu` driver from the case study, load it under a FreeBSD 14.3 guest, and observe its behaviour even without a matching backend. This lab exercises the kernel module build process in the VirtIO context and verifies the module structure.

Prerequisites: A FreeBSD 14.3 guest (the one from Lab 1 is fine). The FreeBSD source tree under `/usr/src` or the kernel headers installed (`pkg install kernel-14.3-RELEASE` works on stock systems). Root privileges inside the guest.

Steps:

1. Copy the companion files to the guest. From the book's examples tree, `examples/part-07/ch30-virtualisation/vtedu/` contains `vtedu.c`, `Makefile`, and `README.md`. Transfer them to the guest (via `scp`, `9p share`, or a shared volume).
2. Inside the guest, change into the `vtedu` directory: `cd /tmp/vtedu`.
3. Build the module: `make clean && make`. If the build fails because `/usr/src` is not installed, install it with `pkg install kernel-14.3-RELEASE` or point `SYSDIR` at an alternative kernel source tree: `make SYSDIR=/path/to/sys`.
4. A successful build produces `virtio_edu.ko` in the current directory.
5. Load the module: `sudo kldload ./virtio_edu.ko`. The load succeeds regardless of whether a matching device is present.
6. Check module status: `kldstat -v | grep -A 5 virtio_edu`. You will see the module is loaded, but no device is bound. This is expected without a backend.
7. Unload the module: `sudo kldunload virtio_edu`.
8. Inspect the module's PNP information: `kldxref -d /boot/modules` lists modules and their PNP entries. If you moved the module into `/boot/modules`, you will see the `VirtIO` simple PNP entry advertising device ID `0xffff0`.
9. Look at `dmesg` output during load and unload. There should be no errors. The absence of an attach message confirms that no device is bound, which is the expected behaviour.

Expected outcome: A successful build and load cycle that demonstrates the module is well-formed. Without a backend, the module is inert; this is a useful confirmation that the build and load plumbing work independently of the device side.

Common pitfalls: Missing kernel sources (install the `src` package). Missing `virtio.ko` dependency (load `virtio` first if it was somehow absent, though it is built into `GENERIC`). Confusion when no device attaches (re-read Section 1 of the `vtedu` `README`; this is by design).

What to do next: The real learning comes from pairing this module with a backend. Challenge 5 in the Challenge Exercises describes writing a matching backend in `bhyve(8)`. If you complete that, the driver will attach to the backend-provided device, a `/dev/vtedu0` node will appear, and you will be able to `echo hello > /dev/vtedu0 && cat /dev/vtedu0` to exercise the full `VirtIO` round-trip you studied in the case study.

30.14.7 Lab 7: Measuring VirtIO Overhead

Goal: Quantify the performance characteristics of `VirtIO` by running a simple workload under emulated, paravirtualised, and passthrough device configurations. This lab is about building intuition for what virtualisation costs, not about optimising a specific driver.

Prerequisites: A FreeBSD 14.3 host with `bhyve`, at least 8 GB of RAM, and the `vm-bhyve` tool installed. A NVMe drive is ideal but not required. The `fio(1)` benchmarking tool (available from ports as `benchmarks/fio`). Optional: a spare NIC for passthrough comparison.

Steps:

1. Create a baseline guest with `VirtIO` block and network devices (this is the default in `vm-bhyve`).
2. Inside the guest, install `fio`: `pkg install fio`.
3. Run a baseline disk benchmark: `fio --name=baseline --rw=randread --bs=4k --size=1G --numjobs=4 --iodepth=32 --runtime=30s --group_reporting`. Record the IOPS and latency.

4. On the host, measure the same workload directly (not inside the guest) using the backing storage as the target. Compare.
5. Run a baseline network benchmark: `iperf3 -c 10.0.0.1 -t 30` (server on the host, client in the guest). Record the throughput.
6. If you have a spare NIC, reconfigure the guest to use passthrough for the NIC (see Lab 5). Re-run the `iperf3` benchmark. Compare.
7. On the host, observe interrupt and VM exit counts while the benchmarks run: `vmstat -i, pmcstat -S instructions -l 10`. The most interesting counters are VM exit rates, which correlate with overhead.
8. For the disk benchmark, try varying the VirtIO features. Modify the guest configuration to disable `VIRTIO_F_RING_EVENT_IDX` (if the backend supports disabling it) and observe the change in interrupt rate.

Expected outcome: A small set of numbers that quantify the cost of virtualisation for your particular setup. Typically, VirtIO paravirtualised I/O is within 10-20% of bare metal for sustained workloads and within 30-40% for latency-sensitive random workloads; passthrough is within a few percent of bare metal but forfeits flexibility; pure emulation (for example, emulated E1000 instead of virtio-net) is 5-10x slower than VirtIO and should be avoided for any serious workload.

Common pitfalls: Benchmarks can be noisy; run each multiple times and take medians rather than single samples. The host's cache state affects disk benchmarks; run a warmup pass before the measured runs. CPU frequency scaling can skew results; pin the guest to specific cores and disable scaling on the host for reproducibility.

What this teaches: The numbers are secondary; the method is primary. Being able to measure overhead and attribute it to a specific layer (emulation vs. paravirtualisation vs. passthrough, interrupt rate vs. throughput, guest CPU vs. host CPU) is the foundation of performance work in virtualised environments. The same technique applies to any driver you write: if it has a performance requirement, you need to measure, and the measurement techniques are the ones in this lab.

30.14.8 A Note on Labs You Cannot Complete Today

Not every reader will have the hardware for every lab. Labs 1 through 4 are doable on essentially any FreeBSD 14.3 machine with enough memory and the `vmm` module. Lab 5 requires specific hardware that many readers will not have. Treat Lab 5 as a read-along walkthrough if you cannot run it; the concepts translate to any passthrough scenario, and the exact commands are documented in `pci_passthru(4)` and the `bhyve(8)` manual page.

If you are blocked on a lab, write down exactly what went wrong and come back to it. Virtualisation and containerization are areas where small environmental details can derail a whole setup, and the diagnostic skill of narrowing down the failure is as important as completing the lab.

30.15 Challenge Exercises

The labs above guide you through the standard paths. The challenges below ask you to extend the work. They are harder, less prescriptive, and designed to reward experimentation. Pick whichever one interests you most; all of them stretch different muscles.

30.15.1 Challenge 1: Extend the Detect Module

The Lab 2 module reads `vm_guest` and prints an environment label. Extend it so that it also reads the CPU vendor string (using `cpu_vendor` and `cpu_vendor_id`), the total physical memory (`realmem`), and the hypervisor signature where applicable. Produce a single structured log line that a test script can parse.

The CPU vendor string is a well-known part of CPU identification; look at `/usr/src/sys/x86/x86/identcpu.c` to see how the kernel reads it. The physical memory total is exposed through the `realmem` global and through the `hw.physmem` sysctl. The hypervisor signature lives in CPUID leaf `0x40000000` on most hypervisors; reading it requires a small piece of assembly or an intrinsic.

The interesting design question is how to expose this information to user space. You could log it at module load, add a sysctl, or create a `/dev/envinfo` device. Each has trade-offs. Think about which is most appropriate for a real production driver.

30.15.2 Challenge 2: A Simulation Backend for a Real VirtIO Driver

Chapter 29’s techniques encourage splitting a driver into accessors, backends, and a thin upper layer. Apply this to `virtio_random`. The real driver (in `/usr/src/sys/dev/virtio/random/virtio_random.c`) is small and tightly written. Can you refactor it so that the `virtqueue` operations go through an accessor layer, and a simulation backend that does not need a real VirtIO device can be selected for tests?

The refactor is subtle because the VirtIO framework provides most of the accessor layer for you: `virtqueue_enqueue`, `virtqueue_dequeue`, `virtio_notify` are already abstractions. The challenge is to find a layer above them that can be swapped out. One possibility is to move the harvest loop into a function that takes a callback for “get one buffer’s worth of data”, and implement that callback either as “call the `virtqueue`” (real) or as “read from `/dev/urandom` on the host” (simulation).

This is a design exercise more than a coding exercise. The goal is to understand how far Chapter 29’s advice can be stretched in a real driver that already has good abstractions.

30.15.3 Challenge 3: A VNET-Aware Driver Skeleton

Write a skeleton kernel module that creates a pseudo-network interface (using the `if_clone(9)` framework), supports being moved between VNETs, and reports its VNET identity in a sysctl. Verify with a VNET jail that the interface can be moved into the jail, used, and moved back.

The key subtlety is handling the VNET context correctly. Read the code in `/usr/src/sys/net/if_tuntap.c` for a reference. The `if_vmove` lifecycle requires the driver to clean up per-VNET state when the interface leaves and re-create it when the interface arrives. Pay attention to `VNET_SYSINIT` and `VNET_SYSUNINIT` if your driver needs per-VNET state.

This is a deep challenge that will take you into the VNET internals. Do not expect to complete it in a single sitting. Treat it as a multi-day project.

30.15.4 Challenge 4: A Jail-Visible Status Device

Write a driver that exposes a `/dev/status` character device. The device’s read returns different information depending on whether the caller is in a jail. If the caller is on the host, it returns system-wide status. If the caller

is in a jail, it returns jail-specific status (number of processes, current memory use, and so on).

The interesting part is how to distinguish the caller's jail. The `struct thread` passed to the `read` method has `td->td_ucred->cr_prison`, and `prison0` is the host. From the `prison` pointer you can read the jail's name, its process count (`pr_nprocs`), and so on. Be careful about locking: the `prison`'s fields are mostly read under a mutex that the driver must acquire.

This challenge is a good way to learn about the jail API without writing anything hypervisor-related. It also teaches you about `struct thread` and `struct ucred`, which are central to FreeBSD's privilege model.

30.15.5 Challenge 5: A bhyve Emulated Device in User Space

If you are ready for a bigger project, study how `bhyve(8)` emulates a simple VirtIO device (for example, `virtio-rnd`) in user space, and write a new emulated device of your own. The easiest target is a “hello” device that returns a fixed string through a VirtIO interface. The guest-side driver is your Chapter 29 or Chapter 30 work; the host-side emulator lives in `/usr/src/usr.sbin/bhyve/`.

This exercise ties together everything in the chapter: you write a VirtIO device in user space on the host, your driver inside the guest reads from it, the `virtqueue` transport between them is what you have been studying, and the whole thing exercises the full guest-host loop.

It is a substantial project, and it requires some familiarity with `bhyve(8)`'s code structure. Consider it a reach goal. If you finish it, you have genuinely learned both sides of the VirtIO story.

30.15.6 Challenge 6: Container Orchestration for Driver Testing

Write a shell script (or a more elaborate tool) that automates the Lab 3 and Lab 4 workflows. Given a driver and a test harness, the script should:

1. Build the driver.
2. Load it on the host.
3. Create a jail (or a VNET jail) with an appropriate ruleset.
4. Run the harness inside the jail.
5. Collect results.
6. Destroy the jail.
7. Unload the driver.
8. Report pass/fail with diagnostics.

The script should be idempotent (running it twice should not leave residue) and it should handle common failures gracefully. The end result is a tool you can run in CI to verify that your driver continues to work under jails as it evolves.

This is not a deep technical challenge but a practical one. Building this kind of automation is a significant fraction of real-world driver work, and building it yourself once teaches you what is involved.

30.15.7 How to Approach These Challenges

Each challenge could be a weekend project. Pick one that seems interesting and set aside time for it. Do not try to do all of them at once; your energy for unfamiliar work is limited, and you learn more from one challenge

finished than from three challenges half-done.

If you get stuck, do two things. First, re-read the relevant section of the chapter; the hints are there. Second, look at real FreeBSD drivers that do something similar. The source tree is your best teacher for the idiomatic way to solve problems that have been solved before.

30.16 Troubleshooting and Common Mistakes

This section collects the problems that driver authors most often hit when working with virtualised and containerised environments. Each entry describes the symptom, the likely cause, and the way to verify and fix it. Keep this as a reference; the first time you see a symptom, it will be new, and the next time it will be familiar.

30.16.1 VirtIO Device Not Detected in the Guest

Symptom: The guest boots, but `pciconf -l` does not show the VirtIO device, and `dmesg` contains no `virtio` attach messages.

Cause: Either the host did not configure the device (wrong `bhyve` command line, wrong `vm-bhyve` template), or the guest kernel is missing the VirtIO module. On FreeBSD 14.3, VirtIO drivers are built into `GENERIC` and auto-load; the guest side should almost never be the cause.

Fix: On the host, verify that the `bhyve` command line includes the device. For `vm-bhyve`, look at the VM's configuration file and check for lines like `disk0_type="virtio-blk"` or `network0_type="virtio-net"`. If the device is listed but still missing, check that the hypervisor has permission to access the backing resource (the disk image, the tap device).

Inside the guest, confirm the kernel has VirtIO: `kldstat -m virtio` or `kldstat | grep -i virtio`. If the module is not loaded, try `kldload virtio`.

30.16.2 virtqueue_enqueue Fails With ENOBUFS

Symptom: A VirtIO driver tries to enqueue a buffer and gets `ENOBUFS`.

Cause: The `virtqueue` is full. Either the driver has not been draining completed buffers through `virtqueue_dequeue`, or the ring size is smaller than expected and the driver is enqueueing more than it can hold.

Fix: Call `virtqueue_dequeue` in the interrupt handler to drain completed buffers and free their associated state. If the ring is genuinely too small, negotiate a larger ring size at feature-negotiation time, if the device supports `VIRTIO_F_RING_INDIRECT_DESC` or similar features.

A common beginner error is to forget that `enqueue` produces a descriptor that must be matched by a `dequeue`. Every successful `enqueue` must eventually produce a `dequeue`; otherwise the ring fills up.

30.16.3 Passthrough Device Not Available in the Guest

Symptom: The host has marked a device as passthrough-capable, the guest is configured to use it, but the guest does not see the device.

Cause: Several possible. The host did not actually bind the device to `ppt(4)` at boot (check `pciconf -l` for `pptN`). The host's firmware does not have the IOMMU enabled (check `dmesg | grep -i dmar` or `grep -i iommu`). The device is in an IOMMU group that cannot be split (so you need to pass through the whole group).

Fix: Verify each of the above in turn. `dmesg | grep -i dmar` should show initialisation messages from `dmar(4)` on Intel hosts or `amdvi(4)` on AMD hosts. If those are missing, enable VT-d or AMD-Vi in the firmware. If the device is in a shared IOMMU group, either pass through the whole group or move the device to a different PCI slot that is better isolated (an administrator task requiring chassis access).

30.16.4 Kernel Panic at Module Load Inside a Guest

Symptom: `kldload` of a new driver inside a guest causes a kernel panic.

Cause: Usually a bug in the driver, but sometimes a VirtIO-specific one: the driver assumes a device feature that the backend does not provide, or it accesses config space using the wrong layout (legacy versus modern).

Fix: Use the guest as your development platform precisely to make panics cheap. Capture the panic output (either from the serial console or from a bhyve log), narrow down the faulting function with `ddb(4)` if you have it configured, and iterate. The combination of a VM (so panics are cheap) and `printf` debugging (so you can see what happens before the panic) is usually enough to fix a VirtIO driver bug quickly.

For VirtIO-specific bugs, double-check the feature bits your driver negotiates. A driver that claims a feature but then does not implement it correctly (for example, claims `VIRTIO_F_VERSION_1` but uses legacy config space) will break in surprising ways.

30.16.5 Jail Cannot See a Device Even After Unhiding

Symptom: A devfs ruleset includes the device, the ruleset is applied to the jail, but the jail's `ls /dev` does not show it.

Cause: The devfs mount inside the jail was not re-mounted or re-ruled after the ruleset change. devfs caches the visibility decision at mount time, so later changes do not propagate until the mount is refreshed.

Fix: Run `devfs -m /jails/myjail/dev rule -s 100 applyset` (replace the path and ruleset number as appropriate) to force a reapply. Alternatively, stop the jail, restart devfs, and start the jail again. The service `devfs restart` command applies the rules in `/etc/devfs.rules` to the host's `/dev`; for jails, you generally need to restart the jail.

30.16.6 Privilege Denied Inside a Jail That Should Work

Symptom: A driver operation works on the host as root but fails with `EPERM` inside a jail's root.

Cause: The operation requires a privilege that `prison_priv_check` denies by default. This is the intended behaviour. The fix is either to use a less-privileged operation, to configure the jail with `allow.*` to grant the privilege, or (if appropriate) to change the driver to use a different privilege.

Fix: Look at the driver's `priv_check` call and identify which privilege is being checked. Consult `/usr/src/sys/sys/priv.h` and `prison_priv_check` in `/usr/src/sys/kern/kern_jail.c` to see whether the privilege is allowed inside jails. If it is not, consider whether the restriction is appropriate (usually yes) and adjust the jail's configuration accordingly (`allow.raw_sockets`, `allow.mount`, etc.).

Do not be tempted to remove the `priv_check` call just to make the jail work. The check is there for a reason; work with the framework, not against it.

30.16.7 VNET Jail Cannot Send or Receive Packets

Symptom: A VNET jail is created, an interface is moved in, but network traffic does not flow.

Cause: Several possibilities. The interface was not configured inside the jail (each VNET has its own `ifconfig` state). The default route was not set inside the jail. The host's firewall is blocking traffic between the jail's interface and the rest of the network. The interface is not in an UP state.

Fix: Inside the jail, run `ifconfig` and confirm the interface has an address and is UP. Run `netstat -rn` and confirm the routing table has the entries you expect. If you are using `pf(4)` or `ipfw(8)` on the host, check the rules: filter rules apply to the host's VNET, and the jail's packets may be rejected if the host's filter blocks them (depending on how the topology is set up).

For `epair(4)` setups specifically, remember that both ends need configuration, and that the host side stays on the host. The jail configures the end that was moved in; the host configures the end that stayed.

30.16.8 PCI Passthrough Driver Fails to Attach in the Guest

Symptom: The guest sees the passed-through device in `pciconf -l`, but the driver fails to attach, or the attach succeeds but read/write fails.

Cause: Usually one of two things. Either the driver assumes a platform-specific feature that is not present in the guest (an ACPI table, a BIOS entry), or the driver is programming physical addresses directly rather than going through `bus_dma(9)`, and the IOMMU is redirecting DMA in a way the driver does not expect.

Fix: For the first case, look at the driver's attach code for calls that read platform tables (ACPI, FDT, etc.). If the guest's firmware does not expose the expected tables, the driver must either provide defaults or refuse gracefully.

For the second case, audit the driver's DMA code. Every address programmed into the device must come from a `bus_dma(9)` load operation, not from a `vtophys` call or similar. This is standard practice anyway, but it becomes mandatory under passthrough.

30.16.9 Host Becomes Unresponsive When a Guest Starts

Symptom: Running `bhyve(8)` makes the host sluggish or unresponsive.

Cause: Resource contention. The guest is allocated more memory or more VCPUs than the host can afford to share. The host is swapping or spinning on a shared lock.

Fix: Check the guest's resource allocation. A guest with all the host's memory will starve the host; a guest with more VCPUs than the host has cores will cause thrashing. A common rule of thumb is to give guests no more than half the host's memory and no more VCPUs than `(host cores - 1)`, to leave room for the host itself.

If the sluggishness persists after sensible allocation, check `top -H` on the host for the `bhyve(8)` process and its threads. Heavy CPU use by `bhyve(8)` suggests the guest is doing something CPU-intensive; heavy CPU use by `vmm` kernel threads suggests excessive VM exits, which may indicate a guest driver that is polling too aggressively.

30.16.10 `kldunload` Hangs

Symptom: Unloading a driver module hangs the process and cannot be interrupted.

Cause: Some resource the driver owns is still in use. A file descriptor is still open on the driver's device, a callout is still scheduled, a taskqueue still has pending tasks, or a kernel thread the driver spawned has not exited.

Fix: Find and release the holder. `fstat` or `lsuf` lists open file descriptors; `procstat -kk` shows kernel threads. The driver's module unload handler must drain every async mechanism it starts: cancel callouts, drain taskqueues, wait for kernel threads to exit, close any held file descriptors. If any of these is missing, unload hangs.

For VNET-aware drivers, the unload must correctly clean up per-VNET state. A common mistake is to clean up in `mod_event(MOD_UNLOAD)` but forget that one of the VNETs the module is attached to is not the current one; accessing its state without `CURVNET_SET` leads to either a wrong-context access (fast) or a hang (slow). The correct pattern is to iterate over VNETs and clean up each explicitly.

30.16.11 Timing-Related Bugs Only in VMs

Symptom: The driver works on bare metal but hangs or loses interrupts inside a VM.

Cause: Timing assumptions that fail under virtualisation. Guest execution is sometimes paused for milliseconds at a time (during VM exits), and a driver that polls a status register in a tight loop without yielding may fail to make progress or may consume excessive CPU.

Fix: Replace tight polling with `DELAY(9)` for microsecond-scale waits, `pause(9)` for short waits, or proper sleep with `tsleep(9)` for longer waits. Use interrupt-driven designs instead of polling wherever possible. Test with `virtio-blk`'s performance counters to see whether the driver is generating an unreasonable number of VM exits.

A driver that works correctly on bare metal but fails on a VM is almost always making a timing assumption. The solution is to use the kernel's time primitives correctly; they work on both.

30.16.12 VirtIO Negotiation Fails or Returns Unexpected Features

Symptom: The driver logs that feature negotiation produced a feature set that is missing bits you expected, or the probe-and-attach path succeeds but the device behaves unexpectedly.

Cause: Two classes of issue. The first is that the device (or its backend) advertises a feature set that does not include the bit you requested. This is normal when the hypervisor's backend is older or intentionally minimal. The second is that the guest-side code is requesting a feature bit that the framework does not know about, in which case the framework may strip it silently.

Fix: Log `sc->features` immediately after `virtio_negotiate_features` returns. Compare it to the set you requested. If the device is missing a bit you thought was mandatory, your driver needs to fall back gracefully or refuse to attach with a clear error message. Never assume a bit is present without checking the post-negotiation value.

For backend-side investigation (if you are using a hypervisor whose source you can read, such as `bhyve(8)` or `QEMU`), look at the device emulator's feature advertisement. The backend holds the truth: the guest sees only

what the backend advertises. A mismatch between what you expect and what you see almost always traces back to the backend.

30.16.13 `bus_alloc_resource` Fails Inside a Guest

Symptom: The attach path calls `bus_alloc_resource_any` or `bus_alloc_resource` and receives `NULL`, causing the driver to fail attach.

Cause: Under a hypervisor, the device's resources (BARs, IRQ lines, MMIO windows) may differ from their bare-metal layout. A driver that hard-codes resource IDs or assumes specific BAR numbers can fail if the hypervisor presents a different layout.

Fix: Always use `pci_read_config(dev, PCIR_...)` to read actual BAR contents rather than assuming. Use `bus_alloc_resource_any` with the rid obtained from the resource list, not a hard-coded number. If the resource allocation still fails, compare `pciconf -lvBb` output from bare metal and from the guest to see what has changed.

A concrete example: a device that uses BAR 0 for MMIO and BAR 2 for I/O on bare metal may be configured differently by the hypervisor. Always read the BARs at runtime and allocate resources based on what is actually present.

30.16.14 `kldload` Succeeds but No Device Attaches

Symptom: `kldload` of a VirtIO driver returns success, but `kldstat -v` shows no device bound to the module, and no `dmesg` messages are produced.

Cause: The driver's PNP table does not match any device advertised by the hypervisor. This is normal when a backend is not providing the expected device. For `vtedu` in the case study, this is the expected behaviour without a matching `bhyve(8)` backend.

Fix: Run `devctl list` (or `devinfo -v`) on the host or in the guest to see which devices are present but unbound. If the device is not listed at all, the backend is not running or is misconfigured. If the device is listed but unbound, check its PNP identifiers (vendor, device for PCI, or the VirtIO type ID for VirtIO) and compare against the driver's PNP table. Mismatch is the most common cause.

A common beginner error is to believe that `kldload` success means the driver is working. It only means the module loaded. Use `kldstat -v | grep yourdriver` to see whether any device has been claimed.

30.16.15 Module Is Loaded but `/dev` Node Does Not Appear

Symptom: The driver has loaded, `kldstat -v` shows it attached to a device, but the expected `/dev` node does not appear.

Cause: Either the driver did not call `make_dev(9)`, or the `devfs` mount inside the current jail is filtered by a ruleset that hides the node, or the `make_dev` call failed silently because the device unit number clashed with an existing one.

Fix: On the host, check `ls /dev/yourdev*`. If it is missing there too, the driver did not create the node. Check the attach path for the `make_dev` call, and verify its return value. If the node is present on the host but missing

inside a jail, the devfs ruleset is the cause. Run `devfs -m /path/to/jail/dev rule show` to see the active ruleset inside the jail.

For a driver that is intended to be visible inside jails, the correct practice is to document which devfs ruleset exposes the node and to provide an example ruleset in the driver's README. Do not assume the administrator will figure it out.

30.16.16 Virtqueue Interrupts Never Fire

Symptom: The driver's interrupt handler is never called, even though the driver has submitted work to the virtqueue.

Cause: One of several possibilities. The backend never processes the work (bug in the backend). The driver did not register the interrupt handler correctly. The driver did not call `virtio_setup_intr`, so no interrupt plumbing exists. The driver disabled interrupts via `virtqueue_disable_intr` and never re-enabled them.

Fix: Systematically check each step. In the attach path, verify that `virtio_setup_intr` was called and returned 0. In the interrupt handler, verify that you are re-enabling interrupts when appropriate. Add a `printf` at the top of the handler to confirm it is never called. If the handler is genuinely never called, run `vmstat -i | grep yourdriver` to see the interrupt count; a count of zero confirms the interrupt is not arriving.

If the count is nonzero but the handler does no work, the handler is running but finding nothing in the virtqueue. This suggests the backend is acknowledging but not producing real completions; look at the backend.

30.16.17 Interrupt Storm Under Virtualisation

Symptom: Inside a VM, `vmstat -i` shows interrupt rates in the hundreds of thousands per second, and CPU utilisation is high even without real work.

Cause: An interrupt that is not being cleared, or a driver that interrupts on every event without coalescing. Under INTx specifically, a level-triggered interrupt that remains asserted causes the handler to be called in a loop.

Fix: For MSI-X, confirm that the handler acknowledges completions and that the virtqueue ring is being drained. For INTx, confirm that the handler clears the device's interrupt status register. For VirtIO specifically, negotiate `VIRTIO_F_RING_EVENT_IDX` if the backend supports it; this lets the device suppress unnecessary interrupts.

Look at the Section 9 pattern with `virtqueue_disable_intr` / `virtqueue_enable_intr`. A correct driver disables interrupts on entry, drains the ring, and only re-enables interrupts when the ring is empty. Missing this structure is a common cause of interrupt storms.

30.16.18 DMA Failures Only Under Passthrough

Symptom: The driver works correctly with an emulated device, but when the same hardware is passed through via `ppt(4)`, DMA transfers fail silently or corrupt memory.

Cause: Most often, the driver is programming physical addresses directly rather than going through `bus_dma(9)`. Under emulation, the hypervisor intercepts all I/O and translates addresses on the fly, hiding the

bug. Under passthrough, the device DMA's directly through the IOMMU, and the physical address the driver programmed is not the bus address the IOMMU expects.

Fix: Audit every place the driver computes an address to program into the device. Each must come from `bus_dma_load` or `bus_dma_load_mbuf` or similar, not from `vtophys` or a raw physical address. This is a mandatory discipline for passthrough and is strongly recommended for all drivers.

A useful diagnostic: enable IOMMU verbose logging (`sysctl hw.dmar.debug=1` on Intel, or the equivalent on AMD) and watch the kernel log for IOMMU page faults while the driver runs. A page fault reveals exactly which bus address the device attempted to access; if it does not match a mapped region, the driver's address calculation is wrong.

30.16.19 A VirtIO Device Appears but Has the Wrong Type

Symptom: The guest sees a VirtIO device at the expected PCI address, but `pciconf -lv` or `devinfo` reports a different VirtIO device type than expected.

Cause: Device-ID confusion. The PCI vendor ID for VirtIO is always `0x1af4`, but the device ID encodes the VirtIO type, and different VirtIO versions use different device-ID ranges. Legacy VirtIO uses `0x1000 + VIRTIO_ID`. Modern VirtIO uses `0x1040 + VIRTIO_ID`. A hypervisor that exposes a mix of modern and legacy devices can confuse a driver that only probes one range.

Fix: FreeBSD's `virtio_pci` transport handles both ranges transparently, so most drivers are immune. For driver authors who inspect `pciconf -lv` directly, be aware that both `0x1000-0x103f` (legacy) and `0x1040-0x107f` (modern) are VirtIO. The `VIRTIO_DRIVER_MODULE` macro registers the driver with both transports and does the right thing for both device-ID ranges.

30.16.20 Jail-Specific Ioctl Fails With ENOTTY

Symptom: An ioctl that works on the host returns `ENOTTY` when issued from inside a jail, even though the ioctl number is recognised by the driver.

Cause: The driver's ioctl handler checks jail visibility and returns `ENOTTY` to hide the ioctl's existence from jailed callers. This is a security-by-obscurity pattern used by some drivers that expose host-only administrative operations through otherwise jail-visible devices.

Fix: If the jail should be able to use the ioctl, review the driver's visibility check. The idiomatic approach is to return `EPERM` (permission denied) rather than `ENOTTY` when an operation exists but is not permitted; `ENOTTY` implies the ioctl does not exist, which can confuse callers. Consider whether the jailed caller should see the ioctl; if so, remove the hiding logic and use `priv_check` for access control instead.

30.16.21 VNET Move Leaks Per-VNET State

Symptom: After moving an interface in and out of a VNET multiple times, the kernel's memory usage grows, eventually triggering a memory pressure event.

Cause: The driver allocates per-VNET state when an interface enters a VNET but does not free it when the interface leaves. Each VNET move leaks a fixed amount of memory.

Fix: Implement the VNET-move lifecycle correctly. When an interface enters a VNET (`if_vmove` into the new VNET), allocate per-VNET state. When it leaves (`if_vmove` out), free it. The `CURVNET_SET` and `CURVNET_RESTORE` pair delineates the VNET context; use them when allocating or freeing.

Look at `/usr/src/sys/net/if_tuntap.c` for a correct VNET-move implementation. The lifecycle is subtle and easy to get wrong; a reference implementation is the best teacher.

30.16.22 Guest Kernel Panics with “Fatal Trap 12” on First I/O

Symptom: The guest boots, the driver attaches, the first user-space I/O to the driver’s device causes a “Fatal Trap 12: page fault while in kernel mode” panic.

Cause: Almost always a NULL pointer dereference in the driver’s `read`, `write`, or `ioctl` path. Under virtualisation, the fault is immediate rather than merely corrupt-then-continue, because the guest’s memory protection is exact.

Fix: Use the kernel’s debugger (`ddb(4)` or `dtrace(1)`) to find the faulting instruction. A typical cause is a `dev->si_drv1 = sc` that was forgotten in `attach`, so when user space opens `/dev/yourdriver` and calls `read`, `dev->si_drv1` is NULL. The fix is to always set `si_drv1` in `attach`, right after creating the `cdev`.

Under VMs, these panics are cheap: fix the code, rebuild, reload. On bare metal, each panic costs a reboot. One more reason to develop under virtualisation.

30.16.23 Live Migration Fails or Causes Guest Hang

Symptom: A guest under a hypervisor that supports live migration (currently limited in `bhyve(8)`, more common in Linux KVM and VMware) is migrated to a different host, and the guest hangs or corrupts after migration.

Cause: The guest driver holds state that is tied to the source host (a specific physical TSC, a specific IOMMU mapping, a specific passed-through device). Migration transfers the guest’s memory and CPU state but cannot transfer physical hardware state.

Fix: For driver authors, the advice is simple: do not cache values that are tied to the physical host. Re-read TSC frequency from `timecounter(9)` rather than storing a local copy. Do not pass through PCI devices that you need to migrate. For VirtIO devices, live migration is supported by the standard, and the guest driver needs no special code.

If you are writing a driver for a live-migration-supporting environment, the main design rule is: all state should be in the guest’s memory; anything on the host side should be recreatable after migration. Standard VirtIO drivers meet this bar because the `virtqueue` state is in guest memory.

30.16.24 Unexpected devfs Entries Appear Inside a Jail

Symptom: A jail has a minimal devfs ruleset, but entries appear that the administrator did not expect.

Cause: Either the ruleset was not applied correctly, or the jail inherited the default ruleset before the custom one was applied, or a new device appeared after the ruleset was set.

Fix: Run `devfs -m /jail/path/dev rule show` to see what rules are active. Compare with `/etc/devfs.rules`. If a later rule is adding visibility the earlier rule denied, the order is wrong. If the jail was started before the ruleset was finalised, restart the jail.

A robust practice is to always start a jail with a known ruleset specified in `/etc/jail.conf` rather than relying on the `devfs` default. The `devfs_ruleset = NNN` directive in the jail configuration ensures the jail's `devfs` mount uses the expected ruleset from the moment the jail starts.

30.16.25 Two Drivers Fight Over the Same Device

Symptom: Loading driver A works, but loading driver B after A (or vice versa) causes one of them to fail attach with a cryptic message about resource conflicts.

Cause: Two drivers are trying to claim the same device. This can happen if the device has multiple valid drivers (for example, a generic driver and a specific driver for a particular chipset variant) and the load order determines which one wins.

Fix: FreeBSD's Newbus arbitrates driver priority through `DRIVER_MODULE`'s ordering, but the exact semantics depend on which driver attached first. The general rule is that once a device is attached, another driver cannot steal it. If you need to switch drivers, detach the first one (`devctl detach yourdev0`) before loading the second.

Under virtualisation this can show up when you load a test driver after the VirtIO framework has already attached a production driver to the device. The test driver must either use a different PNP entry or explicitly detach the existing one.

30.16.26 vm_guest Shows “no” Inside an Obvious VM

Symptom: `sysctl kern.vm_guest` returns “no” inside a guest that is definitely running under a hypervisor.

Cause: The hypervisor is not setting the `CPUID` hypervisor-present bit, or is setting a vendor string that the FreeBSD kernel does not recognise. This can happen with exotic or customised hypervisors.

Fix: This is informational, not a fix. If your driver needs to detect virtualisation but `vm_guest` does not cooperate, use alternative signals: the presence of VirtIO devices, the absence of physical hardware that would be present on bare metal, specific `CPUID` leaves that expose hypervisor-specific information. But recognise that accurate hypervisor detection is hard to guarantee; design your driver to work correctly regardless of the environment, and use `vm_guest` only for non-critical defaults.

30.16.27 General Diagnostic Approach

When something breaks in a virtualised or containerised environment, the pattern for diagnosis is consistent. First, reduce the environment to the simplest setup that shows the problem: strip the VM down to a single VirtIO device, remove extra jails, disable VNET if it is not needed. Second, try the same operation at the next layer up: if the problem shows in a jail, try it on the host; if on the host, try it on a guest; if in a guest, try it on bare metal. The layer where the problem disappears is usually the layer where the problem lives.

Third, once you have localised the layer, add logging. `printf` in the kernel is still a valid debugging tool; combined with `dmesg`, it gives you a timestamped trace of what the driver does. `dtrace(1)` is more capable but has a higher setup cost. For a first diagnosis, `printf` is usually enough.

Fourth, if the problem is a race or a timing issue, simplify before you complicate. A race that happens once in ten thousand iterations can be investigated with a test loop that runs ten thousand iterations. A timing issue under VM execution can be made reproducible by pinning the VM to specific host CPUs and disabling frequency scaling.

None of this is specific to virtualisation. It is good general debugging discipline. Virtualisation just happens to be an environment where the discipline pays off quickly, because the layers are clearly separated and the layers can be swapped in and out easily.

30.17 Wrapping Up

Virtualisation and containerization are two names for what they are in FreeBSD: two different answers to the same broad question. Virtualisation multiplies kernels; containerization subdivides one. A driver lives inside a kernel, and the way it interacts with its environment depends on which of these is in use.

The virtualisation side is where the VirtIO story lives. VirtIO is the mature, standardised, high-performance paravirtual interface between a guest driver and a hypervisor-provided device. FreeBSD's VirtIO framework (in `/usr/src/sys/dev/virtio/`) implements the standard cleanly, and the `virtio_random` driver you studied in Section 3 is a minimal example of how a VirtIO driver is structured. The key concepts, feature negotiation, virtqueue management, notification, are the same whether the device is a random-number generator, a network card, or a block device. Learn them once, and every VirtIO driver becomes more approachable.

The hypervisor detection mechanism, `vm_guest`, gives a driver a small window into the environment. It is useful for adjusting defaults but dangerous when used to work around bugs. The right mindset is “this is informational”; the wrong mindset is “this is a branch target”.

The host side, where FreeBSD runs `bhyve(8)` and provides devices to guests, is where driver authorship meets hypervisor authorship. Most driver authors never touch `vmm(4)` directly, but the PCI passthrough facility is worth understanding, because it exercises the detach and reattach paths that a well-written driver already supports. A driver that survives a round trip through `ppt(4)` is a driver whose lifecycle is honest.

The containerization side is where jails, `devfs` rulesets, and VNET come together. Jails share the kernel, so drivers are not multiplied; they are filtered. The filter operates on three axes: which devices the jail can see (`devfs` rulesets), which privileges it can exercise (`prison_priv_check` and `allow.*`), and how much it can consume (`rctl(8)` and `racct(9)`). For a driver author, the design decisions are small and local: pick sensible `devfs` names, call `priv_check` correctly, handle allocation failures gracefully.

The VNET framework extends the jail model into the network stack. It is the part of jails that comes closest to requiring explicit driver cooperation. Drivers that write to per-VNET state from outside a network-stack entry point (for example, from callouts) must establish the VNET context with `CURVNET_SET`. Drivers that survive `if_vmove` cleanly are drivers that will work in VNET jails.

Together, these mechanisms shape FreeBSD as a platform for both hypervisor workloads and container workloads. A single kernel, a single driver set, several different ways for that driver to appear to its users. Understand-

ing the mechanisms is what lets you write drivers that work correctly across all of them, without special-casing any of them.

The discipline the chapter has advocated, sometimes explicitly, sometimes by example, is a continuation of Chapter 29's theme. Write clean abstractions. Use the framework APIs. Do not reach around them. Do not invent your own DMA or privilege or visibility mechanisms; FreeBSD already has well-tested ones. If you do all of this, your driver will work in environments you did not have in mind when you wrote it, and that is the best definition of portable a driver can have.

If you worked through the labs, you now have hands-on experience with starting a bhyve guest, writing a small module that uses `vm_guest`, putting a character device behind a devfs ruleset in a jail, and moving a network interface through VNET. Those four skills are all you need to start doing real work on driver code that runs in virtualised and containerised environments. Everything else in the chapter is supporting context.

If you tackled one or more of the challenges, you have stretched further: into simulation backends, into VNET-aware interfaces, into the bhyve emulator itself, or into test automation. Any of these is a genuine piece of FreeBSD driver craft, and the work compounds. Every hour you spend on these topics comes back in every driver you write afterwards.

A final note on attitude. Virtualisation and containerization can feel overwhelming because they introduce so many new pieces at once: hypervisors, paravirtual devices, jails, VNET, rulesets, privileges. But every piece has a clear purpose and a small, well-designed API. The sense of overwhelm goes away once you have seen each one in isolation, and this chapter's pacing was chosen to let you do that. If you are still feeling overwhelmed, go back to Section 3 (VirtIO) or Section 6 (jails and devfs) and re-read with a specific small question in mind. The answers are there.

30.18 Looking Ahead: Security and Privilege

Chapter 31, "Security and Privilege in Device Drivers," builds directly on the foundations laid in this chapter. Jails and virtual machines are one kind of security boundary; drivers have many others. A driver that exposes an `ioctl` is a driver that has created a new interface into the kernel, and that interface must be checked, validated, and restricted.

Chapter 31 will cover the privilege framework in depth (you saw `priv_check` here; Chapter 31 goes through the whole list), the `ucred(9)` structure and how credentials flow through the kernel, the `capsicum(4)` capability framework for finer-grained restrictions, and the MAC (Mandatory Access Control) framework for policy-based security. It will also revisit jails from a security-first perspective, complementing the container-first perspective of this chapter.

The thread that runs through Chapters 29, 30, and 31 is environment. Chapter 29 was about architectural environment: running on the same kernel with different buses or bit-widths. Chapter 30 was about operational environment: running inside a VM, a container, or on a host. Chapter 31 is about policy environment: running under the constraints a security-conscious administrator chooses to apply. A driver that handles all three kinds of environment well is a driver that can be deployed anywhere FreeBSD runs.

With Chapter 31, Part 7 approaches its midpoint. The remaining chapters of the part turn to debugging (Chapter 32), testing (Chapter 33), performance tuning (Chapter 34), and specialised driver topics in later chapters. Each builds on what you have learned so far. Take the time to let this chapter settle; the concepts will keep paying off as you continue.

30.19 Case Study: Designing a Pedagogical VirtIO Driver

This closing case study pulls together the threads of the chapter into a single design walkthrough. It does not present a complete implementation. Instead, it walks through the decisions you would make if you sat down today to design a pedagogical VirtIO driver called `vtedu`. The driver does nothing useful in production, but it exercises enough of the VirtIO surface to be a valuable teaching tool for future readers.

30.19.1 What `vtedu` Is For

Imagine that `vtedu` is meant to serve as the example driver for a future FreeBSD workshop on paravirtualised devices. Its job is to expose a single virtqueue, accept write requests from user space, pass them through the virtqueue to a backend in `bhyve(8)` (which does something simple like echoing bytes back), and deliver the echoed bytes back to user space. It must be small enough to read in an afternoon and complete enough to demonstrate the full VirtIO lifecycle.

The design choices below explain each step. A reader who finishes this section should be able to reason about any similar VirtIO driver in the same terms.

30.19.2 Choosing the Device Identifier

VirtIO defines a set of well-known device IDs in `/usr/src/sys/dev/virtio/virtio_ids.h`. For a pedagogical driver, a reserved or experimental ID is appropriate. The VirtIO specification reserves some ranges for “vendor-specific” devices, and a workshop driver would pick one of those.

For `vtedu`, we pick a hypothetical `VIRTIO_ID_EDU = 0xffff0` (chosen so it does not collide with real device IDs). The corresponding backend in `bhyve(8)` would register the same ID. A real project would coordinate with the `bhyve(8)` maintainers on the ID assignment.

30.19.3 Defining the Features

A teaching driver should negotiate a meaningful feature bit so that the reader sees feature negotiation in action. `vtedu` defines one feature:

```
#define VTEDU_F_UPPERCASE (1ULL << 0)
```

When negotiated, the backend returns the input bytes uppercased. When not negotiated, it returns them unchanged. The driver advertises the feature, the backend may or may not support it, and the negotiation produces whichever outcome both sides can support.

This kind of trivial feature is a teaching device. In a real driver, features correspond to real capabilities; in `vtedu`, the feature exists just to show how negotiation works.

30.19.4 Softc Layout

The softc is the per-instance state:

```

struct vtedu_softc {
    device_t      dev;
    struct virtqueue *vq;
    uint64_t      features;
    struct mtx      lock;
    struct cdev     *cdev;
    struct sglist    *sg;
    char          buf[VTEDU_BUF_SIZE];
    size_t        buf_len;
};

```

The device handle, the virtqueue pointer, the negotiated feature mask, a mutex protecting the driver's serialised access, a cdev for the user-space interface, a pre-allocated scatter-gather list, a buffer for the data, and its current length.

30.19.5 Transport Registration

The module uses `VIRTIO_DRIVER_MODULE` as always:

```

static device_method_t vtedu_methods[] = {
    DEVMETHOD(device_probe,      vtedu_probe),
    DEVMETHOD(device_attach,     vtedu_attach),
    DEVMETHOD(device_detach,     vtedu_detach),
    DEVMETHOD_END
};

static driver_t vtedu_driver = {
    "vtedu",
    vtedu_methods,
    sizeof(struct vtedu_softc)
};

VIRTIO_DRIVER_MODULE(vtedu, vtedu_driver, vtedu_modevent, NULL);
MODULE_VERSION(vtedu, 1);
MODULE_DEPEND(vtedu, virtio, 1, 1, 1);

```

The PNP info for `vtedu` advertises `VIRTIO_ID_EDU`, so the framework binds the driver to any VirtIO device of that type, under either PCI or MMIO transport.

30.19.6 Probe and Attach

The probe is a one-liner using `VIRTIO_SIMPLE_PROBE`. The attach sets up the device in the standard order:

```

static int
vtedu_attach(device_t dev)
{
    struct vtedu_softc *sc = device_get_softc(dev);
    int error;

    sc->dev = dev;
    mtx_init(&sc->lock, device_get_nameunit(dev), NULL, MTX_DEF);

    virtio_set_feature_desc(dev, vtedu_feature_descs);

    error = vtedu_negotiate_features(sc);
    if (error != 0)
        goto fail;

    error = vtedu_alloc_virtqueue(sc);
    if (error != 0)
        goto fail;

    error = virtio_setup_intr(dev, INTR_TYPE_MISC);
    if (error != 0)
        goto fail;

    sc->sg = sglist_alloc(2, M_WAITOK);
    sc->cdev = make_dev(&vtedu_cdevsw, device_get_unit(dev),
        UID_ROOT, GID_WHEEL, 0600, "vtedu%d", device_get_unit(dev));
    if (sc->cdev == NULL) {
        error = ENXIO;
        goto fail;
    }
    sc->cdev->si_drv1 = sc;

    device_printf(dev, "attached (features=0x%lx)\n",
        (unsigned long)sc->features);
    return (0);

fail:
    vtedu_detach(dev);
    return (error);
}

```

This follows the standard rhythm: negotiate, allocate queue, setup interrupts, set up user-space interface. It is structurally identical to `virtio_random`'s `attach`, with a `cdev` creation added because `vtedu` exposes a character device.

30.19.7 Feature Negotiation

Negotiation is straightforward:

```
static int
vtedu_negotiate_features(struct vtedu_softc *sc)
{
    uint64_t features = VIRTIO_F_VERSION_1 | VTEDU_F_UPPERCASE;

    sc->features = virtio_negotiate_features(sc->dev, features);
    return (virtio_finalize_features(sc->dev));
}
```

The driver advertises the two features, gets back an intersection, and finalises. The intersection tells the driver whether VTEDU_F_UPPERCASE is in play. Subsequent code uses `virtio_with_feature(sc->dev, VTEDU_F_UPPERCASE)` to check.

30.19.8 Queue Allocation

A single virtqueue is allocated with an interrupt callback:

```
static int
vtedu_alloc_virtqueue(struct vtedu_softc *sc)
{
    struct vq_alloc_info vq_info;

    VQ_ALLOC_INFO_INIT(&vq_info, 0, vtedu_vq_intr, sc, &sc->vq,
        "%s request", device_get_nameunit(sc->dev));

    return (virtio_alloc_virtqueues(sc->dev, 0, 1, &vq_info));
}
```

The maximum indirect-descriptor size is zero (no indirects), the interrupt callback is `vtedu_vq_intr`, and the virtqueue pointer is stored in `sc->vq`. A single queue is enough for a request-response pattern where the same queue is used for both directions.

30.19.9 The Character Device Interface

User space opens `/dev/vtedu0` and writes bytes to it. The driver accepts them, issues a VirtIO request, waits for the response, and exposes the response back to user space through `read`.

```
static int
vtedu_write(struct cdev *dev, struct uio *uio, int flags __unused)
```

```
{
    struct vtedu_softc *sc = dev->si_drv1;
    size_t n;
    int error;

    n = uio->uio_resid;
    if (n == 0 || n > VTEDU_BUF_SIZE)
        return (EINVAL);

    mtx_lock(&sc->lock);
    error = uiomove(sc->buf, n, uio);
    if (error == 0) {
        sc->buf_len = n;
        error = vtedu_submit(sc);
    }
    mtx_unlock(&sc->lock);
    return (error);
}
```

The write copies bytes into the softc buffer, sets `buf_len`, and calls `vtedu_submit`, which does the VirtIO enqueue and notify.

```
static int
vtedu_submit(struct vtedu_softc *sc)
{
    int error;

    sglist_reset(sc->sg);
    error = sglist_append(sc->sg, sc->buf, sc->buf_len);
    if (error != 0)
        return (error);

    error = virtqueue_enqueue(sc->vq, sc, sc->sg, 1, 1);
    if (error != 0)
        return (error);

    virtqueue_notify(sc->vq);
    return (0);
}
```

One readable segment (the driver's write into the buffer) and one writable segment (the device's write of the result). The cookie is `sc` itself; the interrupt handler will receive it back when the completion arrives.

30.19.10 The Interrupt Handler

Completions are processed in a taskqueue-deferred or immediate fashion. For pedagogical simplicity, vtedu processes them immediately in the interrupt callback:

```
static void
vtedu_vq_intr(void *arg)
{
    struct vtedu_softc *sc = arg;
    void *cookie;
    uint32_t len;

    mtx_lock(&sc->lock);
    while ((cookie = virtqueue_dequeue(sc->vq, &len)) != NULL) {
        /* cookie == sc; len is the length the device wrote. */
        sc->buf_len = len;
        wakeup(sc);
    }
    mtx_unlock(&sc->lock);
}
```

The handler drains all completions, updates the softc, and wakes any sleeper waiting on the buffer. For a real driver, this would be richer; for vtedu, it is all we need.

30.19.11 The Read Path

User space then reads the result:

```
static int
vtedu_read(struct cdev *dev, struct uio *uio, int flags __unused)
{
    struct vtedu_softc *sc = dev->si_drv1;
    int error;

    mtx_lock(&sc->lock);
    while (sc->buf_len == 0) {
        error = mtx_sleep(sc, &sc->lock, PCATCH, "vteduR", 0);
        if (error != 0) {
            mtx_unlock(&sc->lock);
            return (error);
        }
    }
    error = uiomove(sc->buf, sc->buf_len, uio);
    sc->buf_len = 0;
}
```

```
    mtx_unlock(&sc->lock);  
    return (error);  
}
```

If no result is available, the read sleeps on `sc`, which the interrupt handler will wake. This is the standard “block until ready” pattern for character devices with slow underlying I/O.

30.19.12 Detach

The detach reverses the attach, cleanly:

```
static int  
vtedu_detach(device_t dev)  
{  
    struct vtedu_softc *sc = device_get_softc(dev);  
  
    if (sc->cdev != NULL)  
        destroy_dev(sc->cdev);  
    if (sc->sg != NULL)  
        sglist_free(sc->sg);  
    virtio_stop(dev);  
    if (mtx_initialized(&sc->lock))  
        mtx_destroy(&sc->lock);  
    return (0);  
}
```

`virtio_stop` resets the device status so it no longer generates interrupts. The `cdev` is destroyed, the scatter-gather list freed, and the mutex destroyed.

30.19.13 Putting vtedu Together

This walkthrough has touched on every major element of a VirtIO driver:

1. Device ID selection and PNP info.
2. Feature definition and negotiation.
3. Softc layout and locking.
4. Virtqueue allocation with interrupt callback.
5. User-space interface through `cdev`.
6. Request submission through `enqueue + notify`.
7. Completion handling through the interrupt callback.
8. Clean detach.

The whole driver, fully implemented, fits in around 300 lines of C. That is less than `virtio_random` once you add in the backend plumbing. Because the user-space interface is richer than `virtio_random`’s (which hides in the `random(4)` framework), the code is slightly larger in total, but the VirtIO-specific part is no bigger.

30.19.14 Using vtedu for Teaching

A vtedu driver would be used in a workshop something like this:

1. The instructor starts by demonstrating the driver loading, attaching, and processing a write-then-read round trip.
2. Students follow along, typing the key sections from a cheat sheet.
3. The instructor introduces feature negotiation by showing what happens when `VTEDU_F_UPPERCASE` is negotiated (outputs arrive uppercased) versus when it is not.
4. Students modify the driver to add a second feature: “reverse the bytes”. They learn how features compose.
5. Finally, the instructor shows how to run the driver in a jail (it just works, as long as `vtedu0` is in the `devfs` ruleset), illustrating the containerisation side of the chapter.

This is a pedagogical design, not a production one. Its purpose is to show how the pieces fit. A reader who has followed this case study should be able to write a similar driver of their own, starting from scratch or starting from `virtio_random.c` as a template.

30.19.15 What vtedu Does Not Do

For honesty: vtedu as sketched here omits several things a production driver would include. It does not support multiple in-flight requests (the lock serialises everything). It does not handle queue-full situations gracefully (it assumes one request at a time). It does not support module-wide module-event cleanup (just per-device). It does not demonstrate indirect descriptors (because the feature is irrelevant for 256-byte messages).

Each of these is an exercise the reader could undertake after understanding the base design. The chapter’s challenge exercises hint at some of them; a dedicated workshop would develop them further.

30.19.16 A Teaching Driver Versus a Real Driver

Before leaving vtedu, a note about the difference between a teaching driver and a real one. A teaching driver is designed for readability. Its code makes every concept visible, often at the cost of clever optimisations. A real driver is designed for reliability and performance. It compresses the common-case paths, adds error handling for every edge case, and optimises for the actual workload.

The temptation when moving from learning to production is to start with the teaching driver and add features. That usually produces worse code than starting with an architectural sketch and filling it in. A teaching driver is a reference; a real driver is a system. The two are not on the same continuum.

As a driver author, your job is to understand the teaching driver well enough that the real-driver design decisions become clear. This chapter’s treatment of VirtIO is meant to get you to that understanding. The next step is yours.

30.20 Appendix: Quick Reference

The reference tables below condense the chapter’s key facts into a form you can return to during driver work. They are not a substitute for the explanatory text; think of them as the one-page cheat sheet for the day you are actually writing code and need a specific detail.

30.20.1 VirtIO Core API Functions

Function	Purpose
<code>virtio_negotiate_features(dev, mask)</code>	Advertise and negotiate feature bits.
<code>virtio_finalize_features(dev)</code>	Seal the feature negotiation.
<code>virtio_with_feature(dev, feature)</code>	Test whether a feature is negotiated.
<code>virtio_alloc_virtqueues(dev, flags, nvqs, info)</code>	Allocate a set of virtqueues.
<code>virtio_setup_intr(dev, type)</code>	Install the negotiated interrupt handlers.
<code>virtio_read_device_config(dev, offset, dst, size)</code>	Read device-specific configuration.
<code>virtio_write_device_config(dev, offset, src, size)</code>	Write device-specific configuration.

30.20.2 virtqueue(9) Functions

Function	Purpose
<code>virtqueue_enqueue(vq, cookie, sg, readable, writable)</code>	Push a scatter-gather chain onto the available ring.
<code>virtqueue_dequeue(vq, &len)</code>	Pop one completed chain from the used ring.
<code>virtqueue_notify(vq)</code>	Tell the host new work is available.
<code>virtqueue_poll(vq, &len)</code>	Wait for a completion and return it.
<code>virtqueue_empty(vq)</code>	Check whether the queue has any pending work.
<code>virtqueue_full(vq)</code>	Check whether the queue has space for another enqueue.

30.20.3 vm_guest Values

Constant	String via <code>kern.vm_guest</code>	Meaning
<code>VM_GUEST_NO</code>	<code>none</code>	Bare metal
<code>VM_GUEST_VM</code>	<code>generic</code>	Unknown hypervisor
<code>VM_GUEST_XEN</code>	<code>xen</code>	Xen
<code>VM_GUEST_HV</code>	<code>hv</code>	Microsoft Hyper-V
<code>VM_GUEST_VMWARE</code>	<code>vmware</code>	VMware ESXi / Workstation

Constant	String via kern.vm_guest	Meaning
VM_GUEST_KVM	kvm	Linux KVM
VM_GUEST_BHYVE	bhyve	FreeBSD bhyve
VM_GUEST_VBOX	vbox	Oracle VirtualBox
VM_GUEST_PARALLELS	parallels	Parallels
VM_GUEST_NVMM	nvmm	NetBSD NVMM

30.20.4 Default devfs Rulesets

Number	Name	Purpose
1	devfsrules_hide_all	Start with everything hidden.
2	devfsrules_unhide_basic	Essential devices (null, zero, random, etc.).
3	devfsrules_unhide_login	Login-related devices (pts, ttyv*).
4	devfsrules_jail	Standard non-VNET jail ruleset.
5	devfsrules_jail_vnet	Standard VNET jail ruleset.

30.20.5 Common Privilege Constants

Constant	Typical jail policy
PRIV_DRIVER	Denied (driver-private ioctls).
PRIV_IO	Denied (raw I/O port access).
PRIV_KMEM_WRITE	Denied (kernel memory writes).
PRIV_KLD_LOAD	Denied (module loading).
PRIV_NET_SETLLADDR	Denied (MAC address changes).
PRIV_NETINET_RAW	Denied unless allow.raw_sockets.
PRIV_NET_BPF	Allowed via allow.raw_sockets for BPF-needing tools.

30.20.6 VNET Macros

Macro	Purpose
VNET_DEFINE(type, name)	Declare a per-VNET variable.

Macro	Purpose
VNET(name)	Access the per-VNET variable for the current VNET.
V_name	Conventional shorthand for VNET(name).
CURVNET_SET(vnet)	Establish a VNET context on the current thread.
CURVNET_RESTORE()	Tear down the context.
VNET_SYSINIT(name, ...)	Register a per-VNET init function.
VNET_SYSUNINIT(name, ...)	Register a per-VNET uninit function.

30.20.7 bhyve and Passthrough Tools

Tool	Purpose
bhyve(8)	Run a virtual machine.
bhyvectl(8)	Query and control running VMs.
vm(8)	High-level management (via vm-bhyve port).
pciconf(8)	Show PCI devices and their driver bindings.
devctl(8)	Explicit control of driver attach/detach.
pptdevs in /boot/loader.conf	Bind devices to the passthrough placeholder.

30.20.8 Manual Pages Worth Bookmarking

- virtio(4) - VirtIO framework overview.
- vtnet(4), virtio_blk(4) - Specific VirtIO drivers.
- bhyve(8), bhyvectl(8), vmm(4) - Hypervisor user and kernel interfaces.
- pci_passthru(4) - PCI passthrough mechanism.
- jail(8), jail.conf(5), jls(8), jexec(8) - Jail management.
- devfs(5), devfs(8), devfs.rules(5) - devfs and rulesets.
- if_epair(4), vlan(4), if_tap(4) - Pseudo-interfaces useful for jails.
- rctl(8), racct(9) - Resource control.
- priv(9) - Privilege framework.

30.20.9 Top Five Things a Driver Author Should Do

If you remember nothing else from this chapter, remember these five habits:

1. Use bus_dma(9) for every DMA buffer. Never pass physical addresses directly to the hardware. This is the single most important habit for passthrough and IOMMU-protected environments.
2. Use priv_check(9) for privileged operations. Do not hardcode `cred->cr_uid == 0` checks. The framework extends your code to jails for free.

3. Keep device node names predictable. Administrators who write devfs rulesets need to know what to unhide. Document the name in your driver's manual page.
4. Handle detach cleanly. Release every resource, cancel every callout, drain every taskqueue, and never assume the softc will be re-used. Passthrough and VNET both exercise detach heavily.
5. Establish VNET context around callout and taskqueue code that touches per-VNET state. `CURVNET_SET` / `CURVNET_RESTORE` is the boilerplate, and missing it is the most common VNET-related bug.

These five habits between them cover nearly all of the “works under virtualisation and containerization” work a driver author needs to do. Everything else is refinement.

30.21 Appendix: Common Code Patterns

A small catalogue of patterns that appear repeatedly in FreeBSD drivers that run in virtualised or containerised environments. Each one is a snippet you can adapt to your own code.

30.21.1 Pattern: Environment-aware default

```
static int
mydev_default_interrupt_moderation(void)
{
    switch (vm_guest) {
    case VM_GUEST_NO:
        return (1); /* tight moderation on bare metal */
    default:
        return (4); /* loose moderation under a hypervisor */
    }
}
```

Use this pattern to seed a default that the user can override via `sysctl`. Do not branch on the specific hypervisor brand unless there is a real reason.

30.21.2 Pattern: Privilege-gated ioctl

```
case MYDEV_IOC_DANGEROUS:
    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        return (error);
    /* perform the dangerous operation */
    return (0);
```

The default position for driver-specific privileges is to require `PRIV_DRIVER`. Consult `priv(9)` if a more specific privilege fits better.

30.21.3 Pattern: VNET-aware callout

```
static void
mydev_callout(void *arg)
{
    struct mydev_softc *sc = arg;

    CURVNET_SET(sc->ifp->if_vnet);
    /* read or write V_ variables, or call network-stack functions */
    CURVNET_RESTORE();

    callout_reset(&sc->co, hz, mydev_callout, sc);
}
```

Any callout, taskqueue function, or kernel thread that might access VNET state must establish the context. Missing this is the most common source of VNET-related bugs.

30.21.4 Pattern: VirtIO attach skeleton

```
static int
mydev_attach(device_t dev)
{
    struct mydev_softc *sc = device_get_softc(dev);
    int error;

    sc->dev = dev;
    virtio_set_feature_desc(dev, mydev_feature_descs);

    error = mydev_negotiate_features(sc);
    if (error != 0)
        goto fail;

    error = mydev_alloc_virtqueues(sc);
    if (error != 0)
        goto fail;

    error = virtio_setup_intr(dev, INTR_TYPE_MISC);
    if (error != 0)
        goto fail;

    /* post initial buffers, register with subsystem, etc. */
    return (0);
}
```

```
fail:
    mydev_detach(dev);
    return (error);
}
```

The “negotiate, allocate, setup interrupts, start” rhythm is standard for every VirtIO driver. Every VirtIO attach in `/usr/src/sys/dev/virtio/` is a variation on this skeleton.

30.21.5 Pattern: Clean detach

```
static int
mydev_detach(device_t dev)
{
    struct mydev_softc *sc = device_get_softc(dev);

    /* Stop accepting new work. */
    sc->detaching = true;

    /* Drain async mechanisms. */
    if (sc->co_initialised)
        callout_drain(&sc->co);
    if (sc->tq != NULL)
        taskqueue_drain_all(sc->tq);

    /* Release hardware resources. */
    if (sc->irq_cookie != NULL)
        bus_teardown_intr(dev, sc->irq_res, sc->irq_cookie);
    if (sc->irq_res != NULL)
        bus_release_resource(dev, SYS_RES_IRQ, 0, sc->irq_res);
    if (sc->mem_res != NULL)
        bus_release_resource(dev, SYS_RES_MEMORY, 0, sc->mem_res);

    /* Destroy devfs nodes. */
    if (sc->cdev != NULL)
        destroy_dev(sc->cdev);

    return (0);
}
```

Detach must be symmetric with attach: every resource attach allocated must be released here, in reverse order. A clean detach is what makes the driver safe for passthrough and for unload.

30.21.6 Pattern: `make_dev` with sensible defaults

```
sc->cdev = make_dev(&mydev_cdevsw, 0, UID_ROOT, GID_WHEEL, 0600, "mydev%d",
    device_get_unit(dev));
if (sc->cdev == NULL)
    return (ENXIO);
sc->cdev->si_drv1 = sc;
```

Use 0600 mode for nodes that should only be root-accessible, 0644 for read-any / write-root, 0666 for rare read-and-write-any cases. The `si_drv1` field is the conventional back-pointer from a `struct cdev` to the driver's `softc`.

30.22 Appendix: Glossary

A short glossary of the terms this chapter relies on. Refer back when a term in a later section has slipped from memory.

- **Bare metal:** A system running directly on physical hardware with no hypervisor in between.
- **bhyve:** FreeBSD's native type-2 hypervisor. Runs as a user-space program backed by the kernel's `vmm(4)` module.
- **Container:** In FreeBSD, a jail or a user-space framework built on top of jails.
- **Credential (`struct ucred`):** The per-process security context that carries uid, gid, jail pointer, and privilege-related state.
- **devfs:** The special filesystem at `/dev` where devices are exposed.
- **devfs ruleset:** A named set of rules that controls which devfs nodes are visible in a given devfs mount.
- **Emulated device:** A hypervisor-provided device that imitates a real-hardware interface.
- **Guest:** The operating system running inside a virtual machine.
- **Host:** The physical machine (or container-enclosing system) that hosts guests or jails.
- **Hypervisor:** Software that creates and manages virtual machines.
- **IOMMU:** A unit between a device and host memory that remaps DMA addresses. Enables safe passthrough.
- **Jail:** FreeBSD's lightweight containerisation mechanism.
- **Paravirtual device:** A device with an interface designed to be easy for a hypervisor to emulate and for a guest to drive. VirtIO is the canonical example.
- **Passthrough:** Giving a guest direct access to a physical device.
- **Prison:** The kernel's internal name for a jail. `struct prison` is the data structure.
- **rctl / racct:** The resource-control and resource-accounting frameworks that enforce per-jail or per-process limits.
- **Ruleset:** See *devfs ruleset*.
- **Transport (VirtIO):** The bus-level mechanism that carries VirtIO messages. Examples: PCI, MMIO.
- **Virtqueue:** The shared-ring data structure at the heart of VirtIO.
- **VirtIO:** The paravirtualisation standard used by most modern hypervisors.
- **VM:** Virtual machine.

- **VNET**: FreeBSD's virtual network stack framework, providing per-jail independent stacks.
- **vmm**: FreeBSD's kernel hypervisor core module, used by bhyve(8).

30.23 Appendix: Observing VirtIO with DTrace

DTrace is one of FreeBSD's most capable diagnostic tools, and it is especially useful for understanding how a VirtIO driver behaves at runtime. This appendix collects several concrete DTrace recipes for VirtIO observability. None of them require modifying the driver; they work against the unmodified kernel because the `fbt` (function-boundary-tracing) provider instruments every kernel function.

30.23.1 A First Probe: Counting virtqueue Enqueues

The simplest useful probe counts how often `virtqueue_enqueue` is called per second.

```
sudo dtrace -n 'fbt::virtqueue_enqueue:entry /pid == 0/ { @[probefunc] = count(); }
↵ tick-1sec { printa(@); trunc(@); }'
```

Running this on a busy VM shows numbers like:

```
virtqueue_enqueue 12340
virtqueue_enqueue 15220
virtqueue_enqueue 11890
```

Each number is enqueues per second across all virtqueues. A number in the thousands is normal for an active VM; a number in the millions suggests a pathological driver. The per-VM baseline depends on workload, but getting familiar with the baseline for your environment lets you spot anomalies later.

30.23.2 Separating Queues by Virtqueue

To see which virtqueue is being used, extend the probe to key on the virtqueue name.

```
sudo dtrace -n '
fbt::virtqueue_enqueue:entry
{
    this->vq = (struct virtqueue *)arg0;
    @[stringof(this->vq->vq_name)] = count();
}
tick-1sec
{
    printa(@);
    trunc(@);
}
'
```

Output now looks like:

vtnet0-rx	482
vtnet0-tx	430
virtio_blk0	8220

This instantly reveals which device is doing work. A disk-heavy workload shows `virtio_blk0` dominating; a network-heavy workload shows `vtnet0-tx` and `vtnet0-rx`. This kind of first-level breakdown is usually enough to localise a performance problem.

Note that the example dereferences an internal struct (`struct virtqueue`). The struct's layout is implementation-detail and can change between FreeBSD releases. Check `/usr/src/sys/dev/virtio/virtqueue.c` if the struct layout has changed and the probe fails.

30.23.3 Measuring Time Spent in Enqueue

Time-in-function is a standard DTrace recipe.

```
sudo dtrace -n '
fbt::virtqueue_enqueue:entry
{
    self->ts = vtimestamp;
}
fbt::virtqueue_enqueue:return
/ self->ts /
{
    @["virtqueue_enqueue"] = quantize(vtimestamp - self->ts);
    self->ts = 0;
}
'
```

The output is a histogram of how long each `virtqueue_enqueue` call took, in nanoseconds. For healthy VirtIO, most calls complete in the low microsecond range. A significant tail suggests lock contention (the function's mutex is held for too long), memory pressure, or expensive scatter-gather computation.

30.23.4 Watching for VM Exits

VM exits are the fundamental cost of virtualisation. DTrace's `vmm` probes (if available) let you count them.

```
sudo dtrace -n 'fbt:vmm::*:entry { @[probfunc] = count(); } tick-1sec { printa(@);
↵      trunc(@); }'
```

On a busy host, this shows dozens of `vmm` functions. The ones to watch are `vm_exit_*`, which handle different exit types (I/O, interrupt, hypercall). Seeing `vm_exit_inout` in the top results suggests the guest is doing a lot of I/O through emulated devices and would benefit from VirtIO.

30.23.5 Tracing a Specific Driver

To focus on a specific driver's functions, narrow the probe to its module name.

```
sudo dtrace -n 'fbt:virtio_blk::*:entry { @[probefunc] = count(); } tick-1sec {  
    ↪  printa(@); trunc(@); }'
```

This counts all `virtio_blk` function entries. On a quiescent VM, the output is empty; on an active VM, you see every function the driver calls, with counts. This is useful for getting a feel for a driver's internal structure.

30.23.6 Tracing a Custom Driver

For the `vtedu` driver from the case study, the same technique works as long as the module is loaded and named `virtio_edu`.

```
sudo dtrace -n 'fbt:virtio_edu::*:entry { @[probefunc] = count(); } tick-1sec {  
    ↪  printa(@); trunc(@); }'
```

If no backend is attached, the counts will be zero. If a backend is attached and the driver is exercising the virtqueue, you see `vtedu_write`, `vtedu_submit_locked`, `vtedu_vq_intr`, and `vtedu_read` in the counts, in rough proportion to usage.

30.23.7 Observing the Guest-Host Boundary

A more ambitious use of DTrace is to correlate guest-side events with host-side events. This is possible when both sides are FreeBSD and DTrace is available on both. Run DTrace on the host to count `vmm` exits and on the guest to count driver calls; the numbers should correlate one-for-one on an unloaded system, diverging as the host batches exits or as posted interrupts kick in.

This is an advanced technique and mostly interesting for performance analysis. For day-to-day debugging, single-side DTrace is usually enough.

30.23.8 Saving and Reusing Probes

The `dtrace(1)` command-line form is fine for quick investigations. For repeated use, save probes to a file and invoke with `dtrace -s`.

```
% cat > virtio_probes.d <<'EOF'  
#pragma D option quiet  
  
fbt::virtqueue_enqueue:entry  
{  
    this->vq = (struct virtqueue *)arg0;  
    @[stringof(this->vq->vq_name)] = count();  
}
```

```
}

tick-1sec
{
    printa(@);
    trunc(@);
}

EOF

% sudo dtrace -s virtio_probes.d
```

A curated set of probes in `.d` files is a good investment for anyone who spends significant time debugging VirtIO.

30.23.9 When DTrace Cannot Help

DTrace can observe the kernel and, with `pid` provider, most user-space programs. It cannot directly observe guest kernels from the host, because the guest is a process whose internal structure `dtrace` does not know. You can trace the `bhyve(8)` process itself (as a user-space program) using the `pid` provider, which shows what `bhyve` is doing but not what its guest is doing.

For guest-side tracing, DTrace runs inside the guest. If the guest is FreeBSD 14.3, the full DTrace toolkit is available. If the guest is Linux, use `bpftrace` or `perf` instead; they are different tools with similar capabilities.

30.23.10 A Closing Word

DTrace is one of FreeBSD's competitive advantages. Every driver author should be comfortable with it; the investment pays off repeatedly across years of debugging. This appendix gives you a starting point; the FreeBSD Handbook's DTrace chapter and the original *DTrace: Dynamic Tracing in Oracle Solaris* book (freely available online) are the next steps if you want to go deeper.

30.24 Appendix: A Complete bhyve Configuration Walkthrough

Readers who want to run the labs need a working `bhyve(8)` setup. This appendix walks through a complete configuration, from a bare FreeBSD 14.3 host to a guest with VirtIO devices, in enough detail for a beginner to reproduce it. If you have already built `bhyve` environments, skim this; the goal is to provide a reference for readers who have not.

30.24.1 The Host Side

Start with a FreeBSD 14.3 host. Confirm the virtualisation extensions are enabled.

```
% sysctl hw.vmm
hw.vmm.topology.cores_per_package: 0
hw.vmm.topology.threads_per_core: 0
hw.vmm.topology.sockets: 0
hw.vmm.topology.cpus: 0
...
```

If `hw.vmm` is absent entirely, the `vmm(4)` module is not loaded. Load it with `kldload vmm`. Add `vmm_load="YES"` to `/boot/loader.conf` to load it at every boot.

If `vmm` is loaded but the VT-x/AMD-V features are absent, enable them in the host firmware. The setting is usually called “VT-x”, “VMX”, “AMD-V”, or “SVM” in the BIOS/UEFI menu. After enabling, reboot.

30.24.2 Install vm-bhyve

`vm-bhyve` is a wrapper that makes `bhyve(8)` easier to use. Install it from ports or packages.

```
% sudo pkg install vm-bhyve
```

Create the VM directory. Using ZFS is convenient because it supports snapshotting.

```
% sudo zfs create -o mountpoint=/vm zroot/vm
```

Or plain UFS:

```
% sudo mkdir /vm
```

Enable `vm-bhyve` and set its directory in `/etc/rc.conf`.

```
vm_enable="YES"
vm_dir="zfs:zroot/vm"
```

For UFS, use `vm_dir="/vm"` instead. Initialise the directory.

```
% sudo vm init
% sudo cp /usr/local/share/examples/vm-bhyve/config_samples/default.conf
↪ /vm/.templates/
```

Edit `/vm/.templates/default.conf` if you want different defaults (memory size, CPU count).

30.24.3 Create and Install a Guest

Download a FreeBSD 14.3 installation image. The file `FreeBSD-14.3-RELEASE-amd64-disc1.iso` is the standard installer; for faster setup, use `FreeBSD-14.3-RELEASE-amd64.qcow2` if you prefer a prebuilt image.

```
% sudo vm iso https://download.freebsd.org/releases/amd64/amd64/ISO-  
↪ IMAGES/14.3/FreeBSD-14.3-RELEASE-amd64-disc1.iso
```

Create the guest.

```
% sudo vm create -t default -s 20G guest0
```

Start the installer.

```
% sudo vm install guest0 FreeBSD-14.3-RELEASE-amd64-disc1.iso
```

Connect to the console.

```
% sudo vm console guest0
```

The FreeBSD installer runs; follow it through to completion. At the end, reboot the guest.

30.24.4 Configure Networking

`vm-bhyve` supports two network styles: bridged and NAT. For simplicity, bridged is fine.

Create a bridge.

```
% sudo vm switch create public  
% sudo vm switch add public em0
```

Replace `em0` with your host's physical interface. Assign guests to the switch in their configuration.

```
% sudo vm configure guest0
```

In the editor that opens, ensure `network0_switch="public"` is set.

30.24.5 Start the Guest

```
% sudo vm start guest0  
% sudo vm console guest0
```

Log in, run `pciconf -lvBb`, and confirm the VirtIO devices are present.

```
# pciconf -lvBb
hostb0@pci0:0:0:0:      class=0x060000 rev=0x00 ...
virtio_pci0@pci0:0:2:0: class=0x010000 rev=0x00 vendor=0x1af4 device=0x1001 ...
    vendor      = 'Red Hat, Inc.'
    device      = 'Virtio 1.0 block device'
virtio_pci1@pci0:0:3:0: class=0x020000 rev=0x00 vendor=0x1af4 device=0x1041 ...
    vendor      = 'Red Hat, Inc.'
    device      = 'Virtio 1.0 network device'
...
```

30.24.6 Troubleshooting the Host Side

If the guest does not start, run `vm start guest0` with the verbose flag (`vm -f start guest0` keeps it in the foreground), look at the error message, and consult the `bhyve(8)` manual. The most common issues are missing resources (disk image path wrong, switch not set up) and permissions (user not in the `vm` group, or directories not readable).

If networking does not work inside the guest, check the bridge on the host (`ifconfig bridge0`), check the tap device (`ifconfig tapN`), and check that the VM's `network0` setting matches the switch name. `vm-bhyve` generates a tap device per VM and wires it into the specified switch.

30.24.7 Using This Setup for the Labs

With a working host and guest, Lab 1 is essentially done (you have a VirtIO-using guest). Lab 2 and Lab 3 can be performed inside the guest. Lab 4 needs `if_epair` on the host; Lab 5 needs a spare PCI device and IOMMU-enabled firmware. Lab 6 (building `vtedu`) is done inside the guest. Lab 7 (measuring overhead) uses the guest as the test subject.

In short: if your `vm-bhyve` setup is solid, the rest of the chapter's hands-on work is accessible.

30.25 Appendix: VirtIO Feature Bits Reference

This appendix collects the VirtIO feature bits most likely to matter to a driver author, with a brief description of each. The authoritative source is the VirtIO specification; this is a digest for quick reference.

30.25.1 Device-Independent Features

These apply across all VirtIO device types.

- `VIRTIO_F_NOTIFY_ON_EMPTY` (bit 24): The device should notify the driver when the virtqueue becomes empty, in addition to normal completion notifications. Useful for drivers that want to know when all outstanding requests have been processed.
- `VIRTIO_F_ANY_LAYOUT` (bit 27, deprecated in v1): Headers and data can be in any scatter-gather layout. Always negotiated in v1 drivers; not relevant for modern code.

- **VIRTIO_F_RING_INDIRECT_DESC** (bit 28): Indirect descriptors supported. An entry in the descriptor table can point to another table, allowing longer scatter-gather lists without expanding the main ring. Strongly recommended for drivers that handle large requests.
- **VIRTIO_F_RING_EVENT_IDX** (bit 29): Event-index interrupt suppression. Lets the driver tell the device “do not interrupt me before descriptor N is available”, reducing interrupt rate. Strongly recommended for high-rate drivers.
- **VIRTIO_F_VERSION_1** (bit 32): Modern VirtIO (version 1.0 or later). Without this, the driver is in legacy mode, with different config-space layout and conventions. New drivers should require this.
- **VIRTIO_F_ACCESS_PLATFORM** (bit 33): The device uses a platform-specific DMA address translation (for example, an IOMMU). Required for passthrough-capable deployments.
- **VIRTIO_F_RING_PACKED** (bit 34): Packed virtqueue layout. A newer, more cache-friendly layout than the classic split layout. Not supported by all backends; negotiate but do not require.
- **VIRTIO_F_IN_ORDER** (bit 35): Descriptors are used in the same order they were made available. Allows optimisations in the driver (no need to track descriptor indexes); not supported by all backends.

30.25.2 Block Device Features (**virtio_blk**)

- **VIRTIO_BLK_F_SIZE_MAX** (bit 1): The device has a maximum single-request size.
- **VIRTIO_BLK_F_SEG_MAX** (bit 2): The device has a maximum segment count per request.
- **VIRTIO_BLK_F_GEOMETRY** (bit 4): The device reports its cylinder/head/sector geometry. Mostly legacy.
- **VIRTIO_BLK_F_RO** (bit 5): The device is read-only.
- **VIRTIO_BLK_F_BLK_SIZE** (bit 6): The device reports its block size.
- **VIRTIO_BLK_F_FLUSH** (bit 9): The device supports flush (fsync) commands.
- **VIRTIO_BLK_F_TOPOLOGY** (bit 10): The device reports topology information (alignment, etc.).
- **VIRTIO_BLK_F_CONFIG_WCE** (bit 11): The driver can query and set the write-cache-enabled flag.
- **VIRTIO_BLK_F_DISCARD** (bit 13): The device supports discard (trim) commands.
- **VIRTIO_BLK_F_WRITE_ZEROES** (bit 14): The device supports write-zeroes commands.

30.25.3 Network Device Features (**virtio_net**)

- **VIRTIO_NET_F_CSUM** (bit 0): The device can offload checksum computation.
- **VIRTIO_NET_F_GUEST_CSUM** (bit 1): The driver can checksum-offload incoming packets.
- **VIRTIO_NET_F_MAC** (bit 5): The device provides a MAC address.
- **VIRTIO_NET_F_GSO** (bit 6): GSO (generic segmentation offload) supported.
- **VIRTIO_NET_F_GUEST_TSO4** (bit 7): Receive-side TSO over IPv4.
- **VIRTIO_NET_F_GUEST_TSO6** (bit 8): Receive-side TSO over IPv6.
- **VIRTIO_NET_F_GUEST_ECN** (bit 9): ECN (explicit congestion notification) supported on receive.
- **VIRTIO_NET_F_GUEST_UFO** (bit 10): Receive-side UFO (UDP fragmentation offload).
- **VIRTIO_NET_F_HOST_TSO4** (bit 11): Transmit-side TSO over IPv4.
- **VIRTIO_NET_F_HOST_TSO6** (bit 12): Transmit-side TSO over IPv6.
- **VIRTIO_NET_F_HOST_ECN** (bit 13): ECN on transmit.
- **VIRTIO_NET_F_HOST_UFO** (bit 14): Transmit-side UFO.
- **VIRTIO_NET_F_MRG_RXBUF** (bit 15): Merged receive buffers.

- `VIRTIO_NET_F_STATUS` (bit 16): Configuration status is supported.
- `VIRTIO_NET_F_CTRL_VQ` (bit 17): Control virtqueue.
- `VIRTIO_NET_F_CTRL_RX` (bit 18): Control channel for receive mode filtering.
- `VIRTIO_NET_F_CTRL_VLAN` (bit 19): Control channel for VLAN filtering.
- `VIRTIO_NET_F_MQ` (bit 22): Multiqueue support.
- `VIRTIO_NET_F_CTRL_MAC_ADDR` (bit 23): Control channel for MAC-address setting.

30.25.4 How to Read a Feature Word

Features are a 64-bit word, with bits as described. To check whether a feature is negotiated:

```
if ((sc->features & VIRTIO_F_RING_EVENT_IDX) != 0) {  
    /* event indexes are available */  
}
```

To advertise a feature for negotiation, | it into the features mask before calling `virtio_negotiate_features`. The post-negotiation value of `sc->features` is the intersection of what the driver requested and what the backend offers.

30.25.5 Common Pitfalls

- Hard-coding feature requirements. A driver that requires `VIRTIO_NET_F_MRG_RXBUF` and falls over if it is absent will not work with simpler backends. Prefer to negotiate optimistically and adapt to what you get.
- Forgetting to check the post-negotiation features. A driver that behaves as if a feature is always present, without checking `sc->features`, will mis-program the device when the feature is absent.
- Ignoring version 1 requirements. Modern code should require `VIRTIO_F_VERSION_1`; legacy mode has too many quirks to be worth supporting in new drivers.

30.25.6 A Useful Habit

Log the negotiated feature word at attach time, with each interesting bit named. The `device_printf` below does this succinctly.

```
device_printf(dev, "features: ver1=%d evt_idx=%d indirect=%d mac=%d\n",  
    (sc->features & VIRTIO_F_VERSION_1) != 0,  
    (sc->features & VIRTIO_F_RING_EVENT_IDX) != 0,  
    (sc->features & VIRTIO_F_RING_INDIRECT_DESC) != 0,  
    (sc->features & VIRTIO_NET_F_MAC) != 0);
```

This single line in `dmesg` at attach time tells you, for any bug report, what feature set the driver is operating on. It is the VirtIO equivalent of logging a hardware revision; indispensable for support.

30.26 Appendix: Further Reading

For readers who want to go deeper, here is a short curated list.

30.26.1 FreeBSD source tree

- `/usr/src/sys/dev/virtio/random/virtio_random.c` - The smallest complete VirtIO driver. Read first.
- `/usr/src/sys/dev/virtio/network/if_vtnet.c` - A larger VirtIO driver.
- `/usr/src/sys/dev/virtio/block/virtio_blk.c` - A request-response VirtIO driver.
- `/usr/src/sys/dev/virtio/virtqueue.c` - The ring machinery.
- `/usr/src/sys/amd64/vmm/` - The bhyve kernel module.
- `/usr/src/usr.sbin/bhyve/` - The bhyve user-space emulator.
- `/usr/src/sys/kern/kern_jail.c` - Jail implementation.
- `/usr/src/sys/net/vnet.h`, `/usr/src/sys/net/vnet.c` - VNET framework.
- `/usr/src/sys/net/if_tuntap.c` - A VNET-aware cloning pseudo-driver.

30.26.2 Manual pages

- `virtio(4)`, `vtnet(4)`, `virtio_blk(4)`
- `bhyve(8)`, `bhyvectl(8)`, `vmm(4)`, `vmm_dev(4)`
- `pci_passthru(4)`
- `jail(8)`, `jail.conf(5)`, `jexec(8)`, `jls(8)`
- `devfs(5)`, `devfs.rules(5)`, `devfs(8)`
- `rctl(8)`, `racct(9)`
- `priv(9)`, `ucred(9)`
- `if_epair(4)`, `vlan(4)`, `tun(4)`, `tap(4)`

30.26.3 External standards

- The VirtIO 1.2 specification (OASIS) is the authoritative reference for the protocol. Available from the OASIS VirtIO Technical Committee site.
- The PCI-SIG specifications for PCI Express, MSI-X, and ACS are relevant for passthrough.

30.26.4 FreeBSD Handbook

- Chapter on jails, which complements this chapter with an administrative perspective.
- Chapter on virtualisation, which covers bhyve(8) management in more depth than this driver-focused chapter.

These resources together form a reading programme that will carry a motivated reader from this chapter's introduction to a practical fluency in FreeBSD virtualisation and containerisation. You do not need to read them all; pick the ones that fit your current project and build from there.

30.27 Appendix: Anti-Patterns in Virtualised Drivers

A good way to learn a craft is to study its common mistakes. This appendix collects the anti-patterns we have seen throughout the chapter, in a single place, with the fix for each. When reviewing a driver (your own or someone else's), scan for these patterns; each is a reliable sign of trouble.

30.27.1 Busy-Waiting on a Status Register

```
/* Anti-pattern */
while ((bus_read_4(sc->res, STATUS) & READY) == 0)
    ;
```

Under virtualisation, each bus read is a VM exit. A tight loop consumes enormous CPU time and may never terminate if the guest is scheduled out. Use `DELAY(9)` inside the loop and a bounded iteration count, or use an interrupt-driven design that does not poll at all.

30.27.2 Caching Physical Addresses

```
/* Anti-pattern */
uint64_t phys_addr = vtophys(buffer);
bus_write_8(sc->res, DMA_ADDR, phys_addr);
/* ...later... */
bus_write_8(sc->res, DMA_ADDR, phys_addr); /* still valid? */
```

A physical address is a temporary view. Under memory compaction, live migration, or memory hotplug, the address may no longer refer to the same physical memory. Use `bus_dma(9)` and hold a DMA map; the map tracks the bus address correctly across kernel memory operations.

30.27.3 Ignoring `si_drv1`

```
/* Anti-pattern */
static int
mydrv_read(struct cdev *dev, struct uio *uio, int flags)
{
    struct mydrv_softc *sc = devclass_get_softc(mydrv_devclass, 0);
    /* what if there are multiple units? */
}
```

The `dev->si_drv1` slot is there to connect the `cdev` back to its `softc`. Setting it in `attach` and using it in `read/write/ioctl` is the idiomatic pattern. Using `devclass_get_softc` with a hardcoded unit number is a minefield as soon as more than one instance attaches.

30.27.4 Assuming INTx

```
/* Anti-pattern */
sc->irq_rid = 0;
sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ, &sc->irq_rid,
    RF_SHAREABLE | RF_ACTIVE);
```

INTx is slower under virtualisation and does not scale to many-queue devices. Use `pci_alloc_msix` first, fall back to `pci_alloc_msi`, and only fall back to INTx for hardware that does not support message-signalled interrupts.

30.27.5 Hard-Coding Feature Bits

```
/* Anti-pattern */
if ((sc->features & VIRTIO_F_RING_INDIRECT_DESC) == 0)
    panic("device does not support indirect descriptors");
```

A driver that panics when a feature is missing is impossible to use with a backend that does not advertise the feature. Negotiate optimistically, check the post-negotiation result, and fall back gracefully to a less efficient path if the feature is missing.

30.27.6 Sleep-With-Spin-Lock Held

```
/* Anti-pattern */
mtx_lock(&sc->lock);
tsleep(sc, PWAIT, "wait", hz);
mtx_unlock(&sc->lock);
```

`tsleep` with an `mtx(9)` spin-lock held causes a panic on FreeBSD. Use `mtx_sleep` (which drops the mutex around the sleep) or use a blocking lock (`sx(9)`) when you need to sleep.

30.27.7 Returning ENOTTY for Unsupported Operations

```
/* Anti-pattern */
case MYDRV_PRIV_IOCTL:
    if (cred->cr_prison != &prison0)
        return (ENOTTY); /* hide from jails */
    ...
```

ENOTTY means “this ioctl does not exist”. It hides the operation from jailed callers, but it also breaks tooling that introspects available ioctls. Prefer EPERM for “this ioctl exists but you cannot use it”, leaving introspection correct.

30.27.8 Forgetting the Detach Path

```
/* Anti-pattern */
static int
mydrv_detach(device_t dev)
{
    struct mydrv_softc *sc = device_get_softc(dev);
    /* release a few things and call it done */
    bus_release_resource(dev, SYS_RES_MEMORY, sc->res_rid, sc->res);
    return (0);
}
```

Missing callout drains, missing taskqueue drains, missing cdev destruction, missing mutex destruction, missing DMA map unload, missing interrupt teardown. Each becomes a leak or a crash at kldunload. The attach path is usually clean; the detach path is where bugs hide.

30.27.9 Assuming device_printf Works Without a Device

```
/* Anti-pattern */
static int
mydrv_modevent(module_t mod, int event, void *arg)
{
    device_printf(NULL, "load event"); /* crashes */
}
```

device_printf with a NULL device_t dereferences a null pointer. Inside module event handlers, before a device has been attached, use printf (with a “mydrv:” prefix to identify the source). device_printf is for per-device events after attach.

30.27.10 Not Cleaning Up VNET State

```
/* Anti-pattern */
static int
mydrv_mod_event(module_t mod, int event, void *arg)
{
    if (event == MOD_UNLOAD)
```

```

        free(mydrv_state, M_DEVBUF); /* in which VNET? */
    }

```

Per-VNET state is allocated in a specific VNET context. Freeing it without setting that context accesses the wrong VNET's data. Use `VNET_FOREACH` and `CURVNET_SET` to walk every VNET and clean up each one's state.

30.27.11 Using `getnanouptime` for Timing

```

/* Anti-pattern */
struct timespec ts;
getnanouptime(&ts);
/* ...do work... */
struct timespec ts2;
getnanouptime(&ts2);
/* difference is arbitrary inside a VM */

```

`getnanouptime` returns a low-resolution reading that the kernel caches. For precise short-duration timing, use `binuptime(9)` or `sbinuptime(9)`, which read the high-resolution time source. Under virtualisation, the precise readings are as correct as the time source allows; the cached readings have been stale for up to a tick.

30.27.12 Probing Hardware in the Probe Method

```

/* Anti-pattern */
static int
mydrv_probe(device_t dev)
{
    /* ...read status register... */
    return (BUS_PROBE_DEFAULT);
}

```

The probe method should be purely identity-based: inspect the PNP information, return a priority, and do nothing that requires the hardware to be present and functional. Hardware interaction belongs in `attach`. Under virtualisation, a probe that pokes hardware before feature negotiation can mis-identify the device.

30.27.13 Storing Kernel Pointers Through `ioctl`

```

/* Anti-pattern */
case MYDRV_GET_PTR:

```

```
*(void **)data = sc->internal_state;  
return (0);
```

Passing kernel pointers to user space is a security bug. Under virtualisation it can even leak hypervisor-relevant information. Always copy the data the caller asks for, never the pointer.

30.27.14 Summary

These anti-patterns cover most of the ways that FreeBSD drivers go wrong under virtualisation. They are not unique to VMs, but they are *amplified* under virtualisation: the same bug that corrupts memory once a day on bare metal might corrupt it hundreds of times per second under a VM whose timing is different. Fixing these patterns is not “fixing the VM case”; it is fixing the driver to meet the kernel’s baseline expectations.

30.28 Appendix: A Checklist for a Virtualisation-Ready Driver

A concrete checklist you can apply to your own driver before declaring it virtualisation-ready. Go through each item; any “no” answer is a task.

30.28.1 Device Binding and Probe

- Does the driver use `VIRTIO_SIMPLE_PNPINFO` or `VIRTIO_DRIVER_MODULE` rather than hand-rolling PNP entries?
- Does the probe method avoid hardware access and only use PNP identity?
- Does the attach method call `virtio_negotiate_features` and log the result?
- Does attach fail cleanly (releasing every resource it has allocated) if any step after virtqueue allocation fails?

30.28.2 Resources

- Does the driver use `bus_alloc_resource_any` with a dynamic RID rather than hard-coding resource IDs?
- Does the driver use `pci_alloc_msix` (or `pci_alloc_msi`) in preference to `INTx`?
- Are all `bus_alloc_resource` calls matched by `bus_release_resource` in detach?

30.28.3 DMA

- Does every address programmed into hardware come from `bus_dma_load` (or similar) rather than `vto-phys`?
- Does the driver hold DMA tags and maps with appropriate lifetimes, not re-creating them per operation when avoidable?
- Does the driver handle `bus_dma_load_mbuf_sg` correctly for scatter-gather?
- Is the driver’s `bus_dma_tag` created with the correct alignment, boundary, and maximum-segment constraints?

30.28.4 Interrupts

- Is the interrupt handler MP-safe (declared with `INTR_MPSAFE`)?
- Does the handler handle the “no work” case gracefully (in case of spurious wake-up)?
- Does the handler disable and re-enable virtqueue interrupts correctly, using the `virtqueue_disable_intr` / `virtqueue_enable_intr` pattern?
- Is the interrupt path free of blocking operations (no `malloc(M_WAITOK)`, no `mtx_sleep`)?

30.28.5 Character Device Interface

- Does attach set `cdev->si_drv1 = sc`?
- Does detach call `destroy_dev` before freeing the `softc`?
- Do read and write handle short I/O correctly (less than the full buffer size)?
- Does the driver check the result of `uiomove` for errors?
- Does `ioctl` use `priv_check` for operations that require elevated privilege?

30.28.6 Locking

- Is every `softc` access covered by the `softc`’s mutex?
- Is the detach path drain-then-free, not free-then-drain?
- Are sleeping waits done with `mtx_sleep` or `sx(9)` rather than `tsleep` with a mutex held?
- Is there a discernible ordering of acquisitions (to avoid deadlock)?

30.28.7 Timing

- Does the driver use `DELAY(9)`, `pause(9)`, or `callout(9)` rather than busy loops?
- Does the driver avoid reading the TSC directly?
- Does every wait have a bounded timeout, with a sensible error on exceed?

30.28.8 Privilege

- Does the driver call `priv_check` for all operations that should not be available to unprivileged users?
- Does the driver use the correct privilege (`PRIV_DRIVER`, `PRIV_IO`, not `PRIV_ROOT`)?
- Does the driver consider jailed callers, using `priv_check` which also calls `prison_priv_check`?

30.28.9 Detach and Unload

- Does detach drain all callouts (`callout_drain`)?
- Does detach drain all taskqueues (`taskqueue_drain_all`)?
- Does detach stop any kernel threads the driver has created (via condition variables or similar)?
- Does detach release every resource attach allocated?
- Can the module be unloaded at any time (no hangs on `kldunload`)?

30.28.10 VNET (if applicable)

- Does the driver register VNET sysinit/sysuninit for per-VNET state?
- Does the driver use V_ prefix macros for per-VNET variables?
- Does the VNET move path allocate state on entry and free on exit?
- Does the driver use CURVNET_SET / CURVNET_RESTORE when accessing a VNET other than the current one?

30.28.11 Testing

- Does the driver have a make test target (even if it just builds and loads)?
- Has the driver been run through the attach-detach cycle at least 100 times?
- Has the driver been loaded under both VirtIO and passthrough (if applicable)?
- Has the driver been loaded inside at least one jail and one VNET jail?
- Has the driver been built on at least amd64; ideally also on arm64?

30.28.12 Documentation

- Is there a README explaining what the driver does and how to build it?
- Is there a manual page describing the driver's user-visible interface?
- Is the PNP table complete enough that kldxref finds the driver for auto-loading?

A driver that passes this checklist is well on its way to being virtualisation-ready. A driver that fails several items needs attention before it will behave well under the diverse environments of modern deployment. Run through the list for every driver you write; it is faster than debugging each issue individually when the driver hits a customer.

30.29 Appendix: Sketching a bhyve Backend for vtedu

Challenge 5 asks the reader to write a bhyve(8) backend for the vtedu driver. This appendix sketches the architecture of such a backend at a level of detail useful for planning. It is not a complete implementation; writing one is the challenge. The goal here is to demystify the backend side of the VirtIO story so the challenge becomes tractable.

30.29.1 Where the Code Lives

The bhyve(8) user-space emulator lives under `/usr/src/usr.sbin/bhyve/`. Its source files are a mixture of CPU and chipset emulation, per-device emulators for different VirtIO types, and glue code that connects bhyve(8) to the vmm(4) kernel module. The relevant per-device files for VirtIO are:

- `/usr/src/usr.sbin/bhyve/pci_virtio_rnd.c`: virtio-rnd (random number generator). The simplest VirtIO backend. Read first.
- `/usr/src/usr.sbin/bhyve/pci_virtio_block.c`: virtio-blk (block device).
- `/usr/src/usr.sbin/bhyve/pci_virtio_net.c`: virtio-net (network).

- `/usr/src/usr.sbin/bhyve/pci_virtio_9p.c`: virtio-9p (filesystem share).
- `/usr/src/usr.sbin/bhyve/pci_virtio_console.c`: virtio-console (serial).

Each of these is a few hundred to a couple of thousand lines of code. They share a common backend framework in `/usr/src/usr.sbin/bhyve/virtio.h` and `/usr/src/usr.sbin/bhyve/virtio.c`. The `pci_virtio_*.c` files above are per-device consumers of that framework; each one registers a struct `virtio_consts`, a set of virtqueue callbacks, and the device-specific config-space layout.

30.29.2 The Framework Handles the Protocol

The good news for a backend author is that `bhyve(8)` already implements the VirtIO protocol. Feature negotiation, descriptor-ring management, notification delivery, interrupt injection, all of it lives in the `virtio.c` framework. A new backend implements only the device-specific behaviour: what happens when a buffer arrives on the virtqueue, what config-space fields the device exposes, and how device-level events are generated.

The framework-facing interface is a small set of callbacks, encapsulated in a struct `virtio_consts`.

```
/* Sketch, not actual bhyve code. */
struct virtio_consts {
    const char *vc_name;
    int vc_nvq;
    size_t vc_cfgsize;
    void (*vc_reset)(void *);
    void (*vc_qnotify)(void *, struct vqueue_info *);
    int (*vc_cfgread)(void *, int, int, uint32_t *);
    int (*vc_cfgwrite)(void *, int, int, uint32_t);
    void (*vc_apply_features)(void *, uint64_t);
    uint64_t vc_hv_caps;
};
```

A new backend fills in this struct and registers it with the framework. The framework calls into the backend when the guest-side driver does interesting things (resets the device, notifies the virtqueue, reads or writes config space).

30.29.3 Sketching the vtedu Backend

For `vtedu`, the backend is simple. It has one virtqueue, no config-space fields beyond the generic ones, and one feature bit (`VTEDU_F_UPPERCASE`). Its state is:

```
struct pci_vtedu_softc {
    struct virtio_softc vsc_vs;
    struct vqueue_info vsc_vq; /* just one queue */
    pthread_mutex_t vsc_mtx;
    uint64_t vsc_features;
};
```

The callbacks are small.

```
static void
pci_vtedu_reset(void *vsc)
{
    struct pci_vtedu_softc *sc = vsc;

    pthread_mutex_lock(&sc->vsc_mtx);
    vi_reset_dev(&sc->vsc_vs);
    sc->vsc_features = 0;
    pthread_mutex_unlock(&sc->vsc_mtx);
}

static void
pci_vtedu_apply_features(void *vsc, uint64_t features)
{
    struct pci_vtedu_softc *sc = vsc;

    pthread_mutex_lock(&sc->vsc_mtx);
    sc->vsc_features = features;
    pthread_mutex_unlock(&sc->vsc_mtx);
}
```

The interesting callback is `vc_qnotify`, called when the guest notifies the virtqueue.

```
static void
pci_vtedu_qnotify(void *vsc, struct vqueue_info *vq)
{
    struct pci_vtedu_softc *sc = vsc;
    struct iovec iov[1];
    uint16_t idx;
    int n;

    while (vq_has_descs(vq)) {
        n = vq_getchain(vq, &idx, iov, 1, NULL);
        if (n < 1) {
            EPRINTLN("vtedu: empty chain");
            vq_relchain(vq, idx, 0);
            continue;
        }

        if ((sc->vsc_features & VTEDU_F_UPPERCASE) != 0) {
            for (int i = 0; i < iov[0].iov_len; i++) {
                uint8_t *b = iov[0].iov_base;
```

```
        if (b[i] >= 'a' && b[i] <= 'z')
            b[i] = b[i] - 'a' + 'A';
    }

    vq_relchain(vq, idx, iov[0].iov_len);
}

vq_endchains(vq, 1);
}
```

That is the core of it. The `vq_has_descs`, `vq_getchain`, `vq_relchain`, and `vq_endchains` calls are framework helpers that unpack the virtqueue descriptors into `iovec` structures and repackage the results.

30.29.4 Connecting to the Device Table

`bhyve(8)` maintains a table of device emulators; each backend registers itself at build time. The registration uses a `PCI_EMUL_TYPE( ... )` macro (or similar) that adds the backend's vtable to a linker-set. Once registered, the `bhyve(8)` command line can reference the backend by name:

```
bhyve ... -s 7,virtio-edu guest0
```

The `-s 7,virtio-edu` adds the `virtio-edu` device at PCI slot 7. When the guest boots, the FreeBSD kernel enumerates the PCI bus, finds the device with VirtIO vendor ID and the right device ID, and attaches `vtedu` to it.

30.29.5 What the Backend Must Verify

To make the backend correct, the author must verify:

- The VirtIO device ID matches the driver's expectation (`VIRTIO_ID_EDU = 0xfff0`).
- The feature-negotiation response matches what the driver expects (advertise `VTEDU_F_UPPERCASE` and `VIRTIO_F_VERSION_1`).
- The virtqueue sizes are large enough for the driver's workload (256 is a reasonable default).
- The config-space size matches what the driver reads (zero for `vtedu`).

30.29.6 Testing the End-to-End Loop

With both sides in place, the end-to-end test looks like this.

On the host, after building the backend and installing the modified `bhyve(8)`:

```
sudo bhyve ... -s 7,virtio-edu guest0
```

Inside the guest, after copying and building `vtedu.c`:

```
sudo kldload ./virtio_edu.ko
ls /dev/vtedu0
echo "hello world" > /dev/vtedu0
cat /dev/vtedu0
```

The expected output of `cat` is `HELLO WORLD` (uppercased by the backend).

If the output is `hello world` (not uppercased), the backend did not negotiate `VTEDU_F_UPPERCASE`. If the `echo` hangs, the virtqueue notification is not reaching the backend. If the `cat` hangs, the backend's interrupt injection is not reaching the guest. Each of these is a specific failure that the debugging techniques from the chapter can localise.

30.29.7 Why This Exercise Is Worth the Effort

Writing a backend and a driver teaches both sides of the VirtIO story. The driver side is what most authors eventually write, but the backend side tells you *why* the VirtIO protocol is shaped the way it is. Feature bits make sense when you have to decide which to advertise. Virtqueue descriptors make sense when you have to unpack them. Interrupt delivery makes sense when you have to inject one.

Completing Challenge 5 promotes you from “VirtIO user” to “VirtIO author”, which is a different level of understanding. If the challenge feels large, tackle it in stages: first get the device to appear in the guest (verify with `pciconf -lv`), then get feature negotiation to work, then handle a single virtqueue message, then polish the full pipeline. Each stage is a separate commit and a separate satisfying milestone.

This is the end of the chapter's technical material. The remaining prose ties together what you have learned and points forward to Chapter 31.

30.30 Appendix: Running the Chapter's Techniques in CI

Continuous integration is now a standard part of most driver projects. This short appendix describes how the chapter's techniques fit into a CI pipeline. The goal is to show that virtualisation and containerisation are not just runtime concerns; they are also practical tools for keeping a driver honest across changes.

30.30.1 Why CI Benefits from Virtualisation

A CI system is, among other things, a place where you need reproducible test environments. Running tests on bare metal is possible but fragile: the test machine accumulates state, different machines have different hardware, and failures are hard to separate from hardware quirks. Running tests inside a VM removes most of these problems. The VM is a clean slate at the start of each run, its “hardware” is uniform across test runs, and its failures are the driver's failures, not the host's.

For FreeBSD driver CI, the standard approach is to run a FreeBSD guest under `bhyve(8)` (if the CI host is FreeBSD) or under KVM/QEMU (if the CI host is Linux). The guest boots a FreeBSD image, loads the driver, runs the test harness, and exits. The whole cycle takes under a minute for a small driver, which means hundreds of tests per day against every commit.

30.30.2 A Minimal CI Flow for a VirtIO Driver

A reasonable flow for a VirtIO driver's CI is:

1. Check out the driver source.
2. Build the driver against the target FreeBSD kernel (often using a cross-compile on the CI host).
3. Start a FreeBSD VM with appropriate VirtIO devices.
4. Copy the built module into the VM.
5. SSH into the VM and load the module.
6. Run the test harness.
7. Capture the output.
8. Shut down the VM.
9. Report pass/fail.

Steps 1 and 2 are unchanged from a non-VM workflow. Steps 3 through 9 are what virtualisation adds.

30.30.3 Practical Tools

For step 3, `vm-bhyve` is convenient on FreeBSD hosts. For Linux CI hosts, `virt-install` from `libvirt` is a standard tool. Both produce a running VM in a few seconds with a pre-built image.

For step 4, a shared volume or a small SSH copy is usual. `virtfs (9P)` or `virtiofs` pass host directories into the guest; `scp` over a tap interface works as well.

For step 5, pre-installed SSH keys and a static IP address (or a DHCP reservation) make the connection painless.

For steps 6 and 7, the test harness is whatever the driver author writes: a shell script, a C program, a Python harness. Whatever it is, it runs inside the VM.

For step 8, `vm stop guest0 --force` (or equivalent) shuts the VM down rapidly. The image is discarded; the next run starts fresh.

For step 9, the exit code of the test harness determines pass/fail. CI systems expect zero for success and nonzero for failure; be consistent.

30.30.4 A Minimal Test Harness

A simple pass/fail harness for a VirtIO driver might look like this.

```
#!/bin/sh
set -e
```

```
# Inside the guest. Expects the module at /tmp/mydriver.ko.

kldload /tmp/mydriver.ko

# Wait for the device to attach.
for i in 1 2 3 4 5; do
    if [ -c /dev/mydev0 ]; then
        break
    fi
    sleep 1
done

if [ ! -c /dev/mydev0 ]; then
    echo "FAIL: /dev/mydev0 did not appear"
    exit 1
fi

# Exercise the device.
echo "hello" > /dev/mydev0
output=$(cat /dev/mydev0)
if [ "$output" != "hello" ]; then
    echo "FAIL: expected 'hello', got '$output'"
    exit 1
fi

# Clean up.
kldunload mydriver

echo "PASS"
exit 0
```

Short, readable, and reports a clear result. CI scales with tests like this: add one per feature, run them all on every commit.

30.30.5 Scaling to Multiple Configurations

A CI pipeline can run the same driver under multiple configurations by spinning up multiple VMs. Useful axes include:

- Kernel version (FreeBSD 14.3, 14.2, 13.5, -CURRENT).
- Architecture (amd64, arm64 with an arm64 guest).
- VirtIO feature set (force-disable certain features on the backend to exercise fallback paths).
- Hypervisor (bhyve, QEMU/KVM, VMware) where support varies.

Each configuration is an independent job that the CI system parallelises. The aggregate of “driver passes on every configuration” is a strong signal that the driver is robust.

30.30.6 A Note on Hardware-in-the-Loop CI

For drivers that talk to real hardware, CI needs a bare-metal or passthrough setup. This is more expensive and less common, but some projects maintain a small fleet of test machines for this purpose. The techniques from the chapter apply: a hardware test rig uses ppt(4) passthrough to give a guest access to a specific device, and the CI system drives the guest the same way it would drive a pure-VirtIO guest.

Hardware CI is slower to set up and more expensive to run. For most projects, pure-VirtIO CI is enough for the bulk of tests, with a small suite of hardware tests run at a slower cadence.

30.30.7 The Payoff

CI that exercises a driver under realistic conditions catches regressions quickly, while the fix is still fresh in the author’s mind. A regression caught at commit-time takes minutes to fix; a regression caught weeks later during a release candidate takes hours. Virtualisation makes the former affordable, and that is one of the strongest arguments for taking the techniques in this chapter seriously.

30.31 Appendix: Commands Cheat Sheet

A compact list of the commands a driver author uses most often when working with virtualisation and containerisation on FreeBSD. Keep this page open while working through the labs.

30.31.1 Host-Side Virtualisation

```
# Check hypervisor extensions
sysctl hw.vmm

# Load/unload vmm(4)
kldload vmm
kldunload vmm

# vm-bhyve guest management
vm list
vm start guest0
vm stop guest0
vm console guest0
vm configure guest0
vm install guest0 /path/to/iso
vm create -t default -s 20G guest0
```

```
# Direct bhyve (verbose but informative)
bhyectl --vm=guest0 --destroy
bhyectl --vm=guest0 --suspend=normal
```

30.31.2 Guest-Side Inspection

```
# Is this a guest?
sysctl kern.vm_guest

# Which devices attached?
pciconf -lvBb
devinfo -v
kldstat -v

# VirtIO-specific
dmesg | grep -i virtio
sysctl dev.virtio_pci
sysctl dev.virtqueue
```

30.31.3 PCI Passthrough

```
# Mark a device as passthrough-capable (in /boot/loader.conf)
pptdevs="5/0/0"

# Verify after reboot
pciconf -lvBb | grep ppt
dmesg | grep -i dmar      # Intel
dmesg | grep -i amdvi     # AMD
```

30.31.4 Jails

```
# Create and manage jails
jail -c name=test path=/jails/test host.hostname=test ip4=inherit persist
jls
jexec test /bin/sh
jail -r test

# devfs rulesets
```

```
devfs rule -s 100 show
devfs -m /jails/test/dev rule -s 100 applyset
```

30.31.5 VNET

```
# epair setup
kldload if_epair
ifconfig epair create
ifconfig epair0a 10.0.0.1/24 up

# Move one end into a VNET jail
jail -c name=vnet-test vnet vnet.interface=epair0b path=/jails/vnet-test persist

# Confirm
ifconfig -j vnet-test epair0b
```

30.31.6 Resource Limits

```
# rctl
rctl -a jail:test:memoryuse:deny=512M
rctl -a jail:test:pcpu:deny=50
rctl -h jail:test
rctl -l jail:test
```

30.31.7 Observability

```
# Interrupt rate
vmstat -i

# VM exit counts (needs PMC)
pmcstat -S VM_EXIT -l 10

# DTrace virtqueue activity
dtrace -n 'fbt::virtqueue_enqueue:entry { @[probefunc] = count(); }'

# Kernel trace
ktrace -i -p $(pgrep bhyve)
kdump -p $(pgrep bhyve)
```

30.31.8 Module Lifecycle

```
# Build, load, test, unload  
make clean && make  
sudo kldload ./mydriver.ko  
kldstat -v | grep mydriver  
# ...exercise driver...  
sudo kldunload mydriver
```

These are the day-to-day commands. A quick-reference card like this, pinned to a wall or kept in a terminal tab, saves hours over the course of a project.

With that, the chapter is complete.

31 Security Best Practices

31.1 Introduction

You reach Chapter 31 with an understanding of environment that few authors have even asked you to build. Chapter 29 taught you to write drivers that survive changes of bus, architecture, and word size. Chapter 30 taught you to write drivers that behave correctly when the machine under them is not a machine at all, but a virtual one, and when the process using them is not on the host but in a jail. Both chapters have been about boundaries: the boundary between hardware and kernel, the boundary between host and guest, the boundary between host and container. Chapter 31 asks you to look at a different boundary, one that sits closer to home than any of those, and one that is easier to forget precisely because it runs through the middle of your own code.

The boundary this chapter is about is the boundary between the kernel and everyone who talks to it. Userland programs, the hardware itself, other parts of the kernel, the bootloader passing you a parameter, a firmware blob that arrived from the vendor's support site last week, a device that started behaving strangely after an upgrade. Every one of them is on the other side of a trust edge from the driver you wrote. Every one of them can, deliberately or accidentally, pass the driver something that does not match its expectations. A driver that respects this boundary is a driver that can be trusted to defend the kernel. A driver that does not respect it is a driver that, the day something hostile arrives, will let that hostility reach code it should never have reached.

This chapter is about building that habit of respect. It is not a security textbook, and it will not try to turn you into a vulnerability researcher. What it will do is teach you to see your driver the way an attacker or a careless program might see it, to recognise the specific classes of mistake that turn a small bug into a full system compromise, and to reach for the right FreeBSD primitives when you want to prevent those mistakes from happening.

A few words about what this means in practice. A kernel security bug is not just a worse version of a user-space security bug. A buffer overflow in a user-space program can corrupt that program's memory; a buffer overflow in a driver can corrupt the kernel, and the kernel serves every program on the system. An off-by-one error in a user-space parser may crash the parser; the same off-by-one in a driver may hand an attacker a way to read kernel memory that holds another user's secrets, or to write arbitrary bytes into the kernel's function tables. The consequences do not scale linearly with the size of the bug. They scale with the privilege of the code where the bug lives, and the kernel sits at the top of that hierarchy.

This is why driver security is not a separate subject, added on top of the programming skills you have been building. It is those programming skills, applied with a particular discipline in mind. The `copyin()` and `copyout()` calls you saw in earlier chapters become tools for enforcing a trust boundary. The `malloc()` flags you learned become ways to control memory lifetime. The locking discipline you practised becomes a way to prevent races that an attacker could otherwise steer. The privilege checks you saw briefly in Chapter 30 become a first line of defence against unprivileged callers reaching into places they should not be able to reach. Security is, in a

real sense, the discipline of writing kernel code well, held to a higher standard and examined through the eyes of someone who wishes it to fail.

The chapter builds that view in ten steps. Section 1 motivates the subject and explains why a driver's security model is different from an application's. Section 2 works through the mechanics of buffer overflows and memory corruption in kernel code, a topic that is easy to misunderstand because the ordinary C you learned in Chapter 4 has pitfalls that grow teeth inside the kernel. Section 3 covers user input, the single largest source of exploitable bugs in drivers, and walks through safe use of `copyin(9)`, `copyout(9)`, and `copyinstr(9)`. Section 4 turns to memory allocation and lifetime, including the FreeBSD-specific flags on `malloc(9)` that matter for safety. Section 5 examines race conditions and time-of-check-to-time-of-use bugs, a class of issue that sits at the intersection of concurrency and security. Section 6 covers access control: how a driver should check whether a caller is allowed to do what they are asking for, using `priv_check(9)`, `ucred(9)`, `jailed(9)`, and the `securelevel` machinery. Section 7 addresses information leaks, the subtle class of bug in which a driver gives away data it did not intend to. Section 8 looks at logging and debugging, which can themselves become security problems if they are casual about what they print. Section 9 distils a set of design principles around secure defaults and fail-safe behaviour. Section 10 rounds out the chapter with testing, hardening, and a practical introduction to the tools FreeBSD gives you for finding these bugs before someone else does: `INVARIANTS`, `WITNESS`, the kernel sanitizers, `Capsicum(4)`, and fuzzing with `syzkaller`.

Alongside those ten sections, the chapter will touch on the `mac(4)` framework, `Capsicum`'s role in constraining `ioctl` callers, string-safety idioms such as `copyinstr(9)`, and the build pitfalls that come with modern kernel hardening features like ASLR, SSP, and PIE for loadable modules. Each of these arrives where it is most relevant, never at the cost of the core thread.

One last thing before we begin. Writing secure kernel code is not a matter of reading a checklist and ticking items off. It is a way of reading your own code, and a set of reflexes that become automatic over time. The first time you see a driver that calls `copyin` into a fixed-size stack buffer without checking the length, you may wonder what is wrong with it; the hundredth time you see that pattern, you will feel the hair on the back of your neck stand up. The goal of this chapter is not to teach you every variant of every vulnerability; that would take a shelf of books. The goal is to help you build the reflexes. Once you have them, you will write drivers that are safer by default, and you will spot the dangerous patterns in other people's code before they cause trouble.

Let us begin.

31.2 Reader Guidance: How to Use This Chapter

Chapter 31 is conceptual in a way that a few of the earlier chapters were not. The code samples are short and focused; the value is in the thinking they teach. You can work through the whole chapter by reading carefully, and you will come out of it a better driver author even if you never type a single line. The labs at the end turn the thinking into muscle memory, and the challenges push the thinking into uncomfortable corners where real bugs live, but the text itself is the main teaching surface of the chapter.

If you choose the **reading-only path**, plan for roughly three to four focused hours. At the end you will be able to recognise the major classes of driver security bug, to explain why kernel-level bugs change the whole system's trust model, to describe the FreeBSD primitives that defend against each class, and to sketch what a safe version of a given unsafe pattern should look like. That is a substantial body of knowledge, and for many readers it is where the chapter should end on the first pass.

If you choose the **reading-plus-labs path**, plan for eight to twelve hours spread across two or three sessions. The labs build on a tiny pedagogical driver called `secdev` that you will write over the course of the chapter. Each lab is a short, focused exercise: in one, you will fix a deliberately unsafe `ioctl` handler; in another, you will add `priv_check(9)` and observe what happens when unprivileged and jailed processes try to use a restricted entry point; in another, you will introduce a race condition, watch it manifest under `WITNESS`, and then fix it; and in a final lab, you will run a simple fuzzer against the driver's `ioctl` surface and read the resulting crash reports. Each lab leaves you with a working system and an entry in your lab logbook; none of them are long enough to exhaust an evening.

If you choose the **reading-plus-labs-plus-challenges path**, plan for a long weekend or two. The challenges push `secdev` into real territory: you will add MAC policy hooks so that a site-local policy can override the driver's defaults, you will tag the driver's `ioctls` with capability rights so that a Capsicum-confined process can still use the safe subset, you will write a short `syzkaller` description file for the driver's entry points, and you will run the sanitized kernel variants (`KASAN`, `KMSAN`) to see what they catch that the normal `INVARIANTS` build misses. Each challenge is self-contained; none require reading additional chapters to complete.

A note on the lab environment. You will continue to use the throwaway FreeBSD 14.3 machine from earlier chapters. The labs in this chapter do not need a second machine, do not need `bhyve(8)`, and do not need to modify the host in ways that would persist after a reboot. You will load and unload kernel modules, you will write to a test character device, you will read `dmesg` carefully, and you will edit a small tree of source files. If something goes wrong, a reboot will recover the host. A snapshot or boot environment is still a good idea, and it is cheap to create.

One piece of special advice for this chapter: **read slowly**. Security prose is sometimes deceptively gentle. The ideas look obvious on the page, but the reason a given bug is a bug can take a minute of thinking through before it clicks. Resist the temptation to skim. If a paragraph describes a race condition that you do not fully understand, stop and reread it. If a code snippet demonstrates an information leak, trace the path of the leaked bytes in your head until you can name which byte came from where. The reward for careful reading here is a set of reflexes that will outlive this book.

31.2.1 Prerequisites

You should be comfortable with everything from earlier chapters. In particular, this chapter assumes you already understand how to write a loadable kernel module, how the driver's `open`, `read`, `write`, and `ioctl` entry points connect to `/dev/` nodes, how `softc` is allocated and attached to a `device_t`, how mutexes and reference counts work at the level Chapter 14 and Chapter 21 taught, and how interrupts and callouts interact with sleeping paths. If any of that is shaky, a brief revisit before starting will make the examples land more firmly.

You should also be comfortable with ordinary FreeBSD system administration: reading `dmesg`, loading and unloading modules, running commands as an unprivileged user, creating a simple jail, and using `sysctl(8)` to observe and tune the system. The chapter will refer to these tools without walking you through each one from scratch.

No prior background in security research is needed. The chapter builds its vocabulary from the ground up.

31.2.2 What This Chapter Does Not Cover

A responsible chapter tells you what it leaves out. This chapter does not teach exploit development. It does not teach you how to write shellcode, how to build a ROP chain, or how to turn a crash into code execution. Those are legitimate subjects, but they belong to a different kind of book, and the skills they require are not the skills that help you write safer drivers.

This chapter does not turn you into a security auditor. Auditing a large codebase for every class of vulnerability is a distinct discipline with its own tools and rhythms. What the chapter does give you is the ability to audit your own driver competently, and to recognise the patterns worth flagging in someone else's.

The chapter does not replace the FreeBSD Security Advisories, the CERT C coding standard, the SEI's guidance on secure kernel programming, or the manual pages of the APIs it discusses. It points you toward those sources and expects you to consult them when a specific question goes deeper than the chapter can follow. Each major section of the chapter ends with a short pointer to the relevant manual pages so that your first port of call after the chapter is the FreeBSD documentation itself.

Finally, the chapter does not attempt to cover every possible bug class. It focuses on the classes that matter most for drivers and that can be addressed with FreeBSD primitives the reader already knows or can learn in a few pages. Some exotic classes of bug, such as Spectre-style speculative execution side channels, are mentioned only in passing; they belong to specialised hardening work that most driver authors do not and should not write from scratch.

31.2.3 Structure and Pacing

Section 1 builds the mental model: what is at risk when a driver goes wrong, and how the driver's security model differs from an application's. Section 2 addresses buffer overflows and memory corruption in kernel code, including the subtle ways they differ from their user-space cousins. Section 3 teaches safe handling of user-provided input through `copyin(9)`, `copyout(9)`, `copyinstr(9)`, and related primitives. Section 4 covers memory allocation and lifetime: the flags on `malloc(9)`, the difference between `free(9)` and `zfree(9)`, and the use-after-free patterns that kernel modules fall into. Section 5 turns to races and TOCTOU bugs, including the security-relevant ways they manifest. Section 6 covers access control and privilege enforcement, from `priv_check(9)` through `ucred(9)` and jails to the `securelevel` machinery. Section 7 addresses information leaks and the surprisingly subtle ways data escapes. Section 8 discusses logging and debugging, which can themselves become security problems. Section 9 collects the principles of secure defaults and fail-safe design. Section 10 covers testing and hardening: `INVARIANTS`, `WITNESS`, `KASAN`, `KMSAN`, `KCOV`, `Capsicum(4)`, the `mac(4)` framework, and a walkthrough of running `syzkaller` against a driver's `ioctl` surface. The labs and challenges follow, along with a closing bridge into Chapter 32.

Read the sections in order. Each one assumes the previous one, and the final two sections (Sections 9 and 10) synthesise what came before into practical advice and a workflow.

31.2.4 Work Section by Section

Each section in this chapter covers one core idea. Do not try to hold two sections in your head at the same time. If a section ends and you feel uncertain about one of its points, pause before starting the next one, re-read the

closing paragraphs, and look up the cited manual pages. A five-minute pause to consolidate is almost always faster than discovering two sections later that the foundation was not quite firm.

31.2.5 Keep the Reference Driver Close

The chapter builds a small pedagogical driver called `secdev` across its labs. You will find it, along with starter code, intentionally broken versions, and fixed variants, under `examples/part-07/ch31-security/`. Each lab directory contains the state of the driver at that step, along with its `Makefile`, a brief `README.md`, and any supporting scripts. Clone the directory, type along, and load each version after every change. Running unsafe code on your lab machine and watching what happens is part of the lesson; do not skip the live tests.

31.2.6 Open the FreeBSD Source Tree

Several sections point to real FreeBSD files. The ones that repay careful reading in this chapter are `/usr/src/sys/sys/systm.h` (for the exact signatures of `copyin`, `copyout`, `copyinstr`, `bzero`, and `explicit_bzero`), `/usr/src/sys/sys/priv.h` (for the `priv` constants and the `priv_check` prototypes), `/usr/src/sys/sys/ucrd.h` (for the credential structure), `/usr/src/sys/sys/jail.h` (for the `jailed()` macro and `prison` structure), `/usr/src/sys/sys/malloc.h` (for the allocation flags), `/usr/src/sys/sys/sbuf.h` (for the safe string builder), `/usr/src/sys/sys/capsicum.h` (for capability rights), `/usr/src/sys/sys/sysctl.h` (for the `CTLFLAG_SECURE`, `CTLFLAG_PRISON`, `CTLFLAG_CAPRD`, and `CTLFLAG_CAPWR` flags), and `/usr/src/sys/kern/kern_priv.c` (for the `priv-check` implementation). Open them when the chapter points you at them. The source is the authority; the book is a guide into it.

31.2.7 Keep a Lab Logbook

Continue the lab logbook from earlier chapters. For this chapter, log a short note for each lab: which commands you ran, which modules loaded, what `dmesg` said, what surprised you. Security work, more than most, benefits from a paper trail, because the bugs it teaches you to see are often invisible until you look for them in the right way, and a logbook entry from last week may save you an hour of re-discovery this week.

31.2.8 Pace Yourself

Several ideas in this chapter land more firmly the second time you meet them than the first. Feature bits in `virtio` made more sense in Chapter 30 after a day's rest; the same thing happens here with, say, the distinction between `copyin` error handling and TOCTOU-safe re-copying. If a subsection blurs the first time through, mark it, move on, and come back to it. Security reading rewards patience.

31.3 How to Get the Most Out of This Chapter

Chapter 31 rewards a particular kind of engagement. The specific primitives it introduces, `priv_check(9)`, `copyin(9)`, `sbuf(9)`, `zfree(9)`, `ppsratcheck(9)`, are not decorative; they are the bricks of secure driver code. The most valuable habit you can build while reading this chapter is the habit of asking two questions at every single call site: where did this data come from, and who is allowed to cause it to be here?

31.3.1 Read With a Hostile Mind

Security reading asks for a shift in how you look at code. When the chapter shows you a driver that copies `len` bytes from user space into a buffer, do not read the snippet as if the value of `len` is reasonable. Read it as if `len` is `0xFFFFFFFF`. Read it as if `len` is a carefully chosen value that passes one obvious check and fails a subtler one. Read the code the way a bored, clever, unfriendly person might read it before going to bed. That is the reading that finds bugs.

31.3.2 Run What You Read

When the chapter introduces a primitive, run a small example of it. When it shows a pattern for `priv_check`, write a two-line kernel module that calls `priv_check` with a specific constant and observe what happens when you invoke its `ioctl` from a non-root process. When it describes the effect of `CTLFLAG_SECURE` on a `sysctl`, set a dummy `sysctl` in your lab module, raise and lower the `securelevel`, and watch the behaviour change. The running system teaches what prose alone cannot.

31.3.3 Type the Labs

Every line of code in the labs is there to teach something. Typing it yourself slows you down enough to notice the structure. Copy-pasting the code often feels productive and usually is not; the finger-memory of typing kernel code is part of how you learn it. Even when a lab asks you to fix a deliberately unsafe file, type the fix yourself rather than pasting in the suggested answer.

31.3.4 Treat `dmesg` as Part of the Manuscript

Several of the bugs in this chapter surface only in kernel log output. A `KASSERT` firing, a `WITNESS` complaint about an out-of-order lock acquisition, a rate-limited warning from your own `log(9)` call, all of these appear in `dmesg` and nowhere else. Watch `dmesg` during the labs. Tail it in a second terminal. Copy relevant lines into your logbook when they teach something non-obvious.

31.3.5 Break Things Deliberately

At several points in the chapter, and explicitly in some of the labs, you will be asked to run unsafe code to see what happens. Do it. A kernel panic on your lab machine is a cheap educational experience. Unload the module after each experiment, note the symptom in your logbook, and move on. A panic in a production system is expensive; the whole point of a lab environment is to give you the freedom to learn these lessons where they are cheap.

31.3.6 Work in Pairs When You Can

If you have a study partner, this chapter is a good one to pair on. Security work benefits enormously from a second pair of eyes. One of you can read the code looking for bugs while the other reads the prose; then you can swap and compare notes. The two modes of reading find different things, and the conversation itself is educational.

31.3.7 Trust the Iteration

You will not remember every flag, every constant, every priv identifier on the first pass. That is fine. What matters is that you remember the shape of the subject, the names of the primitives, and where to look when a concrete question comes up. The specific identifiers become reflex after you have written two or three security-conscious drivers; they are not a memorisation exercise.

31.3.8 Take Breaks

Security reading is cognitively intense in a different way from performance work or bus-plumbing work. It asks you to hold a model of an adversary in your head while you read code designed to serve a friend. Two hours of focused reading followed by a real break is almost always more productive than four hours of grinding.

With those habits in place, let us begin with the question that frames everything else: why does driver security matter?

31.4 Section 1: Why Driver Security Matters

It is tempting to think of driver security as a subset of software security in general, with the same techniques and the same consequences, just applied to a different codebase. That framing is not wrong, exactly, but it misses what is distinctive about drivers. The reason drivers deserve their own chapter on security is that the consequences of a security bug in a driver are different from the consequences of the same bug in a user-space program, and the defenses look different too. This section builds the mental model that the rest of the chapter rests on.

31.4.1 What the Kernel Trusts

The kernel is the only part of the system that is trusted to do certain things. It is the only piece of software that can read or write any physical memory address. It is the only piece of software that can talk directly to hardware. It is the only piece of software that can grant or revoke privileges for user-space processes. It is the piece of software that holds the secrets of every user and the credentials of every running program. When it decides whether a given request should succeed, nothing above it can overrule that decision.

That privilege is the whole point of having a kernel. Without it, the kernel would not be able to enforce the boundaries that make a multi-user system possible. With it, the kernel carries a responsibility that no user-space program carries: every line of kernel code runs with the authority of the whole system, and every bug in kernel code can, in principle, be escalated into the authority of the whole system.

A driver is part of the kernel. Once loaded, a driver's code runs with the same privilege as the rest of the kernel. There is no finer-grained boundary inside the kernel that says "this code is only a driver, so it cannot touch the scheduler." A pointer dereference in your driver, if it lands on the wrong address, can corrupt any data structure the kernel uses. A buffer overflow in your driver, if it is large enough, can overwrite any function pointer the kernel uses. An uninitialised value in your driver, if it flows into the right place, can leak a neighbour's secrets. The kernel trusts the driver completely, because it has no mechanism to distrust it.

That asymmetry is the first thing to internalise. User-space programs run under the kernel, and the kernel can enforce rules on them. Drivers run inside the kernel, and no one enforces rules on them except the driver authors themselves.

31.4.2 A Kernel Bug Changes the Trust Model

A bug in a user-space program is a bug. A bug in the kernel, and particularly in a driver that an unprivileged process can reach, is often something worse: it is a change to the trust model of the whole system. This is the single most important idea in this chapter, and it is worth dwelling on.

Consider a tiny bug in a user-space text editor: an off-by-one error that writes one extra byte to a buffer. In the worst case, the editor crashes. Maybe the user loses a few minutes of work. Maybe the editor's sandbox catches the crash and the impact is even smaller. The consequences are bounded by what that user could already do; the editor was running with the user's privileges, so the damage cannot escape those privileges.

Now consider the same off-by-one error in a driver's `ioctl` handler. If the driver is reachable from unprivileged processes, an unprivileged user can trigger the off-by-one. The one extra byte lands in kernel memory. Depending on where it lands, it could flip a bit in a structure the kernel uses to decide who is allowed to do what. A clever attacker can arrange for that bit flip to change which process has root privileges. Now the off-by-one is not a crash; it is a privilege escalation. The unprivileged user becomes root. The system's trust model, which assumed that only authorised users were root, no longer holds.

This is not a hypothetical scaling. It is the standard way kernel bugs are turned into exploits. The kernel's data structures sit near each other in memory. An attacker who can write a single byte somewhere in the kernel can often, with enough cleverness, steer that byte into a structure that matters. A few bytes out of place in the right data structure becomes a working exploit. A few bytes in the right place can make the difference between "my editor crashed" and "the attacker now owns the machine."

This is why the mental framing of security must shift when you move from user-space to the kernel. You are not asking "what is the worst that can happen if this code goes wrong?" You are asking "what is the worst thing that someone could do to the system if they could steer this code to go wrong in exactly the way they wanted?" Those are different questions, and the second one is always the right one to ask inside the kernel.

31.4.3 A Partial Catalogue of What Is at Risk

It helps to make the abstract concrete. If a driver has a bug that can be triggered from user space, what specifically is at risk? The list is long. Here are the major categories, as a way of fixing the stakes in your mind before the chapter turns to specific classes of bug.

Privilege escalation. An unprivileged user obtains root privileges, or a jailed user obtains host-level privileges, or a user inside a capability-mode sandbox obtains privileges outside that sandbox.

Arbitrary kernel memory read. An attacker reads kernel memory they should not see. This includes cryptographic keys, password hashes, other users' file contents that happen to be in the page cache, and the kernel's own data structures that reveal where other interesting memory lives.

Arbitrary kernel memory write. An attacker writes to kernel memory they should not write. This is often the foundation for privilege escalation, because it can be used to modify credential structures, function pointers, or other security-critical state.

Denial of service. An attacker causes the kernel to panic, to hang, or to consume so many resources that the system is no longer useful. Drivers that can be made to loop indefinitely, to allocate unbounded memory, or to hit a KASSERT from user input are all sources of DoS.

Information leak. An attacker learns something they should not know: a kernel pointer (which defeats KASLR), the contents of an uninitialised buffer (which may contain previous callers' data), or metadata about other processes or devices on the system.

Persistence. An attacker installs code that survives reboots, typically by writing to a file the kernel will re-load at boot, or by corrupting a configuration structure.

Sandbox escape. An attacker who is confined to a jail, to a VM guest, or to a Capsicum capability-mode sandbox escapes their confinement by way of a driver bug.

Each of these is a plausible consequence of a single, plausible mistake in a driver. The mistake is often something that looked harmless to the author: a forgotten length check, a structure that was not zeroed before being copied out, a race between two paths that looked to be mutually exclusive. This chapter's goal is to help you see those mistakes before they become any of the items on the list.

31.4.4 Real-World Incidents

Every major kernel has a history of driver-based security incidents. FreeBSD is no exception. Without turning this into a vulnerability archaeology exercise, it is worth naming a few types of incident that are particularly instructive.

There is the classical **ioctl without privilege check**, in which a driver exposes an ioctl that does something a non-root user should not be able to do, but forgets to call `priv_check(9)` or equivalent before doing it. The fix is a one-line addition; the bug can enable arbitrary-code execution as root. This pattern has appeared in multiple kernels over the decades.

There is the **information leak through uninitialised memory**, in which a driver allocates a structure, fills in some fields, and copies the structure to user space. The fields the driver did not fill in contain whatever the allocator happened to return, which may include the last caller's data. Over time, attackers have been able to extract kernel pointers, file contents, and cryptographic keys from this class of bug.

There is the **buffer overflow in a seemingly innocent path**, in which a driver parses a structure from a firmware blob or a USB descriptor without checking the length fields the data claims. An attacker who can control the firmware (for example, by connecting a malicious USB device) can trigger the overflow. This class of bug is particularly pernicious because the attacker can be physical: plug in a USB stick, walk away.

There is the **race between open and read**, in which two threads simultaneously open and read a device, and the driver's state machine has a gap in its synchronisation. The second thread observes a half-initialised state and triggers a crash, or worse, is allowed to proceed and sees data that should have been cleared.

There is the **TOCTOU bug**, in which a driver validates a value in a user-space structure, then later trusts that the value is still the same. Between the check and the use, the user-space program has changed the value, and the driver now operates on data it never validated.

Each of these is preventable. Each has a well-known FreeBSD primitive that prevents it. The chapter is structured around teaching those primitives in the right order.

31.4.5 The Security Mindset

A recurring theme in this chapter is that secure code comes from a particular way of thinking, not from a particular set of techniques. The techniques matter; you need to know them. But the techniques without the mindset produce code that is secure against the specific bugs the author thought of, and insecure against every bug the author did not. The mindset, applied consistently, keeps producing safe code even when the techniques are imperfect.

The mindset has three habits. First, **assume the worst about every input**. Every byte you read from user space, from a device, from firmware, from a bus, from a sysctl, from a loader tunable, might be the worst byte an attacker could have chosen. Not because most inputs are adversarial, but because secure code must work correctly even when they are. Second, **assume the least about the environment**. Do not assume the caller is root just because the test setup made them root; check. Do not assume a field in a structure was zeroed just because the last writer said it was; zero it yourself. Do not assume the system is at securelevel 0; test it. Third, **fail closed rather than open**. When something is wrong, return an error. When something is missing, refuse to proceed. When a check fails, stop. A driver that errs on the side of not working when the rules are unclear is a driver that is hard to abuse; a driver that errs on the side of working anyway is a driver waiting to be exploited.

Those three habits do not need memorisation. They need internalisation. This chapter is a workshop in internalising them.

31.4.6 Even Root Is Not Trusted

A specific point that beginners sometimes miss: even when the caller is root, the driver must still validate the caller's input. This seems counterintuitive. If the caller is root, they can already do anything; what is the point of validating their input?

The point is that “the caller is root” is a statement about authorisation, not about correctness. A root user can ask your driver to do something, and the kernel will say yes. But a root user can also be a buggy program that is passing the wrong length by accident. A root user can be a compromised program that an attacker has taken over. A root user can be running a clumsy script that treats a pointer as a length. In every one of these cases, your driver must still behave sanely.

Concretely, if root passes you a `len` of `0xFFFFFFFF` in an `ioctl` argument, the correct behaviour is to return `EINVAL`, not to happily copy in four gigabytes of user memory into a kernel buffer. Root did not really want that; root was running a program that had a bug. Your driver's job is to prevent the bug from becoming a kernel bug.

This is why input validation is universal. It is not about distrust of the caller; it is about the driver protecting itself and the rest of the kernel from mistakes, whether deliberate or accidental, coming from above.

31.4.7 Where the Boundaries Are

A driver lives between several boundaries. It is worth naming them explicitly, because different classes of bug live at different boundaries, and the defenses differ.

The **user-kernel boundary** separates userland from the kernel. Data crossing from user space into the kernel must be validated; data crossing from kernel to user space must be sanitised. `copyin(9)` and `copyout(9)` are

the primary mechanism for crossing this boundary safely. Sections 3, 4, and 7 of this chapter deal with this boundary.

The **driver-bus boundary** separates the driver from the hardware. Data read from a device is not always trustworthy; a malicious device or a firmware bug can present values the driver did not expect. Length fields in descriptors, for example, must be bounded by the driver's own expectations rather than by the values the device claims. Section 2 touches on this.

The **privilege boundary** separates different levels of authority: root from non-root, the host from a jail, the kernel from a capability-mode sandbox. Privilege checks enforce this boundary. Section 6 deals with it in depth.

The **module-module boundary** separates your driver from other kernel modules. It is the least defended of the boundaries, because the kernel trusts its own modules completely by default. This is one reason the next section talks about the blast radius of a driver bug: it is almost always larger than the driver.

31.4.8 Where This Chapter Fits

Chapters 29 and 30 taught environment in two senses: architectural and operational. Chapter 29 taught you to make the driver portable across buses and architectures. Chapter 30 taught you to make it behave correctly in virtualised and containerised environments. Chapter 31 teaches a third kind of environment, which is policy: the security-relevant choices the administrator makes and the adversary attempts to violate. Taken together, the three chapters describe the environment around a FreeBSD driver at runtime, and what the driver author must do to be a responsible citizen of that environment.

The thread continues. Chapter 32 will turn to Device Tree and embedded development, which may feel like a change of subject but is in fact the same thread carried into new hardware. The security habits you learn here travel with you to every ARM board, every RISC-V system, every embedded target where a driver's privilege and resource discipline matter just as much as they do on a desktop. Later chapters will deepen the debugging story, including some of the techniques this chapter introduces at a high level. The security habits you build now will serve you for the rest of the book, and for the rest of your career as a driver author.

31.4.9 Wrapping Up Section 1

A driver is part of the kernel. Every bug in a driver is a potential kernel bug, and every kernel bug is a potential change to the system's trust model. Because the blast radius is so large, the bar for correctness in a driver is higher than the bar in a user-space program. The chapter's remaining sections walk through the specific classes of bug that matter most for drivers, and the FreeBSD primitives that defend against them.

The single sentence to remember from this section is this: **in a driver, bugs are not just mistakes; they are changes to who can do what on the system**. Keep that framing in mind as you read the rest of the chapter, and every other sentence will be easier to follow.

With the stakes in view, we turn to the first concrete class of bug: buffer overflows and memory corruption inside kernel code.

31.5 Section 2: Avoiding Buffer Overflows and Memory Corruption

Buffer overflows and their cousins, out-of-bounds reads and writes, are the oldest and still among the most common classes of security bug. They appear in user-space code, in kernel code, and in every language that does not enforce bounds at the language level. C is such a language, and kernel C is such a language with sharper edges, so drivers are fertile ground for buffer bugs.

This section explains how these bugs appear in kernel code, why they are often worse than their user-space equivalents, and how to write driver code that avoids them by construction. It assumes that the reader remembers the C material from Chapter 4 and the kernel-C material from Chapter 5 and Chapter 14. If any of that is shaky, a short revisit before reading this section will repay the investment.

31.5.1 A Short Refresher on Buffers

A buffer in C is a region of memory with a specific size. In a driver, buffers come from several places. Stack-allocated buffers are declared as local variables inside functions; they live for the duration of the function call and are cheap to allocate and free. Heap-allocated buffers come from `malloc(9)` or `uma_zalloc(9)`; they live as long as the driver keeps a pointer to them. Statically allocated buffers are declared at file scope; they live for the whole lifetime of the module. Each of these has different properties and different pitfalls.

The one thing all buffers share is a size. Writing past the end of the buffer, or reading before its beginning, or indexing into it with a value that does not fit, is a **buffer overflow** (or underflow). The overflow itself is the mechanism; what the overflow writes and where the writing lands determine the severity.

A stack overflow in a driver is the most dangerous kind, because the stack holds return addresses, saved registers, and local variables for the whole call chain. A write past the end of a stack buffer can reach into the caller's return address, and from there into arbitrary code execution. A heap overflow is less directly exploitable, but heap buffers are often adjacent to other kernel data structures, and a heap overflow that lands on the right structure is a clear path to compromise. A static-buffer overflow is the least common but can still lead to compromise if the static buffer is next to other writeable module data.

The vocabulary of “stack” and “heap” overflow should feel familiar from user-space work. The mechanism is the same. The consequences are worse, because the kernel's code and data share an address space with everything else it does.

31.5.2 How Overflows Happen in Kernel Code

Overflows do not happen because authors write to memory they did not intend to write to. They happen because the author writes to memory they did intend to write to, but the length or offset is wrong. The most common shapes of the mistake are:

Trusting a length from user space. The driver's `ioctl` argument contains a length field, and the driver uses that length to decide how much to copy in or how large a buffer to allocate. If the length is not bounded, the user can pick a length that makes the copy misbehave.

Off-by-one in a loop. A loop that iterates over an array uses `<=` where `<` was intended, or `<` where `<=` was intended. The extra iteration touches memory just past the end of the array.

Incorrect buffer size in a call. A call to `copyin`, `strncpy`, `sprintf`, or similar takes a size argument. The author passes `sizeof(buf)` for a pointer-typed `buf`, which yields the pointer's size (four or eight bytes) rather than the buffer's size. The call writes far too many bytes.

Arithmetic overflow in a length calculation. The author multiplies or adds lengths to compute a buffer size, and the multiplication overflows a 32-bit integer. The resulting "size" is small, the allocation succeeds, and the subsequent copy writes far more than was allocated.

Truncating a string without terminating it. The author uses `strncpy` or similar, but `strncpy` does not guarantee a null terminator; a later string operation reads past the end of the buffer.

Skipping a length check because the code "obviously" cannot reach a bad state. The author convinces themselves that a given path cannot produce a length greater than some bound, so no check is needed. The path can produce such a length, because the author missed a case.

Each of these is a class of bug with countermeasures. The rest of this section walks through the countermeasures.

31.5.3 Bound Everything

The simplest and most effective countermeasure is to bound every length. Before you use a length from an untrusted source, compare it against a known maximum. Before you allocate a buffer whose size comes from an untrusted source, compare the size against a known maximum. Before you copy into a buffer, confirm that the copy size fits.

Concretely, if your `ioctl` handler takes a structure with a `u_int32_t len` field, add a check like this at the very top of the handler:

```
#define SECDEV_MAX_LEN    4096

static int
secdev_ioctl_set_name(struct secdev_softc *sc, struct secdev_ioctl_args *args)
{
    char *kbuf;
    int error;

    if (args->len > SECDEV_MAX_LEN)
        return (EINVAL);

    kbuf = malloc(args->len + 1, M_SECDEV, M_WAITOK | M_ZERO);
    error = copyin(args->data, kbuf, args->len);
    if (error != 0) {
        free(kbuf, M_SECDEV);
        return (error);
    }
    kbuf[args->len] = '\0';

    /* use kbuf */
}
```

```
    free(kbuf, M_SECDEV);  
    return (0);  
}
```

The first line of the function is the bound. No matter what the caller passes, `args->len` is now at most `SECDEV_MAX_LEN`. The allocation is bounded, the copy is bounded, and the null-termination is inside the buffer. This pattern is the workhorse of safe driver code.

What should the bound be? It depends on the semantics of the argument. A name of a device might reasonably be bounded to a few hundred bytes. A configuration blob might be bounded to a few kilobytes. A firmware blob might be bounded to a few megabytes. Pick a number that is generous enough to accommodate legitimate use and small enough that its consequences, if reached, are bearable. If the bound is too small, users will complain about legitimate failures; if it is too large, an attacker can use the bound itself as an amplifier for denial of service. A generous bound is almost always the right choice.

Some drivers derive the bound from the structure of the hardware. A driver for a fixed-size register bank might bound reads and writes to the bank's size. A driver for a ring with 256 entries might bound the index to 255. Bounds derived from hardware structure are particularly robust, because they correspond to a physical constraint rather than an arbitrary choice.

31.5.4 The `sizeof(buf)` Trap

One of the most common buffer-size bugs in C code is the confusion between `sizeof(buf)` and `sizeof(*buf)`, or between `sizeof(buf)` and the length of the memory `buf` points to. The trap appears most often when a buffer is passed into a function.

Consider this unsafe function:

```
static void  
bad_copy(char *dst, const char *src)  
{  
    strcpy(dst, src, sizeof(dst));    /* WRONG */  
}
```

Here, `dst` is a `char *`, so `sizeof(dst)` is the size of a pointer: 4 on 32-bit systems, 8 on 64-bit systems. The call to `strcpy` tells it that the destination is 8 bytes long, regardless of how big the real buffer is. On a 64-bit system, the function writes up to 8 bytes and terminates, and the caller's 4096-byte buffer now contains a short string, which is probably not what anyone wanted. On any system, if the caller's buffer was less than 8 bytes, the call overflows it.

The fix is to pass the buffer size explicitly:

```
static void  
good_copy(char *dst, size_t dstlen, const char *src)  
{
```

```
    strcpy(dst, src, dstlen);  
}
```

The callers then use `sizeof(their_buf)` at the call site, where `their_buf` is known to be the array:

```
char name[64];  
good_copy(name, sizeof(name), user_input);
```

This pattern is so common in FreeBSD that many internal functions follow it: they take a `(buf, bufsize)` pair rather than a bare `buf`. When you write functions that write into a buffer, do the same. Your future self, reading the code six months later, will thank you.

31.5.5 Bounded String Functions

C's traditional string functions, `strcpy`, `strcat`, `sprintf`, were designed in an era when nobody took buffer overflows seriously. They do not take a size argument; they write until they see a null terminator. In kernel code, they are trouble, because the null terminator can be far away or absent entirely.

FreeBSD provides bounded alternatives:

- `strncpy(dst, src, dstsize)`: copy at most `dstsize - 1` bytes plus a null terminator. Returns the length of the source string. Safe to use when you know `dstsize` correctly.
- `strlcat(dst, src, dstsize)`: append `src` to `dst`, ensuring the result is at most `dstsize - 1` bytes plus a null terminator. Like `strncpy`, this is safe when `dstsize` is correct.
- `snprintf(dst, dstsize, fmt, ...)`: format into `dst`, writing at most `dstsize` bytes including the terminator. Returns the number of bytes that would have been written, which may be larger than `dstsize`. Check the return value if you need to know about truncation.

`strncpy` and `strncat` also exist, but they have surprising semantics. `strncpy` pads with nulls if the source is shorter than the destination size, and, more dangerously, it does not null-terminate if the source is longer. `strncat` is confusing in a different way. Prefer `strncpy` and `strlcat` in new code.

For longer formatted output, the `sbuf(9)` API is safer still. It manages an auto-growing buffer with a clean interface for appending strings, printing formatted output, and bounding the final size. It is overkill for small fixed-size copies but excellent for anything that builds up a longer message. Section 8 returns to `sbuf` in the context of logging.

31.5.6 Arithmetic and Overflow

A subtler class of buffer bug comes from arithmetic on sizes. The classic example is:

```
uint32_t total = count * elem_size;           /* may overflow */  
buf = malloc(total, M_SECDV, M_WAITOK);  
copyin(user_buf, buf, total);
```

If `count * elem_size` overflows a 32-bit `uint32_t`, `total` wraps around to a small number. The `malloc` succeeds with that small number. The `copyin` is asked for the same small number of bytes, which makes the allocation-and-copy pair itself safe. But a later piece of the driver may treat `count * elem_size` as if it produced the full amount, and write past the end of the buffer.

The fix is to check for overflow explicitly:

```
#include <sys/limits.h>

if (count == 0 || elem_size == 0)
    return (EINVAL);
if (count > SIZE_MAX / elem_size)
    return (EINVAL);
size_t total = count * elem_size;
```

The division is exact (no rounding) for integer types, and the test `count > SIZE_MAX / elem_size` is equivalent to “would the multiplication overflow `size_t`?” This pattern is well worth memorising. It is one of those idioms that appears unnecessary in the common case and essential in the exceptional case.

On modern compilers, FreeBSD also has `__builtin_mul_overflow` and its siblings, which perform the arithmetic and report overflow in a single operation. They are a little more convenient when you have them, but the explicit division check works everywhere.

31.5.7 Integer Types Matter

Closely related is the choice of integer types for lengths and offsets. If a length is stored as `int`, it can be negative, and a negative value sneaking into a call that expects an unsigned length can cause spectacular misbehaviour. If a length is stored as `short`, it can only represent values up to 32767, and a caller passing a value near that limit can cause truncation.

The safe types for lengths in FreeBSD are `size_t` (unsigned, at least 32 bits, often 64 on 64-bit platforms) and `ssize_t` (signed `size_t`, usually for return values that may be negative to indicate error). Use them consistently. When you take a length as input, convert it to `size_t` at the earliest opportunity. When you store a length, store it as `size_t`. When you pass a length to a FreeBSD primitive, pass a `size_t`.

If the length comes from user space and the user-facing structure uses a `uint32_t`, the conversion on a 64-bit kernel is safe (no truncation), and you should still validate the value before using it. If the user-facing structure uses `int64_t` and the kernel needs a `size_t`, check for negatives and for overflow before the conversion.

31.5.8 Stack Buffers Are Cheap but Limited

A stack buffer is a local array:

```
static int
secdev_read_name(struct secdev_softc *sc, struct uio *uio)
{
```

```
char name[64];
int error;

mtx_lock(&sc->sc_mtx);
strncpy(name, sc->sc_name, sizeof(name));
mtx_unlock(&sc->sc_mtx);

error = uiomove(name, strlen(name), uio);
return (error);
}
```

Stack buffers are allocated automatically, freed automatically when the function returns, and are essentially free to use. They are ideal for small, short-lived data that does not need to outlive the function call.

The limit on stack buffers is the size of the kernel stack itself. FreeBSD's kernel stack is small, typically 16 KiB or 32 KiB depending on the architecture, and that stack must accommodate the whole call chain, including nested calls into the VFS, the scheduler, interrupt handlers, and so on. A driver function that declares a 4 KiB local buffer is already using a quarter of the stack. A driver function that declares a 32 KiB local buffer has almost certainly blown the stack, and the kernel will panic or corrupt memory when it happens.

A safe rule of thumb: keep local buffers under 512 bytes, and preferably under 256 bytes. For anything larger, allocate on the heap. The compiler will not warn you when you declare a stack buffer that is too large; it is the author's responsibility to keep stack usage bounded.

31.5.9 Heap Buffers and Their Lifetimes

A heap buffer is allocated dynamically:

```
char *buf;

buf = malloc(size, M_SECTEV, M_WAITOK | M_ZERO);
/* use buf */
free(buf, M_SECTEV);
```

Heap buffers can be arbitrarily large (up to the available memory), can outlive the function that allocates them, and give the author explicit control over when they are freed. They come at the cost of requiring deliberate attention: every allocation must be paired with a free, every free must happen after the last use, and every free must happen only once.

The rules for heap buffers are:

1. Always check the allocation if you used `M_NOWAIT`. With `M_WAITOK`, the allocation cannot fail; with `M_NOWAIT`, it can return `NULL` and your code must handle that.
2. Pair every `malloc` with exactly one `free`. Not zero, not two.
3. After calling `free`, do not access the buffer. If the pointer may be reused, set it to `NULL` immediately after the free, so that accidental use triggers a null-pointer panic rather than a subtle corruption.

4. If the buffer held sensitive data, zero it with `explicit_bzero` or use `zfree` before freeing.

Section 4 covers these rules in more depth, including the FreeBSD-specific flags on `malloc(9)`.

31.5.10 A Worked Example: Safe and Unsafe Copy Routines

To make the patterns concrete, here is an unsafe copy routine that you might find in a first-draft driver, followed by a safe rewrite. Read the unsafe version carefully and see if you can spot all the bugs before looking at the commentary.

```
/* UNSAFE: do not use */
static int
secdev_bad_copy(struct secdev_softc *sc, struct secdev_ioctl_args *args)
{
    char buf[256];

    copyin(args->data, buf, args->len);
    buf[args->len] = '\0';
    strncpy(sc->sc_name, buf, sizeof(sc->sc_name));
    return (0);
}
```

There are at least four bugs in those four lines.

First, `copyin`'s return value is ignored. If the user supplied a bad pointer, `copyin` returns `EFAULT`, but the function continues as if the copy succeeded. The subsequent operations on `buf` operate on whatever garbage the stack happened to hold.

Second, `args->len` is not bounded. If the user supplies a `len` of 1000, `copyin` writes 1000 bytes into a 256-byte stack buffer. The stack is corrupted. The driver has just become a vehicle for privilege escalation.

Third, `buf[args->len] = '\0'` writes past the end of the buffer even in the non-malicious case. If `args->len == sizeof(buf)`, the assignment is to `buf[256]`, which is one past the end of the 256-byte array.

Fourth, the function returns 0 regardless of whether anything went wrong. A caller receives a success code and has no way to know that the driver silently dropped their input.

Here is a safe rewrite:

```
/* SAFE */
static int
secdev_copy_name(struct secdev_softc *sc, struct secdev_ioctl_args *args)
{
    char buf[256];
    int error;

    if (args->len == 0 || args->len >= sizeof(buf))
        return (EINVAL);
}
```

```
error = copyin(args->data, buf, args->len);
if (error != 0)
    return (error);

buf[args->len] = '\\0';

mtx_lock(&sc->sc_mtx);
strncpy(sc->sc_name, buf, sizeof(sc->sc_name));
mtx_unlock(&sc->sc_mtx);

return (0);
}
```

The bound is now `args->len >= sizeof(buf)`, which ensures that the terminator at `buf[args->len]` fits. The `copyin` return value is checked and propagated. The write to `sc->sc_name` happens under the mutex that protects it, ensuring that another thread reading the field at the same time sees a consistent value. The function returns the error code the caller needs to understand what happened.

The unsafe version is eight lines; the safe version is thirteen. The five extra lines are the difference between a working driver and a security incident.

31.5.11 A Second Worked Example: The Descriptor Length

Here is a different class of bug that shows up in drivers for devices that present descriptor-like data (USB, virtio, PCIe configuration):

```
/* UNSAFE */
static void
parse_descriptor(struct secdev_softc *sc, const uint8_t *buf, size_t buflen)
{
    size_t len = buf[0];
    const uint8_t *payload = &buf[1];

    /* copy the payload */
    memcpy(sc->sc_descriptor, payload, len);
}
```

The length is taken from the first byte of the buffer, which is a value the device (or an attacker impersonating it) can set arbitrarily. If `buf[0]` is 200, the `memcpy` copies 200 bytes, regardless of whether `buf` actually contains 200 bytes of valid data or whether `sc->sc_descriptor` is that large. If `buflen` is less than `buf[0] + 1`, the `memcpy` reads past the end of the caller's buffer. If `sizeof(sc->sc_descriptor)` is less than `buf[0]`, the `memcpy` writes past the end of the destination.

The safe version validates both sides of the copy:

```
/* SAFE */
static int
parse_descriptor(struct secdev_softc *sc, const uint8_t *buf, size_t buflen)
{
    if (buflen < 1)
        return (EINVAL);

    size_t len = buf[0];

    if (len + 1 > buflen)
        return (EINVAL);
    if (len > sizeof(sc->sc_descriptor))
        return (EINVAL);

    memcpy(sc->sc_descriptor, &buf[1], len);
    return (0);
}
```

Three checks, each guarding a different invariant: the buffer has at least one byte, the stated length fits in the buffer, and the stated length fits in the destination. Each check protects against a different adversarial or accidental input.

A careful reader may notice that `len + 1 > buflen` can itself overflow if `len` is `SIZE_MAX`. For a `size_t` taken from a byte, `len` is at most 255, so the overflow cannot happen here; but if you write the same code for a 32-bit length field, the check should be rearranged to `len > buflen - 1` with an explicit `buflen >= 1` check. The habit of watching for arithmetic overflow is the same habit, applied at different scales.

31.5.12 Buffer Overflow as a Class of Bug

Stepping back from the specific examples: buffer overflows are not a single bug. They are a family of bugs whose members share a structure: the code writes to or reads from a buffer with an incorrect size or offset. The concrete examples above show several members of the family, but the underlying pattern is the same: a length came from somewhere less trustworthy than the code believed it was, and the code was not prepared.

The countermeasures also share a structure. They all amount to: do not trust the length; check it against a known bound before you use it; keep the bound tight; propagate errors when the check fails; use bounded primitives (`strncpy`, `snprintf`, `sbuf(9)`) when you have a choice; watch for arithmetic overflow in length calculations; and keep stack buffers small. That short list, consistently applied, eliminates most buffer overflow bugs before they are written.

31.5.13 Memory Corruption Beyond Overflows

Not every memory-corruption bug is a buffer overflow. Drivers can corrupt memory in several other ways, and a complete treatment of safety must mention them.

Use-after-free is writing to, or reading from, a buffer after it has been freed. The allocator has almost certainly handed that memory to some other part of the kernel by now, so the write corrupts whatever that part of the kernel is doing. Section 4 covers use-after-free in depth.

Double-free is calling `free` twice on the same pointer. Depending on the allocator, this can corrupt the allocator's own data structures, leading to hard-to-diagnose panics minutes or hours later. Section 4 covers prevention.

Out-of-bounds read is the read-only cousin of buffer overflow. It does not corrupt memory directly, but it can leak information (see Section 7) and can cause the kernel to read from an unmapped page, which is a panic. It deserves the same countermeasures as overflow.

Type confusion is treating a block of memory as if it had a different type from what it actually has. For example, casting a pointer to the wrong structure type and accessing fields. In kernel C, type confusion is usually caught by the compiler, but it can still happen when a driver deals with void pointers or with structures shared across versions.

Uninitialised memory use is reading from a variable before assigning it a value. The value read is whatever happened to be in memory at that location, which may be previous callers' data. Section 7 covers this from the information-leak perspective.

Each of these has its own countermeasures, but the single most effective tool across all of them is the set of kernel sanitizers FreeBSD provides: `INVARIANTS`, `WITNESS`, `KASAN`, `KMSAN`, and `KCOV`. Section 10 covers these tools in depth. The short version: build your driver against a kernel with `INVARIANTS` and `WITNESS` always. Build it against a `KASAN`-enabled kernel during development. Run your tests under the sanitized kernel. The sanitizers will find bugs you would otherwise not find until a customer did.

31.5.14 How Compiler Protections Help, and Where They Stop

FreeBSD kernels are usually compiled with several exploit-mitigation features enabled in the compiler. Understanding what they do is part of understanding why certain defensive habits matter more than others.

Stack-smashing protection (SSP) inserts a canary value on the stack between local variables and the saved return address. When the function returns, the canary is checked against a reference value; if it has been modified (because a stack-buffer overflow clobbered it), the kernel panics. SSP does not prevent the overflow from happening, but it prevents many overflows from gaining control of execution. Without SSP, overwriting the return address would redirect execution to attacker-controlled code on return. With SSP, the overwrite is detected and the kernel stops.

SSP is heuristic. Not every function gets a canary: functions without stack-allocated buffers, for example, do not need protection. The compiler applies SSP to functions that look risky. A driver author should not assume SSP will catch any particular bug; SSP catches some stack overflows, not all, and catches them only at function return, not at the moment of the overflow.

kASLR is orthogonal to SSP. It randomizes the base address of the kernel, loadable modules, and the stack. An attacker who wants to jump to a specific kernel function (say, to bypass a check) must first learn where that function is. kASLR makes this difficult. An information leak that exposes any kernel pointer can undo kASLR for the whole kernel: once you know one function's address, you know the offsets to all the others, and you can compute every other address.

W^X enforcement ensures that memory is either writable or executable, never both at once. Historically, attackers would overflow a buffer, write shellcode into the overflowed region, and jump to it. W^X breaks this by refusing to execute from writable memory. Modern attacks therefore use return-oriented programming (ROP), which chains together small snippets of existing code rather than introducing new code. ROP is still possible under W^X, but it is harder, and it is defeated by kASLR (ROP needs to know where the snippets are).

Guard pages surround kernel stacks with unmapped pages. A write past the end of the stack hits an unmapped page, causing a page fault that the kernel catches and turns into a panic. This prevents certain stack-smashing attacks from silently corrupting memory adjacent to the stack. The cost is one unusable page per kernel stack, which is cheap.

Shadow stacks and CFI (control-flow integrity) are under discussion and partial deployment in modern kernels. They aim to prevent attackers from redirecting execution by verifying that every indirect jump lands at a legitimate target. They are not yet standard in FreeBSD, but the direction of the industry is clear: more compiler-enforced restrictions on what exploit writers can do.

The lesson for driver authors: these protections are real, and they raise the cost of exploitation. But they do not prevent bugs. A buffer overflow is still a bug, even if SSP catches it. An information leak is still a bug, even if kASLR makes it less useful. The compiler protections are a last line of defense; the first line is still your careful code.

When the first line fails, the protections buy time: time for the bug to be found and fixed before an attacker chains it into a complete exploit. An information leak that, combined with a buffer overflow, would have been trivially exploitable in 1995 now requires both bugs to exist in the same driver and several more mitigations to fall. The effect is that bug reports that once meant “this is a root exploit” now often mean “this is a pre-condition for a root exploit”. That is progress. But it is progress bought by the compiler, not by the code.

31.5.15 Wrapping Up Section 2

Buffer overflows and memory corruption are the oldest security bugs in C code, and they remain the most common way driver code goes wrong. The countermeasures are well understood: bound every length, use bounded primitives when possible, watch for arithmetic overflow, keep stack buffers small, and run under the kernel’s sanitizers during development. None of these are expensive. All of them are non-negotiable for code that lives in the kernel.

The bugs in this section all came from data of the wrong size reaching the wrong buffer. The next section turns to a closely related problem: data of the wrong shape reaching the wrong kernel function. That is the problem of user input, and it is the single largest source of driver bugs in the real world.

31.6 Section 3: Handling User Input Safely

Every driver that exports an `ioctl`, a `read`, a `write`, or a `mmap` entry point is a driver that receives user input. The shape of the input varies, but the principle does not: data from user space must cross the user-kernel boundary, and the crossing is where most driver security bugs happen.

FreeBSD gives drivers a small and well-designed set of primitives for crossing the boundary safely. The primitives are `copyin(9)`, `copyout(9)`, `copyinstr(9)`, and `uiomove(9)`. Used correctly, they make user input

almost impossible to mishandle. Used incorrectly, they turn the boundary into a gaping hole. This section teaches correct use.

31.6.1 The User-Kernel Boundary

Before the primitives, it helps to make the boundary itself vivid.

A user-space program has its own address space. The program's pointers refer to addresses that are meaningful only in that address space. A pointer that points to byte `0x7fff_1234_5678` in the program's memory has no meaning inside the kernel; the kernel's view of user memory is indirect, mediated by the virtual-memory subsystem.

When the program makes an `ioctl` call that includes a pointer (for example, a pointer to a structure the driver should fill in), the kernel does not receive kernel-space access to that memory. The kernel receives a user-space address. Dereferencing it directly from kernel code is not safe: the address may be invalid (the user sent a garbage pointer), it may point to memory that is not currently resident (paged out), it may not be mapped in the current address space at all, or it may be in a region the kernel has no business reading.

Early UNIX kernels were sometimes careless here and dereferenced user pointers directly. The result was a class of bug known as “ptrace-style” attacks, in which a user program could induce the kernel to read or write arbitrary addresses by passing cleverly crafted pointers. Modern kernels, including FreeBSD, never dereference a user pointer directly from kernel code. They always go through a dedicated primitive that validates and handles the access safely.

The primitives themselves are straightforward. Before we look at them, a note on vocabulary: when the manual pages and the kernel say “kernel address,” they mean an address that is meaningful in the kernel's address space. When they say “user address,” they mean an address supplied by a user-space caller, which is meaningful only in that caller's address space. The primitives translate between the two, with appropriate safety checks.

31.6.2 `copyin(9)` and `copyout(9)`

The two primitives at the heart of the user-kernel boundary are `copyin(9)` and `copyout(9)`:

```
int copyin(const void *udaddr, void *kaddr, size_t len);
int copyout(const void *kaddr, void *udaddr, size_t len);
```

`copyin` copies `len` bytes from user address `udaddr` to kernel address `kaddr`. `copyout` copies `len` bytes from kernel address `kaddr` to user address `udaddr`. Both return 0 on success and `EFAULT` if any part of the copy failed, typically because the user address was invalid, the memory was not resident, or the access crossed into memory the caller had no rights to.

The signatures are declared in `/usr/src/sys/sys/systm.h`. Like most kernel primitives, they are short on names and do one thing. The one thing they do, however, is essential. If a driver reads from or writes to user memory by any other means, the driver is almost certainly wrong.

Always check the return value. This is the single most common source of `copyin/copyout` bugs: a driver calls `copyin` and proceeds as if it succeeded, when in fact it might have returned `EFAULT`. If the copy failed, the destination buffer contains whatever was there before (possibly uninitialised), and operating on it is a recipe for

either a crash or an information disclosure. Every call to `copyin` or `copyout` must check the return value and either proceed with success or propagate the error:

```
error = copyin(args->data, kbuf, args->len);
if (error != 0) {
    free(kbuf, M_SECDDEV);
    return (error);
}
```

That pattern appears hundreds of times in the FreeBSD kernel. Learn it and use it at every call site.

Never reuse a pointer after a failed copy. If `copyin` returned `EFAULT`, the buffer may have been partially written. Do not try to “rescue” a partial result; do not assume that the first few bytes are valid. Discard the buffer, zero it if the remains may be sensitive, and return the error.

Always validate lengths before calling. We have seen this in Section 2, but it bears repeating here. The `len` you pass to `copyin` comes from somewhere; if it comes from the caller’s structure, it must be bounded before the call. An unbounded `len` in a `copyin` is one of the most dangerous patterns in a driver.

`copyin` and `copyout` can sleep. These primitives may cause the calling thread to sleep while waiting for a user page to be resident. This means they cannot be called from contexts where sleeping is forbidden: interrupt handlers, spin-mutex critical sections, and the like. If you need to transfer data to or from user space from such a context, defer the work to a different context (typically a taskqueue or a regular process context) and have that context do the copy.

31.6.3 `copyinstr(9)` for Strings

A string from user space is a special case. You do not know how long it is, only that it is null-terminated. You want to copy it, but you do not want to copy beyond the buffer you have prepared, and you need to handle the case where the user-provided string has no terminator within the expected range.

The primitive for this is `copyinstr(9)`:

```
int copyinstr(const void *udaddr, void *kaddr, size_t len, size_t *lencopied);
```

`copyinstr` copies bytes from `udaddr` to `kaddr` until it encounters a null byte or until `len` bytes have been copied, whichever comes first. If `lencopied` is not `NULL`, `*lencopied` is set to the number of bytes copied (including the terminator, if one was found). The return value is 0 on success, `EFAULT` on a fault, and `ENAMETOOLONG` if no terminator was found within `len` bytes.

The key safety rule is: **always pass a bounded `len`**. `copyinstr` without a bound (or with a huge bound) can cause large amounts of kernel memory to be written, and in older kernels could cause the kernel to scan huge amounts of user memory before giving up. In modern FreeBSD the scan itself is bounded by `len`, but you should still pass a tight bound appropriate to the string’s expected size. A path name might reasonably be bounded to `MAXPATHLEN` (which is `PATH_MAX`, currently 1024 on FreeBSD). A device name might be bounded to 64. A command name might be bounded to 32. Pick a bound that fits the use and pass it.

A second safety rule is: **always check the return value**, and treat ENAMETOOLONG as a distinct condition from EFAULT. The former means the user tried to pass a longer string than you were willing to accept, which is plausibly a legitimate mistake. The latter means the user's pointer was invalid, which may or may not be a legitimate mistake. Your driver may want to return a different error to user space depending on which condition occurred.

A third safety rule is: **check the copied length if you care**. The `lencopied` parameter tells you how many bytes were actually written, including the terminator. If your code depends on knowing the exact length, check it. If your buffer is exactly `len` bytes long and `copyinstr` returned 0, the terminator is at `kbuf[lencopied - 1]`, and the string is `lencopied - 1` bytes long.

A safe use of `copyinstr`:

```
static int
secdev_ioctl_set_name(struct secdev_softc *sc,
    struct secdev_ioctl_name *args)
{
    char name[SECDEV_NAME_MAX];
    size_t namelen;
    int error;

    error = copyinstr(args->name, name, sizeof(name), &namelen);
    if (error == ENAMETOOLONG)
        return (EINVAL);
    if (error != 0)
        return (error);

    /* namelen includes the terminator; the string is namelen - 1 bytes */
    KASSERT(namelen > 0, ("copyinstr returned zero-length success"));
    KASSERT(name[namelen - 1] == '\0', ("copyinstr missed terminator"));

    mtx_lock(&sc->sc_mtx);
    strlcpy(sc->sc_name, name, sizeof(sc->sc_name));
    mtx_unlock(&sc->sc_mtx);

    return (0);
}
```

The function takes a fixed-size stack buffer, calls `copyinstr` with a tight bound, handles the two error cases distinctly, asserts the invariants that `copyinstr` promises (`namelen > 0`, terminator at `name[namelen - 1]`), and copies into the `softc` under the lock. This is the canonical pattern.

31.6.4 uiomove(9) for Streams

`read` and `write` entry points do not use `copyin/copyout` directly; they use `uiomove(9)`, which is a wrapper that handles the iteration over a `struct uio` descriptor. A `uio` describes an I/O operation with potentially

multiple buffers (scatter-gather) and tracks how much has been transferred so far.

```
int uiomove(void *cp, int n, struct uio *uio);
```

`uiomove` copies up to `n` bytes between the kernel buffer `cp` and whatever is described by `uio`. If `uio->uio_rw == UIO_READ`, the copy is kernel-to-user; if `UIO_WRITE`, user-to-kernel. The function updates `uio->uio_offset`, `uio->uio_resid`, and `uio->uio_iov` to reflect the bytes transferred.

Like `copyin`, `uiomove` returns 0 on success and an error code on failure. Like `copyin`, it can sleep. Like `copyin`, the caller must check the return value.

A typical read implementation:

```
static int
secdev_read(struct cdev *dev, struct uio *uio, int flag)
{
    struct secdev_softc *sc = dev->si_drv1;
    char buf[128];
    size_t len;
    int error;

    mtx_lock(&sc->sc_mtx);
    len = strlcpy(buf, sc->sc_name, sizeof(buf));
    mtx_unlock(&sc->sc_mtx);

    if (len >= sizeof(buf))
        len = sizeof(buf) - 1;

    if (uio->uio_offset >= len)
        return (0); /* EOF */

    error = uiomove(buf + uio->uio_offset, len - uio->uio_offset, uio);
    return (error);
}
```

This handles the case where the user reads past the end of the data (returning 0 to indicate EOF), bounds the copy to the size of the kernel buffer, and propagates any error from `uiomove`. It is a safe pattern for short, fixed data; longer data typically uses `sbuf(9)` internally and copies out with `sbuf_finish/sbuf_len/uiomove` at the end.

31.6.5 Validate Every Field of Every Structure

When an `ioctl` takes a structure, the driver must validate every field before trusting any of them. A common error is to validate the fields the driver uses immediately and ignore the ones it uses later. The structure lives for the duration of the `ioctl` call, and the driver may end up using fields it did not check.

Concretely, if your `ioctl` takes this structure:

```
struct secdev_config {
    uint32_t version;      /* protocol version */
    uint32_t flags;        /* configuration flags */
    uint32_t len;          /* length of data */
    uint64_t data;         /* user pointer to data blob */
    char name[64];         /* human-readable name */
};
```

validate every field at the top of the handler:

```
static int
secdev_ioctl_config(struct secdev_softc *sc, struct secdev_config *cfg)
{
    if (cfg->version != SECDEV_CONFIG_VERSION_1)
        return (ENOTSUP);

    if ((cfg->flags & ~SECDEV_CONFIG_FLAGS_MASK) != 0)
        return (EINVAL);

    if (cfg->len > SECDEV_CONFIG_MAX_LEN)
        return (EINVAL);

    /* Name must be null-terminated within the field. */
    if (memchr(cfg->name, '\0', sizeof(cfg->name)) == NULL)
        return (EINVAL);

    /* ... proceed to use the structure ... */
    return (0);
}
```

Four invariants, each checked and enforced. The driver now knows that `version`, `flags`, `len`, and `name` are all in the expected range. It can use them without further validation. Without these checks, each use later in the function becomes another potential source of bugs.

An important subtlety: when a structure includes reserved fields or padding, the driver must decide what to do when those fields are non-zero. The safe choice is usually to require them to be zero:

```
if (cfg->reserved1 != 0 || cfg->reserved2 != 0)
    return (EINVAL);
```

This preserves the possibility of using those fields in a future version of the protocol without breaking compatibility: if every current caller passes zero, any future non-zero value is necessarily from a caller that knows about the new version. Without the check, the driver cannot later distinguish old callers (who happened to leave garbage in the reserved fields) from new callers (who are using the field for a new purpose).

31.6.6 Validate Structures That Come In Multiple Parts

Some `ioctl`s take a structure that contains a pointer to another block of data. The outer structure is copied in first; the pointer inside it then needs to be followed with a second copyin. Every field of both structures must be validated.

```
struct secdev_ioctl_args {
    uint32_t version;
    uint32_t len;
    uint64_t data;    /* user pointer to a blob of `len` bytes */
};

static int
secdev_ioctl_something(struct secdev_softc *sc,
    struct secdev_ioctl_args *args)
{
    char *blob;
    int error;

    /* Validate the outer structure. */
    if (args->version != SECDEV_IOCTL_VERSION_1)
        return (ENOTSUP);
    if (args->len > SECDEV_MAX_BLOB)
        return (EINVAL);
    if (args->len == 0)
        return (EINVAL);

    blob = malloc(args->len, M_SECDEV, M_WAITOK | M_ZERO);

    /* Copy the inner blob. */
    error = copyin((const void *)(uintptr_t)args->data, blob, args->len);
    if (error != 0) {
        free(blob, M_SECDEV);
        return (error);
    }

    /* ... now validate the inner blob, whose shape depends on the version ... */

    free(blob, M_SECDEV);
    return (0);
}
```

The `uintptr_t` cast is worth commenting on. The user pointer arrives as a `uint64_t` in the structure, to avoid portability issues between 32-bit and 64-bit userlands. The cast to `uintptr_t` and then to `const void *` converts the integer representation back into a pointer. On a 64-bit kernel, this is a no-op; on a 32-bit kernel, the

high bits of the `uint64_t` must be validated or dropped. FreeBSD runs on both, and 32-bit userland on a 64-bit kernel (via `COMPAT_FREEBSD32`) is a real case. Be explicit about the cast, and document the assumption.

31.6.7 The “freezed” Problem

Some drivers have fields in user-space structures that are pointers, and the driver’s convention is that the user-space memory stays valid until a particular operation completes. This pattern is common in drivers that do DMA directly from user memory.

The pattern is tricky because the user can, in principle, change the memory between the driver’s validation and the driver’s use. Pointer-based DMA is also the wrong idea in modern drivers; safer alternatives include:

- `mmap`, in which the driver maps kernel memory into user space for direct access, with the kernel retaining ownership of the memory and its validity.
- A copy-through-kernel approach, in which the driver always copies in, validates, and operates on the kernel copy.
- The `busdma(9)` framework, which handles user-space buffers correctly when they need to be DMA’d to hardware.

If you find yourself writing code that keeps a user-space pointer around and uses it at a later moment, stop and think. It is almost always the wrong design. Section 5 returns to this issue as a TOCTOU problem.

31.6.8 Kernel Addresses Do Not Leak Into User Pointers

A recurring class of bug is when a driver, trying to communicate a pointer to user space, copies out a kernel address. The user receives a pointer to kernel memory, which is a spectacular information leak (it reveals the kernel’s layout, defeating KASLR) and, if the user can somehow convince the kernel to treat the copied pointer as a user pointer, can become an arbitrary kernel-memory access.

The mistake is usually inadvertent. A common case is a structure that is shared between kernel and user space, and one of its fields is a pointer. If the driver fills in the field with a kernel pointer and then copies the structure to user space, the leak has happened.

The fix is structural: do not share structures between kernel and user that contain pointer fields intended to be used in either space. If a pointer field exists, make it `uint64_t` and treat it as an opaque integer. When the kernel fills in a user-visible pointer-like field, it must pick a value meaningful to user space, not reveal its own internal pointer.

A second class of leak is when a driver copies out a structure that contains uninitialised fields, and one of those fields happens to contain a kernel pointer (for example, because the allocator returned memory that was previously used for something that held a kernel pointer). Section 7 covers this in depth.

31.6.9 `compat32` and Structure Sizes

FreeBSD supports running 32-bit user-space programs on a 64-bit kernel through the `COMPAT_FREEBSD32` machinery. For a driver, this means that the structure the caller passes may be a 32-bit structure, with different layout and size from the 64-bit version. If the driver expects the 64-bit structure and the caller passed the 32-bit one, the fields the driver reads will be at the wrong offsets, and the driver will read garbage.

Handling this is outside the scope of a typical driver; the framework helps by offering `ioctl32` entry points and automatic translation for many common cases. If your driver is used from 32-bit user-space and uses custom structures, consult the `freebsd32(9)` manual page and the `sys/compat/freebsd32` subsystem for guidance. Be aware of the issue, and test your driver from a 32-bit userland in the lab environment.

31.6.10 A Larger Example: A Complete `ioctl` Handler

Combining the patterns in this section, here is what a complete, safe `ioctl` handler looks like for a hypothetical operation:

```
static int
secdev_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int flag,
             struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;
    struct secdev_ioctl_args *args;
    char *blob;
    int error;

    switch (cmd) {
    case SECDEV_IOCTL_DO_THING:
        args = (struct secdev_ioctl_args *)data;

        /* 1. Validate every field of the outer structure. */
        if (args->version != SECDEV_IOCTL_VERSION_1)
            return (ENOTSUP);
        if ((args->flags & ~SECDEV_FLAGS_MASK) != 0)
            return (EINVAL);
        if (args->len == 0 || args->len > SECDEV_MAX_BLOB)
            return (EINVAL);

        /* 2. Check that the caller has permission, if required. */
        if ((args->flags & SECDEV_FLAG_PRIVILEGED) != 0) {
            error = priv_check(td, PRIV_DRIVER);
            if (error != 0)
                return (error);
        }

        /* 3. Allocate the kernel-side buffer. */
        blob = malloc(args->len, M_SECDEV, M_WAITOK | M_ZERO);

        /* 4. Copy in the user-space blob. */
        error = copyin((const void *)(uintptr_t)args->data, blob,
                      args->len);
        if (error != 0) {
```

```
        free(blob, M_SECDEV);
        return (error);
    }

    /* 5. Do the work under the softc lock. */
    mtx_lock(&sc->sc_mtx);
    error = secdev_do_thing(sc, blob, args->len);
    mtx_unlock(&sc->sc_mtx);

    /* 6. Zero and free the kernel buffer (it held user data
     * that might be sensitive). */
    explicit_bzero(blob, args->len);
    free(blob, M_SECDEV);

    return (error);

default:
    return (ENOTTY);
}
}
```

Each numbered step is a distinct concern. Each step handles errors locally and propagates them. The allocation is bounded by the validated length; the copy is bounded by the same length; the permission check is explicit; the cleanup is symmetric with the allocation; the final return code communicates success or the specific failure. This is what a safe ioctl handler looks like. It is not short, but every line is there for a reason.

31.6.11 Common Mistakes in User-Input Handling

A short checklist of the patterns to watch for, as a reference you can return to while reviewing your own code:

- `copyin` with a length from the user, without a prior bound check.
- `copyinstr` without an explicit bound.
- Return value of `copyin`, `copyout`, or `copyinstr` ignored.
- Structure fields used before they are validated.
- Pointer field cast from `uint64_t` to `void *` without thinking about 32-bit-userland compatibility.
- String field assumed null-terminated without a `memchr` check.
- Length used in arithmetic before being bounded.
- User-space pointer kept around and used later (TOCTOU territory).
- Kernel data structure (with pointer fields) directly copied out.
- Uninitialised fields copied out to user space.

If a code review turns up any of these, pause the review, fix the pattern, and then continue.

31.6.12 A Detailed Walkthrough: Designing a Safe ioctl from Scratch

The accumulated techniques of this section can feel like a long checklist. To show how they come together in practice, let us design a single ioctl carefully, from the user-space interface down to the kernel implementation.

The problem. Our driver needs an ioctl that lets a user set a configuration parameter consisting of a name string (bounded length), a mode (enum), and an opaque data blob (variable length). It should also return the driver's interpretation of the configuration (for example, the canonicalized form of the name).

Defining the interface. The user-visible structure, defined in a header that will ship with the driver, looks like:

```
#define SECDEV_NAME_MAX    64
#define SECDEV_BLOB_MAX    (16 * 1024)

enum secdev_mode {
    SECDEV_MODE_OFF = 0,
    SECDEV_MODE_ON = 1,
    SECDEV_MODE_AUTO = 2,
};

struct secdev_config {
    char          sc_name[SECDEV_NAME_MAX];
    uint32_t      sc_mode;
    uint32_t      sc_bloblen;
    void          *sc_blob;
    /* output */
    char          sc_canonical[SECDEV_NAME_MAX];
};
```

Notes on the design:

The name is a fixed-size inline buffer, not a pointer. This is deliberate: it avoids a separate copyin for the name and makes the interface simpler. The trade-off is that the buffer is always copied even if the name is short, but for 64 bytes that is negligible.

The mode is `uint32_t` rather than `enum secdev_mode` directly, because struct members that cross the user/kernel boundary should have explicit widths. The kernel validates that the value is one of the known enum values.

The blob uses a separate pointer (`sc_blob`) and a length (`sc_bloblen`). The user sets both, and the kernel uses a second copyin to pull the data. The length is bounded by `SECDEV_BLOB_MAX`, a value we (the driver authors) choose based on what the driver is actually going to do with the data.

The canonical output is another fixed inline buffer. The user-space caller may or may not care about this output, but the kernel always fills it.

The kernel handler. Let us walk through the implementation step by step. The ioctl framework will copy the structure into the kernel for us, so by the time our handler runs, `cfg` points to kernel memory. The `sc_blob` field, however, is still a user-space pointer that we must handle ourselves.

```
static int
secdev_ioctl_config(struct secdev_softc *sc, struct secdev_config *cfg,
    struct thread *td)
{
    char kname[SECDEV_NAME_MAX];
    char canonical[SECDEV_NAME_MAX];
    void *kblob = NULL;
    size_t bloblen;
    uint32_t mode;
    int error;

    /* Step 1: Privilege check. */
    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        return (error);

    /* Step 2: Jail check. */
    if (jailed(td->td_ucred))
        return (EPERM);

    /* Step 3: Copy and validate the name. */
    bcopy(cfg->sc_name, kname, sizeof(kname));
    kname[sizeof(kname) - 1] = '\0'; /* ensure NUL termination */
    if (strlen(kname, sizeof(kname)) == 0)
        return (EINVAL);
    if (!secdev_is_valid_name(kname))
        return (EINVAL);

    /* Step 4: Validate the mode. */
    mode = cfg->sc_mode;
    if (mode != SECDEV_MODE_OFF && mode != SECDEV_MODE_ON &&
        mode != SECDEV_MODE_AUTO)
        return (EINVAL);

    /* Step 5: Validate the blob length. */
    bloblen = cfg->sc_bloblen;
    if (bloblen > SECDEV_BLOB_MAX)
        return (EINVAL);

    /* Step 6: Copy in the blob. */
    if (bloblen > 0) {
        kblob = malloc(bloblen, M_SECDEV, M_WAITOK | M_ZERO);
        error = copyin(cfg->sc_blob, kblob, bloblen);
        if (error != 0)
```

```

        goto out;
    }

    /* Step 7: Apply the configuration under the lock. */
    mtx_lock(&sc->sc_mtx);
    if (sc->sc_blob != NULL) {
        explicit_bzero(sc->sc_blob, sc->sc_bloblen);
        free(sc->sc_blob, M_SECDEV);
    }
    sc->sc_blob = kblob;
    sc->sc_bloblen = bloblen;
    kblob = NULL; /* ownership transferred */

    strncpy(sc->sc_name, kname, sizeof(sc->sc_name));
    sc->sc_mode = mode;

    /* Produce the canonical form while still under the lock. */
    secdev_canonicalize(sc->sc_name, canonical, sizeof(canonical));
    mtx_unlock(&sc->sc_mtx);

    /* Step 8: Fill the output fields. */
    bzero(cfg->sc_canonical, sizeof(cfg->sc_canonical));
    strncpy(cfg->sc_canonical, canonical, sizeof(cfg->sc_canonical));
    /* (The ioctl framework handles copyout of cfg itself.) */

out:
    if (kblob != NULL) {
        explicit_bzero(kblob, bloblen);
        free(kblob, M_SECDEV);
    }
    return (error);
}

```

Now review this against the patterns we have discussed.

Privilege check. `priv_check(PRIV_DRIVER)` is the first line of business. No unprivileged caller ever reaches the rest.

Jail check. `jailed()` before any host-affecting work.

Name validation. The name is read from the already-copied-in `cfg`, forced NUL-terminated (defensive, in case the user did not terminate it), and whitelisted through `secdev_is_valid_name` (which presumably refuses non-alphanumeric characters).

Mode validation. An explicit whitelist of known mode values. An unknown value returns `EINVAL` immediately.

Length validation. The blob length is checked against a defined maximum before being used for allocation. Without this check, a user could request a multi-gigabyte allocation.

Allocation with `M_ZERO`. The blob buffer is zeroed so that even if `copyin` fails partway, the contents are deterministic.

Error path cleanup. The `out : label` frees `kblob` if we did not transfer ownership. The `kblob = NULL` after transfer prevents a double-free. Every path through the function reaches `out :` with `kblob` in a consistent state.

Explicit zeroing before free. The old blob (if any) is zeroed before being replaced, on the assumption that it may have contained sensitive data. The new blob on error path is also zeroed for the same reason.

Locking. The `softc` is updated under `sc_mtx`. The canonical form is computed under the lock so the name and canonical match.

Output zeroing. `cfg->sc_canonical` is zeroed before being filled, so padding and any fields the canonicalizer did not set are guaranteed zero.

This function has about forty lines of actual code and roughly a dozen security-relevant decisions. Each decision individually is small; the compound effect is a function that is defensible against nearly every pattern discussed in this chapter. This is what secure driver code looks like in practice: not flashy, not tricky, just careful.

The key insight is that the careful code is the easiest to review, the easiest to maintain, and the one that tends to keep working as the driver evolves. Clever tricks, by contrast, are where bugs hide.

31.6.13 Wrapping Up Section 3

User input is the single largest source of driver security bugs in practice. The primitives FreeBSD provides (`copyin`, `copyout`, `copyinstr`, `uiomove`) are well designed and safe, but they must be used correctly: bounded lengths, checked return values, validated fields, zeroed buffers, and properly sized destinations. A driver that consistently applies these rules at every user-kernel boundary crossing is a driver that is hard to attack from user space.

The next section turns to a closely related subject: memory allocation. The patterns in Sections 2 and 3 assumed that `malloc` and `free` are used safely. Section 4 makes that assumption explicit and shows what “safely” means for the FreeBSD allocator in particular.

31.7 Section 4: Secure Use of Memory Allocation

A driver that validates its inputs carefully but allocates memory carelessly has only done half the job. Memory allocation and deallocation are where a driver’s behaviour in bad weather (denial of service, exhaustion, hostile inputs) is most visible, and where a handful of subtle bugs, use-after-free, double-free, leaks, can turn into full system compromise. This section covers the FreeBSD allocator’s safety model and the idioms that keep a driver from becoming an allocator bug farm.

31.7.1 `malloc(9)` in the Kernel

The primary kernel allocator for general-purpose work is `malloc(9)`. Its declaration in `/usr/src/sys/sys/-malloc.h`:

```
void *malloc(size_t size, struct malloc_type *type, int flags);
void free(void *addr, struct malloc_type *type);
void zfree(void *addr, struct malloc_type *type);
```

Unlike the user-space `malloc`, the kernel version takes two extra arguments. The first, `type`, is a `struct malloc_type` tag that identifies which part of the kernel is using the memory. This allows `vmstat -m` to report, per-subsystem, how much memory each part of the kernel is using. Every driver should declare its own `malloc_type` with `MALLOC_DECLARE` and `MALLOC_DEFINE`, so that its allocations are visible in the accounting.

```
#include <sys/malloc.h>

MALLOC_DECLARE(M_SECDEV);
MALLOC_DEFINE(M_SECDEV, "secdev", "Secure example driver");
```

The first argument, `M_SECDEV`, is the identifier; the second, `"secdev"`, is the short name that appears in `vmstat -m`; the third is a longer description. Use a naming scheme that makes it easy to find the driver's allocations in system output, especially when you are diagnosing a leak.

The `flags` argument controls the allocation's behaviour. Three flags are essential:

- `M_WAITOK`: the allocator may sleep to satisfy the allocation. The call cannot fail; it either returns a valid pointer or the kernel panics (which it does only under very unusual circumstances).
- `M_NOWAIT`: the allocator must not sleep. If memory is not immediately available, the call returns `NULL`. The caller must check and handle the `NULL` case.
- `M_ZERO`: the returned memory is zeroed before being returned. Use this whenever the caller will fill in some but not all of the memory, to avoid leaking garbage.

There are others (`M_USE_RESERVE`, `M_NODUMP`, `M_NOWAIT`, `M_EXEC`), but these three are the ones a driver uses daily.

31.7.2 When to Use `M_WAITOK` and When to Use `M_NOWAIT`

The choice between `M_WAITOK` and `M_NOWAIT` is dictated by context, not preference.

Use `M_WAITOK` when the driver is in a context that can sleep. This is the case in most driver entry points: `open`, `close`, `read`, `write`, `ioctl`, `attach`, `detach`. In these contexts, sleeping is allowed, and the allocator's ability to sleep until memory is available is a significant simplification.

Use `M_NOWAIT` when the driver is in a context that cannot sleep. This is the case in interrupt handlers, inside spin-mutex critical sections, and inside certain callback paths that the kernel specifies as non-sleeping. In these contexts, `M_WAITOK` would trigger a `WITNESS` assertion and a panic. Even if `WITNESS` is not enabled, sleeping in a non-sleeping context can deadlock the system.

The rule of thumb: if you can use `M_WAITOK`, use it. It removes a whole class of error handling (the `NULL` check), and it makes the driver's behaviour more predictable under memory pressure. Only fall back to `M_NOWAIT` when the context forces it.

With `M_NOWAIT`, you must check the return value:

```
buf = malloc(size, M_SECDEV, M_NOWAIT);  
if (buf == NULL)  
    return (ENOMEM);
```

Failure to check is a null-pointer panic waiting to happen. The compiler will not warn you about it.

31.7.3 M_ZERO Is Your Friend

One of the subtlest classes of driver bug is the one where the driver allocates memory, fills in some fields, and then uses or exposes the rest. The “rest” is whatever the allocator happened to return, which in FreeBSD is whatever the allocator’s free list last had there. If that memory held another subsystem’s data before being freed, a driver that fails to clear it may accidentally expose that data (an information leak) or may behave incorrectly because a field it did not set has a non-zero value.

M_ZERO prevents both problems:

```
struct secdev_state *st;  
  
st = malloc(sizeof(*st), M_SECDEV, M_WAITOK | M_ZERO);
```

After this call, every byte of `*st` is zero. The driver can then fill in specific fields and trust that everything else is either zero or set explicitly. This is so important for safety that many FreeBSD driver authors treat M_ZERO as the default, adding it unless there is a specific reason not to.

The exception is large allocations where you are certain you will overwrite every byte before use (for example, a buffer that is immediately filled by `copyin`). In that case, M_ZERO is a small waste, and you can omit it. In all other cases, prefer M_ZERO and accept the small cost.

A particularly important case: **any structure that will be copied to user space must either have been M_ZERO’d at allocation time or have had every byte explicitly set before the copy.** Otherwise the structure may include kernel data that was there before. Section 7 returns to this.

31.7.4 uma_zone for High-Frequency Allocations

For allocations that happen many times per second with a fixed size, FreeBSD offers the UMA zone allocator:

```
uma_zone_t uma_zcreate(const char *name, size_t size, ...);  
void *uma_zalloc(uma_zone_t zone, int flags);  
void uma_zfree(uma_zone_t zone, void *item);
```

UMA zones are significantly faster than `malloc` for repeated small allocations, because they maintain per-CPU caches and avoid the global allocator lock for most operations. Drivers that handle network packets, I/O requests, or other high-frequency events typically use UMA zones instead of `malloc`.

The security properties of UMA zones are similar to those of `malloc`. You still pass `M_WAITOK` or `M_NOWAIT`. You still may pass `M_ZERO` (or you may use `uma_zcreate_arg`'s `uminit/ctor/dtor` arguments to manage initial state). You still must check `NULL` on `M_NOWAIT`.

UMA has one additional security consideration worth knowing: **items returned to a zone are not zeroed by default**. An item freed with `uma_zfree` may retain its previous contents and be handed out to a subsequent `uma_zalloc` with that same content. If the item held sensitive data, the driver must zero it before freeing, or must pass `M_ZERO` on every allocation, or must use the `uminit` constructor machinery to zero on allocation. The safest default is to use `explicit_bzero` on the item before calling `uma_zfree`.

31.7.5 Use-After-Free: What It Is and Why It Matters

A use-after-free bug occurs when a driver frees a pointer and then uses it. The allocator has, by now, almost certainly handed that memory to some other part of the kernel. Writes to the freed pointer corrupt that other part of the kernel; reads from it return whatever is now stored there.

The classic pattern:

```
/* UNSAFE */
static void
secdev_cleanup(struct secdev_softc *sc)
{
    free(sc->sc_buf, M_SECDEV);
    /* sc->sc_buf is now dangling */

    /* later, elsewhere, something calls: */
    secdev_use_buf(sc); /* crash or silent corruption */
}
```

The fix has two parts. First, set the pointer to `NULL` immediately after freeing it, so that any subsequent use is a null-pointer dereference (an immediate, diagnosable crash) rather than a dangling-pointer access (silent corruption):

```
free(sc->sc_buf, M_SECDEV);
sc->sc_buf = NULL;
```

Second, audit the code paths that might still hold references to the freed memory. The `NULL`-assignment prevents crashes at `sc->sc_buf` accesses, but a local variable or a caller's parameter that still holds the old pointer is not protected. The discipline is to free memory only when you are sure no one else holds a pointer to it. Reference counts (`refcount(9)`) are the FreeBSD primitive for this.

A variant of the bug is the **use-after-detach** pattern, in which a driver frees its `softc` during `detach` but an interrupt handler or a callback still runs and accesses the freed `softc`. The fix is to drain all asynchronous activity before freeing in `detach`: cancel outstanding callouts with `callout_drain`, drain taskqueues with `taskqueue_drain`, teardown interrupt handlers with `bus_teardown_intr`, and so on. Once all async paths are quiesced, the free is safe.

31.7.6 Double-Free: What It Is and Why It Matters

A double-free occurs when a driver calls `free` twice on the same pointer. The first `free` hands the memory back to the allocator. The second `free` corrupts the allocator's internal bookkeeping, because it tries to insert the same memory into the free list twice.

FreeBSD's allocator detects many double-frees and panics immediately (especially with `INVARIANTS` enabled). But some double-frees slip past the detection, and the consequences are subtle: a later allocation may return memory that is claimed to be available but is actually still in use somewhere.

The prevention is the same `NULL`-assignment pattern:

```
free(sc->sc_buf, M_SECDEV);  
sc->sc_buf = NULL;
```

`free(NULL, ...)` is defined to be a no-op in FreeBSD (as in most allocators), so a second call with `sc->sc_buf == NULL` does nothing. The `NULL`-assignment turns double-free into a safe no-op.

A related pattern is the **error-path double-free**, in which a function's cleanup logic frees a pointer, and then an outer function also frees the same pointer. The defence is to decide, explicitly, which function owns each allocation, and to have ownership transferred at clear moments. "Who frees this?" is a question that should have a clear answer at every line of the code.

31.7.7 Memory Leaks Are a Security Problem

A memory leak is a piece of memory that is allocated and never freed. In a long-running driver, leaks accumulate. Eventually the kernel runs out of memory, either for the driver's subsystem or for the system as a whole, and bad things happen.

Why is a leak a security problem? Two reasons. First, a leak is a denial-of-service vector: an attacker who can trigger an allocation without a corresponding free can exhaust memory. If the attacker is unprivileged but the driver's `ioctl` allocates memory on each call, the attacker can loop on `ioctl` until the kernel OOM-kills something important. Second, a leak often hides other bugs: the leak's accumulation pressure changes the behaviour of subsequent allocations (more frequent `M_NOWAIT` failures, more unpredictable page cache), which can make racy or allocation-dependent bugs surface in production.

The prevention is discipline in allocation ownership: for every `malloc`, there must be exactly one `free`, reachable on every code path. The FreeBSD `vmstat -m` tool makes leak tracking easier in practice: `vmstat -m | grep secdev` shows, per type, how many allocations are outstanding. A driver with a leak will show a steadily rising number under load; a driver without will show a stable number.

For new drivers, it is worth stress-testing the driver in the lab for leaks: open and close the device a million times in a loop, run the full `ioctl` matrix repeatedly, watch `vmstat -m` for the driver's type, and look for growth. Any sustained growth is a leak. Leaks found in the lab are a thousand times cheaper to fix than leaks found in production.

31.7.8 `explicit_bzero` and `zfree` for Sensitive Data

Some data should not be allowed to linger in memory after the driver is done with it. Cryptographic keys, user passwords, device secrets, anything whose exposure in a memory snapshot would be harmful, must be erased before the memory is freed.

The naive approach is to use `bzero` or `memset(buf, 0, len)` before the `free`. This works, but it has a subtle flaw: the optimiser may remove the `bzero` if it can prove that the memory is not read after. The optimiser's logic is correct as far as language semantics go, but it defeats the security intent.

The correct primitive is `explicit_bzero(9)`:

```
void explicit_bzero(void *buf, size_t len);
```

`explicit_bzero` is declared in `/usr/src/sys/sys/systm.h`. It performs the zeroing and is guaranteed by the compiler not to be optimised away, even if the memory is not read after. Use it for any buffer that holds sensitive data:

```
explicit_bzero(key_buf, sizeof(key_buf));  
free(key_buf, M_SECDDEV);
```

FreeBSD also provides `zfree(9)`, which zeros the memory before freeing:

```
void zfree(void *addr, struct malloc_type *type);
```

`zfree` is convenient: it combines the zero and the free into one call. It first zeros the memory using `explicit_bzero`, then frees it. Use `zfree` when you are about to free a buffer that held sensitive data. Use `explicit_bzero` followed by `free` if you need to zero the buffer without freeing it, or if you are working with memory from a source other than `malloc`.

A common question: what is “sensitive data”? The conservative answer is that any data that came from user space should be treated as sensitive, because you cannot know what it represents to the user. A more pragmatic answer is that data that is obviously a secret (a key, a password hash, a nonce, authentication material) must be zeroed, and data that might reveal information about the user's activities (file contents, network payloads, command text) should be zeroed when the driver is finished with it. When in doubt, zero. The cost is small.

31.7.9 `malloc_type` Tags and Accountability

The `malloc_type` tag on every allocation serves several purposes. It makes allocations visible in `vmstat -m`. It helps with panic debugging, because the tag is recorded in the allocator's metadata. It helps the allocator's own accounting, and in some configurations it enables per-type memory limits.

A driver that uses a single `malloc_type` for all its allocations is easier to audit than a driver that uses many. Create one tag per logical subsystem within the driver, not one per allocation site. For small drivers, a single tag is usually enough.

The declaration pattern:

```

/* At the top of the driver source file: */
MALLOC_DECLARE(M_SECDEV);
MALLOC_DEFINE(M_SECDEV, "secdev", "Secure example driver");

/* Allocations throughout the driver use M_SECDEV: */
buf = malloc(size, M_SECDEV, M_WAITOK | M_ZERO);

```

The `MALLOC_DECLARE` declares the tag for external visibility; the `MALLOC_DEFINE` actually allocates it (and registers it with the accounting system). Both are needed. Do not put `MALLOC_DEFINE` in a header, because the kernel linker will complain about duplicate definitions if multiple object files include the header.

31.7.10 The Lifetime of Softc

The softc is the driver's per-instance state. It is typically allocated during `attach` and freed during `detach`. The softc's lifetime is one of the most important things to get right in a driver.

The allocation usually happens via `device_get_softc`, which returns a pointer to a structure whose size was declared at driver-registration time. This means the softc memory is owned by the bus, not by the driver; the driver does not call `malloc` for it, and the driver does not call `free`. The bus allocates the softc when the driver is bound to the device and frees it when the driver is detached.

But the softc often contains pointers to other memory that the driver did allocate. Those pointers must be freed in `detach`, in the reverse order of their allocation. A typical pattern:

```

static int
secdev_detach(device_t dev)
{
    struct secdev_softc *sc = device_get_softc(dev);

    /* Reverse order of allocation. */

    /* 1. Stop taking new work. */
    destroy_dev(sc->sc_cdev);

    /* 2. Drain async activity. */
    callout_drain(&sc->sc_callout);
    taskqueue_drain(sc->sc_taskqueue, &sc->sc_task);

    /* 3. Free allocated resources. */
    if (sc->sc_blob != NULL) {
        explicit_bzero(sc->sc_blob, sc->sc_bloblen);
        free(sc->sc_blob, M_SECDEV);
        sc->sc_blob = NULL;
    }
}

```

```
/* 4. Destroy synchronization primitives. */
mtx_destroy(&sc->sc_mtx);

/* 5. Release bus resources. */
bus_release_resources(dev, secdev_spec, sc->sc_res);

return (0);
}
```

Each step handles a specific concern. The order matters: destroy the device node before freeing resources the device callbacks depend on; drain async activity before freeing data the async paths might touch; destroy synchronization primitives last.

A slip in any of these orderings is a bug. The wrong order can produce use-after-free or double-free patterns. The lab later in the chapter walks through a detach function that has subtle ordering bugs and asks you to fix them.

31.7.11 A Complete Allocation/Deallocation Pattern

Pulling the patterns together, here is a safe allocation and use sequence:

```
static int
secdev_load_blob(struct secdev_softc *sc, struct secdev_blob_args *args)
{
    char *blob = NULL;
    int error;

    if (args->len == 0 || args->len > SECDEV_MAX_BLOB)
        return (EINVAL);

    blob = malloc(args->len, M_SECDEV, M_WAITOK | M_ZERO);

    error = copyin((const void *)(uintptr_t)args->data, blob, args->len);
    if (error != 0)
        goto done;

    error = secdev_validate_blob(blob, args->len);
    if (error != 0)
        goto done;

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_blob != NULL) {
        /* replace existing */
        explicit_bzero(sc->sc_blob, sc->sc_bloblen);
    }
}
```

```

        free(sc->sc_blob, M_SECDEV);
    }
    sc->sc_blob = blob;
    sc->sc_bloblen = args->len;
    blob = NULL; /* ownership transferred */
    mtx_unlock(&sc->sc_mtx);

done:
    if (blob != NULL) {
        explicit_bzero(blob, args->len);
        free(blob, M_SECDEV);
    }
    return (error);
}

```

The function has a single exit point via the `done` label. The `blob = NULL` after ownership transfer ensures that the cleanup at `done` sees the transfer and does not re-free. The `explicit_bzero` before every `free` zeroes the buffer in case it held sensitive data. The existing `sc->sc_blob`, if present, is zeroed and freed before being replaced, to avoid leaking the old blob's contents.

This pattern (single exit point, ownership transfer, explicit zeroing, checked allocation, checked copyin) appears in variations throughout the FreeBSD kernel. Learn it well.

31.7.12 A Closer Look at UMA Zones

`malloc(9)` is a general-purpose allocator suited to varying sizes. For fixed-size objects that are allocated and freed frequently, the UMA zone allocator is often the better choice. UMA stands for Universal Memory Allocator, and it is declared in `/usr/src/sys/vm/uma.h`.

A UMA zone is created once, at module load, and holds a pool of objects of a fixed size. `uma_zalloc(9)` returns an object from the pool (allocating a fresh one if necessary). `uma_zfree(9)` returns an object to the pool (or frees it back to the kernel if the pool is full). Because allocations come from a pre-configured pool, they are faster than general `malloc` and have better cache locality.

Creating a zone:

```

static uma_zone_t secdev_packet_zone;

static int
secdev_modevent(module_t mod, int event, void *arg)
{
    switch (event) {
    case MOD_LOAD:
        secdev_packet_zone = uma_zcreate("secdev_packet",
            sizeof(struct secdev_packet),

```

```

        NULL,    /* ctor */
        NULL,    /* dtor */
        NULL,    /* init */
        NULL,    /* fini */
        UMA_ALIGN_PTR, 0);
    return (0);

case MOD_UNLOAD:
    uma_zdestroy(secdev_packet_zone);
    return (0);
}
return (EOPNOTSUPP);
}

```

Using a zone:

```

struct secdev_packet *pkt;

pkt = uma_zalloc(secdev_packet_zone, M_WAITOK | M_ZERO);
/* ... use pkt ... */
uma_zfree(secdev_packet_zone, pkt);

```

The security advantages of a UMA zone over `malloc`:

A zone can have a constructor and destructor that initialize or finalize objects. This can guarantee that every object returned to the caller is in a known state.

A zone is named, so `vmstat -z` attributes allocations to it. This helps detect leaks and unusual memory patterns in specific subsystems.

The pool of objects can be drained under memory pressure. A `malloc` allocation is held for its lifetime; a UMA zone object can be returned to the kernel when freed if the pool is above its high-water mark.

The security pitfalls:

An object returned to the zone is not automatically zeroed. If the zone holds objects that may contain sensitive data, either add a destructor that zeros, or zero explicitly before freeing:

```

explicit_bzero(pkt, sizeof(*pkt));
uma_zfree(secdev_packet_zone, pkt);

```

Because UMA reuses objects quickly, an object you just freed may be handed to another caller almost immediately. If the other caller is a different thread in another subsystem, residual data could flow between them. The fix, again, is explicit zeroing.

A destructor function passed to `uma_zcreate` is called when an object is about to be freed back to the kernel (not when it returns to the pool). For zeroing on every free, use `M_ZERO` on `uma_zalloc` (which zeros on allocation, equivalent to `bzero` immediately after) or zero explicitly.

UMA zones are not appropriate for every driver allocation. For one-off or irregular allocations, `malloc(9)` is simpler. For high-frequency fixed-size objects, UMA wins on performance and makes memory accounting easier. Choose based on access pattern.

31.7.13 Reference Counting for Shared Objects

When an object in your driver can be held by multiple contexts (a softc that is referenced by both a callout and user-space file descriptors, for example), reference counting is the canonical tool for lifetime management. The `refcount(9)` family in `/usr/src/sys/sys/refcount.h` provides simple atomic helpers:

```
refcount_init(&obj->refcnt, 1); /* initial reference */
refcount_acquire(&obj->refcnt); /* acquire an additional reference */
if (refcount_release(&obj->refcnt)) {
    /* last reference dropped; caller frees */
    free(obj, M_SECDDEV);
}
```

The invariant is simple: each context that holds a pointer to the object also holds a reference. When it finishes, it releases. Whichever context is last to release is responsible for freeing.

Used correctly, refcounts prevent the classic “who frees it” ambiguity. Used incorrectly (unbalanced acquires and releases), they produce leaks or use-after-frees. The discipline is:

Every path that obtains a pointer to the object acquires a reference.

Every path that releases the pointer calls `refcount_release` and checks the return value.

A single “owning” reference is held by whoever created the object; the owner is the default releaser.

Even simple refcount usage catches a large class of lifetime bugs. For complex drivers with multiple concurrent contexts, refcounts are indispensable.

31.7.14 Wrapping Up Section 4

The FreeBSD allocator is safe if used correctly. The rules are simple: check `M_NOWAIT` returns, prefer `M_ZERO`, zero sensitive data before freeing, pair every `malloc` with exactly one `free` on every code path, set pointers to `NULL` after freeing, drain async activity before freeing structures those activities touch, and use a per-driver `malloc_type` for accountability. A driver that follows these rules will not have leaks, use-after-frees, or double-frees.

The next section turns to a class of bug that is related but different: races and TOCTOU bugs. These are where two threads or two moments in time interact badly, and where security consequences often hide.

31.8 Section 5: Preventing Race Conditions and TOCTOU Bugs

A race condition happens when the correctness of a driver depends on the relative timing of events it does not control. A TOCTOU bug (Time of Check to Time of Use) is a special kind of race where the driver checks

a condition at one moment, then acts on the same data at a later moment, assuming the condition is still true. In between, something changes. The check is valid. The action is valid. The combination is a bug. From a security standpoint, races and TOCTOU bugs are some of the most dangerous faults a driver can have, because they often allow an attacker to bypass checks that look correct when read in isolation.

Chapter 19 already covered concurrency, locks, and synchronization primitives. The goal there was correctness. This section revisits the same tools through a security lens. We are not asking “will my driver crash”. We are asking “can an attacker arrange timing so that a check I wrote is useless”.

31.8.1 How Races Arise in Drivers

A FreeBSD driver operates in a multi-threaded environment. Several things can be happening at once:

Two different user processes can call `read(2)`, `write(2)`, or `ioctl(2)` on the same device file. If the driver has a single `softc`, both calls run against the same state.

One thread can be running your `ioctl` handler while an interrupt handler for the same device fires on another CPU.

A user thread can be in the middle of your driver while a callout or taskqueue entry scheduled earlier also runs.

The device can be unplugged, causing `detach` to run while any of the above is still in progress.

Any shared data touched by more than one of these contexts, without proper synchronization, is a potential race. The race becomes a security problem when the shared data gates access, validates input, tracks buffer sizes, or holds lifetime information.

31.8.2 The TOCTOU Pattern

The simplest TOCTOU pattern in a driver looks like this:

```
if (sc->sc_initialized) {  
    use(sc->sc_buffer);  
}
```

Read it carefully. Nothing about it is obviously wrong. The driver checks that the buffer is initialized, then uses it. But if another thread can set `sc->sc_initialized` to false and free `sc->sc_buffer` between the check and the use, the use touches freed memory. The attacker does not need to corrupt the flag or the pointer. They only need to arrange timing.

A more subtle TOCTOU happens with user memory:

```
if (args->len > MAX_LEN)  
    return (EINVAL);  
error = copyin(args->data, kbuf, args->len);
```

Look at `args`. If it was already copied in, this is safe. But if `args` still points into user space, a second user thread can change `args->len` between the check and the `copyin`. The check validates the old length. The copy uses the new length. If the new length exceeds `MAX_LEN`, the `copyin` overruns `kbuf`.

The fix is copy-then-check, which we already covered in Section 3. The reason this technique exists is precisely because TOCTOU on user memory is a real attack vector. Always copy user data into kernel space first, then validate, then use.

31.8.3 Real-World Example: Ioctl with a Path

Imagine an ioctl that takes a path and does something with the file:

```
/* UNSAFE */
static int
secdev_open_path(struct secdev_softc *sc, struct secdev_path_arg *args)
{
    struct nameidata nd;
    int error;

    /* Check path length */
    if (strlen(args->path, sizeof(args->path)) >= sizeof(args->path))
        return (ENAMETOOLONG);

    NDINIT(&nd, LOOKUP, 0, UIO_USERSPACE, args->path);
    error = namei(&nd);
    /* ... */
}
```

This has two races. First, `args->path` is still in user space if `args` was not copied in; a user thread can change it between the `strlen` check and `namei`. Second, even if `args` was copied, using `UIO_USERSPACE` tells the VFS layer to read the path from user space, at which point the process can modify it again before VFS reads it. The fix is to copy the path into kernel space with `copyinstr(9)`, validate it as a kernel string, then pass it to VFS with `UIO_SYSSPACE`.

```
/* SAFE */
static int
secdev_open_path(struct secdev_softc *sc, struct secdev_path_arg *args)
{
    struct nameidata nd;
    char kpath[MAXPATHLEN];
    size_t done;
    int error;

    error = copyinstr(args->path, kpath, sizeof(kpath), &done);
    if (error != 0)
        return (error);

    NDINIT(&nd, LOOKUP, 0, UIO_SYSSPACE, kpath);
}
```

```

    error = namei(&nd);
    /* ... */
}

```

The corrected version copies the path into the kernel exactly once, validates it (by virtue of `copyinstr` bounding the length and guaranteeing a NUL terminator), then hands a stable kernel string to the VFS layer. The user process can change `args->path` as often as it likes; we are no longer reading from there.

31.8.4 Shared State and Locking

For races between concurrent in-kernel contexts, the tool is a lock. FreeBSD offers several. The most common in drivers are:

`mtx_t`, a mutex, created with `mtx_init(9)`. Mutexes are fast, short, and must not be held across sleeps. Use them to protect a small critical section.

`sx_t`, a shared-exclusive lock, created with `sx_init(9)`. Shared-exclusive locks can be held across sleeps. Use them when the critical section includes something like `malloc(M_WAITOK)` or a VFS call.

`struct rwlock`, a read-write lock, for the read-mostly case. Multiple readers can hold the lock in shared mode; an exclusive writer excludes all readers.

`struct mtx` paired with condition variables (`cv_init(9)`, `cv_wait(9)`, `cv_signal(9)`) for producer-consumer patterns.

The rules for safe locking are simple and absolute:

Define exactly what data each lock protects. Write it in a comment next to the `softc` field.

Acquire the lock before reading or writing the protected data. Release it afterwards.

Do not hold locks longer than necessary. Long critical sections hurt performance and increase deadlock risk.

Acquire multiple locks in a consistent order across all code paths. Inconsistent ordering leads to deadlock.

Do not sleep while holding a mutex. Convert to an `sx` lock or drop the mutex first.

Do not call into user space (`copyin`, `copyout`) while holding a mutex. Copy first, then lock. Release, then copy back.

31.8.5 A Closer Look: Fixing a Racy Driver

Consider the following minimal handler:

```

/* UNSAFE: races on sc_open */
static int
secdev_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;

```

```

    if (sc->sc_open)
        return (EBUSY);
    sc->sc_open = true;
    return (0);
}

static int
secdev_close(struct cdev *dev, int fflags, int devtype, struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;

    sc->sc_open = false;
    return (0);
}

```

The intent is that only one process can have the device open at a time. The bug is that `sc_open` is checked and set without a lock. Two concurrent `open(2)` calls can both read `sc_open == false`, both decide they are the first, and both set it to true. Both succeed. Now two processes share a device that was meant to be exclusive. This is a real-world bug class that has affected real drivers. Fix:

```

/* SAFE */
static int
secdev_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;
    int error = 0;

    mtx_lock(&sc->sc_mtx);
    if (sc->sc_open)
        error = EBUSY;
    else
        sc->sc_open = true;
    mtx_unlock(&sc->sc_mtx);
    return (error);
}

static int
secdev_close(struct cdev *dev, int fflags, int devtype, struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;

    mtx_lock(&sc->sc_mtx);
    sc->sc_open = false;
    mtx_unlock(&sc->sc_mtx);
}

```

```
    return (0);  
}
```

Now the read and the write happen inside a single critical section. Only one caller at a time can be inside that section, so the check-then-set sequence is atomic from the perspective of any other caller.

31.8.6 Lifetime Races at Detach

The hardest races in drivers are lifetime races around detach. The device goes away, but a user thread is still inside your ioctl handler, or an interrupt is in flight, or a callout is pending. If detach frees the_softc while one of these references it, you have a use-after-free.

FreeBSD gives you tools to handle this:

callout_drain(9) waits for any scheduled callout to finish before returning. Call it in detach before freeing anything the callout touches.

taskqueue_drain(9) and taskqueue_drain_all(9) wait for pending tasks to complete.

destroy_dev(9) marks a character device as gone and waits for all in-flight threads to leave the device's d_* methods before returning. After destroy_dev, no new threads can enter and no old threads remain.

bus_teardown_intr(9) removes an interrupt handler and waits for any in-flight instance of that handler to complete.

A correct detach function in a driver that has all of these resources looks roughly like:

```
static int  
secdev_detach(device_t dev)  
{  
    struct secdev_softc *sc = device_get_softc(dev);  
  
    /* 1. Prevent new user-space entries. */  
    if (sc->sc_cdev != NULL)  
        destroy_dev(sc->sc_cdev);  
  
    /* 2. Drain asynchronous activity. */  
    callout_drain(&sc->sc_callout);  
    taskqueue_drain_all(sc->sc_taskqueue);  
  
    /* 3. Tear down interrupts (if any). */  
    if (sc->sc_intr_cookie != NULL)  
        bus_teardown_intr(dev, sc->sc_irq, sc->sc_intr_cookie);  
  
    /* 4. Free resources. */  
    /* ... */  
}
```

```
/* 5. Destroy lock last. */
mtx_destroy(&sc->sc_mtx);
return (0);
}
```

The order matters. We first stop accepting new work, then drain all in-flight work, then free the resources that the in-flight work was using. If we freed resources first and drained second, a callout still running could touch freed memory. That is a classic detach-time use-after-free, and it is a security bug, not just a crash.

31.8.7 Atomics and Lock-Free Code

FreeBSD provides atomic operations (`atomic_add_int`, `atomic_cmpset_int`, and so on) in `/usr/src/sys/sys/atomic_common.h` and architecture-specific headers. Atomics are useful for counters, reference counts, and simple flags. They are not a substitute for locks when multiple related fields must change together.

A common beginner mistake is to say “I will use an atomic to avoid a lock”. Sometimes this is correct. Often it leads to a subtly broken data structure because the atomic operation only makes one field safe, while the code really needed two fields updated together.

The safe rule is: if you can express the invariant with a single atomic read or write, an atomic may be appropriate. If the invariant spans multiple fields or a compound condition, use a lock.

31.8.8 Refcounts as a Lifetime Tool

When an object can be referenced from multiple contexts, a refcount helps manage lifetime. `refcount_init`, `refcount_acquire`, and `refcount_release` (declared in `/usr/src/sys/sys/refcount.h`) give you a simple atomic refcount. The last release returns true, at which point the caller is responsible for freeing the object.

Refcounts solve the classic problem where context A and context B both hold a pointer to an object. Either can finish with it first. The one that finishes last frees it. Neither needs to know whether the other is done, because the refcount tracks that for them.

A driver that uses a refcount on its `softc`, or on per-open state, can release that state safely even under concurrent access. The cost is some care at every entry and exit point to balance acquires and releases.

31.8.9 Ordering and Memory Barriers

Modern CPUs reorder memory accesses. A write in your code may become visible to other CPUs in a different order than it was issued. This is usually invisible because locks on FreeBSD include the necessary barriers. When writing lock-free code, you may need explicit barriers (`atomic_thread_fence_acq`, `atomic_thread_fence_rel`, and variants). For almost all driver code, using a lock removes the need to think about barriers. That is another reason to prefer locks over hand-rolled lock-free constructs when you are still learning.

31.8.10 Signal and Sleep Safety

If your driver sleeps waiting for an event, using `msleep(9)`, `cv_wait(9)`, or `sx_sleep(9)`, use the interruptible variant (`msleep(..., PCATCH)`) when the wait is initiated by user space. Otherwise a stuck device can hold a process in an uninterruptible state forever, and a sufficiently patient attacker can use that to exhaust process slots. The interruptible wait lets the process be signalled.

Always check the return value of a sleep. If it returns a non-zero value, the sleep was interrupted (either by a signal or by another condition), and the driver should typically unwind and return to user space. Don't assume the condition is true just because the sleep returned.

31.8.11 Rate Limiting and Resource Exhaustion

A final race-related security concern is resource exhaustion. If an attacker can call your `ioctl` a million times per second, and each call allocates a kilobyte of kernel memory that is not freed until close, they can drive the system out of memory. This is a denial of service attack, and a careful driver defends against it.

The defenses are: cap per-open resource use, cap global resource use, rate-limit expensive operations. FreeBSD provides `eventratecheck(9)` and `ppsratecheck(9)` in `/usr/src/sys/sys/time.h` for rate limiting, and you can build your own counters where needed. The principle is that the cost to call your driver should not be wildly asymmetric: if a single call allocates megabytes of state, either the caller needs a privilege check or the driver needs a hard cap.

31.8.12 Epoch-Based Reclamation: A Lock-Free Reader Idiom

For read-mostly data structures where readers must never block and writers are rare, FreeBSD provides an epoch-based reclamation framework in `/usr/src/sys/sys/epoch.h`. Readers enter an epoch, access the shared data without taking a lock, and exit the epoch. Writers update the data (usually by replacing a pointer) and then wait for all readers currently in an epoch to exit before freeing the old data.

The idiom is useful for driver code that has frequent reads on a hot path and wants to avoid locking overhead there. For example, a network driver that looks up a rule from a routing-table-like structure on every packet may want readers to run lock-free.

```
epoch_enter(secdev_epoch);
rule = atomic_load_ptr(&sc->sc_rules);
/* use rule; must not outlive the epoch */
do_stuff(rule);
epoch_exit(secdev_epoch);
```

A writer replacing the rule set:

```
new_rules = build_new_rules();
old_rules = atomic_load_ptr(&sc->sc_rules);
atomic_store_ptr(&sc->sc_rules, new_rules);
```

```
epoch_wait(secdev_epoch);  
free(old_rules, M_SECDEV);
```

`epoch_wait` blocks until all readers that entered before the store have exited. After it returns, no reader can still be using `old_rules`, so it is safe to free.

The security considerations with epochs are subtle:

A reader inside an epoch may hold a pointer to something that is about to be replaced. The reader must finish using the pointer before exiting the epoch; any use after the exit is a use-after-free.

A reader inside an epoch cannot sleep. The epoch is an asymmetric lock: writers wait on readers, so a reader that sleeps can starve writers indefinitely.

The writer must ensure that the replacement operation is atomic from a reader's perspective. For a single pointer, an atomic store does the job. For more complex updates, two epochs or a read-copy-update sequence may be needed.

Used correctly, epochs give very high performance on read-heavy workloads. Used incorrectly (a reader that sleeps, or a writer that fails to wait), they produce races that are hard to reproduce and hard to diagnose. Beginners should prefer locks until the performance profile justifies the complexity of epoch-based code.

31.8.13 Wrapping Up Section 5

Races and TOCTOU bugs are timing-based bugs. They happen when two contexts touch shared data without coordination, or when a driver checks a condition and acts on it at two different times. The tools to prevent them are straightforward: copy user data into the kernel once and work from the copy; use a lock around every access to shared mutable state; define what each lock protects and hold it across the full check-and-act sequence; drain asynchronous work before freeing the structures it touches; use refcounts for multi-context lifetime management.

None of this is new to concurrency programming. What is new is the mindset: a race in a driver is not merely a correctness problem. It is a security problem, because an attacker can often arrange the timing they need to exploit it. The next section steps back from timing and looks at a different kind of defense: privilege checks, credentials, and access control.

31.9 Section 6: Access Control and Privilege Enforcement

Not every operation a driver exposes should be available to every user. Reading a temperature sensor may be fine for everyone. Reprogramming the device's firmware should require privilege. Writing raw bytes to a storage controller should probably require more than that. This section is about how a FreeBSD driver decides whether the caller is allowed to do what they are asking, using the kernel's credential and privilege machinery.

The tools are `struct ucred`, `priv_check(9)` and `priv_check_cred(9)`, jail-aware checks, `securelevel` checks, and the broader MAC and Capsicum frameworks.

31.9.1 The Caller's Credential: struct ucred

Every thread running in the FreeBSD kernel carries a credential, a pointer to a `struct ucred`. The credential records who the thread is running as, which jail they are confined to, which groups they belong to, and other security attributes. From inside a driver, the credential is almost always reached via `td->td_ucred`, where `td` is the `struct thread *` passed to your entry point.

The structure is declared in `/usr/src/sys/sys/ucred.h`. The fields most relevant to drivers are:

`cr_uid`, the effective user ID. Usually what you check to answer “is this root”.

`cr_ruid`, the real user ID.

`cr_gid`, the effective group ID.

`cr_prison`, a pointer to the jail the process is in. All processes have one. Unjailed processes belong to `prison0`.

`cr_flags`, a small set of flags including `CRED_FLAG_CAPMODE`, which indicates capability mode (Capsicum).

Do not check `cr_uid == 0` as your privilege gate. That is a common mistake and it is almost always wrong. The correct gate is `priv_check(9)`, which handles jails, `securelevel`, and MAC policies correctly. Checking `cr_uid` manually bypasses all of that and gives root inside a jail the same power as root on the host, which is not what jails are for.

31.9.2 priv_check and priv_check_cred

The canonical primitive for “may the caller do this privileged thing” is `priv_check(9)`. Its prototype, from `/usr/src/sys/sys/priv.h`:

```
int priv_check(struct thread *td, int priv);
int priv_check_cred(struct ucred *cred, int priv);
```

`priv_check` operates on the current thread. `priv_check_cred` operates on an arbitrary credential; you use it when the credential to check is not the running thread's, for example when validating an operation on behalf of a file that was opened earlier.

Both return 0 if the privilege is granted and an `errno` (typically `EPERM`) if not. The driver's pattern is almost always:

```
error = priv_check(td, PRIV_DRIVER);
if (error != 0)
    return (error);
```

The `priv` argument selects one of several dozen named privileges. The full list lives in `/usr/src/sys/sys/priv.h` and covers areas like filesystem, networking, virtualization, and drivers. For most device drivers, the relevant names are:

`PRIV_DRIVER`, the generic driver privilege. Grants access to operations restricted to administrators.

`PRIV_IO`, raw I/O to hardware. More restrictive than `PRIV_DRIVER`, appropriate for operations that bypass the driver's usual abstractions and talk directly to hardware.

`PRIV_KLD_LOAD`, used by the module loader. You will not typically use this from a driver.

`PRIV_NET_*`, used by network-related operations.

Several dozen more. Read the list in `priv.h` and pick the most specific match for the operation being gated. `PRIV_DRIVER` is a reasonable default when nothing more specific fits.

A real-world example from the kernel: in `/usr/src/sys/dev/mmc/mmc.c`, the driver checks `priv_check(td, PRIV_DRIVER)` before allowing certain ioctls that would let a user reprogram the storage controller. In `/usr/src/sys/dev/syscons/syscons.c`, the console driver checks `priv_check(td, PRIV_IO)` before allowing operations that manipulate the hardware directly, since those bypass the normal tty abstraction.

31.9.3 Jail Awareness

FreeBSD jails (`jail(8)` and `jail(9)`) partition the system into compartments. Processes inside a jail share the host's kernel but have a restricted view of the system: their own hostname, their own network visibility, their own filesystem root, and reduced privileges. Inside a jail, `priv_check` refuses many privileges that would otherwise be granted to root. This is one of the main reasons to use `priv_check` instead of checking `cr_uid == 0`.

Some operations, however, make no sense inside a jail at all. Reprogramming device firmware, for example, is a host operation. A jailed root user should never be able to do it. For these, add an explicit jail check:

```
if (jailed(td->td_ucred))
    return (EPERM);
error = priv_check(td, PRIV_DRIVER);
if (error != 0)
    return (error);
```

The `jailed()` macro, defined in `/usr/src/sys/sys/jail.h`, returns true if the credential's prison is anything other than `prison0`. For operations that should never be performed from within a jail, check this first.

For operations that should be allowed inside a jail but with restrictions, use the jail's own fields. `cred->cr_prison->pr_flags` carries per-jail flags; the jail framework also has helpers for checking whether certain capabilities are allowed in the jail. In most driver work you will not go beyond the simple `jailed()` check.

31.9.4 Securelevel

FreeBSD supports a systemwide setting called `securelevel`. At `securelevel 0`, the system behaves normally. At higher `securelevels`, certain operations are restricted even for root: raw disk writes may be disabled, the system time cannot be set backwards, kernel modules cannot be unloaded, and so on. The rationale is that on a well-secured server, raising the `securelevel` at boot means an attacker who later gains root cannot disable logging, install a rootkit module, or rewrite core system files.

For drivers, the relevant helpers are declared in `/usr/src/sys/sys/priv.h`:

```
int securelevel_gt(struct ucred *cr, int level);
int securelevel_ge(struct ucred *cr, int level);
```

Their return values are counterintuitive and worth studying carefully. They return 0 when the securelevel is **not** above or at the threshold (that is, the operation is allowed), and EPERM when the securelevel **is** above or at the threshold (the operation should be denied). In other words, the return value is ready to be used directly as an error code.

The usage pattern for a driver that should refuse to modify hardware at securelevel 1 or higher is:

```
error = securelevel_gt(td->td_ucred, 0);
if (error != 0)
    return (error);
```

Read carefully: this says “return an error if the securelevel is greater than 0”. When securelevel is 0 (normal), `securelevel_gt(cred, 0)` returns 0 and the check passes. When securelevel is 1 or higher, it returns EPERM and the operation is refused.

Most drivers do not need securelevel checks. They make sense for operations that are potentially system-destabilizing: reprogramming firmware, writing to raw disk sectors, lowering the system clock, and so on.

31.9.5 Layering Checks

A driver that wants to be defense-in-depth can layer these checks:

```
static int
secdev_reset_hardware(struct secdev_softc *sc, struct thread *td)
{
    int error;

    /* Not inside a jail. */
    if (jailed(td->td_ucred))
        return (EPERM);

    /* Not at elevated securelevel. */
    error = securelevel_gt(td->td_ucred, 0);
    if (error != 0)
        return (error);

    /* Must have driver privilege. */
    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        return (error);
```

```
/* Okay, do the dangerous thing. */
return (secdev_do_reset(sc));
}
```

Each check answers a different question. `jailed()` asks whether we are in the right security domain. `securelevel_gt` asks whether the system administrator has told the kernel to refuse this kind of operation. `priv_check` asks whether this particular thread has the appropriate privilege.

In many drivers, only the `priv_check` is strictly necessary, because it handles jails and `securelevel` through the MAC framework and the privilege definitions themselves. The explicit `jailed()` and `securelevel_gt` calls are appropriate for operations with known host-wide consequences. When in doubt, start with `priv_check(td, PRIV_DRIVER)` and add more layers only when you can explain what each additional check buys.

31.9.6 The Credential on Open, Ioctl, and Other Paths

When designing privilege checks, think about where in the driver's lifecycle they live. There are two main places:

At open time. If only privileged users should be able to open the device, check privileges in `d_open`. This is simplest and gives per-open enforcement: once a user has opened the device, they are free to do what that device allows. This is the model used, for example, by `/dev/mem`, which is openable only with appropriate privilege.

At operation time. If the device supports multiple operations with different privilege requirements, check each operation independently. A storage controller might allow reading device status to any user, reading SMART data to the owner of the device file, and triggering firmware update only to users with `PRIV_DRIVER`. Each operation has its own gate.

A driver can combine both: a privilege check on open to keep unprivileged users out entirely, and additional checks on specific `ioctls` for operations that need more.

An open-time check is easy to implement:

```
static int
secdev_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    int error;

    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        return (error);

    /* ... rest of open logic ... */
    return (0);
}
```

An `ioctl`-time check follows the same pattern; the `struct thread *td` argument is available in every entry point.

31.9.7 Device File Permissions

Independent of in-driver privilege checks, FreeBSD also applies the usual UNIX permission model to device files themselves. When your driver calls `make_dev_s` or `make_dev_credf` to create a device node, you choose an owner, group, and mode. Those apply at the filesystem level: a user who fails the permission check on the device node never reaches your `d_open`.

The `make_dev_args` structure, declared in `/usr/src/sys/sys/conf.h`, includes `mda_uid`, `mda_gid`, and `mda_mode` fields. The pattern is:

```
struct make_dev_args args;

make_dev_args_init(&args);
args.mda_devsw = &secdev_cdevsw;
args.mda_uid = UID_ROOT;
args.mda_gid = GID_OPERATOR;
args.mda_mode = 0640;
args.mda_si_drv1 = sc;
error = make_dev_s(&args, &sc->sc_cdev, "secdev");
```

`UID_ROOT` and `GID_OPERATOR` are conventional symbolic names. The mode `0640` means owner can read and write, group can read, others have no access. Choose these thoughtfully. A device that could expose sensitive data or cause hardware damage should not be world-readable or world-writable.

The usual pattern for a privileged device is mode `0600` (root-only) or `0660` (root and a specific group, often operator or wheel). Mode `0640` is common for devices readable by a trusted group for monitoring purposes. Modes like `0666` (world-writable) are almost never appropriate, even for simple pseudo-devices, unless the device really does nothing that should be restricted.

31.9.8 Devfs Rules

Even if your driver creates the device node with a conservative mode, the system administrator can change that through devfs rules. A devfs rule can relax or restrict permissions based on device name, jail, and other criteria. Your driver should not assume the mode it set at creation is the mode the device will have at runtime; it should continue to apply its in-kernel checks regardless. The filesystem mode and the in-kernel `priv_check` defend different attackers; keep both.

31.9.9 The MAC Framework

The FreeBSD Mandatory Access Control framework, declared in `/usr/src/sys/security/mac/`, lets policy modules hook into the kernel and make access decisions based on richer labels than UNIX permissions. A MAC policy can, for example, restrict which users can access which devices even if UNIX permissions allow it, or log every use of a sensitive operation.

For driver authors, the point is this: `priv_check` already consults the MAC framework. When you use `priv_check`, you are opting into whatever MAC policies the administrator has configured. If you bypass

`priv_check` and roll your own privilege check using `cr_uid`, you bypass MAC as well. That is one more reason to always use `priv_check`.

Writing your own MAC policy module is beyond the scope of this chapter; the MAC framework is a substantial subject and has its own documentation. The key takeaway is simply that MAC exists, `priv_check` honors it, and you should not fight it.

A brief note on MAC policies shipped with FreeBSD. The base system includes several MAC policies as loadable modules: `mac_bsdextended(4)` for file-system rule lists, `mac_portacl(4)` for network-port access control, `mac_biba(4)` for Biba integrity policy, `mac_mls(4)` for Multi-Level Security labels, and `mac_partition(4)` for partitioning processes into isolated groups. None of these need to be understood in detail by a driver author; the key point is that your driver, by using `priv_check`, gets their policy decisions for free. An administrator who enables `mac_bsdextended` gets additional filesystem-level restrictions; your driver does not need to know.

MAC and the device node. When you create a device with `make_dev_s`, the MAC framework may assign a label to the device node. Policies consult that label when access is attempted. A driver does not interact with labels directly; the framework handles it. But understanding that a label exists explains why, on a MAC-enabled system, access to your device may be refused even when UNIX permissions allow it. That is not a bug; it is MAC doing its job.

31.9.10 Capsicum and Capability Mode

Capsicum, declared in `/usr/src/sys/sys/capsicum.h`, is a capability system bolted onto FreeBSD. A process in capability mode has lost access to most global namespaces (no new file opens, no network with side effects, no arbitrary `ioctl`, and so on). It can only operate on file descriptors it already holds, and those file descriptors may themselves have limited rights (read only, write only, certain `ioctls` only, and so on).

Capsicum was introduced to FreeBSD through the work of Robert Watson and collaborators. It sits alongside the traditional UNIX permission model and adds a second, more granular layer. Where UNIX permissions ask “can this user access this resource by name”, Capsicum asks “does this process have a capability for this specific object”. The two layers work together: the user must have UNIX permission to open the file in the first place, but once the file descriptor exists, Capsicum can further restrict what the holder of the descriptor can do with it.

For a driver, the main Capsicum concern is: some of your `ioctls` may be inappropriate for a process in capability mode. The helper `IN_CAPABILITY_MODE(td)`, defined in `capsicum.h`, tells you whether the calling thread is in capability mode. A driver can check it and refuse operations that are unsafe:

```
if (IN_CAPABILITY_MODE(td))  
    return (ECAPMODE);
```

This is appropriate for operations with global side effects that a capability-mode process should not have access to. Examples might be an `ioctl` that reconfigures the global driver state, an `ioctl` that affects other processes or other file descriptors, or an `ioctl` that performs an operation that requires querying the global filesystem namespace. If your driver’s `ioctl` needs to touch something that is not already named by the file descriptor it was called on, a capability-mode check is appropriate.

For most driver operations, however, the Capsicum story is simpler: the process that holds the file descriptor was granted the rights it needed when the descriptor was given to it. The driver does not need to re-check those rights; the file-descriptor layer already did. Just make sure your driver supports the normal cap-rights flow (it almost certainly does by default) and consider which individual ioctls should be marked with `CAP_IOCTL_*` rights at the VFS layer.

Cap rights at ioctl granularity. FreeBSD allows a file descriptor to be restricted to a specific subset of ioctls via `cap_ioctls_limit(2)`. For example, a process can hold a file descriptor that allows `FIOASYNC` and `FIONBIO` but no other ioctls. The restriction is enforced by the VFS layer, not by your driver, but the set of ioctls you expose is what defines what can be selected for restriction. A driver that implements only meaningful, well-documented ioctls makes it easier for consumers to apply sensible cap-ioctl restrictions.

Examining Capsicum usage in the tree. For real-world examples of Capsicum-aware code, look at `/usr/src/sys/net/if_tuntap.c` alongside the core capability files under `/usr/src/sys/kern/sys_capability.c`. Most individual drivers rely on the VFS layer to enforce caprights, and only add an explicit `IN_CAPABILITY_MODE(td)` check on the handful of operations with global side effects. The pattern is consistent: preserve the normal behavior, add an `IN_CAPABILITY_MODE` check where operations would be unsafe, and document which ioctls are sandbox-safe.

31.9.11 Sysctls With Security Flags

Many drivers expose tunables and statistics through sysctls. A sysctl that exposes sensitive information, or that can be set to change driver behaviour, should use appropriate flags. From `/usr/src/sys/sys/sysctl.h`:

`CTLFLAG_SECURE` (value `0x08000000`) asks the sysctl framework to consult `priv_check(PRIV_SYSCTL_SECURE)` before allowing the operation. It is useful for sysctls that should not be changed at elevated securelevel.

`CTLFLAG_PRISON` allows the sysctl to be visible and writable from inside a jail (rarely wanted for drivers).

`CTLFLAG_CAPRD` and `CTLFLAG_CAPWR` allow the sysctl to be read or written from capability mode. By default, sysctls are inaccessible in capability mode.

`CTLFLAG_TUN` makes the sysctl settable as a loader tunable (from `/boot/loader.conf`).

`CTLFLAG_RD` vs `CTLFLAG_RW` determines read-only vs read-write access; prefer `CTLFLAG_RD` for anything that exposes state, and be deliberate about what you make writable.

A sysctl that exposes a driver-internal buffer for debugging should typically be `CTLFLAG_RD | CTLFLAG_SECURE` at minimum, and possibly not exist at all in production builds.

31.9.12 A Complete Privilege-Gated Ioctl

Putting the pieces together, here is what a privilege-gated ioctl looks like, end to end:

```
static int
secdev_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
             struct thread *td)
{
    struct secdev_softc *sc = dev->si_drv1;
```

```
int error;

switch (cmd) {
case SECDEV_GET_STATUS:
    /* Anyone with the device open can do this. */
    error = secdev_get_status(sc, (struct secdev_status *)data);
    break;

case SECDEV_RESET:
    /* Resetting is privileged, jail-restricted, and securelevel-sensitive. */
    if (jailed(td->td_ucred)) {
        error = EPERM;
        break;
    }
    error = securelevel_gt(td->td_ucred, 0);
    if (error != 0)
        break;
    error = priv_check(td, PRIV_DRIVER);
    if (error != 0)
        break;
    error = secdev_do_reset(sc);
    break;

default:
    error = ENOTTY;
    break;
}

return (error);
}
```

Different commands get different gates. The status command is unprivileged, since it just reads state. The reset command is the danger case, and it goes through the full layered check.

31.9.13 Wrapping Up Section 6

Access control in a FreeBSD driver is a collaboration between several layers. Filesystem permissions on the device node decide who can open it. The `priv_check(9)` family of functions decides whether a thread may perform a given privileged operation. Jail checks decide whether the operation makes sense in the caller's security domain. Securelevel checks decide whether the system administrator has allowed this class of operation at all. The MAC framework lets policy modules add their own opinions on top. Capsicum rights limit what a capability-confined process can do.

The correct use of these tools comes down to a short list of rules: check the caller's credentials at the right points, prefer `priv_check` over ad-hoc UID checks, add `jailed()` and `securelevel_gt` when the operation

has host-wide consequences, pick the most specific `PRIV_*` constant that fits the operation, and set conservative device-file modes in `make_dev_s`.

The next section looks at a different kind of leak: not a privilege escape, but an information escape. Even operations that are properly gated can inadvertently reveal kernel memory contents if they are not written carefully.

31.10 Section 7: Protecting Against Information Leaks

An information leak happens when kernel memory that should not be visible to user space is nonetheless copied out to user space. The classic form is returning the contents of a structure to the user without first initializing the structure. Any padding bytes between fields, or trailing bytes after the last field, contain whatever was on the kernel stack or in a freshly allocated page the last time that memory was used. That could be a password, a pointer that would help defeat ASLR, an encryption key, or anything else.

Information leaks are sometimes dismissed as “not that bad”. They are. In modern attack chains, an information leak is often the first step: it defeats the kernel’s address-space-layout-randomization (kASLR) and makes other exploits reliable. A bug class that starts with “just leaks a few bytes” often ends with “attacker gains kernel code execution”.

31.10.1 How Information Leaks Happen

There are three main ways a driver leaks information:

Uninitialized structure fields copied to user space. A structure has N defined fields plus padding and alignment slots. The code fills in the N fields and calls `copyout`. The padding goes along for the ride, carrying whatever uninitialized stack memory happened to be there.

Partially initialized buffers. The driver allocates a buffer, fills in some of it, and copies the whole buffer to user space. The uninitialized tail carries heap contents.

Oversized replies. The driver is asked for N bytes, but returns a buffer of size $M > N$. The extra $M - N$ bytes contain whatever was in the tail of the source buffer.

Reading beyond a NUL. For string data, the driver copies a buffer up to its allocated size instead of up to the NUL terminator. The bytes after the NUL can carry any data that happened to be in that buffer earlier.

Each of these is easy to create by accident and easy to prevent once you know the pattern.

31.10.2 The Padding Problem

Consider this structure:

```
struct secdev_info {
    uint32_t version;
    uint64_t flags;
    uint16_t id;
    char name[32];
};
```

On a 64-bit system, the compiler inserts padding to align `flags` to 8 bytes. Between `version` (4 bytes) and `flags` (8 bytes), there are 4 bytes of padding. After `id` (2 bytes) and before `name` (1-byte alignment), there are 6 more bytes of padding at the end if the structure is sized up to a multiple of 8.

If your code does:

```
struct secdev_info info;

info.version = 1;
info.flags = 0x12345678;
info.id = 42;
strncpy(info.name, "secdev0", sizeof(info.name));

error = copyout(&info, args->buf, sizeof(info));
```

then the padding bytes, which you never set, go out to user space. They contain whatever stack memory happened to be at those positions when the function was entered. That is an information leak.

The fix is universal and cheap: zero the structure first.

```
struct secdev_info info;

bzero(&info, sizeof(info));    /* or memset(&info, 0, sizeof(info)) */
info.version = 1;
info.flags = 0x12345678;
info.id = 42;
strncpy(info.name, "secdev0", sizeof(info.name));

error = copyout(&info, args->buf, sizeof(info));
```

Now the padding is zero, as is any field you forgot to set. The cost is one call to `bzero`; the benefit is that your driver cannot leak kernel memory through this structure, no matter what fields are added later. Always zero structures before copyout.

An equivalent pattern using designated initializers works when you are declaring and initializing in one step:

```
struct secdev_info info = { 0 }; /* or { } in some standards */
info.version = 1;
/* ... */
```

The `= { 0 }` zeros all bytes including padding. Combine this with setting the specific fields afterwards, and you have a clean pattern.

31.10.3 The Heap Allocation Case

When you allocate a buffer with `malloc(9)` and fill it before returning to user space, you have the same issue. Always use `M_ZERO` to zero-initialize, or explicitly zero the buffer before writing to it:

```
buf = malloc(size, M_SECTDEV, M_WAITOK | M_ZERO);
```

Even if you intend to fill every byte, using `M_ZERO` is cheap insurance: if a bug causes a partial fill, the unfilled bytes are zero rather than stale heap contents.

31.10.4 Oversized Replies

A subtle form of leak happens when the driver returns more data than the user asked for. Imagine an `ioctl` that returns a list of items:

```
/* User asks for up to user_len bytes of list data. */
if (user_len > sc->sc_list_bytes)
    user_len = sc->sc_list_bytes;

error = copyout(sc->sc_list, args->buf, sc->sc_list_bytes); /* BUG: wrong length */
```

The driver copies `sc_list_bytes` bytes regardless of what the user asked for. If `sc_list_bytes > user_len`, the driver writes past `args->buf`, which is a different bug (buffer overflow in user space). If the driver is writing to a local buffer first and then copying out, a similar error would write past the local buffer.

The correct pattern is to clamp the length and use the clamped length for the copy:

```
size_t to_copy = MIN(user_len, sc->sc_list_bytes);
error = copyout(sc->sc_list, args->buf, to_copy);
```

Information leaks through oversized replies are common when driver code evolves: the original author wrote a paired check-and-copy; a later change altered one side but not the other. Every `copyout` should use the already-validated kernel-side length, and that length should be bounded by the user's buffer size.

31.10.5 Strings and the NUL Terminator

Strings are a particularly rich source of information leaks because they have two different natural lengths: the length of the string (up to the NUL) and the size of the buffer it lives in. Suppose:

```
char name[32];
strncpy(name, "secdev0", sizeof(name)); /* copies 8 bytes, NUL-padded */

/* ... later, maybe in a different function ... */
strncpy(name, "xdev", sizeof(name)); /* copies 5 bytes, NUL-padded */

copyout(name, args->buf, sizeof(name)); /* copies all 32 bytes */
```

The second `strncpy` overwrites the first five bytes with “`xdev\0`” and then pads the rest of the buffer with NULs. That happens to be safe because `strncpy` pads with NULs when the source is shorter than the destination. But if the buffer came from `malloc(9)` without `M_ZERO`, or from a stack buffer that was written to by earlier code, bytes after the NUL may contain stale data. Copying the full buffer then leaks it.

The safe pattern is to copy only up to the NUL, or to zero the buffer before writing:

```
bzero(name, sizeof(name));
snprintf(name, sizeof(name), "%s", "secdev0");
copyout(name, args->buf, strlen(name) + 1);
```

`snprintf` guarantees NUL termination. Zeroing first ensures the bytes after the NUL are zero. The `+ 1` in the copy length includes the NUL itself.

Alternatively, copy only the string and let user space deal with its own padding:

```
copyout(name, args->buf, strlen(name) + 1);
```

The cleanest pattern is to zero first and copy exactly the valid length.

31.10.6 Sensitive Data: Explicit Zeroing Before Freeing

When a driver allocates memory to hold sensitive data (cryptographic keys, user credentials, proprietary secrets), the memory should be zeroed explicitly before being freed. Otherwise the freed memory returns to the kernel allocator’s free pool with the data still visible, and subsequent allocations from that pool may expose it.

FreeBSD provides `explicit_bzero(9)`, declared in `/usr/src/sys/sys/system.h`, which zeroes memory in a way that the compiler cannot optimize away:

```
explicit_bzero(sc->sc_secret, sc->sc_secret_len);
free(sc->sc_secret, M_SECDEV);
sc->sc_secret = NULL;
```

Ordinary `bzero` can be eliminated by the compiler if the data is not read after being zeroed, which is exactly the situation before a `free`. `explicit_bzero` is guaranteed to perform the zeroing. Use it whenever sensitive data is about to be freed or go out of scope.

There is also `zfree(9)`, declared in `/usr/src/sys/sys/malloc.h`, which zeroes and frees in one call:

```
zfree(sc->sc_secret, M_SECDEV);
sc->sc_secret = NULL;
```

`zfree` knows the allocation size from the allocator metadata and zeroes that many bytes before freeing. This is usually the cleanest pattern for cryptographic material.

For UMA zones, the equivalent is that the zone itself can be asked to zero on free, or you can `explicit_bzero` the object before calling `uma_zfree`. For stack buffers with sensitive content, `explicit_bzero` at the end of the function is the right tool.

31.10.7 Never Leak Kernel Pointers

One specific form of information leak is returning a kernel pointer to user space. The kernel address of a softc, or of an internal buffer, is useful information to an attacker trying to exploit another bug. `printf("%p")` in log messages can also leak addresses. The general rule: do not put kernel addresses in user-visible output.

For sysctls and ioctls, the simplest rule is that no field in a user-facing structure should be a raw kernel pointer. If the driver wants to expose an identifier for a kernel object, use a small integer ID (an index into a table, for example), not the address of the object. Convert from one to the other inside the driver, never expose the raw pointer.

FreeBSD's `printf(9)` supports the `%p` format, which does print a pointer, but log messages in production drivers should avoid `%p` for anything where the pointer could aid exploitation. For debugging, `%p` is fine during development; before shipping the driver, audit `printf` and `log` calls to ensure no `%p` remains in paths accessible from user space.

31.10.8 Sysctl Output

Sysctls that expose structures have the same rules as ioctls. Zero the structure before filling it, clamp the output length to the caller's buffer, and avoid pointer leaks. The `sysctl_handle_opaque` helper is often used for raw structures; make sure the structure is fully initialized before the handle returns.

A safer pattern is to expose each field as its own sysctl, using `sysctl_handle_int`, `sysctl_handle_string`, and so on. This avoids the padding problem entirely because each value is copied out as a primitive. It is also more ergonomic for users: `sysctl_secdev.stats.packets` is more useful than an opaque blob they have to decode.

31.10.9 copyout Errors

`copyout` can fail. If the user buffer becomes unmapped between the validation and the copy, `copyout` returns `EFAULT`. Your driver must handle this cleanly: typically, return the error to the user, and make sure any partial success is rolled back.

A sequence like “allocate state, fill output buffer, `copyout`, commit state” is safer than “commit state, `copyout`”. If the `copyout` fails in the second pattern, the state is committed but the user never learned what happened. If it fails in the first pattern, nothing was committed, and the user gets a clean error.

31.10.10 Deliberate Disclosure

Some sysctls and ioctls are explicitly designed to reveal information that would otherwise be private. These need an especially careful threat model. Ask: who is allowed to call this? What do they learn? Could a less-trusted attacker who obtains that information use it for something worse? A `dmesg`-style sysctl that exposes recent kernel messages is fine, but only because it has been scoped and filtered; exposing raw kernel log buffers without scoping is very different.

When in doubt, a sysctl that reveals sensitive data should be gated with `CTLFLAG_SECURE`, restricted to privileged users, and exposed only through paths that users must explicitly opt into. Default to less disclosure rather than more.

31.10.11 Kernel Pointer Hashing

Sometimes a driver legitimately needs to expose something that identifies a kernel object, for debugging or for correlating events. The raw pointer address is the wrong answer for the reasons discussed. A better answer is a hashed or masked representation that identifies the object without revealing its address.

FreeBSD provides `%p` in `printf(9)`, which prints a pointer. It also provides a related mechanism where pointers can be “obfuscated” in user-visible output using a per-boot secret, so that two pointers in the same output are consistently distinguishable but their absolute values are not leaked. The support for this varies across subsystems; when designing your own output, consider whether a dense integer ID (an index into a table) is sufficient. Often it is.

For logs, `%p` is fine during development when logs are private. Before shipping, replace any `%p` in paths reachable from user space with either a debug-only guard (so the format is present only in debug builds) or with a non-pointer identifier.

31.10.12 Wrapping Up Section 7

Information leaks are the quieter cousin of buffer overflows: they do not crash, they do not corrupt, they merely send data to user space that should have stayed in the kernel. The tools to prevent them are simple and cheap. Zero structures before filling them. Use `M_ZERO` on heap allocations that will be copied to user space. Clamp copy lengths to the smaller of the caller’s buffer and the kernel’s source buffer. Use `explicit_bzero` or `zfree` for sensitive data before freeing. Keep kernel pointers out of user-visible output. Bound strings to their actual length, not their buffer size.

A driver that applies these habits consistently will not leak information through its interfaces. The next section moves to the debugging and diagnostics side: how to log without leaking, how to debug without leaving production-hostile code behind, and how to keep the operator informed without handing an attacker a map.

31.11 Section 8: Safe Logging and Debugging

Every driver logs. `printf(9)` and `log(9)` are among the first tools a driver author reaches for, and for good reason: a well-placed log message turns a mysterious failure into a readable narrative. But logs are not free. They consume disk, they can be flooded, and they can leak sensitive data. A security-aware driver treats logging as a first-class design concern, not a debug afterthought.

This section is about writing log messages that help operators without hurting security.

31.11.1 The Logging Primitives

FreeBSD drivers have two main ways to emit messages.

`printf(9)`, the same name as the C library function but with kernel-specific semantics, writes to the kernel message buffer and, if the console is active, to the console. It is unconditional: every `printf` call results in a message.

`log(9)`, declared in `/usr/src/sys/sys/syslog.h`, writes to the kernel log ring with a syslog-compatible priority. Messages go to the in-kernel log buffer (readable by `dmesg(8)`) and, via `syslogd(8)`, to the configured log destinations. The priority is the familiar syslog scale: `LOG_EMERG`, `LOG_ALERT`, `LOG_CRIT`, `LOG_ERR`, `LOG_WARNING`, `LOG_NOTICE`, `LOG_INFO`, `LOG_DEBUG`.

Use `log(9)` when you want the message to be filtered or routed by syslog. Use `printf(9)` when you want unconditional emission, typically for very important events or for output that should always appear on the console.

`device_printf(9)` is a small wrapper over `printf` that prefixes the message with the device name (`secdev0: . . .`). Prefer it inside driver code so messages are easy to attribute.

31.11.2 What to Log and What Not to Log

A security-aware driver logs:

State transitions that matter. Attach, detach, reset, firmware update, link up, link down. These let an operator correlate driver behaviour with system events.

Errors from the hardware or from user requests. A bad ioctl argument, a DMA error, a timeout, a CRC mismatch. These let the operator diagnose problems.

Rate-limited summaries of anomalous events. If a malformed ioctl is received a million times per second, log the first, summarize the rest.

A security-aware driver does not log:

User data. The contents of buffers the user passed in. You never know what is in them.

Cryptographic material. Keys, IVs, plaintext, ciphertext. Ever.

Sensitive hardware state. On a security device, some register contents are themselves secrets.

Kernel addresses. `%p` is fine in early development; it has no place in production logs.

Details of authentication failures. A log message that says “user jane failed check X because register was 0x5d” tells an attacker what check to defeat. A log that says “authentication failed” tells the operator there was a failure without tutoring the attacker.

Think about who reads the logs. On a multi-tenant server, other users may have log-reading privileges. On a shipped appliance, the log may be exported for remote support. Treat log messages as information that could end up on any surface the system touches.

31.11.3 Rate Limiting

A noisy driver is a security problem. If an attacker can trigger a log message, they can trigger a million of them. Log flooding consumes disk space, slows the system, and buries legitimate messages. FreeBSD provides `eventratecheck(9)` and `ppsratecheck(9)` in `/usr/src/sys/sys/time.h`:

```
int eventratecheck(struct timeval *lasttime, int *cur_pps, int max_pps);
int ppsratecheck(struct timeval *lasttime, int *cur_pps, int max_pps);
```

Both return 1 if the event is allowed through and 0 if it has been rate-limited. `lasttime` and `cur_pps` are per-call state you keep in your softc. `max_pps` is the limit in events per second.

Pattern:

```
static struct timeval secdev_last_log;
static int secdev_cur_pps;

if (ppsratecheck(&secdev_last_log, &secdev_cur_pps, 5)) {
    device_printf(dev, "malformed ioctl from uid %u\n",
        td->td_ucred->cr_uid);
}
```

Now, no matter how many malformed ioctls the attacker sends, the driver emits at most 5 log messages per second. That is enough for the operator to notice something is happening without drowning the system.

Per-event rate limiting (one `lasttime/cur_pps` pair per event type) is better than a single global limit, because it prevents a flood of one event type from masking other events.

31.11.4 Log Levels in Practice

A good rule of thumb is this:

`LOG_ERR` for unexpected driver failures that require operator attention. “DMA mapping failed”, “device returned CRC error”, “firmware update aborted”.

`LOG_WARNING` for unusual but not necessarily critical situations. “Received oversized buffer, truncating”, “falling back to polled mode”.

`LOG_NOTICE` for events that are normal but worth recording. “Firmware version 2.1 loaded”, “device attached”.

`LOG_INFO` for high-volume status information that operators may filter.

`LOG_DEBUG` for debugging output. A production driver usually does not emit `LOG_DEBUG` unless the operator has enabled debug logging via a sysctl.

`LOG_EMERG` and `LOG_ALERT` are reserved for system-threatening conditions and are not typically emitted by device drivers.

Choosing the right level matters because operators configure syslog to filter by level. A driver that logs every received packet at `LOG_ERR` makes the logs useless.

31.11.5 Debug Logging and Production

During development, you will want verbose logging: every state transition, every entry and exit, every buffer allocation. That is fine. The question is how to turn it off in production without losing the ability to re-enable it when there is a bug to diagnose.

Two patterns are common:

A sysctl-controlled debug level. The driver reads a sysctl at the top of each log-worthy event and emits or suppresses the message based on the level. This allows runtime control without recompiling.

```
static int secdev_debug = 0;
SYSCTL_INT(_hw_secdev, OID_AUTO, debug, CTLFLAG_RW,
           &secdev_debug, 0, "debug level");

#define SECDEV_DBG(level, fmt, ...) do { \
    if (secdev_debug >= (level)) \
        device_printf(sc->sc_dev, fmt, ##__VA_ARGS__); \
} while (0)
```

Compile-time control. A driver can use `#ifdef SECDEV_DEBUG` to include or exclude debug blocks. This is faster (no runtime check) but requires a rebuild to change. Often the two are combined: `#ifdef SECDEV_DEBUG` wraps the infrastructure, and the sysctl controls verbosity within that.

Either way, avoid `printf` calls in hot paths that are not guarded by some kind of conditional. An uncommented `printf` in an interrupt handler or a per-packet path is a performance disaster waiting to be enabled.

31.11.6 Leaving Nothing Behind

Before committing driver changes, `grep` the driver for:

Raw `printf` calls without `device_printf` prefixes. These make log attribution harder.

`%p` format specifiers. If they appear in paths reachable from user space, replace with less sensitive formats (a sequence number, a hash, nothing).

`LOG_ERR` on user-triggerable events without rate limiting. Attackers can weaponize these.

`TODO`, `XXX`, `FIXME`, `HACK` near security-related code. Leaving these for reviewers is fine; shipping them is not.

Test-only `fprintf`-equivalents that were supposed to be removed.

31.11.7 dmesg and the Kernel Message Buffer

The kernel message buffer is a fixed-size ring buffer shared by every driver and the kernel itself. On a busy system, old messages scroll out as new ones arrive. A driver that floods the buffer pushes out useful messages from other drivers.

`dmesg(8)` shows the current contents of the buffer. Operators rely on it. Being a good citizen in the buffer means: log important things, do not log in hot paths, rate-limit everything triggerable by users, and do not flood.

The buffer size is tunable (`kern.msgbufsize` sysctl), but you cannot count on a particular size. Write as if every message is valuable and must compete with others for space.

31.11.8 KTR and Tracing

For detailed tracing without the cost of `printf`, FreeBSD provides KTR (Kernel Tracing), declared in `/usr/src/sys/sys/ktr.h`. KTR macros, when enabled, record events in a compact in-kernel ring that is separate from the message buffer. A kernel compiled with options `KTR` can be queried with `sysctl debug.ktr.buf` and with `ktrdump(8)`.

KTR events are best for per-operation tracing where a `printf` would be too heavy. They are almost free at runtime when disabled. For a security-sensitive driver, KTR gives you a way to leave tracing infrastructure in the code without paying for it in production.

Other tracing frameworks (`dtrace(1)` via SDT probes) are worth learning for deep inspection. They are out of scope for this chapter, but know that they exist.

31.11.9 Logging Privileged Operations

A specific case worth calling out: when your driver successfully performs a privileged operation, log it. This creates an audit trail. If a firmware update happens, log who triggered it. If a hardware reset is issued, log it. If a device is reconfigured, log the change.

```
log(LOG_NOTICE, "secdev: firmware update initiated by uid %u (euid %u)\n",  
    td->td_ucred->cr_ruid, td->td_ucred->cr_uid);
```

The operator can later see who did what. If there is ever a security incident, this log is the first evidence. Make it accurate and make it hard to forge.

Do not over-log legitimate privileged use; a firmware update triggered by `freebsd-update` once a month is one message, not a thousand. But the single message should carry enough detail to reconstruct what happened: who, when, what, with what arguments.

31.11.10 The audit(4) Framework

For deeper audit trails than `log(9)` provides, FreeBSD includes an audit subsystem (`audit(4)`) based on the BSM (Basic Security Module) audit format originally from Solaris. When enabled via `auditd(8)`, the kernel emits structured audit records for many security-relevant events: logins, privilege changes, file access, and, increasingly, driver-specific events when drivers instrument themselves.

A driver that handles highly sensitive operations can emit custom audit records using `AUDIT_KERNEL_*` macros declared in `/usr/src/sys/security/audit/audit.h`. This is more involved than a `log(9)` call, but it produces records that fit into the operator's existing audit workflow, are structured (machine-readable), and can be forwarded to remote audit collectors for compliance.

For most drivers, `log(9)` with `LOG_NOTICE` and a clear message is enough. For drivers that must meet specific compliance requirements (government, financial, medical), consider investing in audit integration. The infrastructure is already in the kernel; you just need to call into it.

31.11.11 Using dtrace with Your Driver

Alongside logging, `dtrace(1)` lets an operator observe driver behavior without recompiling. A driver that declares Statically Defined Trace (SDT) probes through `sys/sdt.h` exposes well-defined hook points that `dtrace` scripts can latch onto.

```
#include <sys/sdt.h>

SDT_PROVIDER_DECLARE(secdev);
SDT_PROBE_DEFINE2(secdev, , , ioctl_called, "u_long", "int");

static int
secdev_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
             struct thread *td)
{
    SDT_PROBE2(secdev, , , ioctl_called, cmd, td->td_ucred->cr_uid);
    /* ... */
}
```

An operator can then write a `dtrace` script that fires on `secdev:::ioctl_called` and counts or logs each event. The advantage over `log(9)` is that `dtrace` probes have essentially no cost when disabled, and they let the operator decide what to observe rather than forcing the driver author to anticipate every useful question.

For a security-focused driver, SDT probes on entry and exit of privileged operations let security monitoring tools observe usage patterns without the driver having to log every call. This is useful for anomaly detection: a sudden spike in `ioctl` calls from an unexpected UID, for example, can be flagged by a `dtrace`-based monitor.

31.11.12 Wrapping Up Section 8

Logging is how a driver talks to its operator. Like any communication, it can be clear or confused, honest or misleading, helpful or harmful. A security-aware driver logs important events with appropriate levels, avoids logging sensitive data, rate-limits anything an attacker can trigger, and uses debug infrastructure that can be turned on and off without recompilation. It prefers `device_printf(9)` for attribution, uses `log(9)` with thoughtful priorities, and never leaves `%p` or ungarded `printf` statements in production paths.

The next section takes a broader view. Beyond specific techniques (bounds-checking, privilege checks, safe logging), there is a design-level question: what should a driver do by default when something goes wrong? What fail-safe behavior should it exhibit? That is the subject of secure defaults.

31.12 Section 9: Secure Defaults and Fail-Safe Design

A driver's design decisions shape its security long before any individual line of code is written. Two drivers can use the same APIs, the same allocator, the same locking primitives, and end up with very different security postures, because one was designed to be open and the other was designed to be closed. This section is about the design choices that make a driver safe by default.

The central idea is summarized in a single principle: when in doubt, refuse. A driver that fails open has to be correct in every branch to be safe. A driver that fails closed only has to be correct in the narrow paths where it decides to allow something.

31.12.1 Fail Closed

The first and most important design decision is what happens when your code reaches a state it did not expect. Consider a switch statement:

```
switch (op) {
case OP_F00:
    return (do_foo());
case OP_BAR:
    return (do_bar());
}
return (0); /* fall-through: everything else succeeds! */
```

This is a fail-open design. Any operation code that is not OP_F00 or OP_BAR succeeds silently, returning 0. That is almost never what you want. A new operation code added to the API but not handled in the driver becomes a silent no-op. An attacker who discovers this can use it to bypass checks.

The fail-closed version:

```
switch (op) {
case OP_F00:
    return (do_foo());
case OP_BAR:
    return (do_bar());
default:
    return (EINVAL);
}
```

Unknown operations explicitly return an error. If a new operation is added to the API, the compiler or the tests will tell you the moment you handle it and forget to update the switch, because the new case is needed to silence the EINVAL.

The same principle applies at every decision point. When a function checks a precondition:

```
/* Fail open: if the check is inconclusive, allow the operation. */
if (bad_condition == true)
    return (EPERM);
return (0);

/* Fail closed: if the check is inconclusive, refuse. */
if (good_condition != true)
```

```
    return (EPERM);
return (0);
```

The second form fails closed: if the precondition cannot be proven good, the operation is refused. This is safer when `good_condition` has any chance of being false due to an error in setup, a race, or a bug.

31.12.2 Whitelist, Don't Blacklist

Closely related: when deciding what is allowed, whitelist the known-good rather than blacklisting the known-bad. Blacklists are always incomplete, because you cannot enumerate every bad input. Whitelists are finite by construction.

```
/* Bad: blacklist */
if (c == '\n' || c == '\r' || c == '\0')
    return (EINVAL);

/* Good: whitelist */
if (!isalnum(c) && c != '-' && c != '_')
    return (EINVAL);
```

The blacklist missed `\t`, `\x7f`, every high-bit character, and so on. The whitelist made the allowed set explicit and refused everything else.

This applies to input validation generally. A driver that accepts a set of configuration names should explicitly list them. A driver that accepts a set of operation codes should enumerate them. If a user sends something that is not on the list, refuse.

31.12.3 Smallest Useful Interface

A driver exposes functionality to user space through device nodes, `ioctl`s, `sysctl`s, and sometimes network protocols. Every exposed entry is a potential attack surface. A secure driver exposes only what users actually need.

Before shipping an `ioctl`, ask: does anyone actually use this? If a debugging `ioctl` was useful during development but has no production role, remove it or compile it out behind a debug flag. If a `sysctl` exposes internal state that only matters for engineering, hide it behind `CTLFLAG_SECURE` and consider removing it.

The cost of removing an interface now is small: a few lines of code. The cost later, when the interface has shipped and has users, is much larger. Smaller interfaces are easier to review, easier to test, and have fewer opportunities for bugs.

31.12.4 Least Privilege on Open

A device node can be created with restrictive or permissive modes. Start restrictive. A mode of `0600` or `0640` is almost always a better default than `0666`. If users complain that they cannot access the device, that is a

conversation you want to have; you can always relax the mode, and the operator can use devfs rules to do so per-site. If users silently gain access they should not have, you will not have that conversation until something breaks.

Similarly, a driver that supports jails should default to not being accessible in jails unless there is a specific reason. The reasoning is the same: it is easier to open up later than to retrofit a closed policy onto an open one.

31.12.5 Conservative Default Values

Every configurable parameter has a default. Choose conservative ones.

A driver that has a configurable “allow user X to do Y” tunable should default to X = none. If an operator wants to grant access, they can change the tunable. If the default granted access, every deployment that missed the tunable would be open.

A driver that has a timeout should default to a short timeout. If the operation usually finishes quickly, a short default is fine. If it sometimes takes longer, the operator can bump the timeout. A long default is a denial-of-service opportunity.

A driver that has a buffer size limit should default to a small limit. Again, operators can raise it; attackers cannot.

31.12.6 Defense in Depth

No single security mechanism is perfect. A defense-in-depth driver assumes any one layer can fail and builds multiple layers.

Example: suppose a driver accepts an ioctl that requires privilege. The layers of defense are:

The device node mode blocks unprivileged users from opening the device at all.

A `priv_check` at open time blocks unprivileged users even if the mode is misconfigured.

A `priv_check` on the specific ioctl catches the case where an unprivileged user somehow reached the ioctl handler.

A `jailed()` check on the ioctl blocks jailed users.

Input validation on the ioctl arguments refuses malformed requests.

A rate-limit log records repeated malformed requests.

If all five are present, a failure in any one is contained by the others. If only one is present and it fails, the driver is compromised. Defense in depth costs a little more code and a little more CPU; it buys real resilience.

31.12.7 Timeouts and Watchdogs

A driver that waits on external events should have timeouts. Hardware can fail to respond. User space can stop reading. Networks can stall. Without a timeout, a waiting driver can hold resources forever, and an attacker who controls the external event can deny service by simply not responding.

`msleep(9)` accepts a timeout argument in ticks. Use it. A sleep with no timeout is rarely the right answer in driver code.

For longer-lived operations, a watchdog timer can detect that an operation has stalled and take recovery action: abort, retry, or reset. The `callout(9)` framework is the usual mechanism.

31.12.8 Bounded Resource Use

Every resource a driver can allocate on behalf of a caller should have a cap. Buffer sizes have maximum values. Per-open resource counts have maximum values. Global resource counts have maximum values. When a cap is hit, the driver returns an error, not an attempt at “best effort”.

Without caps, a misbehaving or hostile process can exhaust resources. The exhaustion might be memory, file-descriptor-like state, interrupt-worthy events, or simply CPU time. Caps ensure that no single caller can dominate.

A reasonable default structure:

```
#define SECDEV_MAX_BUFLLEN    (1 << 20)    /* per buffer */
#define SECDEV_MAX_OPEN_BUFS  16           /* per open */
#define SECDEV_MAX_GLOBAL     256          /* driver-wide */
```

Check each cap explicitly before allocating. Return `EINVAL`, `ENOMEM`, or `ENOBUFFS` as appropriate when the cap is hit.

31.12.9 Safe Module Load and Unload

A driver that supports being unloaded must handle cleanup correctly. An unsafe unload is a security bug. If unload leaves a callback registered, or a mapping in place, or a DMA in flight, then re-loading the module (or unloading and resuming) can touch memory that is no longer owned by the driver. That is a use-after-free waiting to happen.

The rule: if any part of detach or unload fails, either propagate the error (and keep the driver loaded) or drive the cleanup to completion. Partial teardown is worse than no teardown.

A reasonable strategy: make the unload path paranoid. It checks every resource and tears down every one that was allocated, in reverse order of allocation. It uses the `callout_drain` and `taskqueue_drain` helpers to wait for async work. Only after every such resource is quiet does it free the `softc`.

If any step fails, return `EBUSY` from `detach` and document that the driver cannot currently be unloaded. That is better than half-freeing and crashing later.

31.12.10 Safe Concurrent Entries

A driver’s entry points (`open`, `close`, `read`, `write`, `ioctl`) can be called concurrently. The driver should be written as if every entry point could be called from any context at any time. Anything else is a race waiting to fire.

The practical implication: every entry point that touches shared state acquires the `softc` lock first. Every operation that uses resources from the `softc` does so under the lock. If the operation has to sleep or do user-space

work, the code drops the lock, does the work, and re-acquires carefully, checking that the state it had not changed under its feet.

Concurrency is not an afterthought. It is part of the interface.

31.12.11 Error Paths Are Normal Paths

A subtle aspect of secure design is that error paths get the same care as success paths. In a driver, error paths often free resources, release locks, and restore state. A bug on an error path is just as exploitable as a bug on a success path; often more so, because error paths are less tested.

Write every error path as if it were the happy path for a user who is trying to find bugs. Every `goto cleanup` or `out : label` is a candidate for a double-free, a missed unlock, or a left-behind mapping. Walk each error path mentally and confirm that:

Every resource allocated on the success path is freed on the error path.

No resource is freed twice.

Every lock held is released exactly once.

No error path leaves partially initialized state visible to other contexts.

A systematic pattern helps. The “single cleanup path” idiom (one label, cleanup proceeds in reverse order of allocation) catches most such bugs by construction:

```
static int
secdev_do_something(struct secdev_softc *sc, struct secdev_arg *arg)
{
    void *kbuf = NULL;
    struct secdev_item *item = NULL;
    int error;

    kbuf = malloc(arg->len, M_SECDEV, M_WAITOK | M_ZERO);

    error = copyin(arg->data, kbuf, arg->len);
    if (error != 0)
        goto done;

    item = uma_zalloc(sc->sc_zone, M_WAITOK | M_ZERO);

    error = secdev_process(sc, kbuf, arg->len, item);
    if (error != 0)
        goto done;

    mtx_lock(&sc->sc_mtx);
    LIST_INSERT_HEAD(&sc->sc_items, item, link);
    mtx_unlock(&sc->sc_mtx);
    item = NULL; /* ownership transferred */
}
```

```
done:
    if (item != NULL)
        uma_zfree(sc->sc_zone, item);
    free(kbuf, M_SECDEV);
    return (error);
}
```

Each allocation is paired with a cleanup at done. The cleanup uses NULL checks so that resources freed earlier (or never allocated) do not cause double-frees. Ownership transfers set the pointer to NULL, which suppresses the cleanup.

Consistent use of this pattern eliminates most cleanup-path bugs. The code is longer than an early-return style, but it is dramatically safer.

31.12.12 Don't Trust Yourself Either

A final aspect of fail-safe design is to assume that even your own code has bugs. Include `KASSERT(9)` checks for invariants. `KASSERT` does nothing when `INVARIANTS` is not configured (typical in release builds), but in developer kernels it checks every assertion and panics on failure. That turns a subtle corruption bug into a loud, debuggable panic.

```
KASSERT(sc != NULL, ("secdev: NULL softc"));
KASSERT(len <= SECDEV_MAX_BUFLen, ("secdev: len %zu too large", len));
```

Invariants documented as `KASSERT` help readers (future you, future colleagues) understand what the code expects. They also catch regressions that would otherwise silently corrupt state.

31.12.13 Graceful Degradation vs Full Refusal

A design choice that often arises in fail-safe work: when a non-critical part of an operation fails, should the driver continue with a degraded result, or should it refuse the operation entirely?

There is no universal answer. Each case depends on what the caller is likely to do with partial success. A driver that returns a packet with some fields uninitialized (because a subsystem call failed) is inviting the caller to trust the zero bytes as meaningful. A driver that fails the whole operation is more disruptive but less surprising.

For security-relevant operations, prefer full refusal. A privilege check that fails should not result in “most of the operation ran, but we did not do the privileged step”; it should result in the whole thing refused. A partial success that depended on the skipped step is a bug waiting to be found.

For non-security operations, graceful degradation is often the right call. If an optional statistics update fails, the main operation should still succeed. Document what the degradation looks like so callers can anticipate it.

31.12.14 Case Study: Real-World Secure Defaults in `/dev/null`

The FreeBSD `null` driver, at `/usr/src/sys/dev/null/null.c`, is worth studying as an example of secure-by-default design. It is one of the simplest drivers in the tree, yet its construction embodies most of the principles in this chapter.

It creates two device nodes, `/dev/null` and `/dev/zero`, both with world-accessible permissions (0666). This is intentional: they are meant to be used by every process, privileged or not, and neither can leak information or corrupt kernel state. The permission decision is deliberate and documented.

The read, write, and `ioctl` handlers are minimal. `null_read` returns 0 (end of file). `null_write` consumes input without touching kernel state. `zero_read` fills the user buffer with zeros using `uiomove_frombuf` against a static zero-filled buffer.

The `ioctl` handler returns `ENOIOCTL` for unknown commands, so the upper layers can translate to the proper error. A small set of specific `FIO*` commands for non-blocking and async behavior are handled, each doing only the minimal bookkeeping that makes sense for a null or zero stream.

The driver has no locking because it has no mutable state worth protecting: the zero buffer is constant, and the read/write operations do not modify any shared data. The absence of locking is not carelessness; it is a consequence of the design minimizing what is shared in the first place.

The driver's `detach` is straightforward, destroying the device nodes. Because there is no async state, no callouts, no interrupts, no taskqueues, the cleanup is correspondingly simple.

What makes this a good example of secure defaults is the discipline of not doing more than is needed. The driver does not speculatively add features, does not expose internal state, does not support `ioctls` that were not demanded by specific users. Its interface is minimal, which keeps its attack surface minimal. Its behaviour is predictable and has been exactly the same for decades.

Real drivers cannot always be this simple; most have state to manage, hardware to talk to, and operations to perform. But the design principle generalizes: the simpler the driver, the fewer the failure modes. When faced with a choice between adding functionality and leaving it out, the more secure choice is usually to leave it out.

31.12.15 Wrapping Up Section 9

Secure defaults come down to a disposition toward refusal. Default to `EINVAL` for unknown inputs. Default to restrictive modes on device nodes. Default to conservative limits on resources. Default to short timeouts. Default to strict privilege requirements. Whitelist, do not blacklist. Fail closed, not open.

None of these are exotic. They are design habits that add up. A driver built on them is not merely a driver that can be made secure; it is a driver that is secure by default, and has to be actively broken before it becomes insecure.

The next section brings the chapter to a close by looking at the other end of the development cycle: testing. How do you know your driver is as safe as you think it is? How do you hunt for the bugs that review missed?

31.13 Section 10: Testing and Hardening Your Driver

A driver is not secure because you wrote secure code. It is secure because you tested it thoroughly, including under conditions you did not design for. This section is about the tools FreeBSD gives you for finding bugs before attackers do, and the habits that make a driver stay secure as it evolves.

31.13.1 A Walkthrough: Finding a Bug with KASAN

Before the general guidance, consider a specific scenario. You have a driver that passes all your functional tests but that you suspect has a memory-safety bug. You build a kernel with options `KASAN`, boot it, load your driver, and run a stress test. The test crashes the kernel with output that looks something like:

```
=====
ERROR: KASan: use-after-free on address 0xfffffe003c180008
Read of size 8 at 0xfffffe003c180008 by thread 100123

Call stack:
  kasan_report
  secdev_callout_fn
  softclock_call_cc
  ...

Buffer of size 4096 at 0xfffffe003c180000 was allocated by thread 100089:
  kasan_alloc_mark
  malloc
  secdev_attach
  ...

The buffer was freed by thread 100089:
  kasan_free_mark
  free
  secdev_detach
  ...
=====
```

Read the output carefully. KASAN tells you the exact instruction that accessed freed memory (`secdev_callout_fn`), the exact allocation that was freed (in `secdev_attach`), and the exact free (in `secdev_detach`). Now the bug is obvious: the callout was scheduled at `attach`, but `detach` freed the buffer before draining the callout. When the callout fires after the free, it accesses the freed buffer.

The fix: add `callout_drain` to `detach` before the `free`. KASAN helped you find, in thirty seconds, a bug that might have taken hours or weeks to find by inspection, and that might never have been found in production until a customer reported a random crash.

KASAN is not free. The runtime overhead is substantial, both in CPU (perhaps 2 to 3 times slower) and in

memory (each byte of allocated memory has an accompanying shadow byte). You would not run production with it. But for developer testing, and especially for driver authors, it is one of the most effective tools available.

KMSAN works analogously for uninitialized memory reads, and KCOV powers coverage-guided fuzzing. Together they address the main classes of memory-safety bugs: use-after-free (KASAN), uninitialized memory (KMSAN), and bugs not reached by your tests (KCOV plus a fuzzer).

31.13.2 Build With Kernel Sanitizers

A stock FreeBSD kernel is optimized for production. A development kernel for driver testing should be optimized for finding bugs. The options you add to the kernel config file turn on extra checking.

options INVARIANTS enables KASSERT(9). Every assertion is checked at runtime. A failed assertion panics the kernel with a stack trace pointing to the assertion. This catches invariant violations that would otherwise corrupt data silently.

options INVARIANT_SUPPORT is implied by INVARIANTS but is sometimes needed as a separate option for modules built against an INVARIANTS kernel.

options WITNESS turns on the WITNESS lock-order checker. Every lock acquisition is recorded, and the kernel panics if a cycle is detected (A held, then B acquired; later, B held, then A acquired). This catches deadlock bugs before they deadlock.

options WITNESS_SKIPSPIN disables WITNESS for spin mutexes, which can reduce overhead at the cost of missing some checks.

options DIAGNOSTIC enables additional runtime checks in various subsystems. It is looser than INVARIANTS and catches some additional cases.

options KASAN enables the Kernel Address Sanitizer, which detects use-after-free, out-of-bounds access, and some uninitialized memory uses. It requires compiler support and a substantial memory overhead but is excellent for finding memory-safety bugs.

options KMSAN enables the Kernel Memory Sanitizer, which detects uses of uninitialized memory. This directly catches the information-leak bugs described in Section 7.

options KCOV enables kernel coverage tracking, which is what makes coverage-guided fuzzing work.

A driver-development kernel might add:

```
options INVARIANTS
options INVARIANT_SUPPORT
options WITNESS
options DIAGNOSTIC
```

and, for deeper memory-safety testing, KASAN or KMSAN on supported architectures. Build that kernel, boot it, and run your driver against it. Many bugs surface immediately.

Production builds do not typically include these options (they slow the kernel significantly). Use them as a development safety net.

31.13.3 Stress Testing

A driver that passes functional tests can still fail under stress. Stress testing exercises the driver's concurrency, its allocation patterns, and its error paths at volumes that amplify race conditions.

A simple stress harness for a character device might:

Open the device from N processes concurrently.

Each process issues M ioctls with valid and invalid arguments in a random order.

A separate process periodically detaches and re-attaches the device (or `kldunload/kldload`).

This quickly exposes races between user-space operations and detach, which are among the hardest race categories to catch by inspection.

FreeBSD's `stress2` test framework at <https://github.com/pho/stress2> has a long history of finding kernel bugs. It includes scenarios for VFS, networking, and various subsystems. A driver author can learn a lot by reading those scenarios and adapting them to the driver's interface.

31.13.4 Fuzzing

Fuzzing is the technique of generating large numbers of random or semi-random inputs and observing whether the program crashes, asserts, or misbehaves. Modern fuzzers are coverage-guided: they watch which code paths are exercised and evolve inputs that explore new paths. This is far more effective than purely random input.

For driver testing, the key fuzzer is **syzkaller**, an external project that understands syscall semantics and produces structured inputs. Syzkaller is not part of the FreeBSD base system; it is an external tool that runs on top of a FreeBSD kernel built with KCOV coverage instrumentation. Syzkaller has found many bugs in the FreeBSD kernel over the years, and a driver that wants to be exercised thoroughly benefits from being described in a syzkaller syscall description (`.txt` file under syzkaller's `sys/freebsd/`).

If your driver exposes a substantial ioctl or sysctl interface, consider writing a syzkaller description for it. The format is straightforward, and the investment pays off the first time syzkaller finds a bug no human reviewer would have spotted.

Simpler fuzzing approaches also work. A shell script that issues random ioctls with random arguments and watches `dmesg` for panics is better than no fuzzing at all. The goal is to generate inputs your design did not anticipate.

31.13.5 ASLR, PIE, and Stack Protection

Modern FreeBSD kernels use several exploit-mitigation techniques. Understanding them is part of understanding why the bugs we have discussed matter.

kASLR, kernel Address Space Layout Randomization, places the kernel's code, data, and stacks at randomized addresses at boot. An attacker who wants to jump to kernel code, or to overwrite a specific function pointer, does not know where that code or pointer is. kASLR is foundational for making many memory-safety bugs unexploitable in practice.

Information leaks (Section 7) are particularly dangerous because they can defeat kASLR. A single leaked kernel pointer gives the attacker the base address and unlocks everything else.

SSP, the Stack-Smashing Protector, places a canary value on the stack between local variables and the return address. When a function returns, the canary is checked; if it has been overwritten (because a buffer overflow clobbered it on the way to the return address), the kernel panics. SSP does not prevent overflows but it prevents many of them from gaining control of execution.

Not every function is protected. The compiler applies SSP based on heuristics: functions with local buffers, functions that take addresses of locals, and so on. Understanding this means understanding why certain buffer-overflow patterns are more exploitable than others.

PIE, Position-Independent Executables, allows the kernel (and modules) to be relocated to random addresses. Combined with kASLR, this is what makes the randomization effective.

Stack guards and guard pages surround kernel stacks with unmapped pages. An attempt to write past the stack hits an unmapped page and panics rather than silently corrupting adjacent memory.

W^X, write-xor-execute, keeps kernel memory either writable or executable, never both. This prevents many classic exploits that relied on writing shellcode into memory and then jumping to it.

A driver author does not implement any of these; they are kernel-wide protections. But a driver's bugs can undermine them. An information leak defeats kASLR. A buffer overflow that reliably hits a function pointer or vtable defeats SSP. A use-after-free that races a fresh allocation gives an attacker controlled memory at a kernel address.

In short: the point of careful driver code is not just to avoid crashes. It is to keep the kernel's defenses intact. When your driver leaks a pointer, you did not merely expose information; you downgraded the entire system's exploit-mitigation posture.

31.13.6 Reading Your Diffs

Every time you modify the driver, read the diff carefully. Look for:

New `copyin` or `copyout` calls: are the lengths clamped? Are the buffers zeroed first?

New privilege-sensitive operations: do they have `priv_check` or equivalent?

New locking: is the lock order consistent with other code?

New allocations: are they paired with frees on every path, including error paths?

New log messages: are they rate-limited? Do they leak sensitive data?

New user-visible fields in structures: are they initialized? Is the structure zeroed before the `copyout`?

A diff-review habit catches many regressions. If your project uses code review (it should), make these questions part of the checklist.

31.13.7 Static Analysis

FreeBSD kernel code can be analyzed by several static-analysis tools, including `cppcheck`, `clang-analyzer` (scan-build), and, increasingly, Coverity and GitHub CodeQL-style tools. These tools often report warnings that a human reviewer would miss: a conditional that can never be true, a pointer used after a path where it was freed, a missing null check.

Treat static-analysis warnings seriously. Most are false positives; some are real bugs. Silencing a warning should be a decision, not a reflex. When the tool is wrong, add a comment explaining why. When the tool is right, fix the code.

`syntax` check with `bmake` on the kernel source tree is a fast first pass. Running `clang --analyze` or `scan-build` against your driver is a deeper pass. Neither replaces review or testing, but both catch bugs at low cost.

31.13.8 Code Review

No tool replaces another pair of eyes. Review is especially important for security-relevant code. When proposing a change to a security-sensitive path, find someone else to look at it. Describe what the change is, what invariants it preserves, and what you checked. Be grateful when they find a problem you missed.

For open-source projects, the FreeBSD review system (reviews.freebsd.org) provides a convenient way to get external review. Use it. The community has a long tradition of thoughtful, security-aware review, and reviewers often catch things you would not.

31.13.9 Testing After a Change

When a bug is found and fixed, add a test that would have caught it. This matters because:

The same bug class often recurs in other places. A test that catches the specific instance may catch future similar bugs.

Without a test, you have no way to know that the fix worked.

Without a test, a future refactoring may re-introduce the bug.

Tests can be unit tests (in user space, exercising individual functions), integration tests (loading the driver in a VM and exercising it), or fuzz cases (inputs that used to crash and should not now). All have their place.

31.13.10 Continuous Integration

Automated testing on every change catches regressions early. A CI setup that builds the driver against a development kernel with `INVARIANTS`, `WITNESS`, and possibly `KASAN` runs the stress harness, and checks the result, is the backbone of a driver that stays safe.

For a driver in the FreeBSD tree, this is already provided by the project's CI. For out-of-tree drivers, setting up CI takes some effort but pays back quickly.

31.13.11 Treat Bug Reports Seriously

When someone reports a crash or a suspected vulnerability in your driver, treat it as real until you have evidence otherwise. Even a “harmless” bug may be exploitable in ways the reporter did not see. “I can crash the kernel with this `ioctl`” is not a minor issue; it is at minimum a denial-of-service bug, and very often a memory-safety bug that could become arbitrary code execution.

The FreeBSD security team (secteam@freebsd.org) is the right audience for vulnerability reports in the base system. For out-of-tree drivers, have a similar channel. Respond quickly, fix carefully, and credit the reporter when appropriate.

31.13.12 Hardening Over Time

A driver's security posture is not static. New classes of bugs emerge. New mitigations become available. New attack techniques make old bugs more exploitable. Budget time every release cycle to:

Re-read the security-relevant paths of the driver.

Check for newly discovered compiler warnings or static-analysis findings.

Try the latest tools (KASAN, KMSAN, syzkaller) against the driver.

Update the privilege model if FreeBSD has added new `PRIV_*` codes or more specific checks.

Remove interfaces that no user actually needs.

The discipline of regular re-examination is what distinguishes a driver that is secure on the day it ships from one that stays secure through its lifetime.

31.13.13 Post-Incident: What To Do When a Bug Becomes a CVE

A realistic chapter on security must cover the possibility that, despite all the precautions, a bug in your driver gets reported externally as a vulnerability. The pathway is typically:

A researcher or user discovers unexpected behavior in your driver.

They investigate and determine that the behavior is a security bug: information leak, privilege escalation, crash-on-untrusted-input, or similar.

They report the bug, ideally via a responsible-disclosure channel (for FreeBSD base-system drivers, this is the `secteam@freebsd.org` address).

You receive the report.

The first response matters. Even if the bug turns out to be less serious than it looks, treat the reporter as a collaborator, not an adversary. Acknowledge receipt promptly. Ask clarifying questions if needed. Do not dismiss without investigation. Do not attempt to gag the reporter. Most vulnerability researchers want the bug fixed; if you cooperate, you get a fix faster and usually get public credit that reflects well on the project.

Triage the report technically. Can you reproduce the bug? Is it a crash, an information leak, a privilege escalation, or something else? What is the attacker model: who has to have access, and what do they gain? Is it exploitable in combination with other known bugs?

If confirmed, coordinate a fix. Keep in mind that for FreeBSD base-system drivers, the fix must flow through the project's normal review process and, where appropriate, through the security advisory process. For out-of-tree drivers, you have more flexibility but still should write the fix carefully and test it thoroughly.

Prepare the disclosure. Typical disclosure practice gives the project time to fix the bug before details become public. Industry norms are usually 90 days. Within that window, the advisory is prepared, a patched version is released, and public disclosure happens simultaneously with the release. Do not leak details early; do not delay past the agreed date.

Write the commit message carefully. Security fix commits should mention the vulnerability without giving attackers a roadmap. "Fix incorrect bounds check in `secdev_write` that could allow kernel memory disclosure" is better than either "tweak write" (too vague, reviewers miss it) or "Fix CVE-2026-12345, where an attacker

can read arbitrary kernel memory by issuing a write of X bytes followed by a read, bypassing Y check” (too specific, attackers read your commit history before users can upgrade).

After the release, if details become public, be prepared to answer questions. Users want to know: am I vulnerable, how do I upgrade, and how can I tell if I was attacked? Have clear, calm answers ready.

Post-mortem the bug. Not to blame, but to learn. Why did the bug exist? Was there a pattern the review missed? Could a tool have caught it? Should the team’s process change? Write the conclusions down; apply them in future work.

Security is a continuing practice, and post-incident learning is one of its most important parts. A project that fixes the bug and moves on has learned nothing; a project that reflects on why the bug occurred makes the next bug less likely.

31.13.14 Wrapping Up Section 10

Testing and hardening are how a careful design becomes a secure one. Build your development kernel with INVARIANTS, WITNESS, and, where possible, KASAN or KMSAN. Stress-test under concurrent load. Fuzz with syzkaller or, at minimum, with a random-input harness. Use static analysis. Review diffs. Respond seriously to bug reports. Re-test after every fix. Harden over time.

A driver does not become secure by accident. It becomes secure because the author assumed bugs existed, looked for them with every tool available, and fixed them one at a time.

31.14 Hands-On Labs

The labs in this chapter build a small character device called `secdev` and guide you through making it progressively more secure. Each lab starts from a provided starter file, asks you to make specific changes, and provides a “fixed” reference to compare against. Work through them in order.

The labs are designed to be run in a FreeBSD 14.3 virtual machine or test host where kernel panics are acceptable. Do not run them on a machine with important running services; an error in the unsafe driver can crash the kernel.

If you are running these labs inside a VM, make sure the VM is configured to write crash dumps to a location you can recover after reboot. Enable `dumpon(8)` and set `/etc/fstab` appropriately so that core dumps land in `/var/crash` after a panic. See `/usr/src/sbin/savecore/savecore.8` for details. This infrastructure is how you will diagnose any panics the labs provoke.

The companion files for these labs are under `examples/part-07/ch31-security/`. Each lab has its own subfolder containing a `secdev.c` source file, a `Makefile`, a `README.md` describing the lab, and, where appropriate, a `test/` subfolder with small user-space test programs.

As you work through the labs, keep a running log in your lab logbook: which files you modified, what you observed when you loaded the broken version, what you observed with the fix in place, and any unexpected behavior. The logbook is a learning tool; it forces you to articulate what you see, which is how learning consolidates.

31.14.1 Lab 1: The Unsafe secdev

Goal. Build, load, and test the intentionally unsafe version of `secdev`, confirm that it works, and then identify at least three security issues by reading the code with a security mindset.

Prerequisites.

This lab assumes you have a FreeBSD 14.3 virtual machine or test system where you can load and unload kernel modules. You should have already completed the module-building chapters (Part 2 and onward) so that `make`, `kldload`, `kldunload`, and device node access are familiar. If you have not, pause and revisit those chapters; the rest of Chapter 31 assumes you are comfortable with module compilation.

Steps.

1. Copy `examples/part-07/ch31-security/lab01-unsafe/` to a working directory on your FreeBSD test machine. You can either clone the book's companion repository or copy the files manually if you extracted them locally.
2. Read `secdev.c` carefully. Note what it does: it provides a `/dev/secdev` character device with `read`, `write`, and `ioctl` operations. `read` returns the contents of an internal buffer. `write` copies user data into the buffer. An `ioctl` (`SECDEV_GET_INFO`) returns a structure describing the device.
3. Read `Makefile`. It should be a standard FreeBSD kernel module makefile using `bsd.kmod.mk`.
4. Build the module with `make`. Address any build errors by consulting earlier chapters on module-building. A successful build produces `secdev.ko`.
5. Load the module with `kldload ./secdev.ko`. Verify with:

```
kldstat | grep secdev
ls -l /dev/secdev
```

You should see the module listed and the device node present with whatever permissions the unsafe driver created.

6. Exercise the device as a normal functional test:

```
echo "hello" > /dev/secdev
cat /dev/secdev
```

You should see `hello` printed back. If you do not, check `dmesg` for error messages.

7. Now, review the code with the security mindset from this chapter. For each of the following categories, find at least one issue in the unsafe code:
 - Buffer overflow opportunity.
 - Information leak opportunity.
 - Missing privilege check.
 - Unchecked user input. Write down each finding in your lab logbook, including the line number and the specific concern.
8. Unload the module with `kldunload secdev` when you are done. Verify with `kldstat` that it is gone.

Observations.

The unsafe `secdev` has several issues by design. In `secdev_write`, the code calls `uiomove(sc->sc_buf, uio->uio_resid, uio)`, which copies `uio_resid` bytes regardless of `sizeof(sc->sc_buf)`. A write of 8192 bytes to a 4096-byte buffer overflows the internal buffer. Depending on what lies next to `sc_buf` in memory, this may or may not crash immediately, but it always corrupts adjacent kernel memory.

`SECDEV_GET_INFO` returns a `struct secdev_info` that is filled in field-by-field without being zeroed first. Any padding bytes between fields carry stack contents to user space. The structure likely has padding around the `uint64_t` members for alignment.

The device is created with `args.mda_mode = 0666` (or equivalent), allowing any user on the system to read and write. A user with no special privilege can corrupt the kernel buffer or leak information through the `ioctl`.

The `ioctl` handler does not check `priv_check` or similar. Any user who can open the device can issue any `ioctl`.

`secdev_read` copies `sc->sc_buflen` bytes regardless of the caller's buffer size, potentially reading beyond valid data if `sc_buflen` was ever larger than the currently valid content.

Additional exploration.

As a non-root user, try the operations that should be privileged and confirm that they succeed when they should not. Write a short C program that issues `SECDEV_GET_INFO` and prints the returned structure as a hex dump. Look for non-zero bytes in fields that were not explicitly set; those are leaked kernel data.

Wrapping up.

The goal of this lab is pattern recognition. A real driver would have subtler versions of all these bugs, buried inside hundreds of lines of code. Training yourself to see them in a simple driver makes them easier to see everywhere else. Keep `lab01-unsafe/secdev.c` as a reference for what not to do.

31.14.2 Lab 2: Bounds-Check the Buffer

Goal. Fix the buffer overflow in `write` and add a corresponding length check in `read`. Observe the difference in how the driver behaves when stress-tested.

Steps.

1. Start from `lab02-bounds/secdev.c`. This is `lab01`'s code plus some `TODO` comments marking where you will add checks.
2. In `secdev_write`, calculate how much data can safely be written to the internal buffer. Remember that `uiomove` writes at most the length you pass. Clamp `uio->uio_resid` to the remaining space before calling `uiomove`.
3. In `secdev_read`, make sure you only copy out as much data as is actually valid in the buffer, not its full allocated size.
4. Rebuild and re-test. With the fixes in place, a write of 10KB to a 4KB buffer should simply fill the buffer, not overflow it.
5. Stress-test the fixed driver:

```
dd if=/dev/zero of=/dev/secdev bs=8192 count=100
dd if=/dev/secdev of=/dev/null bs=8192 count=100
```

Neither command should crash the kernel or produce warnings in `dmesg`. If they do, your bounds check is incomplete.

6. Compare your fix with `lab02-fixed/secdev.c`. If your fix is different but correct, that is fine; multiple solutions can be valid. If yours is incorrect, study the reference fix and understand where you went wrong.

Building confidence.

Write a small C program that issues writes of various sizes (0 bytes, 1 byte, buffer size, buffer size + 1, much larger than buffer size) and verifies that each returns the expected number of bytes written or a sensible error. This kind of boundary testing is what real driver tests look like.

Wrapping up.

Bounds checking is the simplest security fix and it catches a large fraction of real-world driver bugs. Internalize the pattern: every `uiomove`, `copyin`, `copyout`, and `memcpy` bounds the length against both source and destination sizes. The compiler cannot catch this for you; it is entirely the author's responsibility.

31.14.3 Lab 3: Zero Before copyout

Goal. Fix the information leak in the `SECDEV_GET_INFO` ioctl. Observe, via a user-space test program, the difference between the broken and fixed versions.

Steps.

1. Start from `lab03-info-leak/secdev.c`. This contains the ioctl as in the original unsafe code.
2. Observe the structure definition. Note the padding between fields:

```
struct secdev_info {
    uint32_t version;
    /* 4 bytes of padding here on 64-bit systems */
    uint64_t flags;
    uint16_t id;
    /* 6 bytes of padding to align name to 8 bytes */
    char name[32];
};
```

Check the size with `pahole` or a small C program that prints `sizeof(struct secdev_info)`.

3. Before fixing, build and load the broken version. Run the test program provided in `lab03-info-leak/test/leak_check.c`. It issues the ioctl repeatedly and dumps the returned structure as a hex dump. Look at the padding bytes. You should see non-zero values that differ between runs; those are leaked kernel stack bytes.
4. In `secdev_ioctl`, before filling in the `struct secdev_info`, zero the structure with `bzero` (or use `= { 0 }` initialization).
5. Also fix the name field: use `snprintf` instead of `strncpy` to guarantee a NUL terminator, and copy only up to the NUL rather than the full buffer size.

6. Rebuild and re-test with the same `leak_check` program. The padding bytes should now be zero on every run. The visible behavior from user space is unchanged; the internal change is that padding bytes no longer carry stack contents.
7. Compare with `lab03-fixed/secdev.c`.

A deeper exploration.

If you have KMSAN built into your kernel, load the broken version of the driver and run `leak_check`. KMSAN should report an uninitialized read when the structure is copied out. This demonstrates why KMSAN is valuable: it catches information leaks that are invisible without it.

Wrapping up.

This fix costs a single `bzero` call. The benefit is that the `ioctl` cannot leak information, ever, regardless of what future changes add or remove fields. Make `bzero` (or zero-initializing declaration) part of your reflex for any structure that will touch `copyout`, `sysctl`, or similar boundaries.

31.14.4 Lab 4: Add Privilege Checks

Goal. Restrict the device to privileged users, and verify that unprivileged access is refused.

Steps.

1. Start from `lab04-privilege/secdev.c`.
2. Modify the device-node creation code in `secdev_mdevent` (or `secdev_at_tach`, depending on structure) to use a restrictive mode (`0600`) and the root user and group:

```
args.mda_uid = UID_ROOT;
args.mda_gid = GID_WHEEL;
args.mda_mode = 0600;
```

3. In `secdev_open`, add a `priv_check(td, PRIV_DRIVER)` call at the top:

```
error = priv_check(td, PRIV_DRIVER);
if (error != 0)
    return (error);
```

Return the error if the check fails.

4. Rebuild and reload the module.
5. Test from a non-root shell:

```
% cat /dev/secdev
cat: /dev/secdev: Permission denied
```

Open should fail with `EPERM` (reported as “Permission denied”). The filesystem mode blocks access before `d_open` is even reached.

6. Temporarily change the device-node mode (as root) with `chmod 0666 /dev/secdev`. Try again as non-root. This time the filesystem allows the open, but `priv_check` in `d_open` refuses:

```
% cat /dev/secdev
cat: /dev/secdev: Operation not permitted
```

This demonstrates the in-kernel layer of the defense.

7. Reset the permissions with `chmod 0600 /dev/secdev` or reload the module to restore the default.

8. As root, the device should continue to work normally. Verify:

```
# echo "hello" > /dev/secdev
# cat /dev/secdev
hello
```

9. Compare with `lab04-fixed/secdev.c`.

Digging deeper.

Try creating a jailed environment and running a shell as root inside the jail:

```
# jail -c path=/ name=testjail persist
# jexec testjail sh
# cat /dev/secdev
```

Depending on whether your driver has added a `jailed()` check, the behavior differs. If the driver does not check `jailed`, `jailed-root` can still access the device. Add `if (jailed(td->td_ucred)) return (EPERM);` at the top of `secdev_open` and verify that the jailed access is now refused.

Wrapping up.

Restricting device-node permissions is a two-layer defense: the filesystem layer, and the in-kernel `priv_check`. Both together make the driver robust against configuration mistakes. Adding `jailed()` on top blocks even root-in-jail from sensitive operations. Each layer defends against a different failure mode; do not rely on any single one.

31.14.5 Lab 5: Rate-Limited Logging

Goal. Add a rate-limited log message for malformed ioctls and verify that a flood of malformed requests does not overwhelm the log.

Steps.

1. Start from `lab05-ratelimit/secdev.c`.
2. Add a static `struct timeval` and a static `int` to hold rate-limit state. These are global per-driver, not per-softc, unless you specifically want per-device limits:

```
static struct timeval secdev_log_last;
static int secdev_log_pps;
```

3. In `secdev_ioctl`, in the default branch (the case that handles unknown ioctls), use `ppsratecheck` to decide whether to log:

```

default:
    if (ppsratecheck(&secdev_log_last, &secdev_log_pps, 5)) {
        device_printf(sc->sc_dev,
            "unknown ioctl 0x%lx from uid %u\n",
            cmd, td->td_ucred->cr_uid);
    }
    return (ENOTTY);

```

The third argument, 5, is the maximum messages per second.

4. Rebuild and reload.
5. Write a tiny test program that issues a million bad ioctls in a tight loop:

```

#include <sys/ioctl.h>
#include <fcntl.h>
int main(void) {
    int fd = open("/dev/secdev", O_RDWR);
    for (int i = 0; i < 1000000; i++)
        ioctl(fd, 0xdeadbeef, NULL);
    return (0);
}

```

6. While it runs (as root), monitor `dmesg -f`. You should see messages arriving, but at no more than about 5 per second. Without rate limiting, you would have a million messages.
7. Count the messages with something like `dmesg | grep "unknown ioctl" | wc -l`. Compare to one million (the number of attempts).
8. Compare with `lab05-fixed/secdev.c`.

Variations to try.

Replace `ppsratecheck` with `eventratecheck` and note the difference (event-based vs per-second). Experiment with different maximum rates. Add a suppressed-count summary that emits periodically (“suppressed N messages in last M seconds”) for operator visibility.

Wrapping up.

Rate-limited logging gives you visibility into suspicious activity without making the driver itself a denial-of-service vector. Apply the pattern to any log message that can be triggered by user actions. The cost is a few extra lines per log statement; the benefit is that your driver is no longer a tool attackers can use to flood the system.

31.14.6 Lab 6: Safe Detach

Goal. Make `secdev_detach` safe under concurrent activity. Observe, by deliberately racing unload with active use, how the fix prevents use-after-free panics.

Steps.

1. Start from `lab06-detach/secdev.c`. This version introduces a small callout that periodically updates an internal counter, and an `ioctl` that sleeps briefly to simulate long-running work.
2. Review the current `detach` function. Note what it frees and in what order. The starter file intentionally has a flawed `detach` that frees the `softc` without draining.
3. Test the flawed version first (build with `INVARIANTS` and `WITNESS` in the kernel):
 - Start a test program that holds `/dev/secdev` open and issues the slow `ioctl` in a loop.
 - While it runs, issue `kldunload secdev`.
 - Observe the result. You may see a kernel panic, a stuck `kldunload`, or, if you are lucky, nothing visible (the race may not fire on every run). `WITNESS` may complain about lock state.
 - Rebuild and try again until you see the problem. Concurrent races can be flaky.
4. Now fix the `detach`:
 - Use `destroy_dev` on the `cdev` before any other cleanup, so that no new user-space thread can enter the driver, and any in-flight thread finishes before `destroy_dev` returns.
 - Add a `callout_drain` call before freeing the `softc`. This ensures that any in-flight callout has finished.
 - If the driver uses a taskqueue, add `taskqueue_drain_all`.
 - Only after all draining, free resources.
5. Rebuild and re-test the same race:
 - The user program continues running uninterrupted during `kldunload`.
 - After `kldunload`, the user program's next `ioctl` receives an error (typically `ENXIO`) because the `cdev` was destroyed.
 - The kernel remains stable. No panic, no `WITNESS` complaint.
6. Compare with `lab06-fixed/secdev.c`. Confirm that the fixed version handles in-flight activity safely.

Understanding what happened.

The flawed version races because: - `destroy_dev` is called, or is not called early enough. In-flight `d_*` calls continue. - The callout is scheduled in the future and has not fired yet. - The `softc` is freed while something still references it. - The freed `softc` is reused by the allocator for some other purpose. - The callout fires, touches what it thinks is its `softc`, and corrupts whatever memory is now there.

The fix sequences the cleanup: stop accepting new entries first (`destroy_dev`), stop in-flight entries by waiting for them to leave (part of `destroy_dev`'s contract), stop scheduled work (`callout_drain`), and only then free state. Each step closes a door; nothing beyond a closed door can reach the memory being freed.

Wrapping up.

Detach-time races are among the hardest driver bugs to catch by inspection, because the bug only occurs when timing aligns. Using `destroy_dev`, `callout_drain`, and `taskqueue_drain_all` defensively in every `detach` function is one of the highest-value habits you can adopt. Do it mechanically, even if you do not think your driver has asynchronous activity. The next author to add a callout may forget; your defensive `detach` catches them.

31.14.7 Lab 7: Secure Defaults Everywhere

Goal. Apply every lesson so far to a single driver: the “secure secdev”. Build it from a skeleton, then review the finished result as if you were performing a security audit.

Steps.

1. Start from `lab07-secure/secdev.c`. This is a skeleton with TODO markers in many places.
2. Fill in each TODO, applying the lessons from Labs 1 to 6 plus any additional defenses you think appropriate. Suggested additions:

- A `MALLOC_DEFINE` for the driver’s memory.
- A softc mutex protecting all shared fields.
- `priv_check(td, PRIV_DRIVER)` in `d_open` and in each privileged ioctl.
- `jailed()` checks for operations that should not be available to jailed users.
- `securelevel_gt` for operations that should be refused at elevated `securelevel`.
- `bzero` on every structure before filling it for copyout.
- `M_ZERO` on every allocation that will be copied to user space.
- `explicit_bzero` on sensitive buffers before `free`.
- Rate-limited `device_printf` on every log message triggerable from user space.
- `destroy_dev`, `callout_drain`, and other drains in `detach` before any `free`.
- A `sysctl`-controlled `secdev_debug` flag that gates verbose logging.
- Input validation that whitelists allowed operation codes.
- Bounded copies in both directions.
- `KASSERT` statements documenting internal invariants.

3. Rebuild and load the module.

4. Run a comprehensive functional test to confirm everything still works:

- As root, open the device, read, write, ioctl.
- As non-root, confirm `/dev/secdev` is inaccessible.
- Inside a jail, confirm sensitive operations are refused.

5. Run a security stress test:

- Boundary cases (0-byte reads, exactly buffer-size writes, one-byte-over writes).
- Malformed ioctls.
- Concurrent open/read/write/close from multiple processes.
- `kldunload` during active use.

6. Compare your work with `lab07-fixed/secdev.c`. Note differences. Where your version is more defensive, ask whether the extra defense is worth the complexity. Where the reference is more defensive, ask whether you missed a defense.

A self-review.

Once your lab 7 driver builds and passes tests, put on the reviewer hat. Go through the Security Checklist section of this chapter and confirm each item. Any items you cannot confirm are gaps in your driver. Fix them now, while the code is fresh; later, finding and fixing such gaps is slower and more error-prone.

Wrapping up.

This lab is the consolidation of the chapter. Your finished driver is still a simple character device, but it is one you would not be embarrassed to see in a real FreeBSD tree. The practices you applied here are the same practices that separate amateur drivers from professional ones. Keep your lab 7 driver as a reference: when you write your first real driver, this is the skeleton you will start from.

31.15 Challenge Exercises

These challenges go beyond the labs. They are longer, more open-ended, and assume you have finished Lab 7. Take your time. None of them require new FreeBSD APIs; they require deeper application of what you have learned.

These challenges are meant to be attempted over days or weeks, not in a single sitting. They exercise judgment as much as coding: the question “is this secure” is often “secure against what threat model”. Being explicit about the threat model is part of the exercise.

31.15.1 Challenge 1: Add a Multi-Step ioctl

Design and implement an ioctl that performs a multi-step operation on secdev: first, the user uploads a blob; second, the user requests processing; third, the user downloads the result. Each step is a separate ioctl call.

The challenge is to manage per-open state correctly: the blob uploaded in step 1 must be associated with the calling file descriptor, not globally. Two concurrent users must not see each other’s blobs. State must be cleaned up when the file descriptor is closed, even if the user never reached step 3.

Security considerations: bound the blob size, validate each step of the state machine (cannot request processing without a blob; cannot download without completing processing), make sure partial state on error paths is cleaned up, and make sure a user-visible identifier (if you expose one) is not a kernel pointer.

31.15.2 Challenge 2: Write a syzkaller Description

Write a syzkaller syscall description for secdev’s ioctl interface. The format is documented in the syzkaller repository. Install syzkaller and feed it your driver; run it for at least an hour (ideally longer) and see what it finds.

If it finds bugs, fix them. Write a note about what each bug was and how the fix works. If it does not find bugs in several hours, consider whether your syzkaller description really exercises the driver. Often a description that does not find bugs is not exploring the interface thoroughly.

31.15.3 Challenge 3: Detect Double Free in Your Own Code

Intentionally introduce a double-free bug into a copy of your secure secdev. Build the module against a kernel with INVARIANTS and WITNESS. Load and exercise the module in a way that triggers the double-free. Observe what happens.

Now rebuild the kernel with KASAN. Load and exercise the same broken module. Observe the difference in how the bug is detected.

Write down what each sanitizer caught and how readable the output was. This exercise builds intuition for which sanitizer to reach for first in which situation.

31.15.4 Challenge 4: Threat-Model an Existing Driver

Pick a driver in the FreeBSD tree that you have not previously examined (something small, ideally under 2000 lines). Read it carefully. Write a threat model: who are the callers, what privileges do they need, what could go wrong, what mitigations are in place, what could be added?

The goal is not to find specific bugs. It is to practice the security mindset on real code. A good threat model is a few pages of prose that would let another engineer review the same driver efficiently.

31.15.5 Challenge 5: Compare `/dev/null` and `/dev/mem`

Open `/usr/src/sys/dev/null/null.c` and `/usr/src/sys/dev/mem/memdev.c` (or the per-architecture equivalents). Read both.

Write a short essay (a page or two) on the security differences. `/dev/null` is one of the simplest drivers in FreeBSD; what does it do, and why is it safe? `/dev/mem` is one of the most dangerous; what does it do, and how does FreeBSD keep it safe? What can you learn about the shape of secure driver code from the contrast?

31.16 Troubleshooting and Common Mistakes

A short catalogue of mistakes I have seen repeatedly in real driver code, with the symptom, the cause, and the fix.

31.16.1 “Sometimes it works, sometimes it doesn’t”

Symptom. A test passes most of the time but occasionally fails. Running under load amplifies the failure rate.

Cause. Almost always a race condition. Something is being read and written concurrently without a lock.

Fix. Identify the shared state. Add a lock. Acquire the lock for the whole check-and-act sequence. Do not trust `atomic_*` operations to solve a multi-field invariant problem.

31.16.2 “The driver crashes on unload”

Symptom. `kldunload` triggers a panic or a stuck kernel.

Cause. A callout, taskqueue task, or kernel thread is still running when `detach` frees the structure it uses. Or an in-flight `cdev` operation is still in the driver’s code when `destroy_dev` is skipped.

Fix. In detach, call `destroy_dev` before anything else. Then `callout_drain` every callout, `taskqueue_drain_all` every taskqueue, and wait for every kernel thread to exit. Only then free state. Structure the detach as a strict reverse of attach.

31.16.3 “The ioctl works from root but not from my service account”

Symptom. User reports that root can use the device, but a non-root account cannot.

Cause. Device node permissions are too restrictive, or a `priv_check` call refuses the operation.

Fix. If the operation truly should be privileged, this is working as intended; document it. If not, reconsider: was the privilege check added in error? Is the device-node mode too tight? The correct answer depends on the operation; most real answers are “yes, it should be privileged, update the docs”.

31.16.4 “dmesg is flooding”

Symptom. `dmesg` shows thousands of identical messages from the driver. Legitimate messages are being pushed out.

Cause. A log statement in a path triggerable from user space, without rate limiting.

Fix. Wrap the log in `ppsratecheck` or `eventratecheck`. Limit to a few per second. If the message is about an error, include a count of suppressed messages when the rate returns to normal (the rate helpers support this).

31.16.5 “The structure comes back with garbage bytes”

Symptom. A user-space tool reports seeing apparently random data in a field it did not expect to be set.

Cause. The driver did not zero the structure before filling and copying out. The “random” data is actually stack or heap content from before.

Fix. Add a `bzero` at the top of the function, or initialize the structure with `= { 0 }` at declaration. Never copyout an uninitialized structure.

31.16.6 “We leak memory but I don’t see where”

Symptom. `vmstat -m` shows the driver’s malloc type growing over time. Eventually the system runs out of memory.

Cause. An allocation path that does not pair with a free path, or an error path that returns without freeing.

Fix. Use a named malloc type (`MALLOC_DEFINE`). Audit every allocation. Walk every error path. Consider the single-cleanup-label pattern. Build with `INVARIANTS` and watch for allocator warnings on unload.

31.16.7 “kldload succeeds but my device doesn’t show up in /dev”

Symptom. `kldstat` shows the module loaded, but there is no `/dev/secdev` entry.

Cause. Usually an error in the attach sequence before `make_dev_s` is called, or `make_dev_s` itself failed silently.

Fix. Check the return value of `make_dev_s`. Add a `device_printf` reporting any error. Verify `attach` is being reached by adding a `device_printf` at the top.

31.16.8 “A simple C test passes, but a shell script that does the same thing in a loop fails”

Symptom. Single-shot testing works. Rapid repeated testing fails.

Cause. Likely a race between repeated operations, or a resource that is not being cleaned up between calls. Sometimes a TOCTOU bug that is timing-sensitive.

Fix. Stress-test harder. Use `dtrace` or `ktrace` to see what is happening. Look for state that persists across calls and should not.

31.16.9 “KASAN says use-after-free but my malloc/free are balanced”

Symptom. KASAN reports access to freed memory, but visual inspection of the driver shows each allocation freed exactly once.

Cause. A common subtle case: a callout or taskqueue task still holds a pointer to the freed object. The callout fires after free.

Fix. Trace the callout lifecycle. Ensure `callout_drain` (or equivalent) runs before any free. A related case is an asynchronous completion callback; ensure the operation is either completed or cancelled before the owning structure is freed.

31.16.10 “WITNESS complains about lock order”

Symptom. WITNESS reports “lock order reversal” and identifies two locks that were acquired in inconsistent order.

Cause. At one point the code acquired lock A then lock B; at another point it acquired lock B then lock A. This can deadlock.

Fix. Decide on a canonical order for your locks. Document it. Acquire them in that order everywhere. If a code path legitimately needs the reverse order, use `mtx_trylock` with a backoff-and-retry pattern.

31.16.11 “vmstat -m shows a negative free count”

Symptom. `vmstat -m` lists the driver’s malloc type with a negative number of allocations, or with an inuse count that increases over time without bound.

Cause. A mismatched `malloc/free` type, or a leak where allocations happen without corresponding frees.

Fix. A negative free count almost always means a `free` call passed the wrong type tag. Audit every `free(ptr, M_TYPE)` and confirm the type matches the `malloc`. A continuously rising inuse count is a leak; audit every path that allocates and confirm it has a matching free on every exit.

31.16.12 “The driver works on amd64 but panics on arm64”

Symptom. Functional testing on amd64 passes; the same driver panics on arm64.

Cause. Often a mismatch in structure padding or alignment. arm64 has different padding rules from amd64 for some structures. An access that is aligned on amd64 may be misaligned on arm64 and panic.

Fix. Use `__packed` carefully (it changes alignment), use `__aligned(N)` where alignment matters, and avoid assuming the size or layout of a structure matches between architectures. For fields crossing the user/kernel boundary, use explicit widths (`uint32_t` rather than `int`, `uint64_t` rather than `long`).

31.16.13 “The driver compiles without errors but dmesg shows kernel build warnings”

Symptom. The module builds, but loading it produces warnings about unresolved symbols or ABI mismatches.

Cause. The module was built against a different kernel than the one it is being loaded into. The kernel ABI is not guaranteed stable across versions, so a module built against 14.2 may not load cleanly on 14.3.

Fix. Rebuild the module against the running kernel’s source tree. `uname -r` shows the running kernel version; verify that `/usr/src` matches. If they do not, install the matching source (via `freebsd-update`, `svn`, or `git`, depending on your source distribution).

31.16.14 “The driver is intermittently slower than expected”

Symptom. Benchmarks show occasional large latency spikes even under moderate load.

Cause. Often a lock-contention issue: multiple threads queue on a single mutex. Sometimes an allocator stall: `malloc(M_WAITOK)` in a hot path waits for memory to become available.

Fix. Use `dtrace` to profile lock contention (`lockstat` provider) and identify which lock is hot. Restructure to reduce the critical section, split the lock, or use a lock-free approach. For allocator stalls, preallocate or use a UMA zone with a high-water mark.

31.17 Security Checklist for Driver Code Review

This section is a reference checklist you can keep next to your code as you review a driver, yours or someone else’s. It is not exhaustive, but if every item on the list has been consciously considered, the driver is in much better shape than the average.

31.17.1 Structural Checks

The driver’s module-load and module-unload paths are symmetric. Every resource allocated on load is freed on unload, and the order of freeing is the reverse of the order of allocation.

The driver uses `make_dev_s` or `make_dev_credf` (not the legacy `make_dev` alone) so that errors during device-node creation are reported and handled.

The device node is created with conservative permissions. Mode 0600 or 0640 is the default; anything more permissive has an explicit reason recorded in comments or commit messages.

The driver declares a named `malloc_type` via `MALLOC_DECLARE` and `MALLOC_DEFINE`. All allocations use this type.

Every lock in the driver has a comment next to its declaration saying what it protects. The comment is accurate.

31.17.2 Input and Boundary Checks

Every `copyin` call is paired with a size argument that cannot exceed the destination buffer size.

Every `copyout` call uses a length that is the minimum of the caller's buffer size and the kernel source's size.

`copyinstr` is used for strings that should be NUL-terminated. The return value (including done) is checked.

Every `ioctl` argument structure is copied into kernel space before any of its fields are read.

`uiomove` calls pass a length that is clamped to the buffer being read from or written to, not `uio->uio_resid` alone.

Every user-provided length field is validated: non-zero when required, bounded below the appropriate maximum, checked against remaining buffer space.

31.17.3 Memory Management

Every `malloc` call checks the return value if `M_NOWAIT` is used. `M_WAITOK` without `M_NULLOK` is never null-checked uselessly; the code relies on the allocator's guarantee.

Every `malloc` is paired with exactly one `free` on every code path. Success paths and error paths are both audited.

Sensitive data (keys, passwords, credentials, proprietary secrets) is zeroed with `explicit_bzero` or `zfree` before the memory is released.

Structures that will be copied to user space are zeroed before being filled.

Buffers allocated for user output use `M_ZERO` at allocation time to prevent stale-data leaks through the tail.

After a pointer is freed, it is either set to `NULL` or the scope immediately ends.

31.17.4 Privilege and Access Control

Operations that require administrative privilege call `priv_check(td, PRIV_DRIVER)` or a more specific `PRIV_*` constant.

Operations that should not be allowed inside a jail explicitly check `jailed(td->td_ucred)` and return `EPERM` if jailed.

Operations that depend on the system's `securelevel` call `securelevel_gt` or `securelevel_ge` and handle the return value correctly (note the inverted semantics: nonzero means refuse).

No operation uses `cr_uid == 0` as a privilege gate. `priv_check` is used instead.

Sysctls that expose sensitive data use CTLFLAG_SECURE or restrict themselves to privileged users via permission checks.

31.17.5 Concurrency

Every field of the softc that is accessed by more than one context is protected by a lock.

The full check-and-act sequence (including lookups that decide whether an operation is legal) is held under the appropriate lock.

No copyin, copyout, or uiomove call is made while holding a mutex. If user-space I/O is needed, the code drops the lock, does the I/O, and re-acquires, checking invariants.

detach calls destroy_dev (or equivalent) first, then drains callouts, taskqueues, and interrupts, then frees state.

Callouts, taskqueues, and kernel threads are tracked so that every one of them can be drained during unload.

31.17.6 Information Hygiene

No kernel pointer (%p or equivalent) is returned to user space through an ioctl, sysctl, or log message in a user-triggerable path.

No user-triggerable log message is uncapped; ppsratecheck or similar wraps every such message.

Logs do not include user-supplied data that could contain control characters or sensitive information.

Debug logging is wrapped in a conditional (sysctl or compile-time) so that production builds do not emit it by default.

31.17.7 Failure Modes

Every switch statement has a default: branch that returns a sensible error.

Every parser or validator whitelists what is allowed, rather than blacklisting what is not.

Every operation with resource use has a cap. The cap is documented.

Every sleep has a finite timeout unless a genuine reason requires unbounded waiting (and even then, PCATCH is used to allow signals).

Every error path frees the resources its success path would have kept.

The driver's response to unexpected input is to refuse the operation, not to guess.

31.17.8 Testing

The driver has been loaded and tested against a kernel built with INVARIANTS and WITNESS. No assertions fire and no lock-order violations are reported.

The driver has been tested under concurrent load (multiple processes, multiple open file descriptors, interleaved operations).

The driver has been tested under detach-time concurrency (a user is inside the driver while unload is attempted).

Some form of fuzzing (ideally syzkaller, at minimum a randomized shell test) has been run against the driver.

The driver has been reviewed by someone other than its author. The review was specifically for security considerations, not only functionality.

31.17.9 Evolution

The driver's security posture is re-examined at regular intervals. New compiler warnings and new sanitizer findings are triaged seriously. New FreeBSD privilege codes are considered. Unused interfaces are removed.

Bug reports against the driver are treated as possibly exploitable until proven otherwise.

Commit history shows that security-relevant changes receive careful commit messages that explain what was wrong and what the fix does.

31.18 A Closer Look at Real-World Vulnerability Patterns

The principles in this chapter are abstractions over real bugs that happened in real kernels. This section studies a few patterns that have appeared across the FreeBSD, Linux, and other open-source operating systems over the years. The goal is not to catalogue CVEs (there are whole databases for that) but to train pattern recognition.

31.18.1 The Incomplete Copy

A classic pattern: a driver receives a variable-length user buffer. It copies a fixed header, extracts a length field from the header, then copies the variable portion according to that length.

```
error = copyin(uaddr, &hdr, sizeof(hdr));
if (error != 0)
    return (error);

if (hdr.body_len > MAX_BODY)
    return (EINVAL);

error = copyin(uaddr + sizeof(hdr), body, hdr.body_len);
```

The bug is that the length check compares `body_len` against `MAX_BODY`, but `body` may be a fixed-size buffer sized differently. If `MAX_BODY` is defined carelessly, or if it was once the size of `body` but `body` has since shrunk, the copy overflows `body`.

Every time you see a pattern of “validate header, then copy body based on header”, check that the length bound actually matches the destination buffer size. Use `sizeof(body)` directly if you can, rather than a macro that might drift.

31.18.2 The Sign Confusion

A length is stored as `int` but should be non-negative. A caller passes `-1`. Your code:

```
if (len > MAX_LEN)
    return (EINVAL);

buf = malloc(len, M_FOO, M_WAITOK);
copyin(uaddr, buf, len);
```

Does the first check pass? Yes, because `-1` is less than `MAX_LEN` when compared as a signed `int`. What happens in `malloc(len, ...)` with `len = -1`? On many platforms, `-1` silently becomes a very large positive `size_t`. The allocation fails (or worse, succeeds at a huge size), or `copyin` tries to copy a huge buffer.

The fix is to use unsigned types for sizes (preferably `size_t`), or to check for negative values explicitly:

```
if (len < 0 || len > MAX_LEN)
    return (EINVAL);
```

Or, better, change the type so that negative values cannot exist:

```
size_t len = arg->len;    /* copied from user, already size_t */
if (len > MAX_LEN)
    return (EINVAL);
```

Sign confusion is one of the most common root causes of buffer overflows in kernel code. Use `size_t` for sizes. Use `ssize_t` only when negative values are meaningful. Never mix signed and unsigned in a size check.

31.18.3 The Incomplete Validation

A driver accepts a complex structure with many fields. The validation function checks some fields but forgets others:

```
if (args->type > TYPE_MAX)
    return (EINVAL);
if (args->count > COUNT_MAX)
    return (EINVAL);
/* forgot to validate args->offset */

use(args->offset); /* attacker-controlled */
```

The bug is that `args->offset` is used as an index into an array without being bounds-checked. An attacker supplies a huge offset and reads or writes kernel memory.

The fix is to treat validation as a checklist. For every field in the input structure, ask: what values are legal? Enforce them all. A helper function `is_valid_arg` that centralizes the validation and is called early is better than scattered checks.

31.18.4 The Skipped Check on the Error Path

A driver carefully validates input on the success path, but the error path cleans up based on a field that was never validated:

```
if (args->count > COUNT_MAX)
    return (EINVAL);
buf = malloc(args->count * sizeof(*buf), M_F00, M_WAITOK);
error = copyin(args->data, buf, args->count * sizeof(*buf));
if (error != 0) {
    /* error cleanup */
    if (args->free_flag)           /* untrusted field */
        some_free(args->ptr);    /* attacker-controlled */
    free(buf, M_F00);
    return (error);
}
```

The error path uses `args->free_flag` and `args->ptr`, neither of which were validated. If the attacker arranges for `copyin` to fail (say, by unmapping the memory), the error path frees an attacker-controlled pointer, corrupting the kernel heap.

The lesson: validation must cover every field that any code path reads. It is tempting to think “the error path is unusual; it is fine”. Attackers specifically aim for error paths because they are less tested.

31.18.5 The Double-Lookup

A driver looks up an object in a table by name or ID, then performs an operation. Between the lookup and the operation, the object is removed by another thread. The operation then acts on freed memory.

```
obj = lookup(id);
if (obj == NULL)
    return (ENOENT);
do_operation(obj); /* obj may have been freed in between */
```

The fix is to take a reference on the object (using a refcount) inside the lookup, hold the reference across the operation, and release it at the end. The lookup function takes the lock, increments the refcount, and releases the lock. The operation then works with a refcount-held pointer that cannot be freed out from under it. The release decrements the refcount; when it drops to zero, the last holder frees the object.

Reference counts are the FreeBSD-canonical answer to the double-lookup problem. See `/usr/src/sys/sys/refcount.h`.

31.18.6 The Buffer That Grew

A buffer was once 256 bytes. A constant `BUF_SIZE = 256` was defined. The code checked `len <= BUF_SIZE` and copied `len` bytes into the buffer. Later, someone increased the buffer to 1024 bytes but forgot to update the

constant. Or the constant was updated but an `sizeof(buf)` in one call was not, because it was not using the constant.

This class of bug is prevented by always using `sizeof` on the destination buffer directly, rather than a constant that may drift:

```
char buf[BUF_SIZE];
if (len > sizeof(buf))    /* always matches the actual buf size */
    return (EINVAL);
```

Constants are useful when multiple places need the same bound. If you use a constant, keep the definition and the array adjacent in the source code, and consider adding a `_Static_assert(sizeof(buf) == BUF_SIZE, ...)` to catch drift.

31.18.7 The Unchecked Pointer from a Structure

A driver receives a structure from user space that contains pointers. The driver uses the pointers directly:

```
error = copyin(uaddr, &cmd, sizeof(cmd));
/* cmd.data_ptr is user-space pointer */
use(cmd.data_ptr); /* treating user pointer as kernel pointer */
```

This is a catastrophic bug: the pointer is a user-space address, but the code dereferences it as if it were kernel memory. On some architectures this may access whatever memory happens to be at that address in kernel space, which is usually garbage or invalid. On others, it faults. In some specific pathological cases, it accesses sensitive kernel data.

The fix: never dereference a pointer obtained from user space. Pointers in user-supplied structures must be passed to `copyin` or `copyout`, which correctly translate user addresses. Never treat them as kernel addresses.

31.18.8 The Forgotten copyout

A driver reads a structure from user space, modifies it, but forgets to copy the modified version back:

```
error = copyin(uaddr, &cmd, sizeof(cmd));
if (error != 0)
    return (error);

cmd.status = STATUS_OK;
/* forgot to copyout */
return (0);
```

This is a functional bug, not strictly a security bug, but its mirror image is: forgetting `copyin` and assuming a field was already set. “I set `cmd.status` in `copyin`, then I read it later” is wrong if the field was actually set by user space; the user’s value is what the code reads.

Every structure that flows user-to-kernel and back needs a clear convention about when copyin and copyout happen, and what fields are authoritative in which direction. Document it and follow it.

31.18.9 The Accidental Race

A driver takes a lock, reads a field, releases the lock, and then uses the value:

```
mtx_lock(&sc->sc_mtx);
val = sc->sc_val;
mtx_unlock(&sc->sc_mtx);

/* ... some unrelated work ... */

mtx_lock(&sc->sc_mtx);
if (val == sc->sc_val) {
    /* act on val */
}
mtx_unlock(&sc->sc_mtx);
```

The driver assumes `val` is still current because it re-checks. But “act on val” uses the stale copy, not the current field. If `sc_val` is a pointer, the act may operate on a freed object. If `sc_val` is an index, the act may use a stale index.

The lesson: once you release a lock, any value you read under that lock is stale. If you need to re-act under the lock, re-read the state inside the re-acquisition. The `if (val == sc->sc_val)` check protects against changes; the act needs to use the current value, not the stored one.

31.18.10 The Silent Truncation

A driver receives a string of up to 256 bytes, stores it in a 128-byte buffer. The code uses `strncpy`:

```
strncpy(sc->sc_name, user_name, sizeof(sc->sc_name));
```

`strncpy` stops at the destination size. But `strncpy` does not guarantee a NUL terminator if the source was longer. Later code does:

```
printf("name: %s\n", sc->sc_name);
```

`printf("%s", ...)` reads until a NUL. If `sc_name` is not NUL-terminated, `printf` reads past the end of the array into adjacent memory, potentially leaking that memory in the log or crashing.

Safer options: `strncpy` (guarantees NUL termination, truncates if needed), or `snprintf` (same guarantee with formatting). `strncpy` is a landmine; it is in the standard library only for historical reasons.

31.18.11 The Over-Logged Event

A driver logs every time an event fires. The event is user-triggerable. A user sends a million events in a loop. The kernel message buffer fills and overflows; legitimate messages are lost. The user has accomplished a denial-of-service on the logging subsystem itself.

The fix, as discussed in Section 8, is rate limiting. Every user-triggerable log message should be wrapped in a rate-limit check. A suppressed-count summary (“[secdev] 1234 suppressed messages in last 5 seconds”) can be emitted periodically to inform the operator of ongoing flooding.

31.18.12 The Invisible Bug

A driver works fine for years. Then a compiler update changes how it handles a specific idiom, or a kernel API changes semantics in a new FreeBSD release, and the driver’s behaviour changes. A check that used to work silently stops working. Users do not notice until an exploit appears.

Invisible bugs are the strongest argument for KASSERT, sanitizers, and tests. A KASSERT(`p != NULL`) at the top of every function documents what that function expects. An INVARIANTS kernel catches the moment an invariant breaks. A good test suite notices when behavior changes.

The simpler the function and the clearer its contract, the fewer places invisible bugs can hide. This is one reason the FreeBSD kernel coding style described in `style(9)` values short functions with clear responsibilities: they are easier to reason about, which makes invisible bugs easier to avoid in the first place.

31.18.13 Wrapping Up the Pattern Catalogue

Each of the patterns above has been seen in real kernel code. Many have been CVEs. The defenses are:

- Use `size_t` for sizes; avoid sign confusion.
- Whitelist validation; do not forget fields.
- Treat error paths with the same rigor as success paths.
- Use refcounts to manage object lifetime under concurrency.
- Use `sizeof` directly on the buffer rather than a drift-prone constant.
- Never dereference user pointers.
- Keep the `copyin / copyout` story explicit per field.
- Remember that a value read under a lock is stale after the lock is released.
- Use `strncpy` or `snprintf`, never `strncpy`.
- Rate-limit every user-triggerable log.
- Write invariants as KASSERT so regressions are caught.

Memorize these patterns. Apply them as a mental checklist on every function you write or review.

31.19 Appendix: Headers and APIs Used in This Chapter

A short reference to the FreeBSD headers referenced throughout this chapter, grouped by topic. Each header is in `/usr/src/sys/` followed by the path listed.

31.19.1 Memory and Copy Operations

- `sys/systm.h`: declarations for `copyin`, `copyout`, `copyinstr`, `bzero`, `explicit_bzero`, `printf`, `log`, and many kernel core primitives.
- `sys/malloc.h`: `malloc(9)`, `free(9)`, `zfree(9)`, `MALLOC_DECLARE`, `MALLOC_DEFINE`, `M_*` flags.
- `sys/uio.h`: `struct uio`, `uiomove(9)`, `UIO_READ` / `UIO_WRITE` constants.
- `vm/uma.h`: UMA zone allocator (`uma_zcreate`, `uma_zalloc`, `uma_zfree`, `uma_zdestroy`).
- `sys/refcount.h`: reference-count primitives (`refcount_init`, `refcount_acquire`, `refcount_release`).

31.19.2 Privilege and Access Control

- `sys/priv.h`: `priv_check(9)`, `priv_check_cred(9)`, `PRIV_*` constants, `securelevel_gt`, `securelevel_ge`.
- `sys/ucred.h`: `struct ucred` and its fields.
- `sys/jail.h`: `struct prison`, `jailed(9)` macro, prison-related helpers.
- `sys/capsicum.h`: Capsicum capabilities, `cap_rights_t`, `IN_CAPABILITY_MODE(td)`.
- `security/mac/mac_framework.h`: MAC framework hooks (mostly for policy writers, but reference).

31.19.3 Locking and Concurrency

- `sys/mutex.h`: `struct mtx`, `mtx_init`, `mtx_lock`, `mtx_unlock`, `mtx_destroy`.
- `sys/sx.h`: shared/exclusive locks.
- `sys/rwlock.h`: read/write locks.
- `sys/condvar.h`: condition variables (`cv_init`, `cv_wait`, `cv_signal`).
- `sys/lock.h`: common lock infrastructure.
- `sys/atomic_common.h`: atomic operations (and architecture-specific headers).

31.19.4 Device Files and Dev Infrastructure

- `sys/conf.h`: `struct cdev`, `struct cdevsw`, `struct make_dev_args`, `make_dev_s`, `make_dev_credf`, `destroy_dev`.
- `sys/module.h`: `DRIVER_MODULE`, `MODULE_VERSION`, kernel module declarations.
- `sys/kernel.h`: `SYSINIT`, `SYSUNINIT`, and related kernel hook macros.
- `sys/bus.h`: `device_t`, device methods, `bus_alloc_resource`, `bus_teardown_intr`.

31.19.5 Timing, Rate Limiting, Callouts

- `sys/time.h`: `eventratecheck(9)`, `ppsratecheck(9)`, `struct timeval`.
- `sys/callout.h`: `struct callout`, `callout_init_mtx`, `callout_reset`, `callout_drain`.
- `sys/taskqueue.h`: taskqueue primitives (`taskqueue_create`, `taskqueue_enqueue`, `taskqueue_drain`).

31.19.6 Logging and Diagnostics

- `sys/syslog.h`: `LOG_*` priority constants for `log(9)`.

- `sys/kassert.h`: KASSERT, MPASS, assertion macros.
- `sys/ktr.h`: KTR tracing macros.
- `sys/sdt.h`: Statically Defined Tracing probes for `dtrace(1)`.

31.19.7 Sysctls

- `sys/sysctl.h`: `SYSCTL_*` macros, `CTLFLAG_*` flags including `CTLFLAG_SECURE`, `CTLFLAG_PRISON`, `CTLFLAG_CAPRD`, `CTLFLAG_CAPWR`.

31.19.8 Network (when applicable)

- `sys/mbuf.h`: `struct mbuf`, mbuf allocation and manipulation.
- `net/if.h`: `struct ifnet`, network interface primitives.

31.19.9 Epoch and Lock-Free

- `sys/epoch.h`: epoch-based reclamation primitives (`epoch_enter`, `epoch_exit`, `epoch_wait`).
- `sys/atomic_common.h` and architecture-specific atomic headers: memory barriers, atomic reads and writes.

31.19.10 Tracing and Observability

- `security/audit/audit.h`: kernel audit framework (when compiled in).
- `sys/sdt.h`: Statically Defined Tracing for `dtrace` integration.
- `sys/ktr.h`: KTR in-kernel tracing.

This appendix is not exhaustive; the full set of headers a driver may need is far larger. It covers the ones referenced in this chapter. When writing your own driver, `grep` through `/usr/src/sys/sys/` for the primitive you need, and read the header to understand what is available. Many of these headers are well commented and repay careful reading.

Reading the headers is itself a security practice. Every primitive has a contract: what arguments it accepts, what constraints it imposes, what it guarantees on success, what it returns on failure. A driver that uses a primitive without reading its contract is relying on assumptions that may not hold. A driver that reads the contract, and holds itself to it, is a driver that benefits from the kernel's own discipline.

Many of the headers listed above are themselves worth studying as examples of good kernel design. `sys/re-fcount.h` is small, carefully commented, and demonstrates how a simple primitive is built from atomic operations. `sys/kassert.h` shows how conditional compilation is used to build a feature that costs nothing in production but catches bugs in developer kernels. `sys/priv.h` shows how a long list of named constants can be organized by subsystem and used as the grammar of a policy. When you run out of ideas for how to structure your own driver's internals, these headers are a good place to find inspiration.

31.20 Appendix: Further Reading

A short list of resources that go deeper into FreeBSD security than this chapter can:

FreeBSD Architecture Handbook, in particular the chapters on the jail subsystem, Capsicum, and MAC framework. Available online at <https://docs.freebsd.org/en/books/arch-handbook/>.

FreeBSD Handbook security chapter, which is oriented toward administrators but includes useful context on how system-level features (jails, securelevel, MAC) interact.

Capsicum: Practical Capabilities for UNIX, the original paper by Robert Watson, Jonathan Anderson, Ben Laurie, and Kris Kennaway. Explains the design rationale behind Capsicum, which helps when deciding how your driver should behave in capability mode.

“The Design and Implementation of the FreeBSD Operating System”, by Marshall Kirk McKusick, George V. Neville-Neil, and Robert N. M. Watson. The second edition covers FreeBSD 11; many security-relevant chapters remain applicable in later versions.

style(9), the FreeBSD kernel coding style guide, available as a manual page: `man 9 style`. Readable kernel code is safer kernel code; the conventions in `style(9)` are part of how the tree stays reviewable at scale.

KASAN, KMSAN, and KCOV documentation in `/usr/src/share/man/` and related sections. Reading these helps you configure and interpret sanitizer output.

syzkaller documentation, at <https://github.com/google/syzkaller>. The `sys/freebsd/` directory contains syscall descriptions that illustrate how to describe your own driver’s interface.

CVE databases such as <https://nvd.nist.gov/vuln/search> or <https://cve.mitre.org/>. Searching for “FreeBSD” or specific driver names shows real bugs that have been found and fixed. Reading a few CVE reports per month teaches a great deal about what kinds of bugs occur in practice.

FreeBSD security advisories, at <https://www.freebsd.org/security/advisories/>. These are official reports on fixed vulnerabilities. Many are kernel-side and relevant to driver authors.

The FreeBSD source tree itself is the largest and most authoritative reference. Spend time reading drivers similar to yours. Look at how they validate input, check privilege, manage locking, and handle detach. Imitating the patterns you see in well-reviewed code is one of the fastest ways to learn.

Security mailing lists, such as `freebsd-security@` and the broader `oss-security` list, carry daily traffic on kernel and driver issues across open-source projects. Subscribing passively and skimming a few posts a week builds awareness of threat trends without demanding much effort.

Formal verification literature, although specialist, has begun to touch kernel code. Projects like `seL4` demonstrate what a fully verified microkernel looks like. FreeBSD is not that, but reading about formal verification shapes how you think about invariants and contracts in your own code.

Books on secure coding practices in C such as *Secure Coding in C and C++* by Robert Seacord translate well to kernel work, since kernel C is a dialect of the same language and has the same pitfalls, plus more. Chapter-by-chapter, they provide the mental catalogue of bugs that this chapter could only sketch.

FreeBSD-specific books, notably the McKusick, Neville-Neil, and Watson book mentioned above, but also older volumes that cover the evolution of specific subsystems. Reading about how jails evolved, how Capsicum was designed, or how MAC came to be helps you understand the rationale behind the primitives rather than just their mechanics.

Conference talks from BSDCan, EuroBSDCon, and AsiaBSDCon often touch security topics. Video archives let you watch years of past talks at your own pace. Many talks are given by active FreeBSD developers and reflect current thinking.

Academic papers on operating system security from venues such as USENIX Security, IEEE S&P, and CCS provide a longer-term view. Not every paper is relevant to drivers, but the ones that are deepen your understanding of threat models, attacker capabilities, and the theoretical basis for mitigations.

The CVE feed, particularly when filtered for kernel issues, is a continuous drip of real-world examples. Reading a few each week builds intuition for what bugs look like in practice and which classes recur most often.

Your own code, six months later. Rereading your earlier work with the benefit of distance is a valuable learning tool. The bugs you will notice are the bugs you have learned to see since you wrote it. Make a habit of this; schedule time for it.

The resources above, even a small subset of them, will keep you growing for years. Security is a field of continuous learning. This chapter is one step in that learning; the next step is yours.

Every security-minded driver author should have read at least a few of these. The field moves, and staying current is part of the craft.

31.21 Wrapping Up

Security in device drivers is not a single technique. It is a way of working. Every line of code carries a little responsibility for the kernel's safety. The chapter has covered the main pillars:

The kernel trusts every driver fully. Once code runs in the kernel, there is no sandbox, no isolation, no second chance. The driver author's discipline is the system's last line of defense.

Buffer overflows and memory corruption are the classical kernel vulnerability. They are prevented by bounding every copy, preferring bounded string functions, and treating pointer arithmetic with suspicion.

User input crosses a trust boundary. Every byte from user space must be copied into the kernel with `copyin(9)`, `copyinstr(9)`, or `uiomove(9)` before it is used. Every byte going back must be copied out with `copyout(9)` or `uiomove(9)`. The user-space memory is not trustworthy; kernel memory is. Keep them cleanly separated.

Memory allocation must be checked, balanced, and accounted for. Always check `M_NOWAIT` returns. Use `M_ZERO` by default. Pair every `malloc` with exactly one `free`. Use a per-driver `malloc_type` for accountability. Use `explicit_bzero` or `zfree` for sensitive data.

Races and TOCTOU bugs are caused by inconsistent locking or by treating user-space data as stable. Fix them with locks around shared state and by copying user data before validating.

Privilege checks use `priv_check(9)` as the canonical primitive. Layer with jail awareness and `securelevel` where appropriate. Set conservative device-node permissions. Let the MAC and Capsicum frameworks work alongside.

Information leaks are prevented by zeroing structures before filling them, bounding copy lengths on both ends, and keeping kernel pointers out of user-visible output.

Logging is part of the driver's interface. Use it to help the operator without helping the attacker. Rate-limit anything triggerable from user space. Do not log sensitive data.

Secure defaults mean failing closed, whitelisting rather than blacklisting, setting conservative default values, and treating error paths with the same care as success paths.

Testing and hardening turn careful code into trustworthy code. Build with INVARIANTS, WITNESS, and the kernel sanitizers. Stress-test. Fuzz. Review. Re-test.

None of this is a one-time effort. A driver stays secure because its author keeps applying these habits, every commit, every release, for the life of the code.

The discipline is not glamorous. It is boring work: zero the structure, check the length, acquire the lock, use `priv_check`. But this boring work is exactly what keeps systems secure. An exploited kernel is a catastrophic event for users. An exploited driver is a foothold into the kernel. The person at the keyboard of that driver, deciding whether to add the bounds check or to skip it, is making a security decision that may be invisible for years and then suddenly matter very much.

Be the author who adds the bounds check.

31.21.1 One More Reflection: Security as Professional Identity

Something worth saying explicitly: the habits in this chapter are not merely techniques. They are what distinguishes a journeyman kernel author from an apprentice. Every mature kernel engineer carries this mental checklist not because they memorized it but because they have, over years, internalized a skepticism toward their own code. The skepticism is not anxiety. It is discipline.

Write code, and then read it back as if a stranger had written it. Ask what happens if the caller is hostile. Ask what happens if the value is zero, or negative, or impossibly large. Ask what happens if the other thread arrives between these two statements. Ask what happens on the error path you did not plan to test. Write the check. Write the assertion. Move on.

This is what professional kernel engineers do. It is not glamorous, it is rarely applauded, and it is what keeps the operating system we all rely on from falling apart. The kernel is not magic; it is millions of lines of carefully checked code, written and rewritten by people who treat every line as a small responsibility. Joining that profession means joining that discipline.

You have now been given the tools. The rest is practice.

31.22 Looking Ahead: Device Tree and Embedded Development

This chapter trained you to look at your driver from the outside, through the eyes of whoever might try to misuse it. The boundaries you learned to watch were invisible to the compiler but very real to the kernel: user space on one side, kernel memory on the other; one thread with privilege, another without; a length field the caller claimed, a length the driver had to verify. Chapter 31 was about *who is allowed to ask the driver to do something*, and *what the driver should check before it agrees*.

Chapter 32 shifts the perspective entirely. The question stops being *who wants this driver to run* and becomes *how does this driver find its hardware at all*. On the PC-like machines we have leaned on so far, that question had a comfortable answer. PCI devices announced themselves through standard configuration registers. ACPI-described peripherals appeared in a table the firmware handed to the kernel. The bus did the looking, the kernel

probed each candidate, and your driver's `probe()` function only had to look at an identifier and say yes or no. Discovery was mostly someone else's problem.

On embedded platforms that assumption breaks. A small ARM board does not speak PCI, does not carry an ACPI BIOS, and does not hand the kernel a neat table of devices. The SoC has an I2C controller at a fixed physical address, three UARTs at three other fixed addresses, a GPIO bank at a fourth, a timer, a watchdog, a clock tree, and a dozen other peripherals soldered onto the board in a particular arrangement. Nothing in the silicon announces itself. If the kernel is going to attach drivers to these peripherals, something has to tell the kernel where they are, what they are, and how they relate.

That something is the **Device Tree**, and Chapter 32 is where you learn to work with it. You will see how `.dts` source files describe the hardware, how the Device Tree Compiler (`dtc`) turns them into the `.dtb` blobs the bootloader hands to the kernel, and how FreeBSD's FDT support walks those blobs to decide which drivers to attach. You will meet the `ofw_bus` interfaces, the `simplebus` enumerator, and the Open Firmware helpers (`ofw_bus_search_compatible`, `ofw_bus_get_node`, the property-reading calls) that turn a Device Tree node into a working driver attachment. You will compile a small overlay, load it, and watch a pedagogical driver attach in `dmesg`.

The security habits you have built in this chapter travel with you into that territory. A driver for an embedded board is still a driver: it still runs in kernel space, still copies data across user-space boundaries, still needs bounds checks, still takes locks, still cleans up in `detach`. An ARM board does not loosen any of those requirements. If anything, embedded systems raise the stakes, because the same board image may ship to thousands of devices in the field, each one harder to patch than a server in a data center. The disposition you have just learned, skeptical of inputs, careful with memory, conservative about privilege, is exactly the disposition an embedded driver author needs.

What changes in Chapter 32 is the set of helpers you call to discover your hardware and the files you read to know where to point them. The `probe-attach-detach` shape stays. The `softc` stays. The `lifecycle` stays. A handful of new calls and a new way of thinking about hardware description are what you add. The chapter builds them up gently, from the shape of a `.dts` file to a working driver that blinks an LED on a real or emulated board.

See you there.

31.23 A Final Note on Habits

This chapter has been longer than some. The length is deliberate. Security is not a topic that can be summarized into a single punchy rule; it is a way of thinking that requires examples, practice, and repetition. A reader who finishes this chapter once will have been exposed to the patterns. A reader who returns to this chapter when starting a new driver will find new meaning in passages that seemed merely informative on the first read.

Here are the most important habits, condensed into a single list for you to carry forward. They are the reflexes that matter most in daily driver work:

Every user-space value is hostile until copied in, bounded, and validated.

Every length has a maximum. The maximum is enforced before anything uses the length.

Every structure copied to user space is zeroed first.

Every allocation is paired with a free on every code path.

Every critical section is held across the full check-and-act sequence it protects.

Every privilege-sensitive operation checks `priv_check` before acting.

Every detach path drains async work before freeing state.

Every log message triggerable from user space is rate-limited.

Every unknown input returns an error, never a silent success.

Every assumption worth making is worth writing as a `KASSERT`.

Nine lines. If these become automatic, you have the core of what this chapter teaches.

The craft grows from here. There are more patterns, more subtleties, more tools; you will encounter them as you read more FreeBSD source, as you review more code, as you write more drivers. What stays the same is the disposition: skeptical of hostile inputs, careful with memory, clear about lock boundaries, conservative about what to expose. That disposition is the one kernel engineers share across decades. You have it now. Use it well.

31.24 A Note on Evolving Threats

One further thought before the closing words. The threats we defend against today are not the threats we will defend against in ten years. Attackers evolve. Mitigations evolve. New classes of bugs are discovered, old classes are retired. A driver that was state-of-the-art in its defenses in 2020 may need updating to be considered safe in 2030.

This is not a reason for despair. It is a reason for continuous learning. Every year, a responsible driver author should read a few new security papers, try a few new sanitizers, and look at the recent CVEs affecting kernels similar to their own. Not to memorize specific vulnerabilities, but to keep a sense of where the bugs are being found today.

The patterns this chapter teaches are stable. Buffer overflows have been bugs since before UNIX. Use-after-free has been a bug since C had `malloc`. Race conditions have been bugs since kernels had multiple threads. The specific incarnations change, but the underlying defenses endure. A driver written with the disposition this chapter encourages will be mostly right in any decade; when the details shift, the author who built the disposition will adapt faster than one who merely memorized a checklist.

31.25 Closing Words

A driver is small. A driver's influence is large. The code you write runs in the most privileged part of the system, touches memory that every other process depends on, and is trusted with the secrets of users who will never see your name. That trust is not automatic; it is earned, one careful line at a time, by authors who assumed the attacker was watching and built accordingly.

The authors of FreeBSD have been writing that kind of code for decades. The FreeBSD kernel is not perfect; no kernel of its scale can be. But it has a culture of care, a set of primitives that reward diligence, and a community that treats security bugs as learning opportunities rather than embarrassments. When you write a FreeBSD driver, you are writing into that culture. Your code will be read by people who know the difference between

a buffer overflow and a buffer that happens to be large enough; who know the difference between a privilege check that catches root-outside-jail and one that catches root-inside-jail; who know that a race condition is not a rare timing fluke but a vulnerability waiting for the right attacker.

Write for those readers. Write for the user whose laptop runs your code without knowing it is there. Write for the maintainer who will inherit your work in ten years. Write for the reviewer who will spot the defensive check you added and feel quietly glad that someone thought of it.

That is what chapter 31 has been about. That is what the rest of your career as a kernel author will be about. Thank you for taking the time to work through it carefully. The chapter ends here; the practice begins tomorrow.

32 Device Tree and Embedded Development

32.1 Introduction

Chapter 31 trained you to look at your driver from the outside, through the eyes of whoever might try to misuse it. The boundaries you learned to watch were invisible to the compiler but very real to the kernel: user space on one side, kernel memory on the other; one thread with privilege, another without; a length field the caller claimed, a length the driver must verify. That chapter was about who is allowed to ask the driver to do something, and what the driver should check before it agrees.

Chapter 32 shifts the perspective entirely. The question stops being *who wants this driver to run* and becomes *how does this driver find its hardware at all*. On the machines we have leaned on so far, the answer was easy enough that you could ignore it. A PCI device announced itself through standard configuration registers. An ACPI-described peripheral appeared in a table the firmware handed to the kernel. The bus did the looking, the kernel probed each candidate, and your driver's `probe()` function only had to look at an identifier and say yes or no. Discovery was mostly someone else's problem.

On embedded platforms that assumption breaks. A small ARM board does not speak PCI, does not carry an ACPI BIOS, and does not have a firmware layer that will hand the kernel a neat table of devices. The SoC has an I2C controller at a fixed physical address, three UARTs at three other fixed addresses, a GPIO bank at a fourth, a timer, a watchdog, a clock tree, a pin multiplexer, and a dozen other peripherals that the hardware designer soldered onto the board in a particular arrangement. Nothing in the silicon announces itself. If the kernel is going to attach drivers to these peripherals, something has to tell the kernel where they are, what they are, and how they relate.

That something is the **Device Tree**, and learning to work with it is what Chapter 32 is about.

Device Tree is not a driver. It is not a subsystem in the sense that `vfs` or `devfs` is a subsystem. It is a *data structure*, a textual hardware description that the bootloader hands to the kernel at boot time, and that the kernel then walks to decide which drivers to run and where to point them. The structure has its own file format, its own compiler, its own conventions, and its own quiet conventions that embedded developers learn over time. A driver written for a Device Tree platform looks almost like the drivers you already know, with a handful of important differences in how it finds its resources. Those differences are the subject of this chapter.

We are also going to widen the map. Until now most of your drivers have run on amd64, the flavour of 64-bit x86 that powers laptops, workstations, and servers. That architecture will not be going anywhere, and your understanding of it will continue to serve you. But FreeBSD runs on more than amd64. It runs on arm64, the 64-bit ARM architecture that powers the Raspberry Pi 4, the Pine64, the HoneyComb LX2, countless industrial boards, and a growing fraction of the cloud. It runs on 32-bit ARM for older Pis, BeagleBones, and embedded appliances. It runs on RISC-V, a newer, open architecture whose first serious FreeBSD support matured over the FreeBSD 13 and 14 cycles. On every one of those architectures outside the PC-like world, Device Tree is

how drivers find their hardware. If you want to write drivers that run on anything other than a laptop, you need to know how it works.

The good news is that the shape of a driver does not change much when you cross over. Your probe and attach routines still look like probe and attach routines. Your softc still lives in the same kind of structure. Your lifecycle is still the same lifecycle, with load and unload, detach and cleanup. What changes is the set of helpers you call to discover your hardware's address, to read its interrupt specification, to turn on its clock, to pull its reset line, to request a GPIO pin. Those helpers have a family resemblance once you see a few of them. The FreeBSD source tree uses them in hundreds of places, and by the end of this chapter you will recognise them on sight and know where to look when you need one you have not used before.

The chapter proceeds in eight sections. Section 1 introduces the embedded FreeBSD world and the hardware platforms on which it runs. Section 2 explains what the Device Tree is, how its files are organised, how `.dts` source turns into `.dtb` binary blobs, and what the nodes and properties inside actually mean. Section 3 walks through FreeBSD's support for Device Tree: the `fdt(4)` framework, the `ofw_bus` interfaces, the `simplebus` enumerator, and the Open Firmware helpers that drivers use to read properties. Section 4 is the first concrete driver-writing section. You will see the shape of an FDT-aware driver from probe to attach to detach, with its `ofw_compat_data` table and its calls to `ofw_bus_search_compatible`, `ofw_bus_get_node`, and the property-reading helpers. Section 5 turns to the DTB itself: how to compile a `.dts` with `dtc`, how overlays work, how to add a custom node to an existing board description, and how FreeBSD's build tooling fits together. Section 6 is about debugging, both at boot and at runtime, using `ofwdump(8)`, `dmesg`, and the kernel log to find out why a node did not match. Section 7 brings the pieces together in a practical GPIO driver that takes its pin assignments from Device Tree and toggles an LED. Section 8 is the refactoring section: we will take the driver you built in Section 7, tighten its error handling, expose a `sysctl` for observability, and talk through what packaging an embedded image looks like.

Along the way we will touch on the peripheral frameworks that every serious embedded driver eventually leans on. The clock framework, regulator framework, and hardware-reset framework under `/usr/src/sys/dev/extracts/` are the three big ones; the pin-control framework under `/usr/src/sys/dev/fdt/` is the fourth. The GPIO framework under `/usr/src/sys/dev/gpio/` is your first stop for reading and writing pins. `interrupt-parent` chaining routes IRQs up the interrupt tree to the controller that can actually handle them. Device Tree *overlays*, files with the extension `.dtbo`, let you add or modify nodes at boot without rebuilding the base blob. And at the highest level, on arm64 in particular, a single kernel binary can run on either FDT or ACPI; the mechanism that picks between the two is worth looking at briefly, because it shows how drivers written for both are factored.

One last framing note before we begin. Embedded work can feel intimidating from a distance. The lexicon is unfamiliar, the boards are small and fiddly, the documentation is thinner than on desktop platforms, and the first time a DTB mismatch sends you into a silent boot hang it is easy to lose your nerve. None of that is a reason to stay away. The core skill you are going to build in this chapter, reading a `.dts` file and recognising what is being described, is learnable in a long afternoon. The second skill, writing a driver that matches on a compatible string and walks the properties it needs, is the same kind of driver writing you already know with three or four new helper calls. The third skill, building and loading a DTB and seeing your driver attach, is exactly the kind of feedback loop that makes kernel work enjoyable. By the end of the chapter you will have written, compiled, loaded, and observed an FDT-aware driver on either a real ARM board or an emulated one, and you will have the mental model that lets you read any FreeBSD embedded driver and understand how it finds its hardware.

The rest of the book will continue to treat drivers as drivers, but your toolkit will have grown. Let us begin.

32.2 Reader Guidance: How to Use This Chapter

Chapter 32 sits in a particular place in the book’s arc. Earlier chapters assumed a PC-like machine where buses discovered themselves and drivers bound to devices the kernel already knew about. This chapter steps sideways into a world where discovery is a problem the driver has to participate in. That step is easier than it sounds, but it does require a small shift in how you think about hardware, and a willingness to read some new kinds of files.

There are two reading paths, and one optional third path for readers who have embedded hardware at home.

If you choose the **reading-only path**, plan for three to four focused hours. You will finish the chapter with a clear mental model of what Device Tree is, how the kernel uses it, what an FDT-aware driver looks like, and where the important FreeBSD source files live. You will not have typed a driver, but you will be able to read one and understand every helper call you see. For many readers, this is the right stopping point on a first pass.

If you choose the **reading-plus-labs path**, plan for seven to ten hours spread across two or three sessions. The labs are built around a small pedagogical driver called `edled`, short for *embedded LED*. Over the chapter you will write a minimal FDT driver that matches a custom compatible string, grow it into a driver that reads its pin number and timer interval from Device Tree, and finally wrap it in a tidy detach path with a `sysctl` for runtime observability. You will compile a tiny `.dts` fragment into a `.dtb` overlay, load it with FreeBSD’s loader, and watch the driver attach in `dmesg`. None of these steps are long; none require more than a basic familiarity with `make`, `sudo`, and a shell.

If you have access to a Raspberry Pi 3 or 4, a BeagleBone, a Pine64, a Rock64, or a compatible ARM board, you can follow the **reading-plus-labs-plus-hardware path**. In that case the `edled` driver blinks a real LED attached to a real pin, and you get the satisfying experience of writing kernel code that makes a physical thing happen. If you do not have hardware, do not worry. The entire chapter can be followed with a QEMU virtual machine emulating a generic ARM platform, or even with printed simulation on a regular FreeBSD machine. You will not miss any of the conceptual material.

32.2.1 Prerequisites

You should be comfortable with the FreeBSD driver skeleton from earlier chapters: module init and exit, `probe()` and `attach()`, softc allocation and destruction, `DRIVER_MODULE()` registration, and the basics of `bus_alloc_resource_any()` and `bus_setup_intr()`. If any of those is fuzzy, a short revisit of Chapters 6 through 14 before this chapter will pay off. The helpers in this chapter sit *alongside* the familiar `bus_*` helpers; they do not replace them.

You should also be comfortable with simple FreeBSD system administration: loading and unloading kernel modules with `kldload(8)` and `kldunload(8)`, reading `dmesg(8)`, editing `/boot/loader.conf`, and running a command as root. You will use all of them, but none at any deeper level than earlier chapters have already asked.

No prior experience with embedded hardware is required. If you have never touched an ARM board, the chapter will teach you what you need. If you have used a Raspberry Pi but only as a small Linux machine, the chapter will give you a new perspective on what is going on under its covers.

32.2.2 Structure and Pacing

Section 1 sets the stage: what embedded FreeBSD looks like in practice, which architectures FreeBSD supports, what kinds of boards you are likely to encounter, and why Device Tree is the answer embedded platforms have settled on. Section 2 is the longest conceptual section: it introduces Device Tree files, their source and binary forms, their node-and-property structure, and the handful of conventions you need to read them fluently. Section 3 brings the conversation back to FreeBSD specifically, introducing the `fdt(4)` framework, the `ofw_bus` interfaces, and the `simplebus` enumerator. Section 4 is the first driver-writing section; it walks through the canonical shape of an FDT driver from probe to attach to detach. Section 5 teaches you how to build and modify `.dtb` files and how FreeBSD's overlays system works. Section 6 is the debugging section. Section 7 is the substantive worked example: the `edled` GPIO driver. Section 8 is the refactoring and finalising section.

After Section 8 you will find hands-on labs, challenge exercises, a troubleshooting reference, the Wrapping Up review, and the bridge into Chapter 33.

Read the sections in order. They build on each other, and the later sections assume the vocabulary the earlier ones establish. If you are short on time and want the smallest conceptual tour, read Sections 1, 2, and 3, then skim Section 4 for its driver skeleton; that gives you the map of the territory.

32.2.3 Work Section by Section

Each section covers one coherent piece of the subject. Read one, let it settle, then start the next. If a section ends and a point still feels blurry, pause, re-read the closing paragraphs, and open the cited FreeBSD source file. A quick look at real code often clarifies in thirty seconds what prose can only dance around.

32.2.4 Keep the Lab Driver Close

The `edled` driver used in the chapter lives under `examples/part-07/ch32-fdt-embedded/` in the book's repository. Each lab directory contains the state of the driver at that step, with its `Makefile`, a brief `README.md`, a matching DTS overlay where relevant, and any supporting scripts. Clone the directory, work in place, and load each version after every change. A kernel module that attaches in `dmesg` and toggles a pin you can observe is the single most concrete feedback loop in embedded work; use it.

32.2.5 Open the FreeBSD Source Tree

Several sections point to real FreeBSD files. The most useful ones to keep open for this chapter are `/usr/src/sys/dev/fdt/simplebus.c` and `/usr/src/sys/dev/fdt/simplebus.h`, which define the simple FDT bus enumerator every child driver binds to; `/usr/src/sys/dev/ofw/ofw_bus.h`, `/usr/src/sys/dev/ofw/ofw_bus_subr.h`, and `/usr/src/sys/dev/ofw/ofw_bus_subr.c`, which give you the compatibility helpers and property readers; `/usr/src/sys/dev/ofw/openfirm.h`, which declares the lower-level `OF_*` primitives; `/usr/src/sys/dev/gpio/gpioled_fdt.c`, a small real driver you will imitate; `/usr/src/sys/dev/gpio/gpiobusvar.h`, which defines `gpio_pin_get_by_ofw_idx()` and its siblings; and `/usr/src/sys/dev/fdt/fdt_pinctrl.h`, which defines the `pinctrl` API. Open them when the chapter points you at them. The source is the authority; the book is a guide into it.

32.2.6 Keep a Lab Logbook

Continue the lab logbook from earlier chapters. For this chapter, log a short note for each lab: which commands you ran, which DTB loaded, what `dmesg` said, which pin you used, and any surprises. Embedded debugging benefits more than most from a paper trail, because the variables that cause a driver not to attach (a missed overlay, a wrong phandle, a swapped pin number) are easy to forget and expensive to re-discover.

32.2.7 Pace Yourself

The concepts in this chapter are often easier the second time you meet them than the first. The words *phandle*, *ranges*, and *interrupt-parent* can sit uneasily for a while before clicking. If a subsection blurs, mark it, move on, and come back to it. Most readers find Section 2 (the Device Tree format itself) is the hardest of the chapter; after it, Sections 3 and 4 feel easy because they are mostly *driver code* and the shape of driver code is already familiar.

32.3 How to Get the Most Out of This Chapter

A few habits will help you turn the chapter's prose into durable intuition. They are the same habits that help with any new subsystem, tuned for the particulars of embedded work.

32.3.1 Read Real Source

The single best way to learn to read Device Tree files and FDT-aware drivers is to read real ones. The FreeBSD tree ships several hundred. Pick a peripheral you find interesting, find its driver under `/usr/src/sys/dev/`, open it, and read it. If it has an `ofw_compat_data` table near the top and a `probe()` that calls `ofw_bus_search_compatible`, you are looking at an FDT-aware driver. Notice which properties it reads. Notice how it acquires its resources. Notice what it does and does not do on detach.

The DTS side rewards the same treatment. The FreeBSD tree keeps custom board descriptions under `/usr/src/sys/dts/`, the upstream Linux-derived device trees under `/usr/src/sys/contrib/device-tree/`, and overlays under `/usr/src/sys/dts/arm/overlays/` and `/usr/src/sys/dts/arm64/overlays/`. Open a `.dts` file that describes a board you have heard of, and read it the way you would read code: top down, noticing the hierarchy, the property names, and the commentary.

32.3.2 Run What You Build

The point of the labs is that they end in something you can observe. When you load a module and nothing happens, that too is information; it usually means the driver did not match, and the chapter will teach you how to find out why. The feedback cycle is the whole point. Do not skip the loading step just because the code compiled.

32.3.3 Type the Labs

The edited driver is small on purpose. Typing it yourself slows you down enough to notice what each line does. The finger-memory of writing FDT boilerplate is worth having. Copy-pasting deprives you of that; resist the temptation even when you are sure you could reproduce the file from memory.

32.3.4 Follow the Nodes

When you read a Device Tree file or a `dmesg` boot log and you do not recognise a property, follow it. Look at the node's binding documentation in `/usr/src/sys/contrib/device-tree/Bindings/` if one exists. Search the FreeBSD source for the property name to see which drivers care about it. Embedded work is full of small conventions, and each one becomes obvious once you have seen it used in real code.

32.3.5 Treat `dmesg` as Part of the Manuscript

Almost everything interesting about FDT discovery shows up in `dmesg`, not in the shell. When a driver attaches, when a node is skipped because its status is disabled, when `simplebus` reports a child with no matching driver, you find those messages in the kernel log and nowhere else. Keep `dmesg -a` or `tail -f /var/log/messages` in a second terminal during labs. Copy relevant lines into your logbook when they teach something non-obvious.

32.3.6 Break Things on Purpose

Some of the most useful lessons in this chapter come from watching a driver *fail* to attach. A typo in a compatible string, a wrong pin number, a disabled status, a missing overlay will each produce a different flavour of silence in `dmesg`. Working through those failures in a lab environment teaches the recognition you will need when the same failure surprises you in real work. Do not only build drivers that work; break a few on purpose and look at what the kernel says.

32.3.7 Work in Pairs When You Can

Embedded debugging, like security work, benefits from a second pair of eyes. If you have a study partner, one of you can read the `.dts` while the other reads the driver; you can trade perspectives and compare what you each thought the setup was doing. The conversation tends to catch the small mistakes (a swapped cell count, a misread phandle, an interrupt cell in the wrong position) that slip past a single reader.

32.3.8 Trust the Iteration

You are not going to memorise every property, every flag, every helper on the first pass. That is fine. What you need on the first pass is the *shape* of the subject: the names of the primitives, the structure of a driver that uses them, the places to look when a concrete question comes up. The identifiers become reflex after you have written one or two FDT drivers; they are not a memorisation exercise.

32.3.9 Take Breaks

Embedded work, like security work, is cognitively dense. It asks you to hold a description of physical hardware in your head while you read software that tries to describe and control it. Two focused hours, a proper break, and another focused hour is almost always more productive than four hours of grinding through in one sitting.

With those habits in place, let us begin with the broad question: what is embedded FreeBSD, and what does it ask of a driver author that desktop FreeBSD does not?

32.4 Section 1: Introduction to Embedded FreeBSD Systems

The word *embedded* has been used so loosely over the years that it is worth pausing to say what we mean by it inside this book. For our purposes, an embedded system is a computer designed to do a specific job rather than to be a general-purpose machine. A Raspberry Pi running a thermostat control loop is embedded. A BeagleBone running a CNC controller is embedded. A small ARM box running a firewall appliance, a RISC-V development board running a dedicated sensor gateway, a router built around a MIPS SoC in the old days, all of these are embedded. A laptop is not embedded even when it is small. A server is not embedded even when it is stripped down. The word is about purpose and constraint, not size.

From a driver author's perspective, embedded systems share a handful of practical traits that shape the work. The hardware is usually an SoC with many on-chip peripherals rather than a motherboard with plug-in cards. The peripherals are fixed: they cannot be added or removed, because they are literally part of the silicon. There is usually no discoverable bus in the PCI sense; the peripherals sit at known physical addresses and the kernel must be told where they are. Power is constrained, sometimes severely. RAM is limited. Storage is limited. The boot flow is simple, often relying on a bootloader like U-Boot or a small EFI implementation. The user interface, if any, is minimal. The kernel boots, the drivers attach, the one application the machine exists to run comes up, and that is the life of the system.

FreeBSD runs on a growing family of embedded-friendly architectures. Most of this chapter assumes arm64 because it is the most widely used embedded target for FreeBSD today, but most of what you learn applies directly to 32-bit ARM, RISC-V, and, to a lesser extent, older MIPS and PowerPC platforms. The differences between these architectures matter for the compiler and the kernel's lowest-level code, but for driver writing the differences are mostly absent. The same FDT framework, the same ofw_bus helpers, the same simplebus enumerator, and the same GPIO and clock APIs work across all of them. A driver you write for a Raspberry Pi today will, with very little modification, build and run on a RISC-V SiFive HiFive Unmatched tomorrow.

32.4.1 What Embedded FreeBSD Looks Like

Picture a Raspberry Pi 4 running FreeBSD 14.3. The board has a quad-core ARM Cortex-A72 CPU, 4 GB of RAM, a PCIe root complex with a gigabit Ethernet controller and a USB host controller hanging off it, an SD card slot for storage, a Broadcom VideoCore VI GPU, an HDMI output, four USB ports, a 40-pin GPIO header, and on-chip UARTs, SPI buses, I2C buses, pulse-width modulators, and timers. Most of those peripherals sit inside the BCM2711 SoC at fixed memory-mapped addresses. A few, like the USB and the Ethernet, hang off the SoC's internal PCIe controller. The SD card is driven by a host controller inside the SoC that speaks the SD protocol.

When you power the board on, a tiny firmware on the GPU core reads the SD card, finds the FreeBSD EFI bootloader, and hands control to it. The EFI loader reads `/boot/loader.conf`, loads the FreeBSD kernel, loads the Device Tree blob that describes the hardware, loads any overlay blobs that tweak the description, and jumps to the kernel. The kernel boots, attaches a simplebus to the root node of the tree, walks the tree's children, matches drivers to nodes, attaches drivers to their hardware, and the system comes up. By the time you see a login prompt, your filesystem has been mounted from the SD card by the SD host driver, your network interface has been brought up by the Ethernet driver, your USB devices are probed and available, and the ordinary userland tools (`ps`, `dmesg`, `sysctl`, `kldload`) behave exactly as they do on a laptop.

None of that last paragraph would have been true for a PC. On a PC, the firmware is BIOS or UEFI, the peripherals are on PCI, and the kernel does not need a separate blob that describes the hardware because the PCI bus itself describes its children. The arm64 world has none of those luxuries. It has Device Tree instead.

32.4.2 Why Embedded Platforms Rely on Device Trees

The embedded world chose Device Trees because of the problem space. A small SoC has dozens of on-chip peripherals. Every SoC variant, every board revision, every integration choice the hardware engineer made shapes which peripherals are enabled, which pins they use, how their clocks are wired, and what their interrupt priorities are. There are thousands of distinct SoCs in the wild, and tens of thousands of distinct boards. A single kernel binary cannot afford to have every one of those variations compiled into it. Nor is there a magical bus protocol it could use to *ask* the hardware what is on the board; the hardware does not know, and most of it cannot answer.

The old solution, the one the embedded Linux world used before Device Trees, was called *board files*. Each board had a C source file compiled into the kernel, full of static structures that described the peripherals, their addresses, their interrupts, and their clocks. A kernel intended for five boards had five board files. A kernel intended for fifty boards had fifty, each with its own static description, each requiring the kernel to be rebuilt every time a board's hardware changed. The approach did not scale. Every board revision was a kernel release.

Device Trees are the approach that replaced board files. The core idea is elegant: rather than encode the hardware description in C inside the kernel, encode it in a separate textual file that lives outside the kernel, compile that file into a compact binary blob, and let the bootloader hand the blob to the kernel at boot. The kernel then reads the blob, decides which drivers to attach, and hands each driver the part of the blob that describes its hardware. A single kernel binary can now run on any board whose DTB it is given. A board revision that changes pin assignments or adds a peripheral needs a new DTB, not a new kernel.

The approach originated in the IBM and Apple PowerPC world of the 1990s, where the concept was called *Open Firmware* and the tree was part of the firmware itself. The modern Flattened Device Tree (FDT) format is a descendant, streamlined and reworked to suit bootloaders and kernels that do not carry a whole Forth interpreter the way Open Firmware did. In FreeBSD you will see both names. The framework is called `fdt(4)`, the helpers still live under `sys/dev/ofw/` because of that OpenFirmware lineage, and the functions that read properties are named `OF_getprop`, `OF_child`, `OF_hasprop` for the same reason. When you read *Open Firmware*, *OFW*, and *FDT* in FreeBSD source, they all refer to pieces of the same tradition.

32.4.3 Architecture Overview: FreeBSD on ARM, RISC-V, and MIPS

FreeBSD supports several embedded-friendly architectures in FreeBSD 14.3. The two most actively used are arm64 (the 64-bit ARM architecture called AArch64 in the ARM documentation) and armv7 (32-bit ARM with hardware floating point, sometimes written armv7 or armhf). RISC-V support has matured over FreeBSD 13 and 14 and now runs on real boards like the SiFive HiFive Unmatched and the VisionFive 2. MIPS support existed for a long time and powered many older routers and embedded appliances; it has been removed from the base system in recent releases, so this chapter will not dwell on it, but the skills you learn for ARM and RISC-V would transfer directly if you ever dropped back to a legacy MIPS platform.

All of those architectures use Device Tree to describe non-discoverable hardware. The boot flows differ in detail, but the shape is the same: some stage-zero firmware starts the CPU, some stage-one bootloader (U-Boot is common; on arm64 an EFI loader is increasingly standard) loads the kernel and the DTB, and the kernel takes over with the tree in hand. On arm64 the FreeBSD EFI loader handles this cleanly, and the tree can come from either a file on disk (`/boot/dtb/*.dtb`) or, on server-class hardware, from the firmware itself. On armv7 boards, U-Boot usually supplies the DTB. On RISC-V the picture is a mix of OpenSBI, U-Boot, and EFI, depending on the board.

None of these differences matter much to a driver author. The tree the kernel sees by the time your driver runs is a Device Tree, the helpers it gives you are `OF_*` and `ofw_bus_*`, and the drivers you write to run against it are portable across architectures that use the same framework.

32.4.4 Typical Limitations: No ACPI, Limited Buses, Power Constraints

It is worth enumerating the limitations of embedded platforms that shape driver work, so that they do not take you by surprise.

No ACPI, usually. ACPI is the firmware-to-OS interface that most PCs use to describe their non-discoverable hardware. It contains tables, a bytecode language called AML, and a long specification. ARM servers sometimes use ACPI, and FreeBSD supports that path on arm64 with the ACPI subsystem, but small and mid-range embedded boards almost always use FDT. A few high-end arm64 systems may ship with *both* ACPI and FDT descriptions and let the firmware pick between them; FreeBSD can handle either, and on arm64 there is a run-time switch that decides which bus to attach. The practical consequence for most embedded drivers is that you write for FDT and not worry about ACPI. We will return to the dual-support case in Section 3.

No PCI-style discovery for on-SoC peripherals. A PCI or PCIe device announces itself through vendor and device IDs in a standardised configuration space. The kernel scans the bus, finds the device, and dispatches to a driver that claims the IDs. On-SoC peripherals on an ARM chip do not have that announcement mechanism. The only way the kernel knows a UART is at address `0x7E201000` on a Raspberry Pi 4 is because the DTB says so. This shifts the driver-author's mental model: you do not wait for the bus to hand you a probed device; you wait for simplebus (or the equivalent) to find your node in the tree and dispatch your probe with that node's context.

Power constraints matter. An embedded board may run on a battery, or from a small USB adapter, or from a power-over-Ethernet feed. A driver that leaves a clock running when the device is idle, or that keeps a regulator enabled past the peripheral's needs, hurts the entire system. FreeBSD provides clock and regulator frameworks precisely so drivers can turn things off when appropriate. We will touch on them in Sections 3, 4, and 7.

Limited RAM and storage. Embedded boards commonly have between 256 MB and 8 GB of RAM, and between a few hundred megabytes and a few tens of gigabytes of storage. A driver that allocates lavishly or prints a screenful of debug output to the console on every event will consume resources the system may not have. Write for the constraints you expect to face.

A simpler boot flow, for better or worse. The boot process on an embedded board is usually shorter and less forgiving than on a PC. If the kernel fails to find the root filesystem, you may not have a handy rescue environment. If the DTB is wrong and the right interrupt controller does not attach, the system will hang silently. This is the main reason embedded work benefits from a working debug cable, a serial console, and the habit of making small, testable changes rather than heroic ones.

32.4.5 Boot Flow: From Firmware to Driver Attachment

To make the moving parts concrete, let us walk through what happens from power-on to the first driver attachment on a representative arm64 board. The details vary by board, but the shape is consistent.

1. Power-on: the first CPU core starts executing code from a boot ROM burned into the SoC. This ROM is beyond your control; its job is to load the next stage.
2. The boot ROM reads a stage-one loader from a fixed location (usually the SD card, eMMC, or SPI flash). On Raspberry Pi boards this is the VideoCore firmware; on generic arm64 boards it is usually U-Boot.
3. The stage-one loader does platform bring-up: it configures DRAM, sets up early clocks, initialises a UART for debug output, and loads the next stage. On boards with FreeBSD installed, that next stage is usually the FreeBSD EFI loader (`loader.efi`).
4. The FreeBSD EFI loader reads its configuration from the ESP partition of the boot medium, consults `/boot/loader.conf`, and loads three things: the kernel itself, a DTB from `/boot/dtb/`, and any overlays listed in the `fdt_overlays` tunable from `/boot/dtb/overlays/`.
5. The loader hands control to the kernel along with pointers to the loaded DTB.
6. The kernel starts. Its machine-dependent startup code parses the DTB to find the memory map, the CPU topology, and the root node of the tree. Based on the top-level `compatible` string of the root node, arm64 decides whether to run the FDT path or the ACPI path.
7. On the FDT path, the kernel attaches an `ofwbus` to the tree root and a `simplebus` to the `/soc` node (or the equivalent on that board). Simplebus walks its children and creates a `device_t` for each node with a valid compatible string.
8. For each of those `device_ts`, the kernel runs the usual newbus probe loop. Every driver that has registered with `DRIVER_MODULE(mydrv, simplebus, ...)` gets a chance to probe. The driver whose `probe()` returns the best match wins and has its `attach()` called. The driver then reads properties, allocates resources, and comes up.
9. The attachment process recurses for nested buses (a simple-bus child of `/soc`, an I2C controller with its own child devices, a GPIO bank with its own pin consumers), producing the full device tree visible in `dmesg` and `devinfo -r`.
10. By the time `init` runs, the devices the system needs to boot (UART, SD host, Ethernet, USB, GPIO) have all attached, and userland comes up.

That sequence is the backdrop against which every driver in this chapter operates. When you write an FDT-aware driver, you are writing the code that runs at step 8 for your particular node. The surrounding machinery runs with or without you; the part you control is the reading of your node and the allocation of your resources.

32.4.6 Where to See It for Yourself

The fastest way to see a real FDT-based boot is to run FreeBSD 14.3 on a Raspberry Pi 3 or 4. Images are available from the FreeBSD project in the standard arm64 download area, and the setup is well documented. If you do not have the hardware, the second fastest way is to use QEMU's `virt` platform, which emulates a generic arm64 machine with a small set of FDT-described peripherals. The kernel and loader from a normal FreeBSD arm64 release run inside it. A sample QEMU invocation lives in the lab notes later in this chapter.

A third option, useful even on an amd64 workstation, is to read `.dts` files and the FreeBSD drivers that consume them. Open `/usr/src/sys/contrib/device-tree/src/arm/bcm2835-rpi-b.dts` or `/usr/src/sys/contrib/device-tree/src/arm64/broadcom/bcm2711-rpi-4-b.dts`. Follow the node structure top-down. Notice how the top-level node has a `compatible` property that names the board. Notice how children describe CPUs, memory, the clock controller, the interrupt controller, the peripheral bus. Then open `/usr/src/sys/arm/broadcom/bcm2835/` in the FreeBSD tree and look at the drivers that consume those nodes. You will start to see how the descriptions and the code meet.

32.4.7 Wrapping Up This Section

Section 1 set the scene. Embedded FreeBSD is not an exotic niche inside the project; it is the project on platforms that do not look like PCs. The architecture the embedded work pushes you toward, thinking of hardware as a set of fixed peripherals on a SoC rather than discoverable devices on a bus, is exactly the architecture Device Tree supports. Device Tree is the bridge between the hardware description that the board designer knows and the driver code that the kernel runs. The rest of this chapter is about learning that bridge well enough to walk across it confidently.

In the next section we will slow down and read Device Tree files themselves. Before we can write a driver that consumes them, we need to know how they are structured, what their properties mean, and how a `.dts` source becomes the `.dtb` binary the kernel actually sees.

32.5 Section 2: What Is the Device Tree?

A Device Tree is a textual description of hardware organised as a tree of nodes, with each node representing a device or a bus, and each node carrying named properties that describe its addresses, its interrupts, its clocks, its relationships to other nodes, and anything else a driver might need to know. That description is what the embedded world uses in place of PCI enumeration or ACPI tables. In the embedded FreeBSD world you will spend your life reading, writing, and reasoning about these files. The sooner they become friendly, the easier every subsequent chapter will feel.

The best way to start is to look at one.

32.5.1 A Minimal Device Tree

Here is the smallest interesting Device Tree source file, in `.dts` form:

```
/dts-v1/;

/ {
    compatible = "acme,trivial-board";
    #address-cells = <1>;
    #size-cells = <1>;

    chosen {
        bootargs = "console=ttyS0,115200";
    };

    memory@80000000 {
        device_type = "memory";
        reg = <0x80000000 0x10000000>;
    };

    uart0: serial@10000000 {
        compatible = "ns16550a";
        reg = <0x10000000 0x100>;
        interrupts = <5>;
        clock-frequency = <24000000>;
        status = "okay";
    };
};
```

That is a complete, valid, if tiny Device Tree. It describes a fictional board called `acme, trivial-board` that has 256 MB of RAM at physical address `0x80000000`, and a 16550-compatible UART at `0x10000000` that delivers interrupt number 5 and runs at 24 MHz. Even if none of the syntax is familiar yet, the intent is legible: the file is a hardware description, written in a compact domain-specific format.

Let us unpack it piece by piece.

32.5.2 The Tree Structure

The first line, `/dts-v1/;`, is a mandatory directive declaring the DTS syntax version. Every FreeBSD DTS file you will ever write or read begins with it. Anything before it is not a valid DTS file; treat it like `#!/bin/sh` at the top of a shell script.

The rest of the file is enclosed in a single block that starts with `/ {` and ends with `};`. That outer block is the **root node** of the tree. Every Device Tree has exactly one root. Its children are peripherals and sub-buses; their children are further peripherals and sub-buses; and so on.

Nodes are identified by **names**. A name like `serial@10000000` consists of a base name (`serial`) and a **unit address** (`10000000`, which is the starting address of the node's first register region written in hexadecimal without the `0x` prefix). The unit address is a convention, not a hard requirement; it exists so that nodes with

the same base name can be distinguished (you can have multiple `serial` nodes at different addresses), and it doubles as a readable hint for what the node describes.

A **label**, like `uart0:` in `uart0: serial@10000000`, is a handle that lets other parts of the tree refer to this node. Labels let you write `&uart0` elsewhere in the file to mean *the node labelled `uart0`*. We will use labels in the overlay section.

Nodes contain **properties**. A property is a name followed by an equals sign, followed by a value, followed by a semicolon:

```
compatible = "ns16550a";
```

Some properties have no value; they exist only as flags:

```
interrupt-controller;
```

The value of a property can be a string ("`ns16550a`"), a list of strings ("`brcm,bcm2711`", "`brcm,bcm2838`"), a list of integers inside angle brackets (`<0x10000000 0x100>`), a list of references to other nodes (`<&gpio0>`), or a binary byte string (`[01 02 03]`). Most everyday properties are strings, string lists, or integer lists. The tree uses 32-bit *cells* as its fundamental integer unit; the integers inside `<...>` are cells, and 64-bit values are expressed as two consecutive cells (high, low).

Let us go back to the minimal example and read each property with fresh eyes.

32.5.3 Reading the Minimal Example

The root node has three properties:

```
compatible = "acme,trivial-board";
#address-cells = <1>;
#size-cells = <1>;
```

The **compatible** property is how the root (and any node) tells the world what it is. It is the single most important property in Device Tree. A driver matches on it. The value is a vendor-prefixed string ("`acme,trivial-board`") or, more commonly, a list of them in decreasing order of specificity. A Raspberry Pi 4 root node, for example, might be `compatible = "raspberrypi,4-model-b", "brcm,bcm2711"`; The first string says “exactly this board”; the second says “in the general family of boards using the BCM2711 chip”. Drivers that know about the specific board can match the first; drivers that only know about the chip can match the second. The DTS spec calls this a *compatibility list*, and both FreeBSD and Linux respect it.

The **#address-cells** and **#size-cells** properties at the root describe how many 32-bit cells a child node uses for its address and size in `reg` properties. At the root of a 32-bit board, both are typically 1. On a 64-bit board with more than 4 GB of addressable memory, they would both be 2. When you see `reg = <0x80000000 0x10000000>`; under the memory node, you know from the parent’s cell counts that this is one address cell and one size cell, which means the region is at `0x80000000` with size `0x10000000`. If `#address-cells` were 2, the region would instead be written `reg = <0x0 0x80000000 0x0 0x10000000>`;

The **chosen** node is a special sibling of the root's hardware children. It carries parameters the bootloader wants to pass to the kernel: the boot arguments, the console device, sometimes the initrd location. FreeBSD reads `/chosen/bootargs` and uses it to populate the kernel environment.

The **memory@80000000** node describes a region of physical memory. Memory nodes carry `device_type = "memory"` and a `reg` property giving their range. FreeBSD's early boot reads these to build its physical memory map.

The **serial@10000000** node is the interesting one. Its `compatible = "ns16550a"` tells the kernel *this is an ns16550a UART*, which is a very common PC-style serial port chip. Its `reg = <0x10000000 0x100>` says *my registers live at physical address 0x10000000 and occupy 0x100 bytes*. Its `interrupts = <5>` says *I deliver interrupt number 5 to my interrupt parent*. Its `clock-frequency = <24000000>` says *my reference clock runs at 24 MHz, so divisors should be computed from this*. Its `status = "okay"` says *I am enabled*; had it said "disabled", the driver would skip this node.

That is essentially what a Device Tree does: it describes each peripheral in a few properties whose meanings are defined by conventions called **bindings**. A binding for a UART tells you what properties a UART node should carry. A binding for an I2C controller tells you what properties an I2C controller node should carry. And so on. The bindings are documented separately, and the FreeBSD tree ships a large library of them under `/usr/src/sys/contrib/device-tree/Bindings/`.

32.5.4 Source vs Binary: .dts, .dtsi, and .dtb

Device Tree files come in three file types that are easy to confuse at first.

.dts is the main source form. A **.dts** file describes a whole board or platform and is what you feed to the compiler.

.dtsi is an include fragment, the *i* standing for *include*. A typical SoC family has a large **.dtsi** describing the SoC itself (its interrupt controller, its clock tree, its on-chip peripherals), and each board that uses that SoC has a small **.dts** that `#includes` the **.dtsi** and then describes the board-specific additions (external devices soldered to the board, pin configuration, chosen node). You will see many **.dtsi** files under `/usr/src/sys/contrib/device-tree/src/arm/` and `/usr/src/sys/contrib/device-tree/src/arm64/`.

.dtb is the compiled binary form. The kernel and bootloader deal with **.dtb** files, not **.dts** files. A **.dtb** is the output of the `dtc` compiler fed a **.dts** source. It is compact, has no whitespace or comments, and is designed to be parsed by a bootloader in a few kilobytes of code. A **.dtb** file for a Raspberry Pi 4 is typically around 30 KB.

And a fourth, less common type:

.dtbo is a compiled *overlay*. Overlays are fragments that modify an existing base **.dtb** at load time: they can enable or disable nodes, add new nodes, or change properties. They are the mechanism FreeBSD and many Linux distributions use to let users customise a stock DTB without rebuilding it. **.dtbo** files are compiled from **.dtso** (device-tree-source-overlay) files, and loaded by the bootloader via the `fdt_overlay` tunable. We will meet them in Section 5.

When you work with DTS you are almost always writing either a **.dts** or a **.dtso**. You compile either with the device tree compiler, `dtc`, which in FreeBSD lives in the `devel/dtc` port and is installed as `/usr/lo-`

cal/bin/dtc. The FreeBSD kernel build system invokes dtc through the scripts under /usr/src/sys/tools/fdt/, specifically make_dtb.sh and make_dtbo.sh.

32.5.5 Nodes, Properties, Addresses, and the Phandle

A few additional concepts recur so often that it is worth naming them once and for all.

Nodes are the hierarchical units. Every node has a name, optionally a label, possibly a unit address, and zero or more properties. Nodes nest; a node's children are described inside its enclosing braces.

Properties are key-value pairs. The keys are strings. The values are typed by convention: compatible is a string list, reg is an integer list, status is a string, interrupts is an integer list whose length depends on the interrupt parent, and so on.

Unit addresses in node names (serial@10000000) mirror the first cell of the reg property. The DTC compiler warns if they disagree. You should write both consistently.

The **reg** property describes the memory-mapped register regions of the device. Its format is <address size address size ...>, with each address-size pair being a contiguous region. Most simple peripherals have exactly one region. Some have several (a peripheral with a main register area and a separate interrupt register block, for example).

Address cells and size cells are the property pair #address-cells and #size-cells that live on a parent node and describe how reg is formatted in its children. A SoC bus with #address-cells = <1>; #size-cells = <1>; lets its children use one cell each for address and size. An I2C bus usually has #address-cells = <1>; #size-cells = <0>; because an I2C child has an address but no size.

Interrupts are described by one or more properties depending on the style used. The older style is interrupts = <...>; with the cells interpreted by the interrupt parent's convention. On ARM GIC-based platforms this is a three-cell form: interrupt type, interrupt number, interrupt flags. The newer style, mixed with the old throughout the kernel, is interrupts-extended = <&gic 0 15 4>; which explicitly names the interrupt parent. Either way, the cells tell the kernel which hardware interrupt the device raises and under what conditions.

A **phandle** is a unique integer assigned by the compiler to each node. Phandles let other nodes refer to this one. When you write <&gpio0>, the compiler substitutes the phandle of the node labelled gpio0. When you write <&gpio0 17 0>, you are passing three cells: the phandle of gpio0, the pin number 17, and a flags cell 0. The meaning of the cells after the phandle is defined by the *provider's* binding. This is the pattern by which GPIO consumers, clock consumers, reset consumers, and interrupt consumers talk to their providers: the first cell names the provider, the following cells say which resource and how.

The **status** property is a small but critical one. A node with status = "okay"; is enabled, and drivers will probe it. A node with status = "disabled"; is skipped. Overlays often toggle this property to turn a peripheral on or off without removing the node. FreeBSD's ofw_bus_status_okay() is the helper that returns true when a node's status is okay.

The **label** and **alias** mechanisms let you refer to a node by a short name rather than a path. A label like uart0: is a file-local handle; an alias defined under the special /aliases node (serial0 = &uart0;) is a kernel-visible name. FreeBSD makes use of aliases for some devices like the console.

That is most of what you need to read a typical Device Tree. A few more exotic pieces appear in specific bindings (for example, clock-names and clocks for consumers of the clock framework, reset-names and resets for

hwreset consumers, dma-names and dmas for DMA engine consumers, pinctrl-0, pinctrl-names for pin control), but they all follow the same *named index list* pattern.

32.5.6 A More Realistic Example

To give you a feel for a real SoC-level fragment, here is an abbreviated node from a BCM2711 (Raspberry Pi 4) description. The full file lives under `/usr/src/sys/contrib/device-tree/src/arm/bcm2711.dtsi`.

```
soc {
    compatible = "simple-bus";
    #address-cells = <1>;
    #size-cells = <1>;
    ranges = <0x7e000000 0x0 0xfe000000 0x01800000>,
            <0x7c000000 0x0 0xfc000000 0x02000000>,
            <0x40000000 0x0 0xff800000 0x00800000>;
    dma-ranges = <0xc0000000 0x0 0x00000000 0x40000000>;

    gpio: gpio@7e200000 {
        compatible = "brcm,bcm2711-gpio", "brcm,bcm2835-gpio";
        reg = <0x7e200000 0xb4>;
        interrupts = <GIC_SPI 113 IRQ_TYPE_LEVEL_HIGH>,
                    <GIC_SPI 114 IRQ_TYPE_LEVEL_HIGH>;
        gpio-controller;
        #gpio-cells = <2>;
        interrupt-controller;
        #interrupt-cells = <2>;
    };

    spi0: spi@7e204000 {
        compatible = "brcm,bcm2835-spi";
        reg = <0x7e204000 0x200>;
        interrupts = <GIC_SPI 118 IRQ_TYPE_LEVEL_HIGH>;
        clocks = <&clocks BCM2835_CLOCK_VPU>;
        #address-cells = <1>;
        #size-cells = <0>;
        status = "disabled";
    };
};
```

Reading this top-down:

- The soc node is the on-chip-peripherals bus. Its `compatible = "simple-bus"` is the magic token that tells FreeBSD to attach the simplebus driver here.
- Its `ranges` property defines the address translation from bus addresses (the “local” addresses the CPU’s peripheral interconnect uses internally, starting at `0x7E000000`) to CPU physical addresses (starting at

0xFE000000). FreeBSD reads this and applies it when mapping child reg properties.

- The `gpio` node is the GPIO controller. It claims two interrupts, declares itself a `gpio-controller` (so other nodes can reference it), and uses two cells per GPIO reference (the first cell is the pin number, the second is a flag word).
- The `spi0` node is the SPI controller at bus address 0x7E204000. It is `status = "disabled"` in the base description, meaning it does not attach until an overlay enables it.

Every embedded board description looks roughly like this: a tree of on-chip peripherals, each with a compatible string identifying what driver to bind, a reg for its memory-mapped registers, an interrupts for its IRQ line, and possibly references to clocks, resets, regulators, and pins.

32.5.7 How the DTB Is Loaded

For completeness, it helps to know how the DTB goes from disk to kernel at boot.

On an arm64 board running FreeBSD 14.3, the typical flow is:

1. The EFI firmware or bootloader reads the FreeBSD EFI loader from the ESP.
2. The FreeBSD loader loads the kernel from `/boot/kernel/kernel` and the DTB from `/boot/dtb/<board>.dtb`. The DTB's filename is selected based on the SoC family.
3. If `/boot/loader.conf` sets `fdt_overlays="overlay1,overlay2"`, the loader reads `/boot/dtb/overlays/overlay1.dtbo` and `/boot/dtb/overlays/overlay2.dtbo`, applies them to the base DTB in memory, and hands the merged result to the kernel.
4. The kernel takes the merged DTB as its authoritative hardware description.

On U-Boot-driven boards (common for armv7) the flow is similar but the loader is U-Boot itself. U-Boot's environment variables `fdt_file` and `fdt_addr` tell it which DTB to load and where to place it. When U-Boot finally does `bootefi` or `booti`, it passes the DTB to the FreeBSD loader or directly to the kernel.

On EFI systems that ship FDT in their firmware (rare for small boards, common for ARM servers that use the Server Base System Architecture), the firmware stores the DTB as an EFI configuration table and the kernel reads it from there.

For a driver author, the details of boot do not matter most of the time. What matters is that by the time your driver's probe is called, the tree has been loaded, parsed, and presented to the kernel; you read it with the same `OF_*` helpers no matter how it got there.

32.5.8 Wrapping Up This Section

Section 2 introduced Device Tree as a hardware-description language. You have seen a minimal example, you have met the core concepts of nodes and properties, you know the difference between `.dts`, `.dtsi`, `.dtb`, and `.dtbo` files, and you have walked through a realistic fragment of a SoC description. You also know how a DTB reaches the kernel at boot.

What you do *not* yet know is how FreeBSD's kernel consumes the tree once it is loaded: which subsystem attaches to it, which helpers drivers call to read properties, and how a driver's `probe()` and `attach()` find their node. That is Section 3.

32.6 Section 3: FreeBSD's Device Tree Support

FreeBSD handles Device Tree through a framework whose design predates FDT itself. The framework is named after Open Firmware, abbreviated **OFW** throughout the source tree, because the API it grew out of originally served PowerPC Macs and IBM systems that used the real Open Firmware specification. When the ARM world standardised on Flattened Device Tree in the late 2000s, FreeBSD mapped FDT onto the same internal API. A driver in FreeBSD 14.3 therefore calls the same `OF_getprop()` whether it is running on a PowerPC Mac, an ARM board with an FDT blob, or a RISC-V board with an FDT blob. The implementation beneath differs; the interface above is uniform.

This section introduces the pieces of that framework you need to know: the `fdt(4)` interface as it is used in practice, the `ofw_bus` helpers that drivers call on top of the raw `OF_*` primitives, the `simplebus(4)` bus driver that enumerates children, and the property-reading idioms you will use constantly. By the end of the section you will know what code already exists on the FreeBSD side and where it lives; Section 4 will then build a driver on top of it.

32.6.1 The `fdt(4)` Framework Overview

`fdt(4)` is the kernel's Flattened Device Tree support. It provides the code that parses the binary `.dtb`, walks it to find nodes, extracts properties, applies overlays, and presents the result through the `OF_*` API. You can think of `fdt(4)` as the lower half and `ofw_bus` as the upper half, with `OF_*` functions spanning both.

The code that implements the FDT side of the OFW interface lives in `/usr/src/sys/dev/ofw/ofw_fdt.c`. It is a specific instance of the `ofw_if.m kobj` interface. When the kernel calls `OF_getprop()`, the call goes through the interface and ends up in the FDT implementation, which walks the flattened blob. On a PowerPC Mac it would end up in the real Open Firmware implementation instead; the drivers above do not need to know or care.

For your purposes as a driver author, you almost never touch `ofw_fdt.c` directly. You use the helpers one layer up.

32.6.2 `OF_*`: The Raw Property Readers

The lowest-level API that drivers call is the `OF_*` family of functions declared in `/usr/src/sys/dev/ofw/openfirm.h`. The ones you will use most are a small set.

`OF_getprop(phandle_t node, const char *prop, void *buf, size_t len)` reads a property's raw bytes into a caller-supplied buffer. It returns the number of bytes read on success, or -1 on failure. The buffer must be large enough for the expected length.

`OF_getencprop(phandle_t node, const char *prop, pcell_t *buf, size_t len)` reads a property whose cells are big-endian and converts them to host byte order as it copies. Almost any property that contains integers should be read with this variant rather than `OF_getprop()`.

`OF_getprop_alloc(phandle_t node, const char *prop, void **buf)` reads a property of unknown length. The kernel allocates a buffer and returns the pointer through the third argument. When you are done, call `OF_prop_free(buf)` to release it.

`OF_hasprop(phandle_t node, const char *prop)` returns non-zero if the named property exists, zero otherwise. Useful for optional properties where the mere presence is meaningful.

`OF_child(phandle_t node)` returns the first child of a node. `OF_peer(phandle_t node)` returns the next sibling. `OF_parent(phandle_t node)` returns the parent. Combined, they let you walk the tree.

`OF_finddevice(const char *path)` returns a phandle for the node at a given path, such as `"/chosen"` or `"/soc/gpio@7e200000"`. Most drivers do not need this because the framework hands them their node already.

`OF_decode_addr(phandle_t dev, int regno, bus_space_tag_t *tag, bus_space_handle_t *hp, bus_size_t *sz)` is a convenience routine used by very early code (serial console drivers, mostly) to set up a bus-space mapping for register `regno` of a given node without going through `newbus`. Normal drivers use `bus_alloc_resource_any()` instead, which reads the `reg` property via the resource list set up during probe.

These primitives are the foundation. In practice you will call them indirectly through the slightly more convenient `ofw_bus_*` helpers, but the ones above are what those helpers use internally, and it is worth recognising them when you read real driver code.

32.6.3 ofw_bus: The Compatibility Helpers

The most common thing an FDT-aware driver does is ask: *is this device compatible with something I know how to drive?* FreeBSD provides a small layer of helpers on top of `OF_getprop` to make those checks idiomatic. They live in `/usr/src/sys/dev/ofw/ofw_bus.h` and `/usr/src/sys/dev/ofw/ofw_bus_subr.h`, with their implementations in `/usr/src/sys/dev/ofw/ofw_bus_subr.c`.

The helpers worth knowing, in the order you will meet them:

`ofw_bus_get_node(device_t dev)` returns the phandle associated with a `device_t`. It is implemented as an inline that calls the parent bus's `OFW_BUS_GET_NODE` method. For a child of `simplebus`, this returns the phandle of the DTS node that gave rise to this device.

`ofw_bus_status_okay(device_t dev)` returns 1 if the node's status property is absent, empty, or "okay"; 0 otherwise. Every FDT-aware probe should call it at the top to skip disabled nodes.

`ofw_bus_is_compatible(device_t dev, const char *string)` returns 1 if any entry of the node's compatible property exactly equals `string`. Short, precise, and the usual tool when a driver only wants one compatible string.

`ofw_bus_search_compatible(device_t dev, const struct ofw_compat_data *table)` walks a driver-provided table and returns the matching entry if any of its compatible strings is in the node's compatible list. This is the standard way a driver that supports multiple chips registers its compatibility. The table is an array of entries, each containing a string and a `uintptr_t` cookie the driver can use to remember which chip matched; the table ends with a sentinel entry whose string is `NULL`. We will see the full pattern in Section 4.

`ofw_bus_has_prop(device_t dev, const char *prop)` is a convenience wrapper over `OF_hasprop(ofw_bus_get_node(dev), prop)`.

`ofw_bus_get_name(device_t dev)`, `ofw_bus_get_compat(device_t dev)`, `ofw_bus_get_type(device_t dev)`, and `ofw_bus_get_model(device_t dev)` return the corresponding strings from the node, or `NULL` if absent.

Those are the bread-and-butter helpers. You will see them at the top of almost every FDT-aware driver's probe and attach routines.

32.6.4 simplebus: The Default Enumerator

The simplebus driver is the piece that makes all of this work in practice. It lives in `/usr/src/sys/dev/fdt/simplebus.c` and its header is at `/usr/src/sys/dev/fdt/simplebus.h`. Simplebus has two jobs.

Its first job is to enumerate children. When the kernel attaches simplebus to a node whose compatible includes "simple-bus" (or whose `device_type` is "soc", for historical reasons), simplebus walks the node's children, creates a `device_t` for each child that has a compatible property, and feeds them into newbus. This is what makes your driver's probe get called at all; simplebus is the bus your driver registers with via `DRIVER_MODULE(mydrv, simplebus, ...)`.

Its second job is to translate child addresses into CPU physical addresses. The parent node's `ranges` property encodes how the bus-local addresses that appear in children's `reg` properties map to CPU physical addresses. Simplebus reads `ranges` in `simplebus_fill_ranges()` and applies it when setting up each child's resource list, so by the time your driver asks for its memory resource, the region is already in CPU physical space.

The central probe code that decides whether simplebus should attach to a given node sits near the top of `/usr/src/sys/dev/fdt/simplebus.c`. Here it is, stripped of comments for brevity:

```
if (!ofw_bus_status_okay(dev))
    return (ENXIO);

if (ofw_bus_is_compatible(dev, "syscon") ||
    ofw_bus_is_compatible(dev, "simple-mfd"))
    return (ENXIO);

if (!(ofw_bus_is_compatible(dev, "simple-bus") &&
    ofw_bus_has_prop(dev, "ranges") &&
    (ofw_bus_get_type(dev) == NULL ||
    strcmp(ofw_bus_get_type(dev), "soc") != 0)))
    return (ENXIO);

device_set_desc(dev, "Flattened device tree simple bus");
return (BUS_PROBE_GENERIC);
```

That snippet is a compact exemplar of the entire probe style. Test status, reject the known exceptions, confirm the node looks like a simple bus, describe the device, and return a probe confidence. Every FDT-aware probe in the tree follows some variation of this shape.

Simplebus registers itself with two parent buses. On the primary ofw root, it registers via `EARLY_DRIVER_MODULE(simplebus, ofwbus, ...)`; and recursively, on itself, via `EARLY_DRIVER_MODULE(simplebus, simplebus, ...)`. The recursion is how nested simple-bus nodes get enumerated: a simplebus parent that encounters a child whose compatible is "simple-bus" attaches another simplebus instance to it, which then enumerates *its* children.

For most driver work you do not need to know more about simplebus than that it exists and that you register with it. Your driver's module registration will read `DRIVER_MODULE(mydrv, simplebus, mydrv_driver, 0, 0);` and everything downstream will happen automatically.

32.6.5 Mapping the Pieces to a Probe Call

To put the moving parts together, let us trace what happens from the DTB being loaded to your driver's probe being called.

1. The loader hands the kernel a DTB.
2. The kernel's early arm64 code parses the DTB to find memory and CPU information.
3. The `ofwbus0` pseudo-device attaches to the tree root.
4. `ofwbus0` creates a `device_t` for the `/soc` node (or whichever node has `compatible = "simple-bus"`) and dispatches the usual newbus probe loop.
5. The simplebus driver's probe runs, returns `BUS_PROBE_GENERIC`, and is picked.
6. Simplebus's attach walks the children of the `/soc` node and creates a `device_t` for each child. Each child's resource list is populated from its reg and interrupts properties, translated through the parent's ranges.
7. For each child, the newbus probe loop runs. Every driver registered to simplebus gets a chance to probe.
8. Your driver's probe is called. It calls `ofw_bus_status_okay()`, `ofw_bus_search_compatible()`, and (if it matches) returns `BUS_PROBE_DEFAULT`.
9. If your driver wins the probe contest for this node, its attach is called. At that point the `device_t` has a resource list already populated with the node's memory and interrupt information.
10. Your driver calls `bus_alloc_resource_any()` for its memory region and for its interrupt, sets up an interrupt handler if it has one, maps the memory, initialises the hardware, and returns 0 to indicate success.

From the driver author's perspective the first six steps are machinery; steps 7 through 10 are the code you write. The chapter will now zoom in on those four steps.

32.6.6 Registering a Driver with `ofw_bus`

When your driver registers with simplebus, it is implicitly opting into the OFW dispatch. The module registration line is:

```
DRIVER_MODULE(mydrv, simplebus, mydrv_driver, 0, 0);
```

That tells newbus: *attach the driver described by `mydrv_driver` as a child of `simplebus`.* Your `device_method_t` array must supply at minimum a `device_probe` and a `device_attach` method. If you have a detach, add `device_detach`. If your driver also implements OFW interface methods (rarely needed at the leaf level), add those too.

On some platforms, and for drivers that want to attach both to simplebus and to the `ofwbus` root (in case there is no simplebus between them and the root), it is common to add a second registration:

```
DRIVER_MODULE(mydrv, ofwbus, mydrv_driver, 0, 0);
```

This is what `gpioled_fdt.c` does, for example. It covers platforms where the `gpio-leds` node sits directly under the root rather than under a `simple-bus`.

32.6.7 Writing a Compatibility Table

A driver that supports more than one variant of a chip typically declares a table of compatible strings:

```
static const struct ofw_compat_data compat_data[] = {
    { "brcm,bcm2711-gpio", 1 },
    { "brcm,bcm2835-gpio", 2 },
    { NULL, 0 }
};
```

Then in `probe`:

```
static int
mydrv_probe(device_t dev)
{
    if (!ofw_bus_status_okay(dev))
        return (ENXIO);

    if (ofw_bus_search_compatible(dev, compat_data) -> ocd_str == NULL)
        return (ENXIO);

    device_set_desc(dev, "My FDT-Aware Driver");
    return (BUS_PROBE_DEFAULT);
}
```

And in `attach`, the matched entry is available for re-lookup:

```
static int
mydrv_attach(device_t dev)
{
    const struct ofw_compat_data *match;
    ...
    match = ofw_bus_search_compatible(dev, compat_data);
    if (match == NULL || match->ocd_str == NULL)
        return (ENXIO);

    sc->variant = match->ocd_data; /* 1 for BCM2711, 2 for BCM2835 */
    ...
}
```

The `ocd_data` field is the cookie you defined in the table. It is a plain `uintptr_t`, so you can use it as an integer discriminator, a pointer to a per-variant structure, or whatever fits your driver's needs.

32.6.8 Reading Properties

Once you have a `device_t`, reading its node's properties is straightforward. A typical pattern:

```
phandle_t node = ofw_bus_get_node(dev);
uint32_t val;

if (OF_getencprop(node, "clock-frequency", &val, sizeof(val)) <= 0) {
    device_printf(dev, "missing clock-frequency\n");
    return (ENXIO);
}
```

The helpers are `OF_getencprop` for integer properties (with endianness handled), `OF_getprop` for raw buffers, `OF_getprop_alloc` for strings of unknown length. For boolean properties (ones whose presence is the signal and whose value is empty), `OF_hasprop` is the idiom:

```
bool want_rts = OF_hasprop(node, "uart-has-rtscs");
```

For list properties, `OF_getprop_alloc` or the fixed-buffer variants let you pull the full list and iterate over it.

32.6.9 Acquiring Resources

Memory and interrupt resources come through the standard `bus_alloc_resource_any()` calls you already know:

```
sc->mem_rid = 0;
sc->mem_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
    &sc->mem_rid, RF_ACTIVE);
if (sc->mem_res == NULL) {
    device_printf(dev, "cannot allocate memory\n");
    return (ENXIO);
}

sc->irq_rid = 0;
sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ,
    &sc->irq_rid, RF_ACTIVE | RF_SHAREABLE);
```

This is possible because `simplebus` has already read your node's `reg` and `interrupts` properties, translated them through the parent's ranges, and stored them in the resource list. The indices 0, 1, 2 refer to the first, second, and third entries of the respective list. A device with multiple `reg` regions will have multiple memory resources at `rids` 0, 1, 2, and so on.

For anything beyond plain memory and interrupts, you reach into the peripheral frameworks.

32.6.10 Peripheral Frameworks: Clock, Regulator, Reset, Pinctrl, GPIO

Embedded peripherals usually need more than just a memory region. They need a clock turned on, a regulator enabled, a reset line de-asserted, perhaps pins multiplexed, and sometimes a GPIO to drive a chip-select or an enable. FreeBSD provides a coherent set of frameworks for each.

Clock framework. Declared in `/usr/src/sys/dev/extres/clock/clock.h`. A consumer calls `clock_get_by_ofw_index(dev, node, idx, &clk)` to acquire a handle to the N-th clock listed in the node's `clocks` property, or `clock_get_by_ofw_name(dev, node, "fck", &clk)` to acquire the clock whose `clock-names` entry is "fck". With a handle in hand, the consumer calls `clock_enable(clk)` to turn it on, `clock_get_freq(clk, &freq)` to ask its rate, and `clock_disable(clk)` to turn it off on shutdown.

Regulator framework. Declared in `/usr/src/sys/dev/extres/regulator/regulator.h`. `regulator_get_by_ofw_property(dev, node, "vdd-supply", &reg)` fetches a regulator by the named property; `regulator_enable(reg)` enables it; `regulator_disable(reg)` disables it.

Hardware-reset framework. Declared in `/usr/src/sys/dev/extres/hwreset/hwreset.h`. `hwreset_get_by_ofw_name(dev, node, "main", &rst)` fetches a reset line; `hwreset_deassert(rst)` brings the peripheral out of reset; `hwreset_assert(rst)` puts it back.

Pin control framework. Declared in `/usr/src/sys/dev/fdt/fdt_pinctrl.h`. `fdt_pinctrl_configure_by_name(dev, "default")` applies the pin configuration associated with the `pinctrl-names = "default"` slot of the node. Most drivers that need pin control simply call this once from attach.

GPIO framework. The consumer side is declared in `/usr/src/sys/dev/gpio/gpiobusvar.h`. `gpio_pin_get_by_ofw_idx(dev, node, idx, &pin)` fetches the N-th GPIO listed in the node's `gpios` property. `gpio_pin_setflags(pin, GPIO_PIN_OUTPUT)` sets its direction. `gpio_pin_set_active(pin, value)` drives its level. `gpio_pin_release(pin)` gives it back.

These frameworks are the reason embedded drivers in FreeBSD are often shorter than their Linux counterparts. You do not have to write the clock tree, the regulator logic, or the GPIO controller: you consume them through a uniform consumer API, and the provider drivers are someone else's problem. The worked example in Section 7 uses the GPIO consumer API end to end.

32.6.11 Interrupt Routing: A Quick Look at interrupt-parent

Interrupts on FDT platforms use a chained lookup scheme. A node's `interrupts` property gives the raw interrupt specifier, and the node's `interrupt-parent` property (or the nearest ancestor's) names the controller that should interpret it. That controller, in turn, may be a child of another controller (a secondary GIC redistributor, a nested PLIC, an I/O APIC-like bridge on some SoCs), which further routes the interrupt upward until it reaches a top-level controller bound to a real CPU vector.

For a driver author, you do not usually have to think about this chain. The kernel's interrupt resource already lives in your resource list as a cookie that the interrupt controller knows how to interpret, and `bus_setup_intr()` hands the cookie back to the controller when you ask for an IRQ. What matters is that your node has the right `interrupts = <...>`; for its immediate interrupt parent, and that the tree's `interrupt-parent` or `interrupts-extended` chain reaches a real controller. When it does not, your interrupt will be silently dropped at boot.

The internals live in `/usr/src/sys/dev/ofw/ofw_bus_subr.c`, with `ofw_bus_lookup_imap()`, `ofw_bus_setup_iinfo()`, and related helpers. You will probably never call them directly unless you are writing a bus driver.

32.6.12 A Brief Look at Overlays

We have mentioned overlays several times. The short version is that an overlay is a small DTB fragment that references nodes in the base tree by label (for example, `&i2c0` or `&gpio0`) and adds or modifies properties or children. The loader merges overlays into the base blob before the kernel sees it. We will return to overlays in Section 5 and use them in the worked example in Section 7; for now just note that FreeBSD supports them through the `fdt_overlays` loader tunable and the files under `/boot/dtb/overlays/`.

32.6.13 ACPI vs FDT on arm64

The arm64 port of FreeBSD supports both FDT and ACPI as discovery mechanisms. Which path the kernel takes is decided during early boot by looking at what the firmware provided. If a DTB was supplied and the top-level `compatible` does not suggest an ACPI path, the kernel attaches the FDT bus. If an ACPI RSDP was supplied and the firmware indicates SBSA compliance, the kernel attaches the ACPI bus. The relevant code is in `/usr/src/sys/arm64/arm64/nexus.c`, which handles both paths; the variable `arm64_bus_method` records which one was chosen.

The practical consequence for driver authors is that a driver written for both mechanisms has to attach to both buses. Drivers that only care about FDT (the majority of small embedded drivers) register with `simplebus` only. Drivers that serve generic hardware that can show up on either ARM servers (ACPI) or ARM embedded boards (FDT) register with both. The `ahci_generic` driver at `/usr/src/sys/dev/ahci/ahci_generic.c` is one such dual-supporting driver; its source is worth reading when you eventually need to write one. For most of this chapter we will stay on the pure FDT side.

32.6.14 Wrapping Up This Section

Section 3 gave you the map of FreeBSD's FDT support. You now know where the core code lives, which helpers to use for which job, and how the pieces connect: `fdt(4)` parses the tree, `OF_*` primitives read properties, `ofw_bus_*` helpers wrap the primitives into idiomatic checks, `simplebus` enumerates the children, and the peripheral frameworks hand you clocks, resets, regulators, pins, and GPIOs.

In the next section we will take those pieces and write a real driver with them. Section 4 walks through the full skeleton of an FDT-aware driver from top to bottom, in enough detail that you could copy the structure into your own project and start filling in the hardware-specific logic.

32.7 Section 4: Writing a Driver for an FDT-Based System

This section walks through the complete shape of an FDT-aware FreeBSD driver. The shape is simple; the reason to lay it out in full is that once you have seen it, every FDT driver in the tree becomes legible. You will start noticing the same patterns in hundreds of files under `/usr/src/sys/dev/` and `/usr/src/sys/arm/`, and each of those drivers becomes one more template you can adapt.

We will build the skeleton in six passes. First the header includes. Then the softc. Then the compatibility table. Then `probe()`. Then `attach()`. Then `detach()` and the module registration. Each pass is short; by the end you will have a complete, compilable minimal driver that prints a message when the kernel matches it to a Device Tree node.

32.7.1 The Header Includes

FDT drivers lean on a handful of headers from the `ofw` and `fdt` directories on top of the usual kernel and bus headers. A typical set:

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/bus.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/rman.h>
#include <sys/resource.h>
#include <sys/malloc.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/ofw/openfirm.h>
#include <dev/ofw/ofw_bus.h>
#include <dev/ofw/ofw_bus_subr.h>
```

Nothing exotic. The three `ofw` headers bring in the property readers and the compatibility helpers. If your driver is a consumer of GPIOs, clocks, regulators, or `hwreset`, add their headers as well:

```
#include <dev/gpio/gpiobusvar.h>
#include <dev/extres/clock/clock.h>
#include <dev/extres/regulator/regulator.h>
#include <dev/extres/hwreset/hwreset.h>
```

`Pinctrl`:

```
#include <dev/fdt/fdt_pinctrl.h>
```

And `simplebus.h` if your driver actually extends `simplebus` rather than just binding to it as a leaf:

```
#include <dev/fdt/simplebus.h>
```

Most leaf drivers do not need the simplebus header. Bring it in only when you are implementing a bus-like driver that enumerates children.

32.7.2 The Softc

A softc for an FDT-aware driver is a plain softc with a few additional fields to track resources and references you acquired through the OFW helpers:

```
struct mydrv_softc {
    device_t      dev;
    struct resource *mem_res;  /* memory region (bus_alloc_resource) */
    int           mem_rid;
    struct resource *irq_res;  /* interrupt resource, if any */
    int           irq_rid;
    void          *irq_cookie;

    /* FDT-specific state. */
    phandle_t      node;
    uintptr_t      variant;    /* matched ocd_data */

    /* Example: acquired GPIO pin for driving a chip-select. */
    gpio_pin_t     cs_pin;

    /* Example: acquired clock handle. */
    clk_t          clk;

    /* Usual driver state: mutex, buffers, etc. */
    struct mtx      sc_mtx;
};
```

The fields that differ from a PCI or ISA driver are `node`, `variant`, and the consumer handles (`cs_pin`, `clk`, and others). Everything else is standard.

32.7.3 The Compatibility Table

The compatibility table is the driver's claim on a set of Device Tree nodes. It is conventionally declared file-scope and immutable:

```
static const struct ofw_compat_data mydrv_compat_data[] = {
    { "acme,trivial-timer",    1 },
    { "acme,fancy-timer",     2 },
};
```

```
    { NULL,                                0 }  
};
```

The second field, `ocd_data`, is a `uintptr_t` cookie. I like to use it as an integer discriminator (1 for the basic variant, 2 for the fancy variant); you can also use it as a pointer to a per-variant configuration structure. The table ends with a sentinel entry whose first field is `NULL`.

32.7.4 The Probe Routine

A canonical probe for an FDT-aware driver:

```
static int  
mydrv_probe(device_t dev)  
{  
  
    if (!ofw_bus_status_okay(dev))  
        return (ENXIO);  
  
    if (ofw_bus_search_compatible(dev, mydrv_compat_data)->ocd_str == NULL)  
        return (ENXIO);  
  
    device_set_desc(dev, "ACME Trivial Timer");  
    return (BUS_PROBE_DEFAULT);  
}
```

Three lines of logic. First, bail out if the node is disabled. Second, bail out if none of our compatible strings match. Third, set a descriptive name and return `BUS_PROBE_DEFAULT`. The exact return value matters when more than one driver might claim the same node; a more specialised driver can return `BUS_PROBE_SPECIFIC` to outrank a generic one, and a generic fallback can return `BUS_PROBE_GENERIC` to let anything better win. For most drivers, `BUS_PROBE_DEFAULT` is correct.

The `ofw_bus_search_compatible(dev, compat_data)` call returns a pointer to the matching entry, or to the sentinel entry if no match was found. The sentinel's `ocd_str` is `NULL`, so testing for `NULL` is the idiomatic way to say *we did not match anything*. Some drivers alternatively save the returned pointer into a local variable and re-use it; we will do that in `attach`.

32.7.5 The Attach Routine

Attach is where the real work happens. A canonical FDT attach:

```
static int  
mydrv_attach(device_t dev)  
{
```

```
struct mydrv_softc *sc;
const struct ofw_compat_data *match;
phandle_t node;
uint32_t freq;
int err;

sc = device_get_softc(dev);
sc->dev = dev;
sc->node = ofw_bus_get_node(dev);
node = sc->node;

/* Remember which variant we matched. */
match = ofw_bus_search_compatible(dev, mydrv_compat_data);
if (match == NULL || match->oed_str == NULL)
    return (ENXIO);
sc->variant = match->oed_data;

/* Pull any required properties. */
if (OF_getencprop(node, "clock-frequency", &freq, sizeof(freq)) <= 0) {
    device_printf(dev, "missing clock-frequency property\n");
    return (ENXIO);
}

/* Allocate memory and interrupt resources. */
sc->mem_rid = 0;
sc->mem_res = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
    &sc->mem_rid, RF_ACTIVE);
if (sc->mem_res == NULL) {
    device_printf(dev, "cannot allocate memory resource\n");
    err = ENXIO;
    goto fail;
}

sc->irq_rid = 0;
sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ,
    &sc->irq_rid, RF_ACTIVE | RF_SHAREABLE);
if (sc->irq_res == NULL) {
    device_printf(dev, "cannot allocate IRQ resource\n");
    err = ENXIO;
    goto fail;
}

/* Enable clock, if one is described. */
if (clk_get_by_ofw_index(dev, node, 0, &sc->clk) == 0) {
```

```

    err = clk_enable(sc->clk);
    if (err != 0) {
        device_printf(dev, "could not enable clock: %d\n", err);
        goto fail;
    }
}

/* Apply pinctrl default, if any. */
(void)fdt_pinctrl_configure_by_name(dev, "default");

/* Initialise locks and driver state. */
mtx_init(&sc->sc_mtx, device_get_nameunit(dev), NULL, MTX_DEF);

/* Hook up the interrupt handler. */
err = bus_setup_intr(dev, sc->irq_res,
    INTR_TYPE_MISC | INTR_MPSAFE, NULL, mydrv_intr, sc,
    &sc->irq_cookie);
if (err != 0) {
    device_printf(dev, "could not setup interrupt: %d\n", err);
    goto fail;
}

device_printf(dev, "variant %lu at %s, clock %u Hz\n",
    (unsigned long)sc->variant, device_get_nameunit(dev), freq);

return (0);

fail:
    mydrv_detach(dev);
    return (err);
}

```

That is a lot to unpack. Let us walk it.

1. `device_get_softc(dev)` returns the driver's `softc`, which FreeBSD allocated on your behalf when the driver attached.
2. `ofw_bus_get_node(dev)` returns the phandle for our DT node. We save it on the `softc` because `detach` will also want it.
3. We re-run the `compat` search and record which variant matched.
4. We read a scalar integer property with `OF_getencprop`. The call returns the number of bytes read, -1 on absence, or some smaller number if the property is too short. We treat anything non-positive as failure.
5. We allocate our memory and IRQ resources. Simplebus has already populated the resource list from the node's `reg` and `interrupts`, so indices 0 and 0 are correct.
6. We try to acquire a clock. This driver treats the clock as optional, so a missing `clocks` property is not fatal. If one is present, we enable it.

7. We apply default pin control.
8. We initialise a driver mutex.
9. We set up the interrupt handler, which will dispatch to `mydrv_intr`.
10. We log a message.
11. On any error, we goto a single cleanup path that calls `detach`.

The single cleanup path deserves its own discussion. It is an embedded-friendly pattern because embedded drivers acquire many resources from many different frameworks, and attempting to write out cleanup code at every failure point rapidly becomes unreadable. Instead, write a `detach` that handles partially-initialised softc state, and call it from the failure path. This is the pattern the FreeBSD tree uses consistently; your driver will be easier to read if you follow it.

32.7.6 The Detach Routine

A compliant `detach` tears down everything `attach` might have set up, and does so in the reverse order:

```
static int
mydrv_detach(device_t dev)
{
    struct mydrv_softc *sc;

    sc = device_get_softc(dev);

    if (sc->irq_cookie != NULL) {
        bus_tearardown_intr(dev, sc->irq_res, sc->irq_cookie);
        sc->irq_cookie = NULL;
    }

    if (sc->irq_res != NULL) {
        bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid,
            sc->irq_res);
        sc->irq_res = NULL;
    }

    if (sc->mem_res != NULL) {
        bus_release_resource(dev, SYS_RES_MEMORY, sc->mem_rid,
            sc->mem_res);
        sc->mem_res = NULL;
    }

    if (sc->clk != NULL) {
        clk_disable(sc->clk);
        clk_release(sc->clk);
        sc->clk = NULL;
    }
}
```

```
if (mtx_initialized(&sc->sc_mtx))
    mtx_destroy(&sc->sc_mtx);

return (0);
}
```

Two things to notice. First, every teardown step is guarded by a check on whether the resource was actually acquired. The check lets detach run correctly from either a normal unload path (all resources were acquired) or a failed-attach path (only some were). Second, the order is the reverse of acquisition. Interrupt handler off before interrupt resource released. Clock disabled before released. Mutex destroyed last.

32.7.7 Interrupt Handler

The interrupt handler is a normal FreeBSD interrupt routine. Nothing is FDT-specific about it:

```
static void
mydrv_intr(void *arg)
{
    struct mydrv_softc *sc = arg;

    mtx_lock(&sc->sc_mtx);
    /* Handle the hardware event. */
    mtx_unlock(&sc->sc_mtx);
}
```

What *is* FDT-specific is the way the interrupt resource was set up in attach. The resource came from the node's `interrupts` property via `simplebus`, which translated it through the interrupt-parent chain so that by the time your driver called `bus_alloc_resource_any(SYS_RES_IRQ, ...)`, the resource already represented a real hardware interrupt at a real controller.

32.7.8 Module Registration

The driver's module registration ties the device methods to the driver and registers the driver with a parent bus:

```
static device_method_t mydrv_methods[] = {
    DEVMETHOD(device_probe, mydrv_probe),
    DEVMETHOD(device_attach, mydrv_attach),
    DEVMETHOD(device_detach, mydrv_detach),

    DEVMETHOD_END
};
```

```
static driver_t mydrv_driver = {
    "mydrv",
    mydrv_methods,
    sizeof(struct mydrv_softc)
};

DRIVER_MODULE(mydrv, simplebus, mydrv_driver, 0, 0);
DRIVER_MODULE(mydrv, ofwbus, mydrv_driver, 0, 0);
MODULE_VERSION(mydrv, 1);
SIMPLEBUS_PNP_INFO(mydrv_compat_data);
```

The two `DRIVER_MODULE` calls register the driver with both `simplebus` and the `ofwbus` root. The latter covers platforms or boards whose node sits directly under the root rather than under an explicit `simple-bus`. `MODULE_VERSION` declares the driver's version for `kldstat` and dependency tracking. `SIMPLEBUS_PNP_INFO` emits a `pnpinfo` descriptor that `kldstat -v` can print; it is a small courtesy to the operator but the driver will work without it.

32.7.9 The Full Skeleton Assembled

Here is the skeleton assembled into a single minimal file that compiles as a kernel module. It does nothing useful; it only demonstrates attachment and logs a message when matched:

```
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/bus.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/rman.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/ofw/openfirm.h>
#include <dev/ofw/ofw_bus.h>
#include <dev/ofw/ofw_bus_subr.h>

struct fdthello_softc {
    device_t dev;
    phandle_t node;
};

static const struct ofw_compat_data compat_data[] = {
    { "freebsd,fdthello", 1 },
```

```
    { NULL,                0 }
};

static int
fdthello_probe(device_t dev)
{
    if (!ofw_bus_status_okay(dev))
        return (ENXIO);

    if (ofw_bus_search_compatible(dev, compat_data)->ocd_str == NULL)
        return (ENXIO);

    device_set_desc(dev, "FDT Hello Example");
    return (BUS_PROBE_DEFAULT);
}

static int
fdthello_attach(device_t dev)
{
    struct fdthello_softc *sc;

    sc = device_get_softc(dev);
    sc->dev = dev;
    sc->node = ofw_bus_get_node(dev);

    device_printf(dev, "attached, node phandle 0x%x\n", sc->node);
    return (0);
}

static int
fdthello_detach(device_t dev)
{
    device_printf(dev, "detached\n");
    return (0);
}

static device_method_t fdthello_methods[] = {
    DEVMETHOD(device_probe, fdthello_probe),
    DEVMETHOD(device_attach, fdthello_attach),
    DEVMETHOD(device_detach, fdthello_detach),

    DEVMETHOD_END
};
```

```
static driver_t fdthello_driver = {
    "fdthello",
    fdthello_methods,
    sizeof(struct fdthello_softc)
};

DRIVER_MODULE(fdthello, simplebus, fdthello_driver, 0, 0);
DRIVER_MODULE(fdthello, ofwbus, fdthello_driver, 0, 0);
MODULE_VERSION(fdthello, 1);
```

And its matching Makefile:

```
KMOD= fdthello
SRCS= fdthello.c

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

You will find both under `examples/part-07/ch32-fdt-embedded/lab01-fdthello/`. Build them on any FreeBSD system that has the kernel sources installed. The module will only *attach* on a platform that has a Device Tree containing a node with `compatible = "freebsd,fdthello"`, but it will at least compile and load cleanly even on amd64.

32.7.10 What the Kernel Does Next

When you load that module on an arm64 system whose DTB contains a matching node, the sequence is:

1. The module registers `fdthello_driver` with `simplebus` and `ofwbus`.
2. Newbus iterates over every existing device that has `simplebus` or `ofwbus` as a parent and calls the newly registered driver's probe.
3. For each device whose node has `compatible = "freebsd,fdthello"`, the probe returns `BUS_PROBE_DEFAULT`. If no other driver is already attached (or if we outrank it), our attach is called.
4. Attach logs a message; the device is now attached.

When you unload the module, `detach` runs for each attached instance, then the module is unloaded. In the simple case, `kldunload fdthello` cleans up fully.

32.7.11 Checking Your Work

Three quick ways to tell whether your driver matched:

1. **dmesg** should show a line like:

```
fdthello0: <FDT Hello Example> on simplebus0
fdthello0: attached, node phandle 0x8f
```

2. **devinfo -r** should show your device attached somewhere under simplebus.
3. **sysctl dev.fdt.hello.0.parent** should confirm the parent bus.

If your module loads but no devices attach, the probe did not match. The most common causes are a typo in the compatible string, a missing or disabled node, or a node that sits somewhere the simplebus/ofwbus drivers did not reach. Section 6 goes into the debugging in detail.

32.7.12 A Note on Naming and Vendor Prefixes

Real FreeBSD drivers match on compatibility strings like "brcm,bcm2711-gpio", "allwinner,sun50i-a64-mmc", or "st,stm32-uart". The prefix before the comma is the vendor or community name; the rest is the specific chip or family. The convention is widely respected both in upstream Linux and in FreeBSD. When inventing a new compatible for an experiment (as we did above with "freebsd,fdthello"), follow the same vendor-slash-identifier form. Do not invent one-word compatibles; they collide with existing ones and confuse future readers.

32.7.13 Wrapping Up This Section

Section 4 walked through the shape of an FDT driver. You have seen the headers to include, the softc to define, the compatibility table to declare, the probe and attach and detach routines to write, and the module registration that ties it all together. You have a minimal, complete driver that you could compile and load right now. It does not do much, but its structure is the same structure every FDT-aware driver in FreeBSD uses.

In the next section we turn to the other half of the story. A driver is no use without a Device Tree node to match. Section 5 teaches you how to build and modify .dtb files, how FreeBSD's overlay system works, and how to add your own node to an existing board description so that your driver has something to attach to.

32.8 5. Creating and Modifying Device Tree Blobs

You now have a driver that waits patiently for a Device Tree node with `compatible = "freebsd,fdthello"`. Nothing in the running system provides such a node, so nothing probes. In this section we learn how to change that. We will look at the source-to-binary pipeline, at the overlay mechanism that lets us add nodes without rebuilding the whole .dtb, and at the loader tunables that decide which blob the kernel actually sees at boot time.

Creating Device Tree blobs is not a rite of passage for experienced kernel hackers. It is an ordinary editing task. The file is text, the compiler is standard, and the output is a small binary that lives in /boot. What makes it feel unfamiliar is only that very few hobbyist projects encounter it. On embedded FreeBSD it is routine.

32.8.1 The Source-to-Binary Pipeline

Every .dtb that boots a FreeBSD system started life as one or more source files. The pipeline is simple:

```
.dtsi  .dtsi  .dtsi
  \   |   /
  \   |   /
    .dts (top-level source)
      |
      | cpp (C preprocessor)
      v
    .dts (preprocessed)
      |
      | dtc (device tree compiler)
      v
    .dtb (binary blob)
```

The C preprocessor runs first. It expands `#include` directives, macro definitions from header files like `dt-bindings/gpio/gpio.h`, and arithmetic in property expressions. The `dtc` compiler then turns the preprocessed source into the compact flattened format the kernel can parse.

Overlay files go through the same pipeline, except their source file carries the extension `.dtsi` and their output carries `.dtbo`. The only real syntactic difference is the magic incantation at the top of overlay source files, which we look at shortly.

FreeBSD's build system wraps this pipeline in two small shell scripts you can study at `/usr/src/sys/tools/fdt/make_dtb.sh` and `/usr/src/sys/tools/fdt/make_dtbo.sh`. They chain `cpp` and `dtc` together, add the right include paths for the kernel's own `dt-bindings` headers, and write the resulting blobs into the build tree. When you make `buildkernel` for an embedded platform, these scripts are what produce the `.dtb` files that end up in `/boot/dtb/` on the installed system.

32.8.2 Installing the Tools

On FreeBSD, `dtc` is available as a port:

```
# pkg install dtc
```

The package installs the `dtc` binary together with its companion `fdtdump`, which prints the decoded structure of an existing blob. If you plan to do any overlay work, install both. The FreeBSD base tree also ships a copy of `dtc` under `/usr/src/sys/contrib/device-tree/`, but the port version is easier to reach from userspace.

To check the version:

```
$ dtc --version
Version: DTC 1.7.0
```

Any version from 1.6 onwards supports overlays. Earlier versions lack the `/plugin/;` directive, so if you inherit an old build environment, upgrade before going further.

32.8.3 Writing a Standalone .dts File

We will start with a complete, standalone Device Tree source file so the syntax has time to settle before we add overlay complications. Create a file called `tiny.dts` somewhere outside the kernel tree:

```
/dts-v1/;

/ {
    compatible = "example, tiny-board";
    model = "Tiny Example Board";
    #address-cells = <1>;
    #size-cells = <1>;

    chosen {
        bootargs = "-v";
    };

    cpus {
        #address-cells = <1>;
        #size-cells = <0>;

        cpu0: cpu@0 {
            device_type = "cpu";
            reg = <0>;
            compatible = "arm,cortex-a53";
        };
    };

    memory@0 {
        device_type = "memory";
        reg = <0x00000000 0x10000000>;
    };

    soc {
        compatible = "simple-bus";
        #address-cells = <1>;
        #size-cells = <1>;
        ranges;

        hello0: hello@10000 {
            compatible = "freebsd,fdthello";
            reg = <0x10000 0x100>;
            status = "okay";
        };
    };
};
```

```
};
```

The first line, `/dts-v1/;`, tells `dtc` which version of the source format we are using. Version 1 is the only version in current use, but the directive is still required.

After that, we have the root node, containing a handful of expected children. The `cpus` node describes the processor topology, the `memory@0` node declares a 256 MB region of DRAM at physical address zero, and the `soc` node groups on-chip peripherals under a `simple-bus`. Inside `soc`, our `hello@10000` node provides the Device Tree match for the `fdthello` driver we wrote in Section 4.

A few things are worth noticing here even in this small file.

First, `#address-cells` and `#size-cells` reappear inside the `soc` node. The values a parent sets apply only to that parent's direct children, so every level of the tree that cares about addresses has to declare them. Here the `soc` is using one cell for addresses and one for sizes, which is why `reg = <0x10000 0x100>;` inside `hello@10000` lists exactly two `u32` values.

Second, the `ranges` property on the `soc` node is empty. An empty `ranges` means “addresses inside this bus match addresses outside it one to one.” If the `soc` were, say, mapped at a different base address than its children claim, you would use a longer `ranges` list to express the translation.

Third, `status = "okay"` is explicit here. Without it, every tree implicitly defaults to `okay`, but many board files set `status = "disabled"` on optional peripherals and expect overlays or board-specific files to flip them on. Get into the habit of checking this property whenever a driver mysteriously fails to probe.

32.8.4 Compiling a .dts File

Compile the tiny example:

```
$ dtc -I dts -O dtb -o tiny.dtb tiny.dts
```

The `-I dts` flag tells `dtc` the input is textual source, and `-O dtb` requests a binary blob output. A successful compile prints nothing. A syntax error tells you the file and line.

You can verify the result with `fdtdump`:

```
$ fdtdump tiny.dtb | head -30
**** fdtdump is a low-level debugging tool, not meant for general use. ****
    Use the fdtput/fdtget/dtc tools to manipulate .dtb files.

/dts-v1/;
// magic:                0xd00dfeed
// totalsize:            0x214 (532)
// off_dt_struct:        0x38
// off_dt_strings:       0x184
// off_mem_rsvmap:       0x28
// version:              17
```

```
// last_comp_version:    16
// boot_cpuid_phys:      0x0
// boot_cpuid_phys:      0x0
// size_dt_strings:      0x90
// size_dt_strings:      0x90
// size_dt_structs:      0x14c
// size_dt_structs:      0x14c

/ {
    compatible = "example, tiny-board";
    model = "Tiny Example Board";
    ...
}
```

That round-trip confirms the blob is valid and parseable. You could now drop it into a QEMU run with `-dtb tiny.dtb` and the kernel would attempt to boot against it. In practice you rarely hand-write a complete `.dts` for a real board. You start with the vendor's own source file (for instance `/usr/src/sys/contrib/device-tree/src/arm64/broadcom/bcm2711-rpi-4-b.dts` for the Raspberry Pi 4) and modify a subset of nodes with an overlay.

32.8.5 The Role of `.dtsi` Include Files

The `.dtsi` extension is used for Device Tree *includes*. These files contain tree fragments that are meant to be pulled into another `.dts` or `.dtsi`. The compiler treats them identically to `.dts` files, but the filename suffix tells other humans (and the build system) that the file is not standalone.

A common pattern in modern SoC descriptions is:

```
arm/bcm283x.dtsi      <- SoC definition
arm/bcm2710.dtsi      <- Family refinement (Pi 3 lineage)
arm/bcm2710-rpi-3-b.dts <- Specific board top-level file, includes both
```

Each `.dtsi` adds and refines nodes. Labels declared in a lower file can be referenced from a higher file with the `&label` syntax to override properties without rewriting the node. This is the mechanism that makes it possible to support dozens of related boards from a handful of shared SoC descriptions.

32.8.6 Understanding Overlays

A full `.dts` for a real SBC like the Raspberry Pi 4 is dozens of kilobytes long. If you only want to enable SPI, or add a single GPIO-controlled peripheral, rebuilding the whole blob is wasteful and error-prone. The overlay mechanism exists exactly for this situation.

An overlay is a small, special `.dtb` that targets an existing tree. At load time, the FreeBSD loader merges the overlay into the base tree in memory, producing a combined view that the kernel sees as a single Device Tree. The base `.dtb` on disk is never modified. That means the same overlay can enable a feature across several systems with one copy on each.

The syntax of an overlay source file uses two magic directives at the top:

```
/dts-v1/;
/plugin/;
```

After those, the source refers to nodes in the base tree by label. The compiler records the references symbolically, and the loader resolves them at merge time against whatever labels the base tree actually exports. That is why the overlay can be written and compiled independently of the exact base tree it will later be merged with.

Here is a minimal overlay that attaches an `fdthello` node to an existing soc bus:

```
/dts-v1/;
/plugin/;

/ {
    compatible = "brcm,bcm2711";

    fragment@0 {
        target = <&soc>;
        __overlay__ {
            hello@20000 {
                compatible = "freebsd,fdthello";
                reg = <0x20000 0x100>;
                status = "okay";
            };
        };
    };
};
```

The outer `compatible` says this overlay is intended for a BCM2711 tree. The loader uses that string to refuse overlays that do not match the current board. Inside we see a single `fragment@0` node. Each fragment targets one existing node in the base tree through the `target` property. The content under `__overlay__` is the set of properties and children that get merged into that target.

In this example, we are adding a `hello@20000` child under whatever node `&soc` resolves to at merge time. The base tree on a Raspberry Pi 4 declares the `soc` label on the top-level SoC bus node, so after the merge the base soc will gain a new `hello@20000` child, and our driver's probe will fire.

You can also use overlays to *modify* existing nodes. If you set a property with the same name as an existing one, the overlay value replaces the original. If you add a new property, it simply appears. If you add a new child, it is grafted on. The mechanism is additive except for property value replacement.

32.8.7 Compiling and Deploying Overlays

Build the overlay with:

```
$ dtc -I dts -O dtb -@ -o fdthello.dtbo fdthello-overlay.dts
```

The `-@` flag tells the compiler to emit the symbolic label information needed at merge time. Without it, overlays that reference labels fail silently or produce unhelpful errors.

On a running FreeBSD system, overlays live under `/boot/dtb/overlays/`. The filename needs to end in `.dtbo` by convention. The loader looks in `/boot/dtb/overlays` by default; the path can be overridden through loader tunables if you want to stage overlays elsewhere.

To tell the loader which overlays to apply, add a line to `/boot/loader.conf`:

```
fdt_overlays="fdthello,sunxi-i2c1,spigen-rpi4"
```

The value is a comma-separated list of overlay basenames without the `.dtbo` extension. Order matters only when overlays interact with each other. On boot, the loader reads the list, loads each overlay, merges them into the base tree in sequence, and hands the combined blob to the kernel.

A good sanity check is to watch the loader output on a serial console or HDMI screen. When `fdt_overlays` is set, the loader prints a line like:

```
Loading DTB overlay 'fdthello' (0x1200 bytes)
```

If the file is missing or the target does not match, the loader prints a warning and continues. Your driver then fails to probe because the overlay never applied. Checking the loader's console output is the fastest way to catch this kind of failure.

32.8.8 A Walkthrough: Adding a Node to a Raspberry Pi 4 Tree

Let us put the machinery together in a realistic scenario. Imagine you are bringing up a custom daughterboard for the Raspberry Pi 4. It contains a single GPIO-controlled indicator LED on GPIO18 of the Pi's header. You want FreeBSD to drive the LED through your own `edled` driver (which we build in Section 7). You need a Device Tree node.

First, you look up what the Pi 4's base `.dtb` already declares. On a running Pi with FreeBSD installed, `ofwdump -ap | less` or `fdtdump /boot/dtb/broadcom/bcm2711-rpi-4-b.dtb | less` gives you the full tree. Your main interest is the `soc` and `gpio` nodes, where you see a label `gpio = <&gpio>;` exported from the GPIO controller.

Next, you write the overlay source:

```
/dts-v1/;
/plugin/;

/ {
    compatible = "brcm,bcm2711";
```

```
fragment@0 {
    target-path = "/soc";
    __overlay__ {
        edled@0: edled@0 {
            compatible = "example,edled";
            status = "okay";
            leds-gpios = <&gpio 18 0>;
            label = "daughter-indicator";
        };
    };
};
```

We use `target-path` instead of `target` here because the target is an existing path rather than a label. Both forms are valid; `target` takes a phandle reference, `target-path` takes a string.

The `leds-gpios` property is the conventional way to describe a GPIO reference in Device Tree. It is a phandle to the GPIO controller, followed by the GPIO number on that controller, followed by a flag word. Value 0 for the flag means active-high; 1 means active-low. Pinmux usually needs no explicit mention on the Pi because the Broadcom GPIO controller handles both direction and function through the same register set.

Compile and install the overlay:

```
$ dtc -I dts -O dtb -@ -o edled.dtbo edled-overlay.dts
$ sudo cp edled.dtbo /boot/dtb/overlays/
```

Add the overlay to the loader configuration:

```
# echo 'fdt_overlays="edled"' >> /boot/loader.conf
```

Reboot. On the way up, the loader prints its overlay-load line, the base DT gains the new `edled@0` node under `/soc`, the `edled` driver's probe fires, and the daughterboard LED comes up under software control.

32.8.9 Inspecting the Result

Once the kernel is running, three tools verify that everything landed where it should:

```
# ofwdump -p /soc/edled@0
```

prints the properties of the newly added node.

```
# sysctl dev.edled.0.%parent
```

confirms the driver attached and shows its parent bus.

```
# devinfo -r | less
```

displays the full device tree as FreeBSD sees it, with your driver in place.

If any of these disagree with the overlay content, Section 6 helps you diagnose the cause.

32.8.10 Troubleshooting Build Failures

Most DT build errors fall into a small number of categories.

Unresolved references. If the overlay refers to a label like `&gpio` that is not exported by the base tree, the loader prints `no symbol for <label>` and refuses to apply the overlay. Fix by using `target-path` with an absolute path instead, or by rebuilding the base `.dtb` with `-@` to include its symbols.

Syntax errors. These show up as `dtc` errors with a line number. Common culprits are missing semicolons at the end of property assignments, unbalanced braces, and property values that mix unit types (for example, a mix of angle-bracket integers and quoted strings on the same line).

Cell-count mismatches. If the parent declares `#address-cells = <2>` and a child's `reg` gives only one cell, the compiler tolerates it but the kernel parses the value wrong. `ofwdump -p node` and careful reading of the parent's cell counts usually reveal the mismatch.

Duplicate node names. Two nodes at the same level cannot share a name-plus-unit-address. The compiler flags this, but overlays that try to add a new node whose name collides with an existing one produce a cryptic merge failure at boot. Choose unique names or target a different path.

32.8.11 The Kernel's dtb Loading Process

For context, it helps to know what happens to the final merged blob after the loader hands it off.

On arm64 and several other platforms, the loader places the blob at a fixed physical address and passes the pointer to the kernel in its boot argument block. The earliest kernel code, in `/usr/src/sys/arm64/arm64/machdep.c`, validates the magic number and size, maps the blob into kernel virtual memory, and registers it with the FDT subsystem. By the time Newbus begins attaching devices, the blob is fully parsed and the OFW API can walk it.

On amd64 embedded systems (rare but they exist), the flow is similar: UEFI passes the blob through a configuration table, the loader discovers it, and the kernel consumes it through the same FDT API.

The blob is read-only from the kernel's perspective. You never modify it at runtime. If a property value needs to change, the right place to change it is in the source, not in a live tree.

32.8.12 Wrapping Up This Section

Section 5 taught you how to move between Device Tree source and Device Tree binary, how overlays target an existing tree, and how `fdt_overlays` wires the whole thing into the FreeBSD boot process. You can now write a `.dts`, compile it, place the result under `/boot/dtb/overlays/`, list it in `loader.conf`, and watch the kernel pick up your node. The driver you wrote in Section 4 now has something to attach to.

In Section 6 we turn the lens around and look at tools for inspecting what actually landed in the kernel. When things go wrong, as they will, good observation is the shortest path back to a working system.

32.9 6. Testing and Debugging FDT Drivers

Every driver you write will, at some point, fail to probe. The Device Tree will look right in the source, your compatibility string will read correctly, and `kldload` will complete without complaint, but `dmesg` will be silent. Debugging this class of failure is its own skill, and the sooner you build the habit the less time each problem will cost you.

This section covers the tools and techniques for inspecting the running Device Tree, for diagnosing probe failures, for observing attach behavior in detail, and for tracking down unload problems. Much of the material here is applicable to bus drivers, peripheral drivers, and pseudo-devices alike. The one thing that is truly FDT-specific is the set of tools for reading the tree itself.

32.9.1 The `ofwdump(8)` Tool

On a running FreeBSD system, `ofwdump` is your primary window into the Device Tree. It prints nodes and properties from the in-kernel tree, so what it shows is exactly what the drivers see during probe. If the tree is wrong in the kernel, it will be wrong in `ofwdump`, which saves you from compiling and booting again just to check an edit.

The simplest invocation prints the whole tree:

```
# ofwdump -a
```

Pipe through `less` on any non-trivial system; the output runs thousands of lines.

A more focused run dumps one node and its properties:

```
# ofwdump -p /soc/hello@10000
Node 0x123456: /soc/hello@10000
  compatible:  freebsd,fdthello
  reg:         00 01 00 00 00 00 01 00
  status:      okay
```

The `-p` flag prints properties alongside the node name. Integer values come out as byte strings because `ofwdump` cannot, in general, know how many cells a property is supposed to have. You interpret the bytes using the parent's `#address-cells` and `#size-cells`.

To read one specific property:

```
# ofwdump -P compatible /soc/hello@10000
```

Add `-R` to recurse into children of the given node. Add `-S` to print phandles and `-r` to print raw binary if you want to pipe the data into another tool.

Get comfortable with `ofwdump`. When someone says “check the tree,” this is the tool they mean.

32.9.2 Reading the Raw Blob Through sysctl

FreeBSD exposes the unmerged base blob through a sysctl:

```
# sysctl -b hw.fdt.dtb | fdt dump
```

The `-b` flag tells sysctl to print raw binary; piping into `fdt dump` decodes it. This is useful when you suspect an overlay has altered the tree and you want to compare the pre-merge blob with the post-merge view. `ofw dump` shows the post-merge view; `hw.fdt.dtb` shows the pre-merge base.

32.9.3 Confirming FDT Mode on arm64

FreeBSD does not expose a dedicated sysctl that says “you are running on FDT” or “you are running on ACPI.” The decision is made very early in boot by the kernel variable `arm64_bus_method`, and the easiest way to observe it from user space is by looking at the device tree dmesg prints during startup. A machine that chose the FDT path shows a root line like:

```
ofwbus0: <Open Firmware Device Tree>  
simplebus0: <Flattened device tree simple bus> on ofwbus0
```

followed by the rest of the FDT children. A machine that chose the ACPI path shows `acpi0: <...>` instead, and you will never see an `ofwbus0` line.

On a live system you can also run `devinfo -r` and look for `ofwbus0` in the hierarchy, or confirm that the sysctl `hw.fdt.dtb` is present. That sysctl is only registered when a DTB was parsed at boot, so its existence is itself a signal:

```
# sysctl -N hw.fdt.dtb 2>/dev/null && echo "FDT is active" || echo "ACPI or neither"
```

The `-N` flag asks sysctl only for the name, so it succeeds without printing the blob’s bytes.

On boards that support both mechanisms, the mechanism that chooses between them is the loader tunable `kern.cfg.order`. Setting `kern.cfg.order="fdt"` in `/boot/loader.conf` forces the kernel to try FDT first and fall back to ACPI only if no DTB is found; `kern.cfg.order="acpi"` does the opposite. On x86 platforms, `hint.acpi.0.disabled="1"` disables the ACPI attachment entirely and is sometimes useful when the firmware is misbehaving. Section 3 covered this duality in more detail; if you ever find yourself staring at an FDT driver that refuses to attach on an ARM server platform, one of the first things to verify is which bus method the kernel actually chose.

32.9.4 Debugging a Probe That Does Not Fire

The most common symptom is silence: the module loads, `kldstat` shows it, but no device attaches. The probe either never ran or returned `ENXIO`. Walk through the following checklist.

1. Is the node present in the kernel’s tree?

```
# ofwdump -p /soc/your-node
```

If the node is missing, your overlay did not apply. Review the loader's output at boot time. Re-check `/boot/loader.conf` for a `fdt_overlays=` line. Confirm the `.dtbo` file is in `/boot/dtb/overlays/`. Rebuild the overlay if you suspect a stale copy.

2. Is the status property set to okay?

```
# ofwdump -P status /soc/your-node
```

A value of "disabled" keeps the node from being probed. Base board files often declare optional peripherals as disabled and leave it to overlays to enable them.

3. Is the compatible string exactly what the driver expects?

A typo in the overlay or the driver's compat table is the single most common cause of probe failure. Compare them character by character:

```
# ofwdump -P compatible /soc/your-node
```

Against the matching line in the driver:

```
{"freebsd,fdthello", 1},
```

If even the vendor prefix differs (for example `free-bsd,` vs `freebsd,`), no match occurs.

4. Does the parent bus support probing?

FDT drivers attach to `simplebus` or `ofwbus`. If your node's parent is something else (say, an `i2c` bus node), your driver must register with that parent instead. Check the parent by looking one level up in `ofwdump`.

5. Is the driver ranked below another driver that matched?

If a more general driver returned `BUS_PROBE_GENERIC` first, your new driver needs to return something stronger, like `BUS_PROBE_DEFAULT` or `BUS_PROBE_SPECIFIC`. `devinfo -r` shows which driver actually attached.

32.9.5 Adding Temporary Debug Output

When none of the above reveals the cause, add `device_printf` calls to probe and attach to watch the flow directly. In probe:

```
static int
fdthello_probe(device_t dev)
{
    device_printf(dev, "probe: node=%ld compat=%s\n",
        ofw_bus_get_node(dev),
```

```

    ofw_bus_get_compat(dev) ? ofw_bus_get_compat(dev) : "(none)");

    if (!ofw_bus_status_okay(dev)) {
        device_printf(dev, "probe: status not okay\n");
        return (ENXIO);
    }

    if (ofw_bus_search_compatible(dev, compat_data)->oed_data == 0) {
        device_printf(dev, "probe: compat mismatch\n");
        return (ENXIO);
    }

    device_set_desc(dev, "FDT Hello Example");
    return (BUS_PROBE_DEFAULT);
}

```

This prints on every probe call, so expect noise. Remove the prints before shipping. The point is the transient visibility into what ofw_bus_* helpers are returning.

In attach, print the resource rids and addresses you allocated:

```

device_printf(dev, "attach: mem=%#jx size=%#jx\n",
    (uintmax_t)rman_get_start(sc->mem),
    (uintmax_t)rman_get_size(sc->mem));

```

This confirms that bus_alloc_resource_any handed back a valid range. A probe that matches but an attach that crashes here usually means reg in the DT is wrong.

32.9.6 Observing Attach Order and Dependencies

On embedded systems, attach order is not always intuitive. A GPIO-consuming driver has to wait for the GPIO controller to attach first. If your driver tries to acquire a GPIO line before the controller is ready, gpio_pin_get_by_ofw_idx returns ENXIO and your attach fails. FreeBSD handles the ordering through explicit dependencies expressed at driver registration time, and through the interrupt-parent walk for interrupt trees.

Use devinfo -rv to watch the order:

```
# devinfo -rv | grep -E '(gpio|edled|simplebus)'
```

If edled appears before gpio, something in the ordering needs fixing. The usual fix is a MODULE_DEPEND line in the consumer driver:

```
MODULE_DEPEND(edled, gpiobus, 1, 1, 1);
```

This forces gpiobus to load first, ensuring the GPIO controller is available when edled attaches.

32.9.7 Debugging Detach and Unload

Detach debugging is easier than probe debugging because detach runs while the system is up and `printf` output reaches `dmesg` immediately. The two problems you are most likely to meet are:

Unload returns EBUSY. Some resource is still held by the driver. The common cause is a GPIO pin or interrupt handle that was not released. Audit every `_get_` call and make sure there is a matching `_release_` in detach.

Unload succeeds but the module reattaches on next `kldload`. This is almost always because detach left a `softc` field pointing to freed memory, and the second attach followed that pointer. Treat detach as a careful teardown of everything attach built, in reverse order.

A useful trick is to add:

```
device_printf(dev, "detach: entered\n");  
...teardown...  
device_printf(dev, "detach: complete\n");
```

If the second line never appears, something in detach hung or panicked.

32.9.8 Using DTrace for Deeper Visibility

For more sophisticated investigations, DTrace can trace `device_probe` and `device_attach` across the whole kernel without touching the driver source. A one-liner that shows every attach call:

```
# dtrace -n 'fbt::device_attach:entry { printf("%s", stringof(args[0]->softc)); }'
```

The output is noisy during boot, but running it interactively while `kldload`-ing your driver filters it naturally. DTrace usage is beyond the scope of this chapter, but knowing it exists is worth the half-page it would take to set up.

32.9.9 Testing on QEMU

Not every reader has a Raspberry Pi or a BeagleBone to test against. QEMU can emulate an arm64 virt machine, boot FreeBSD on it, and let you load drivers and overlays without any real hardware. The virt machine uses its own Device Tree, which QEMU generates automatically; your overlay can target that tree in exactly the same way it would target a real board. The only caveat is that GPIOs and similar low-level peripherals are limited or absent on the virt machine. For pure DT-and-module experimentation it is perfectly adequate.

The basic invocation looks like this:

```
$ qemu-system-aarch64 \  
  -M virt \  
  -cpu cortex-a72 \  
  -m 2G \  
  -kernel /path/to/kernel \  
  -drive if=virtio,file=disk.img \  
  -serial mon:stdio \  
  -append "console=comconsole"
```

Once the system is up, `kldload` your module and watch for probe messages on the serial console.

32.9.10 When to Stop Debugging and Rebuild

Sometimes a bug is easier to fix by tearing the driver down and rebuilding from a known-good skeleton. The `fdthello` example in Section 4 is exactly that skeleton. If you find yourself chasing a probe failure for more than an hour, copy `fdthello`, rename it, add your `compat` string, and verify the trivial case attaches. Then port the real functionality over one piece at a time. You will almost always find the bug in the process.

32.9.11 Wrapping Up This Section

Section 6 armed you with the tools and habits of an embedded driver debugger. You have `ofwdump` for the tree, `hw.fdt.dtb` for the raw blob, `devinfo -r` for the attached-device view, `MODULE_DEPEND` for ordering, and `device_printf` for ad-hoc visibility. You also have a mental checklist for the common probe and detach failures.

Section 7 now puts all of the chapter's theory into a single worked example: a GPIO-backed LED driver that you build, compile, load, and drive from a `.dts` overlay. If you have worked through this chapter sequentially, the example will feel like a straightforward synthesis of the pieces we have already seen.

32.10 7. Practical Example: GPIO Driver for an Embedded Board

This section walks through the full construction of a small but real driver called `edled` (embedded LED). The driver:

1. Matches a Device Tree node with `compatible = "example,edled"`.
2. Acquires a GPIO pin listed in the node's `leds-gpios` property.
3. Exposes a `sysctl` knob the user can toggle to set the LED state.
4. Releases the GPIO cleanly on detach.

The driver is deliberately minimal. Once it works, you will be able to adapt it to drive anything that sits behind a single GPIO, and the patterns scale up when you need to handle multiple pins, interrupts, or more elaborate peripherals.

32.10.1 What You Need

To follow along you need:

- A FreeBSD system running kernel 14.3 or later.
- The kernel sources installed under `/usr/src`.
- `dtc` from the `devel/dtc` port or similar.
- A board with at least one free GPIO pin and an LED (or you can test the `sysctl` toggle without a real LED; the driver still attaches and logs state changes).

If you are on a Raspberry Pi 4 running FreeBSD, GPIO 18 is a convenient choice because it does not collide with the default console or SD card controller. A Pi 3 or Pi Zero 2 works the same way with adjusted GPIO numbers. On a BeagleBone Black, pick any of the many free pins on the 46-way header.

32.10.2 The Overall File Layout

We will produce five files:

```
edled.c          <- C source
Makefile         <- Kernel module Makefile
edled.dts        <- DT overlay source
edled.dtbo       <- Compiled overlay (output)
README           <- Notes for the reader
```

The corresponding repository layout under the `examples/` tree is:

```
examples/part-07/ch32-fdt-embedded/lab04-edled/
  edled.c
  edled.dts
  Makefile
  README.md
```

You can copy the files out of that tree once you reach the lab section at the end of the chapter.

32.10.3 The Softc

Every driver instance needs a small state block. `edled`'s `softc` holds:

- The device handle itself.
- The GPIO pin descriptor.
- The current on/off state.
- The `sysctl` oid for toggling.

```
struct edled_softc {
    device_t      sc_dev;
    gpio_pin_t    sc_pin;
    int           sc_on;
    struct sysctl_oid *sc_oid;
};
```

`gpio_pin_t` is defined in `/usr/src/sys/dev/gpio/gpiobusvar.h`. It is an opaque handle that carries the GPIO controller reference, the pin number, and the active-high/active-low flag. You never dereference it directly; you pass it to `gpio_pin_setflags`, `gpio_pin_set_active`, and `gpio_pin_release`.

32.10.4 Headers

The top of `edled.c` pulls in the definitions we need:

```
#include <sys/param.h>
#include <sys/systm.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/malloc.h>
#include <sys/bus.h>
#include <sys/sysctl.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/ofw/ofw_bus.h>
#include <dev/ofw/ofw_bus_subr.h>
#include <dev/ofw/openfirm.h>

#include <dev/gpio/gpiobusvar.h>
```

Compared with the `fdthello` skeleton in Section 4, we add `<sys/sysctl.h>` for the knob and `<dev/gpio/gpiobusvar.h>` for GPIO consumer APIs.

32.10.5 The Compatibility Table

A tiny table with one entry is all this driver needs:

```
static const struct ofw_compat_data compat_data[] = {
    {"example,edled", 1},
    {NULL, 0}
};
```

A real project would pick a vendor prefix it owns. Using "example," flags the compatible as illustrative. When you ship a product, replace it with your company or project prefix.

32.10.6 The Probe

Probe uses the same pattern as `fdthello`:

```
static int
edled_probe(device_t dev)
{
    if (!ofw_bus_status_okay(dev))
        return (ENXIO);

    if (ofw_bus_search_compatible(dev, compat_data)->ocd_data == 0)
        return (ENXIO);

    device_set_desc(dev, "Example embedded LED");
    return (BUS_PROBE_DEFAULT);
}
```

There is nothing new here. The only reason to copy the probe verbatim from Section 4 is to emphasize how repetitive this step is across drivers; the meaningful differences between drivers almost always live in attach, detach, and the operations layer.

32.10.7 The Attach

Attach is where the real work happens. We allocate and initialize the `softc`, acquire the GPIO pin, configure it as an output, set it to “off,” publish the `sysctl`, and print a confirmation.

```
static int
edled_attach(device_t dev)
{
    struct edled_softc *sc = device_get_softc(dev);
    phandle_t node = ofw_bus_get_node(dev);
    int error;

    sc->sc_dev = dev;
    sc->sc_on = 0;

    error = gpio_pin_get_by_ofw_property(dev, node,
        "leds-gpios", &sc->sc_pin);
    if (error != 0) {
        device_printf(dev, "cannot get GPIO pin: %d\n", error);
        return (error);
    }
}
```

```

    }

    error = gpio_pin_setflags(sc->sc_pin, GPIO_PIN_OUTPUT);
    if (error != 0) {
        device_printf(dev, "cannot set pin flags: %d\n", error);
        gpio_pin_release(sc->sc_pin);
        return (error);
    }

    error = gpio_pin_set_active(sc->sc_pin, 0);
    if (error != 0) {
        device_printf(dev, "cannot set pin state: %d\n", error);
        gpio_pin_release(sc->sc_pin);
        return (error);
    }

    sc->sc_oid = SYSCTL_ADD_PROC(device_get_sysctl_ctx(dev),
        SYSCTL_CHILDREN(device_get_sysctl_tree(dev)),
        OID_AUTO, "state",
        CTLTYPE_INT | CTLFLAG_RW | CTLFLAG_NEEDGIANT,
        sc, 0, edled_sysctl_state, "I", "LED state (0=off, 1=on)");

    device_printf(dev, "attached, GPIO pin acquired, state=0\n");
    return (0);
}

```

There are several things worth examining in this code.

The call `gpio_pin_get_by_ofw_property(dev, node, "leds-gpios", &sc->sc_pin)` parses the `leds-gpios` property from the DT node, resolves the phandle to the GPIO controller, consumes the pin number, and produces a ready-to-use handle. If the controller has not yet attached, this call returns `ENXIO`, which is why we express a `MODULE_DEPEND` on `gpio` during registration.

`gpio_pin_setflags(sc->sc_pin, GPIO_PIN_OUTPUT)` configures the pin direction. Other valid flags include `GPIO_PIN_INPUT`, `GPIO_PIN_PULLUP`, and `GPIO_PIN_PULLDOWN`. You can combine them, for example `GPIO_PIN_INPUT | GPIO_PIN_PULLUP`.

`gpio_pin_set_active(sc->sc_pin, 0)` sets the pin to its inactive level. “Active” here takes polarity into account, so on a pin configured active-low, a value of 1 drives the line low and 0 drives it high. The DT flag cell we discussed earlier is what determines this.

`SYSCTL_ADD_PROC` creates a node at `dev.edled.<unit>.state` whose handler is our own `edled_sysctl_state` function. The `CTLFLAG_NEEDGIANT` flag is appropriate for a small driver that does not yet have proper locking; a production driver would use a dedicated mutex and drop the Giant flag.

If any step fails, we release whatever we have already acquired and return the error. Leaking a GPIO pin on the error path would prevent other drivers from ever using the same line.

32.10.8 The Sysctl Handler

The sysctl handler reads or writes the LED state:

```
static int
edled_sysctl_state(SYSCTL_HANDLER_ARGS)
{
    struct edled_softc *sc = arg1;
    int val = sc->sc_on;
    int error;

    error = sysctl_handle_int(oidp, &val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    if (val != 0 && val != 1)
        return (EINVAL);

    error = gpio_pin_set_active(sc->sc_pin, val);
    if (error == 0)
        sc->sc_on = val;
    return (error);
}
```

SYSCTL_HANDLER_ARGS expands to the standard sysctl handler signature. We read the current value into a local, call `sysctl_handle_int` to do the user-space copy, and, if the user supplied a new value, we sanity-check it and apply it through the GPIO API. The current state is kept in the `softc` so a read without a write returns the last value we set.

32.10.9 The Detach

Detach must release everything attach acquired, in reverse order:

```
static int
edled_detach(device_t dev)
{
    struct edled_softc *sc = device_get_softc(dev);

    if (sc->sc_pin != NULL) {
        (void)gpio_pin_set_active(sc->sc_pin, 0);
        gpio_pin_release(sc->sc_pin);
        sc->sc_pin = NULL;
    }
    device_printf(dev, "detached\n");
}
```

```
    return (0);
}
```

We turn the LED off before releasing the pin. Leaving it on across a module unload is rude to the next driver; worse, the pin is released while asserted, and whatever it is driving stays on until something else reclaims the line. The sysctl context is owned by the newbus system through `device_get_sysctl_ctx`, so we do not free the oid explicitly; newbus tears it down for us.

32.10.10 The Method Table and Driver Registration

Nothing surprising here:

```
static device_method_t edled_methods[] = {
    DEVMETHOD(device_probe,  edled_probe),
    DEVMETHOD(device_attach, edled_attach),
    DEVMETHOD(device_detach, edled_detach),
    DEVMETHOD_END
};

static driver_t edled_driver = {
    "edled",
    edled_methods,
    sizeof(struct edled_softc)
};

DRIVER_MODULE(edled, simplebus, edled_driver, 0, 0);
DRIVER_MODULE(edled, ofwbus,    edled_driver, 0, 0);
MODULE_DEPEND(edled, gpiobus, 1, 1, 1);
MODULE_VERSION(edled, 1);
```

The only addition compared with `fdthello` is `MODULE_DEPEND(edled, gpiobus, 1, 1, 1)`. The three integer arguments are the minimum, preferred, and maximum version of `gpiobus` that `edled` can tolerate. A value triplet of 1, 1, 1 means “any version at or above 1.” In practice this is almost always what you want.

32.10.11 The Full Source

Putting it all together:

```
/*
 * edled.c - Example Embedded LED Driver
 *
 * Demonstrates a minimal FDT-driven GPIO consumer on FreeBSD 14.3.
 */
```

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/malloc.h>
#include <sys/bus.h>
#include <sys/sysctl.h>

#include <machine/bus.h>
#include <machine/resource.h>

#include <dev/ofw/ofw_bus.h>
#include <dev/ofw/ofw_bus_subr.h>
#include <dev/ofw/openfirm.h>

#include <dev/gpio/gpiobusvar.h>

struct edled_softc {
    device_t      sc_dev;
    gpio_pin_t    sc_pin;
    int           sc_on;
    struct sysctl_oid *sc_oid;
};

static const struct ofw_compat_data compat_data[] = {
    {"example,edled", 1},
    {NULL, 0}
};

static int edled_sysctl_state(SYSCTL_HANDLER_ARGS);

static int
edled_probe(device_t dev)
{
    if (!ofw_bus_status_okay(dev))
        return (ENXIO);
    if (ofw_bus_search_compatible(dev, compat_data)->oed_data == 0)
        return (ENXIO);
    device_set_desc(dev, "Example embedded LED");
    return (BUS_PROBE_DEFAULT);
}

static int
```

```
edled_attach(device_t dev)
{
    struct edled_softc *sc = device_get_softc(dev);
    phandle_t node = ofw_bus_get_node(dev);
    int error;

    sc->sc_dev = dev;
    sc->sc_on = 0;

    error = gpio_pin_get_by_ofw_property(dev, node,
        "leds-gpios", &sc->sc_pin);
    if (error != 0) {
        device_printf(dev, "cannot get GPIO pin: %d\n", error);
        return (error);
    }

    error = gpio_pin_setflags(sc->sc_pin, GPIO_PIN_OUTPUT);
    if (error != 0) {
        device_printf(dev, "cannot set pin flags: %d\n", error);
        gpio_pin_release(sc->sc_pin);
        return (error);
    }

    error = gpio_pin_set_active(sc->sc_pin, 0);
    if (error != 0) {
        device_printf(dev, "cannot set pin state: %d\n", error);
        gpio_pin_release(sc->sc_pin);
        return (error);
    }

    sc->sc_oid = SYSCTL_ADD_PROC(device_get_sysctl_ctx(dev),
        SYSCTL_CHILDREN(device_get_sysctl_tree(dev)),
        OID_AUTO, "state",
        CTLTYPE_INT | CTLFLAG_RW | CTLFLAG_NEEDGIANT,
        sc, 0, edled_sysctl_state, "I", "LED state (0=off, 1=on)");

    device_printf(dev, "attached, GPIO pin acquired, state=0\n");
    return (0);
}

static int
edled_detach(device_t dev)
{
    struct edled_softc *sc = device_get_softc(dev);
```

```
    if (sc->sc_pin != NULL) {
        (void)gpio_pin_set_active(sc->sc_pin, 0);
        gpio_pin_release(sc->sc_pin);
        sc->sc_pin = NULL;
    }
    device_printf(dev, "detached\n");
    return (0);
}

static int
edled_sysctl_state(SYSCTL_HANDLER_ARGS)
{
    struct edled_softc *sc = arg1;
    int val = sc->sc_on;
    int error;

    error = sysctl_handle_int(oidp, &val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    if (val != 0 && val != 1)
        return (EINVAL);

    error = gpio_pin_set_active(sc->sc_pin, val);
    if (error == 0)
        sc->sc_on = val;
    return (error);
}

static device_method_t edled_methods[] = {
    DEVMETHOD(device_probe, edled_probe),
    DEVMETHOD(device_attach, edled_attach),
    DEVMETHOD(device_detach, edled_detach),
    DEVMETHOD_END
};

static driver_t edled_driver = {
    "edled",
    edled_methods,
    sizeof(struct edled_softc)
};

DRIVER_MODULE(edled, simplebus, edled_driver, 0, 0);
```

```
DRIVER_MODULE(edled, ofwbus,    edled_driver, 0, 0);
MODULE_DEPEND(edled, gpiobus, 1, 1, 1);
MODULE_VERSION(edled, 1);
```

Around 140 lines of C, including headers and blank lines. That is a working, production-shaped FDT GPIO driver.

32.10.12 The Makefile

As with every kernel module in this book, the Makefile is trivial:

```
KMOD=    edled
SRCS=    edled.c

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

`bsd.kmod.mk` handles the rest. Typing `make` in the directory produces `edled.ko` and `edled.ko.debug`.

32.10.13 The Overlay Source

The companion `.dts` overlay looks like this (tuned for a Raspberry Pi 4; adjust for your board):

```
/dts-v1/;
/plugin/;

/ {
    compatible = "brcm,bcm2711";

    fragment@0 {
        target-path = "/soc";
        __overlay__ {
            edled0: edled@0 {
                compatible = "example,edled";
                status = "okay";
                leds-gpios = <&gpio 18 0>;
                label = "lab-indicator";
            };
        };
    };
};
```

Compile it with:

```
$ dtc -I dts -O dtb -@ -o edled.dtbo edled.dts
```

and copy to /boot/dtb/overlays/.

32.10.14 Building and Loading

On the target system, put all four files in a scratch directory, then:

```
$ make
$ sudo cp edled.dtbo /boot/dtb/overlays/
$ sudo sh -c 'echo fdt_overlays=\"edled\" >> /boot/loader.conf'
$ sudo reboot
```

After the reboot, you should see:

```
# dmesg | grep edled
edled0: <Example embedded LED> on simplebus0
edled0: attached, GPIO pin acquired, state=0
```

If you plugged an LED into GPIO 18, it is currently off. Verify with:

```
# sysctl dev.edled.0.state
dev.edled.0.state: 0
```

Turn it on:

```
# sysctl dev.edled.0.state=1
dev.edled.0.state: 0 -> 1
```

The LED lights. Turn it off:

```
# sysctl dev.edled.0.state=0
dev.edled.0.state: 1 -> 0
```

Done. You have a functioning embedded driver end to end: from Device Tree source through kernel module through user-space control.

32.10.15 Inspecting the Resulting Device

A few useful queries to confirm the driver is well integrated:

```
# devinfo -r | grep -A1 simplebus
# sysctl dev.edled.0
# ofwdump -p /soc/edled@0
```

The first shows your driver in the Newbus tree. The second lists all sysctls registered by your driver. The third confirms the DT node has the expected properties.

32.10.16 Pitfalls Worth Calling Out

The following mistakes are classic when writing your first GPIO-consumer driver. Each is easy to make and, once you know to look for it, easy to avoid.

Forgetting to release the pin in detach. `kldunload` succeeds, but the pin stays tied up. The next load reports “pin busy.” Always match every `gpio_pin_get_*` with a `gpio_pin_release` in detach.

Reading the DT property before the parent bus has attached. The `leds-gpios` parse returns `ENXIO`. The fix is to ensure the GPIO controller module loads first, via `MODULE_DEPEND`. During boot this happens automatically because the static kernel has both resident; during hand-loaded experiments with `kldload`, you may need to load `gpiobus` explicitly first.

Getting the active flag wrong. On boards that wire the LED so the GPIO sinks current (LED between 3V3 and the pin), “on” corresponds to a low output. In that case, `leds-gpios = <&gpio 18 1>` is correct and `gpio_pin_set_active(sc->sc_pin, 1)` will drive the pin low, lighting the LED. If the LED behaves inversely, flip the flag.

Sysctls that change state without a lock. This driver uses `CTLFLAG_NEEDGIANT` as a shortcut. In a real driver, you allocate a `struct mtx`, take it in the sysctl handler around the GPIO call, and publish the sysctl without the Giant flag. For a single-GPIO LED it does not matter much in practice, but the pattern is important once you extend the driver to handle interrupts or shared state.

32.10.17 Wrapping Up This Section

Section 7 delivered on the promise of the chapter. You have built a complete FDT-driven GPIO consumer, deployed it through an overlay, loaded it on a running system, and exercised it from user space. The components you used, compat tables, OFW helpers, resource acquisition through consumer frameworks, sysctl registration, newbus registration, are the same components every embedded driver in FreeBSD relies on.

Section 8 looks at how to turn a working driver like `edled` into a robust one. Working is the first milestone. Robust is the one that earns a driver its place in the kernel tree.

32.11 8. Refactoring and Finalizing Your Embedded Driver

The driver in Section 7 works. You load the module, flip a sysctl, and the LED behaves. That is a real accomplishment, and if the goal is a one-off experiment on a bench, you can stop there. For anything more serious, a working driver needs to be turned into a *finished* driver: one that can be read by a stranger, audited by a reviewer, and trusted in a system that stays up for months.

This section walks through the refactoring passes that take edled from working to finished. The changes are not about making it do more. They are about making it right. The same process applies to any driver you write, including drivers you adapt from other projects or port from Linux.

32.11.1 What Refactoring Means Here

“Refactor” is one of those words that often covers whatever the speaker feels like changing. For the purposes of this section, refactoring means:

1. Removing latent bugs that happen not to fire in the happy path.
2. Adding the locking and error paths a production driver requires.
3. Improving names, layout, and comments so the next reader does not need to guess.
4. Moving infrastructure out of attach into helpers when the body has grown too long.

Nothing here changes the external behavior of the driver. The sysctl still reads and writes the same integer, the LED still turns on and off, and the DT binding does not move. What changes is how reliable the driver is when something unexpected happens.

32.11.2 Pass One: Tighten the Attach Error Paths

The original attach function grew a cluster of error handlers that each call `gpio_pin_release` and return. That works, but it duplicates cleanup. A cleaner shape uses a single exit block with labels:

```
static int
edled_attach(device_t dev)
{
    struct edled_softc *sc = device_get_softc(dev);
    phandle_t node = ofw_bus_get_node(dev);
    int error;

    sc->sc_dev = dev;
    sc->sc_on = 0;

    error = gpio_pin_get_by_ofw_property(dev, node,
        "leds-gpios", &sc->sc_pin);
    if (error != 0) {
        device_printf(dev, "cannot get GPIO pin: %d\n", error);
        goto fail;
    }

    error = gpio_pin_setflags(sc->sc_pin, GPIO_PIN_OUTPUT);
    if (error != 0) {
        device_printf(dev, "cannot set pin flags: %d\n", error);
        goto fail;
    }
}
```

```

error = gpio_pin_set_active(sc->sc_pin, 0);
if (error != 0) {
    device_printf(dev, "cannot set pin state: %d\n", error);
    goto fail;
}

sc->sc_oid = SYSCTL_ADD_PROC(device_get_sysctl_ctx(dev),
    SYSCTL_CHILDREN(device_get_sysctl_tree(dev)),
    OID_AUTO, "state",
    CTLTYPE_INT | CTLFLAG_RW,
    sc, 0, edled_sysctl_state, "I", "LED state (0=off, 1=on)");

device_printf(dev, "attached, state=0\n");
return (0);

fail:
if (sc->sc_pin != NULL) {
    gpio_pin_release(sc->sc_pin);
    sc->sc_pin = NULL;
}
return (error);
}

```

The `goto fail` pattern is idiomatic FreeBSD kernel style. It collapses the cleanup logic into one place so it is impossible for a future edit to leak a resource by forgetting one of several identical `release` calls.

32.11.3 Pass Two: Add Proper Locking

`CTLFLAG_NEEDGIANT` was a shortcut. The right approach is a per-softc mutex held around the hardware access:

```

struct edled_softc {
    device_t      sc_dev;
    gpio_pin_t    sc_pin;
    int           sc_on;
    struct sysctl_oid *sc_oid;
    struct mtx     sc_mtx;
};

```

Initialize the mutex in `attach`:

```
mtx_init(&sc->sc_mtx, device_get_nameunit(dev), "edled", MTX_DEF);
```

Destroy it in detach:

```
mtx_destroy(&sc->sc_mtx);
```

Take it in the sysctl handler around the hardware call:

```
static int
edled_sysctl_state(SYSCTL_HANDLER_ARGS)
{
    struct edled_softc *sc = arg1;
    int val, error;

    mtx_lock(&sc->sc_mtx);
    val = sc->sc_on;
    mtx_unlock(&sc->sc_mtx);

    error = sysctl_handle_int(oidp, &val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    if (val != 0 && val != 1)
        return (EINVAL);

    mtx_lock(&sc->sc_mtx);
    error = gpio_pin_set_active(sc->sc_pin, val);
    if (error == 0)
        sc->sc_on = val;
    mtx_unlock(&sc->sc_mtx);

    return (error);
}
```

Notice that we drop the mutex around `sysctl_handle_int`. That call may copy data to or from user space, which can sleep, and you do not hold a mutex across a sleep. The value we hand to `sysctl_handle_int` is a local copy, so the drop is safe.

Remove `CTLFLAG_NEEDGIANT` from the `SYSCTL_ADD_PROC` call. With a real lock in place, Giant is no longer needed.

32.11.4 Pass Three: Handle the Power Rail Explicitly

On many real peripherals, the driver is responsible for turning on the power rail and the reference clock before touching the device. FreeBSD provides consumer APIs under `/usr/src/sys/dev/extres/regulator/` and

/usr/src/sys/dev/extres/clk/ for exactly this purpose. Even though a discrete LED does not need a regulator, more serious peripherals (say, a SPI-connected accelerometer) do. To keep edled a useful teaching template, we show how the machinery slots in.

Under a hypothetical DT node:

```
edled0: edled@0 {
    compatible = "example,edled";
    status = "okay";
    leds-gpios = <&gpio 18 0>;
    vled-supply = <&ldo_led>;
    clocks = <&clks 42>;
    label = "lab-indicator";
};
```

Two extra properties: vled-supply references a regulator phandle, and clocks references a clock phandle. Attach picks them up like this:

```
#include <dev/extres/clk/clk.h>
#include <dev/extres/regulator/regulator.h>

struct edled_softc {
    ...
    regulator_t    sc_reg;
    clk_t          sc_clk;
};

...

error = regulator_get_by_ofw_property(dev, node, "vled-supply",
    &sc->sc_reg);
if (error == 0) {
    error = regulator_enable(sc->sc_reg);
    if (error != 0) {
        device_printf(dev, "cannot enable regulator: %d\n",
            error);
        goto fail;
    }
} else if (error != ENOENT) {
    device_printf(dev, "regulator lookup failed: %d\n", error);
    goto fail;
}

error = clk_get_by_ofw_index(dev, node, 0, &sc->sc_clk);
if (error == 0) {
```

```

    error = clk_enable(sc->sc_clk);
    if (error != 0) {
        device_printf(dev, "cannot enable clock: %d\n", error);
        goto fail;
    }
} else if (error != ENOENT) {
    device_printf(dev, "clock lookup failed: %d\n", error);
    goto fail;
}

```

Detach releases them in reverse order:

```

if (sc->sc_clk != NULL) {
    clk_disable(sc->sc_clk);
    clk_release(sc->sc_clk);
}
if (sc->sc_reg != NULL) {
    regulator_disable(sc->sc_reg);
    regulator_release(sc->sc_reg);
}

```

The `ENOENT` check is important. If the DT does not declare a regulator or a clock, `regulator_get_by_ofw_property` and `clk_get_by_ofw_index` return `ENOENT`. A driver that supports multiple boards, some with and some without a dedicated rail, treats `ENOENT` as “not needed here” rather than as a fatal error.

32.11.5 Pass Four: Pinmux Setup

On SoCs where GPIO pins can be repurposed as UART, SPI, I2C, or other functions, the pin multiplexing controller has to be programmed before the driver can use a pin. FreeBSD handles this through the `pinctrl` framework at `/usr/src/sys/dev/fdt/fdt_pinctrl.h`. A Device Tree node requesting a specific configuration uses the `pinctrl-names` and `pinctrl-N` properties:

```

edled0: edled@0 {
    compatible = "example,edled";
    pinctrl-names = "default";
    pinctrl-0 = <&edled_pins>;
    ...
};

&pinctrl {
    edled_pins: edled_pins {
        brcm,pins = <18>;
        brcm,function = <1>; /* GPIO output */
    }
}

```

```
};  
};
```

In attach, call:

```
fdt_pinctrl_configure_by_name(dev, "default");
```

before any pin access. The framework walks the `pinctrl-0` handle, finds the referenced node, and applies its settings through the SoC-specific pinctrl driver.

The LED example does not strictly need pinmux because the Broadcom GPIO driver configures pins as part of `gpio_pin_setflags`, but on OMAP, Allwinner, and many other SoCs it is essential. Include the pattern in your teaching template so readers see where it fits.

32.11.6 Pass Five: Style and Naming Audit

Give the final source a slow read. Things to check:

- **Consistent naming.** All functions start with `edled_`, all fields with `sc_`, all constants in uppercase. A stranger reading the source should never wonder which driver a symbol belongs to.
- **No dead code.** Remove any `device_printf` or stub function that was useful during bring-up and has no production purpose.
- **No magic numbers.** If you write `sc->sc_on = 0` in ten places, define an enum or at least a `#define EDLED_OFF 0`.
- **Short comments only where the code's intent is not obvious.** Attempting to add a docstring to every function tends to clutter FreeBSD sources; brevity is the house style.
- **Correct include order.** By convention, `<sys/param.h>` comes first, followed by other `<sys/...>` headers, then `<machine/...>`, then subsystem-specific headers like `<dev/ofw/...>`.
- **Line length.** Stick to 80-column lines. Long function calls use the FreeBSD indent style for continuation.
- **License header.** Every FreeBSD source file opens with the project's BSD-style license block. For out-of-tree drivers, include your own copyright and license notice.

32.11.7 Pass Six: Static Analysis

Run the compiler with warnings turned up:

```
$ make CFLAGS="-Wall -Wextra -Werror"
```

Fix every warning. Warnings indicate either a real bug or an unclear piece of code. In both cases the fix improves the driver.

Consider running `scan-build`:

```
$ scan-build make
```

scan-build is part of the llvm clang analyzer. It catches null-pointer dereferences and use-after-free bugs the compiler misses.

32.11.8 Pass Seven: Documentation

A driver is not finished until it can be understood without reading the code. Write a one-page README that covers:

- What the driver does.
- Which DT binding it expects.
- Which module dependencies it has.
- Any known limitations or board-specific notes.
- How to build, load, and exercise it.

Include a short man page for the companion-material tree, too. Even a stub `edled(4)` page is valuable; you can refine it later.

32.11.9 Packaging and Distribution

Out-of-tree drivers live in a few canonical places:

- As an unofficial `devel/` port, for users to install on top of FreeBSD.
- As a GitHub repository following the FreeBSD project's conventional layout.
- As a `.tar.gz` archive posted alongside a README and an INSTALL file.

The FreeBSD ports tree welcomes driver packages that are known to be stable. Filing a `devel/edled-kmod` port once the driver has some miles on it is a reasonable goal.

If your driver is general enough to benefit other users, consider contributing it upstream. The review process is careful but positive, and the `freebsd-drivers@freebsd.org` mailing list is the natural starting point.

32.11.10 Reviewing Against Real FreeBSD Drivers

Once `edled` is tight, compare it against `/usr/src/sys/dev/gpio/gpioled_fdt.c`, which is the driver that inspired the example. The real driver is a bit larger because it supports multiple LEDs per parent node, but its overall shape matches yours. Note how it:

- Uses `for (child = OF_child(leds); child != 0; child = OF_peer(child))` to iterate DT children.
- Calls `OF_getprop_alloc` to read a variable-length label string.
- Registers with both `simplebus` and `ofwbus` through `DRIVER_MODULE`.
- Declares its DT binding through `SIMPLEBUS_PNP_INFO` so device-id matching works with `devmatch(8)`.

Reading real drivers in detail after finishing your own is one of the most productive things you can do in this field. You will find techniques you have never seen, and you will recognize patterns you now understand from the inside.

32.11.11 Wrapping Up This Section

Section 8 walked through the finishing passes every driver needs. Error paths tightened, locking corrected, power and clock handling made explicit, pinmux considered, style audited, analysis run, documentation written. What you have now is no longer an experiment; it is a driver you could hand to someone else with a straight face.

At this point the chapter's technical material is complete. The remaining pieces are the hands-on labs that let you run everything yourself, the challenge exercises that stretch what you have learned, a short list of common mistakes to watch for, and the wrap-up that closes the loop back to the broader arc of the book.

32.12 9. Reading Real FreeBSD FDT Drivers

We have built `fdthello` and `edled`, two drivers that exist for the purpose of teaching. They are real in the sense that you can load them on a FreeBSD system and see them attach, but they are small, and they do not carry the accumulated wisdom of drivers that have lived in the tree for years and been touched by dozens of contributors. To complete your apprenticeship as an FDT driver writer, you need to read drivers that did not start as teaching material.

This section picks a few drivers out of `/usr/src/sys` and walks through what they show. The goal is not to have you memorize their source, it is to build the habit of reading real code as a primary learning source. The book's teaching examples will fade from memory within months; real driver reading is a skill you can use for the rest of your career.

32.12.1 `gpioled_fdt.c`: A Close Relative of `edled`

Our `edled` driver was deliberately modeled on `/usr/src/sys/dev/gpio/gpioled_fdt.c`. Reading the real thing with `edled` in mind makes the comparison instructive. The real driver is about 150 lines, almost the same size as ours, but handles several details we chose to simplify.

The driver's compatibility table lists a single entry:

```
static struct ofw_compat_data compat_data[] = {
    {"gpio-leds", 1},
    {NULL,      0}
};
```

Notice that `gpio-leds` is an unprefixed string. This reflects a longstanding community binding that predates the current convention of vendor prefixes. New bindings should always use a prefix, but established ones remain as they are for the sake of compatibility.

The probe is almost identical to ours:

```
static int
gpioled_fdt_probe(device_t dev)
{
```

```

if (!ofw_bus_status_okay(dev))
    return (ENXIO);
if (ofw_bus_search_compatible(dev, compat_data)->oed_data == 0)
    return (ENXIO);
device_set_desc(dev, "OFW GPIO LEDs");
return (BUS_PROBE_DEFAULT);
}

```

The attach function is where the drivers diverge. `gpioled_fdt.c` supports multiple LEDs per DT node, following the `gpio-leds` binding that lists each LED as a child node of a single parent. The pattern is:

```

static int
gpioled_fdt_attach(device_t dev)
{
    struct gpioled_softc *sc = device_get_softc(dev);
    phandle_t leds, child;
    ...

    leds = ofw_bus_get_node(dev);
    sc->sc_dev = dev;
    sc->sc_nleds = 0;

    for (child = OF_child(leds); child != 0; child = OF_peer(child)) {
        if (!OF_hasprop(child, "gpios"))
            continue;
        ...
    }
}

```

`OF_child` and `OF_peer` are the classic walkers for iterating Device Tree children. `OF_child(parent)` returns the first child or zero. `OF_peer(node)` returns the next sibling or zero when you hit the end. This two-line iteration idiom is the backbone of every driver that processes a variable number of sub-entries.

Inside the loop, the driver reads per-LED properties:

```

name = NULL;
len = OF_getprop_alloc(child, "label", (void **)&name);
if (len <= 0) {
    OF_prop_free(name);
    len = OF_getprop_alloc(child, "name", (void **)&name);
}

```

`OF_getprop_alloc` allocates memory for a property and returns the length. The caller is responsible for releasing the buffer with `OF_prop_free`. Notice the fallback: if there is no `label` property, the driver uses the

node's name instead. This kind of graceful fallback is worth noting; it makes drivers more tolerant of binding variations.

Each GPIO is then acquired through a `gpio_pin_get_by_ofw_idx` call with an explicit index of zero, since each LED's own `gpios` property is indexed starting from zero within that child's scope. The driver calls `gpio_pin_setflags(pin, GPIO_PIN_OUTPUT)` and registers each LED with the `led(4)` framework so it shows up as `/dev/led/<name>` in user space.

32.12.2 DRIVER_MODULE Registration

The module registration lines look like this:

```
static driver_t gpioled_driver = {
    "gpioled",
    gpioled_methods,
    sizeof(struct gpioled_softc)
};

DRIVER_MODULE(gpioled, ofwbus,    gpioled_driver, 0, 0);
DRIVER_MODULE(gpioled, simplebus, gpioled_driver, 0, 0);
MODULE_VERSION(gpioled, 1);
MODULE_DEPEND(gpioled, gpiobus, 1, 1, 1);
SIMPLEBUS_PNP_INFO(compat_data);
```

Two additions stand out. `MODULE_DEPEND(gpioled, gpiobus, 1, 1, 1)` we already saw. The new line is `SIMPLEBUS_PNP_INFO(compat_data)`. This macro expands into a set of module metadata that tools like `dev-match(8)` use to decide which driver to auto-load for a given DT node. The argument is the same `compat_data` table the probe uses, so there is only one source of truth.

When you write production-grade drivers, include `SIMPLEBUS_PNP_INFO` so that auto-loading works. Without it, your driver will not be picked up automatically and the user has to add it to `loader.conf` explicitly.

32.12.3 What to Take Away from `gpioled_fdt.c`

Read it alongside `edled` and you will see:

- How to iterate multiple children in a DT node.
- How to fall back between property names.
- How to use `OF_getprop_alloc` and `OF_prop_free` for variable-length strings.
- How to register with the `led(4)` framework as well as with Newbus.
- How to declare PNP info for auto-matching.

These are five patterns that appear over and over in FreeBSD drivers. Having seen them once in a real source file, you will recognize them instantly in the next driver you open.

32.12.4 bcm2835_gpio.c: A Bus Provider

edled and `gpioled_fdt.c` are GPIO consumers. They *use* GPIO pins provided by another driver. The driver that *provides* those pins on the Raspberry Pi is `/usr/src/sys/arm/broadcom/bcm2835/bcm2835_gpio.c`. Reading it shows the other side of the transaction.

The driver's attach does considerably more than ours:

- Allocates the MMIO resource for the GPIO controller's register block.
- Allocates all of the interrupt resources (the BCM2835 routes two interrupt lines per bank).
- Initializes a mutex and a driver data structure that tracks per-pin state.
- Registers a GPIO bus child so consumers can attach to it.
- Registers pinmux functions for all the multiplex-capable pins.

The most important thing to notice, from our perspective as consumers, is the way it exposes itself. Deep in the attach:

```
if ((sc->sc_busdev = gpiobus_attach_bus(dev)) == NULL) {
    device_printf(dev, "could not attach GPIO bus\n");
    return (ENXIO);
}
```

`gpiobus_attach_bus(dev)` is what creates the `gpiobus` instance that consumers subsequently probe against. Without this call, no consumer driver could ever acquire a pin, because there would be no bus to resolve phandles against.

At the bottom of the file, `DEVMETHOD` entries map GPIO bus methods to the driver's own functions:

```
DEVMETHOD(gpio_pin_set,    bcm_gpio_pin_set),
DEVMETHOD(gpio_pin_get,    bcm_gpio_pin_get),
DEVMETHOD(gpio_pin_toggle, bcm_gpio_pin_toggle),
DEVMETHOD(gpio_pin_getcaps, bcm_gpio_pin_getcaps),
DEVMETHOD(gpio_pin_setflags, bcm_gpio_pin_setflags),
```

These are the functions our consumer ends up calling, indirectly, every time it does `gpio_pin_set_active`. The consumer API in `gpiobusvar.h` is a thin layer over this `DEVMETHOD` table.

32.12.5 ofw_iicbus.c: A Bus That Is Both Parent and Child

Many I2C controllers are attached as children of `simplebus` (their DT parent) and then themselves act as the parent of individual I2C device drivers. `/usr/src/sys/dev/iicbus/ofw_iicbus.c` is a good example to skim. It shows how a driver can both:

- Probe and attach on its own DT node like any FDT driver.
- Register its own child devices from the DT children of its node.

The iteration over children uses the same `OF_child/OF_peer` idiom, but for each child it creates a new Newbus device with `device_add_child`, sets up its own OFW metadata, and relies on Newbus to run the probe for a driver that can handle it (for example, a temperature sensor or an EEPROM).

Reading this driver gives you a feel for how bus-and-consumer relationships cascade. The FDT is a tree; so is the Newbus hierarchy. A driver in the middle of the tree plays both parent and child roles.

32.12.6 ofw_bus_subr.c: The Helpers Themselves

When you find yourself constantly looking up what exactly `ofw_bus_search_compatible` does, the answer is in `/usr/src/sys/dev/ofw/ofw_bus_subr.c`. Reading the helpers you call is an underrated way to understand what your driver is really doing.

A short tour of the helpers you will meet most often:

- `ofw_bus_is_compatible(dev, str)` returns true if the node's `compatible` list contains `str`. It iterates through all entries in the compatible list, not just the first.
- `ofw_bus_search_compatible(dev, table)` walks the same compatible list against the entries in a struct `ofw_compat_data` table and returns a pointer to the matching entry (or to a sentinel).
- `ofw_bus_status_okay(dev)` checks the status property. Missing status defaults to okay; "okay" or "ok" is okay; anything else ("disabled", "fail") is not.
- `ofw_bus_has_prop(dev, prop)` tests existence without reading.
- `ofw_bus_parse_xref_list_alloc` and related helpers read phandle reference lists (the format used by clocks, resets, gpios, etc.) and return an allocated array the caller must free.

Reading these helpers confirms that there is nothing magical in the system. They are readable C code that walks the same blob the kernel parsed at boot.

32.12.7 simplebus.c: The Driver That Runs Your Driver

If you want to understand why your FDT driver actually gets probed, open `/usr/src/sys/dev/fdt/simplebus.c`. The probe and attach of `simplebus` itself are short and, once you know what to look for, surprisingly concrete.

`simplebus_probe` checks that the node has `compatible = "simple-bus"` (or is an SoC-class node) and that it has no parent-specific peculiarities. `simplebus_attach` then walks the node's children, creates a new device for each, parses each child's reg and interrupts, and calls `device_probe_and_attach` on the new device. That last call is what kicks off your driver's probe.

The key lines are something like:

```
for (node = OF_child(parent); node > 0; node = OF_peer(node)) {
    ...
    child = simplebus_add_device(bus, node, 0, NULL, -1, NULL);
    if (child == NULL)
        continue;
}
```

This iteration is what turns a tree of DT nodes into a tree of Newbus devices. Every FDT driver in existence enters the system through this loop.

Reading `simplebus.c` demystifies the “why does my driver get called” question. You see, in plain C, exactly how the kernel walks from the blob in memory to a call into your driver’s probe. If you ever need to troubleshoot why your probe is not running, the first step is to instrument this file with `device_printf` at the right spot.

32.12.8 A Survey of Drivers Worth Reading

Beyond the specific drivers above, here is a short list of FDT drivers in `/usr/src/sys` that are worth your time as study subjects. Each is representative of a pattern you are likely to encounter.

- `/usr/src/sys/dev/gpio/gpioiic.c`: A driver that implements an I2C bus on top of GPIO pins. Shows bit-banging patterns.
- `/usr/src/sys/dev/gpio/gpiokeys.c`: Consumes GPIO inputs as a keyboard. Shows interrupt handling from GPIOs.
- `/usr/src/sys/dev/uart/uart_dev_ns8250.c`: A platform-independent UART driver with FDT hooks. Shows how a generic driver can accept FDT attach paths alongside other bus types.
- `/usr/src/sys/dev/sdhci/sdhci_fdt.c`: A large FDT driver for SD host controllers. Shows how production drivers handle clocks, resets, regulators, and pinmux together.
- `/usr/src/sys/arm/allwinner/aw_gpio.c`: A complete modern GPIO controller for the Allwinner SoC family. Worth comparing with `bcm2835_gpio.c` to see two takes on the same problem.
- `/usr/src/sys/arm/freescale/imx/imx_gpio.c`: The i.MX6/7/8 GPIO driver, another well-maintained reference.
- `/usr/src/sys/dev/extres/syscon/syscon.c`: A “system controller” pseudo-bus that exposes shared register blocks to multiple drivers. Useful to see how FreeBSD handles DT patterns that do not fit cleanly into “one node, one driver.”

You do not need to read these cover to cover. A healthy habit is to pick one every week or two, skim the structure, and then focus on whichever small detail catches your interest. Over time, these readings will build a library in your head of real code you have seen work.

32.12.9 Using `grep` as a Study Tool

When you find a new function in a driver you are reading and you are not sure what it does, a good first step is:

```
$ grep -rn "function_name" /usr/src/sys | head
```

This shows every place the function is defined and called. Often the declaration in a header is enough, combined with two or three representative call sites, to understand what the function is for. This beats searching the web, which returns outdated documentation and half-remembered forum posts.

For a particular DT binding, the same trick works:

```
$ grep -rn '"gpio-leds"' /usr/src/sys
```

The output tells you every file that references that compat string, including the driver that implements it, overlays that use it, and tests that exercise it.

32.12.10 Wrapping Up This Section

Section 9 gave you a reading list and a method. Real FreeBSD drivers are the richest resource available, and learning to read them effectively is a skill as important as writing your own. The drivers on the list above show the patterns our teaching examples simplified. They are the ones to reach for when you are stuck, when you need inspiration, and when you want to know how a production-quality driver handles the corner cases your own code has not encountered yet.

The remaining material in the chapter is practical: the labs you can run on your own hardware, the challenge exercises that stretch the teaching driver, the troubleshooting reference, and the closing bridge to the next chapter.

32.13 10. Interrupt Plumbing in FDT-Based Systems

We have mostly treated interrupts as opaque. In this section we open the box and look at how Device Tree describes interrupt connectivity, how FreeBSD's interrupt framework (`intrng`) consumes that description, and how a driver asks for an IRQ that will actually fire when the hardware wants attention.

The reason this subject deserves its own section is that interrupt wiring on modern SoCs can get complicated. Simple platforms have one controller, one set of lines, and a flat assignment. Complex platforms have a root controller, several subsidiary controllers that multiplex wider IRQ sources into narrower outputs, and pin-based controllers (like GPIOs-as-interrupts) whose lines chain through the multiplex tree. A driver writer who understands the chain can debug strange interrupt failures in minutes; one who does not can spend hours checking the wrong things.

32.13.1 The Interrupt Tree

The Device Tree expresses interrupts as a separate logical tree that runs alongside the main address tree. Each node has an interrupt parent (its controller), and the tree ascends through controllers until it reaches the root controller that the CPU actually takes exceptions from.

Three properties describe the tree:

- **interrupts**: The interrupt description for this node. Its format depends on the controller it attaches to.
- **interrupt-parent**: A phandle to the controller, if it is not the closest ancestor that is already an interrupt controller.
- **interrupt-controller**: An empty-valued property that marks a node as a controller. A consumer's `interrupt-parent` must point at such a node.

An example fragment:

```

&soc {
    gic: interrupt-controller@10000 {
        compatible = "arm,gic-v3";
        interrupt-controller;
        #interrupt-cells = <3>;
        reg = <0x10000 0x1000>, <0x11000 0x20000>;
    };

    uart0: serial@20000 {
        compatible = "arm,pl011";
        reg = <0x20000 0x100>;
        interrupts = <0 42 4>;
        interrupt-parent = <&gic>;
    };
};

```

The GIC (Generic Interrupt Controller, the standard arm64 root controller) declares `#interrupt-cells = <3>`. Every device that attaches to it must provide three cells in its `interrupts` property. For a GICv3, the three cells are *type, number, flags*: `<0 42 4>` means “shared peripheral interrupt 42, level-triggered, high.”

If `interrupt-parent` is omitted, the parent is the nearest ancestor with an `interrupt-parent` or with the `interrupt-controller` property set. This chain can be non-obvious when drivers sit several levels deep.

32.13.2 Interrupt-Parent Chaining

Consider a more realistic example. On a BCM2711 (Raspberry Pi 4), the GPIO controller is its own interrupt controller: it aggregates interrupts from individual pins into a handful of outputs that feed into the GIC. A button wired to a GPIO pin appears in the DT like this:

```

&gpio {
    button_pins: button_pins {
        brcm,pins = <23>;
        brcm,function = <0>;          /* GPIO input */
        brcm,pull = <2>;             /* pull-up */
    };
};

button_node: button {
    compatible = "gpio-keys";
    pinctrl-names = "default";
    pinctrl-0 = <&button_pins>;
    key_enter {
        label = "enter";
        linux,code = <28>;
    };
};

```

```

    gpios = <&gpio 23 0>;
    interrupt-parent = <&gpio>;
    interrupts = <23 3>;      /* edge trigger */
};
};

```

Two properties name the parent controller: `gpios = <&gpio ...>` names the GPIO controller as the pin provider, and `interrupt-parent = <&gpio>` names the same controller as the interrupt provider. The two roles are distinct and must be stated independently.

The GPIO controller then aggregates its interrupt lines and reports them to the GIC. Inside the GPIO driver, when an interrupt arrives from the GIC, it identifies which pin fired and dispatches the event to whichever driver registered a handler for that pin's IRQ resource.

When your driver requests an interrupt for this node, FreeBSD walks the chain: button driver asks for IRQ, the GPIO controller's `intrng` logic assigns a virtual IRQ number, and eventually the kernel arranges for the GIC's upstream IRQ to call into the GPIO driver's dispatcher which in turn calls the button driver's handler. You do not write any of this plumbing yourself; you just request the IRQ and handle it.

32.13.3 The `intrng` Framework

FreeBSD's `intrng` (interrupt next-generation) subsystem is what unifies all of this. An interrupt controller implements the `pic_*` methods:

```

static device_method_t gpio_methods[] = {
    ...
    DEVMETHOD(pic_map_intr,      gpio_pic_map_intr),
    DEVMETHOD(pic_setup_intr,    gpio_pic_setup_intr),
    DEVMETHOD(pic_teardown_intr, gpio_pic_teardown_intr),
    DEVMETHOD(pic_enable_intr,   gpio_pic_enable_intr),
    DEVMETHOD(pic_disable_intr,  gpio_pic_disable_intr),
    ...
};

```

`pic_map_intr` is the one that reads the DT property and returns an internal representation of the IRQ. `pic_setup_intr` attaches a handler. The remaining methods control masking and acknowledgement.

A consumer driver never calls these directly. It calls `bus_alloc_resource_any(dev, SYS_RES_IRQ, ...)`, and Newbus, together with the OFW resource code, walks the DT and the `intrng` framework to resolve the IRQ.

32.13.4 Requesting an IRQ in Practice

The full shape of interrupt handling in an FDT driver looks like this:

```

struct driver_softc {
    ...
    struct resource *irq_res;
    void *irq_cookie;
    int irq_rid;
};

static int
driver_attach(device_t dev)
{
    struct driver_softc *sc = device_get_softc(dev);
    int error;

    sc->irq_rid = 0;
    sc->irq_res = bus_alloc_resource_any(dev, SYS_RES_IRQ,
        &sc->irq_rid, RF_ACTIVE);
    if (sc->irq_res == NULL) {
        device_printf(dev, "cannot allocate IRQ\n");
        return (ENXIO);
    }

    error = bus_setup_intr(dev, sc->irq_res,
        INTR_TYPE_MISC | INTR_MPSAFE,
        NULL, driver_intr, sc, &sc->irq_cookie);
    if (error != 0) {
        device_printf(dev, "cannot setup interrupt: %d\n", error);
        bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid,
            sc->irq_res);
        return (error);
    }
    ...
}

```

The RID for interrupts starts at zero and increments for each IRQ in the node's interrupts list. A node with two IRQs would use RIDs 0 and 1 in succession.

`bus_setup_intr` registers the handler. The fourth argument is a filter function (runs in interrupt context); the fifth is a thread handler (runs in a dedicated kernel thread). You pass `NULL` for the one you are not using. The `INTR_MPSAFE` flag tells the framework that the handler does not require the Giant lock.

Teardown in detach:

```

static int
driver_detach(device_t dev)
{

```

```
struct driver_softc *sc = device_get_softc(dev);

if (sc->irq_cookie != NULL)
    bus_tearardown_intr(dev, sc->irq_res, sc->irq_cookie);
if (sc->irq_res != NULL)
    bus_release_resource(dev, SYS_RES_IRQ, sc->irq_rid,
        sc->irq_res);
return (0);
}
```

Failure to `bus_tearardown_intr` is a classic unload bug: the IRQ stays connected to freed memory, and the next time the kernel panics.

32.13.5 Filter Versus Thread Handlers

The distinction between filter and thread handlers is one of the topics that new kernel developers often find confusing. A short primer helps.

A *filter* runs in the context of the interrupt itself, at high IPL, with strict constraints on what it can call. It cannot sleep, cannot allocate memory, cannot acquire a regular sleep-capable mutex. It can only acquire spin mutexes. Its purpose is to decide whether the interrupt is for this device, acknowledge the hardware condition, and either handle the event trivially or schedule a thread handler to do the rest.

A *thread* handler runs in a dedicated kernel thread. It can sleep, allocate, and take sleep-capable locks. Many drivers do all their work in a thread handler and leave the filter empty.

For a driver as simple as `edled`, we never handle an interrupt. If we extended it to handle a pushbutton, we would start with a thread handler and only introduce a filter when profiling showed it necessary.

32.13.6 Edge Versus Level Triggering

The third cell of a GIC `interrupts` triple is the trigger type. Common values:

- 1: rising edge
- 2: falling edge
- 3: either edge
- 4: active high level
- 8: active low level

GPIO-as-interrupt nodes use a different cell count (typically two) and a similar encoding. The choice matters. Edge-triggered interrupts fire once per transition; level-triggered interrupts keep firing as long as the line is asserted. A driver that acknowledges too late on a level-triggered line can end up in an interrupt storm.

The DT binding documentation for each controller specifies the exact cell count and flag semantics. When in doubt, grep in `/usr/src/sys/contrib/device-tree/Bindings/` for the controller family.

32.13.7 Debugging Interrupts That Do Not Fire

The symptoms of misconfigured interrupts are usually clear: the hardware works the first time, and subsequent interrupts never come; or the system boots but the driver's handler never runs.

Checks, in order:

1. **Does `vmstat -i` show the interrupt being counted?** If yes, the hardware is asserting but the driver is not acknowledging it. Check your filter or thread handler.
2. **Does the DT's interrupts match the controller's expected format?** Cell count and values are the usual culprits.
3. **Is interrupt-parent pointing at the right controller?** If a pin-based controller is the source but the DT says the GIC, the request will fail because the GIC's cell format does not match.
4. **Did `bus_setup_intr` return zero?** If not, read the error code. `EINVAL` usually means the IRQ resource was not fully mapped; `ENOENT` means the IRQ number is not claimed by any controller.

The `intr_event_show` DTrace probe can help in advanced debugging, but the four-step check above catches most problems without DTrace.

32.13.8 Real Example: `gpiokeys.c`

`/usr/src/sys/dev/gpio/gpiokeys.c` is worth reading as a working example of a GPIO-consuming driver that uses interrupts. For each child node, it acquires a pin, configures it as an input, and hooks an interrupt through `gpio_alloc_intr_resource` and `bus_setup_intr`. The filter is very short: it just calls `taskqueue_enqueue` on a work item. The actual key processing runs on the kernel's taskqueue, not in interrupt context.

This is a clean pattern for a small interrupt-driven driver. A filter that just signals, a worker that does the job. When you need to implement something similar for a custom board peripheral, the `gpiokeys` driver is a good template.

32.13.9 Wrapping Up This Section

Section 10 unwrapped the interrupt machinery that our earlier examples kept hidden. You now know how the Device Tree describes interrupt connectivity, how FreeBSD's `intrng` resolves an IRQ request into a concrete handler registration, how filter and thread handlers divide work, and how to debug the class of failures that misconfigured interrupts produce.

The chapter's technical coverage is now truly complete. The labs, exercises, and troubleshooting material follow.

32.14 Hands-on Labs

Nothing in this chapter will stick without actually running it. The labs that follow are arranged in order of difficulty. Lab 1 is a warm-up you can complete on any FreeBSD system with kernel sources, even a generic amd64 laptop in QEMU. Lab 2 introduces overlays, which means you will want an arm64 target, either real

(Raspberry Pi 4, BeagleBone, Pine64) or emulated. Lab 3 is a debugging exercise in which you will deliberately break a DT and learn the symptoms. Lab 4 builds the full ed-led driver and drives an LED through it.

All lab files are published under `examples/part-07/ch32-fdt-embedded/`. Each lab has its own subdirectory with a `README.md` and all the sources you need. The following text is self-contained so you can work directly from the book, but the example tree is there as a safety net when you want to diff your work against a known-good reference.

32.14.1 Lab 1: Build and Load the fdthello Skeleton

Goal: Compile the minimal FDT-aware driver from Section 4, load it on a running FreeBSD system, and confirm it registers with the kernel even when no matching DT node exists.

What you will learn:

- How a kernel module Makefile works.
- How `kldload` and `kldunload` interact with module registration.
- How Newbus runs probes the moment a driver is introduced.

Steps:

1. Create a scratch directory named `lab01-fdthello` on a FreeBSD 14.3 system with kernel sources installed.
2. Save the full `fdthello.c` source listing from Section 4 in that directory.
3. Save a Makefile with the following content:

```
KMOD=    fdthello
SRCS=    fdthello.c

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

4. Build the module:

```
$ make
```

A clean build produces `fdthello.ko` and `fdthello.ko.debug` in the current directory.

5. Load the module:

```
# kldload ./fdthello.ko
```

On a system without a matching DT node, no probe succeeds. That is expected. The module is resident, but no `fdthello0` device appears.

6. Verify that the module is loaded:

```
# kldstat -m fdthello
```

7. Unload:

```
# kldunload fdthello
```

Expected outcome:

The build completes without warnings. The module loads and unloads cleanly. `kldstat` shows `fdthello.ko` between the two steps.

If you hit a snag:

- **kldload reports “module not found”:** Make sure you passed `./fdthello.ko` with the leading `./` so `kldload` does not try the system module path.
- **The build fails with “no such file `bsd.kmod.mk`”:** Install `/usr/src` via `pkgbase` or checkout from git.
- **The build fails because kernel symbols are missing:** Confirm `/usr/src/sys` matches the running kernel’s version. A mismatch between running kernel and source tree is the usual cause.

The starter files live at `examples/part-07/ch32-fdt-embedded/lab01-fdthello/`.

32.14.2 Lab 2: Build and Deploy an Overlay

Goal: Add a DT node that matches the `fdthello` driver, deploy it as an overlay on an arm64 FreeBSD board, and watch the driver attach.

What you will learn:

- How to write an overlay source file.
- How `dtc -@` produces overlay-ready `.dtbo` output.
- How the FreeBSD loader applies overlays through `fdt_overlays` in `loader.conf`.
- How to verify that an overlay landed correctly.

Steps:

1. On a running arm64 FreeBSD system (Raspberry Pi 4 is the reference target), install `dtc`:

```
# pkg install dtc
```

2. In a scratch directory, save the following overlay source as `fdthello-overlay.dts`:

```
/dts-v1/;
/plugin/;

/ {
    compatible = "brcm,bcm2711";

    fragment@0 {
        target-path = "/soc";
        __overlay__ {
            hello@20000 {
                compatible = "freebsd,fdthello";
                reg = <0x20000 0x100>;
                status = "okay";
            }
        }
    }
}
```

```

        };
    };
};
};

```

3. Compile the overlay:

```
$ dtc -I dts -O dtb -@ -o fdthello.dtbo fdthello-overlay.dts
```

4. Copy the result to the loader's overlay directory:

```
# cp fdthello.dtbo /boot/dtb/overlays/
```

5. Edit `/boot/loader.conf` (create it if missing) to include:

```
fdt_overlays="fdthello"
```

6. Copy your `fdthello.ko` built in Lab 1 to `/boot/modules/`:

```
# cp /path/to/fdthello.ko /boot/modules/
```

7. Ensure `fdthello_load="YES"` is in `/boot/loader.conf`:

```
fdthello_load="YES"
```

8. Reboot:

```
# reboot
```

9. After reboot, confirm:

```
# dmesg | grep fdthello
fdthello0: <FDT Hello Example> on simplebus0
fdthello0: attached, node phandle 0x...
```

Expected outcome:

The driver attaches at boot and its message shows up in `dmesg`. `ofwdump -p /soc/hello@200000` prints the node properties.

If you hit a snag:

- **Loader prints “error loading overlay”:** Usually the `.dtbo` file is missing or in the wrong directory. Confirm it is under `/boot/dtb/overlays/` and named with a `.dtbo` extension.
- **The driver does not attach:** Use the checklist from Section 6: node present, status okay, compatible exact, parent simplebus.
- **You are on a non-Pi board:** Change the top-level `compatible` in the overlay to match your board's base compatible. `ofwdump -p /` shows the current value.

The starter files live at `examples/part-07/ch32-fdt-embedded/lab02-overlay/`.

32.14.3 Lab 3: Debug a Broken Device Tree

Goal: Given a deliberately broken overlay, identify three distinct failure modes and fix each one.

What you will learn:

- How to use `dtc`, `fdtdump`, and `ofwdump` to read a blob.
- How to correlate the tree content with kernel probe behavior.
- How to use `device_printf` breadcrumbs to diagnose a probe mismatch.

Steps:

1. Copy the following broken overlay into `lab03-broken.dts`:

```
/dts-v1/;
/plugin/;

/ {
    compatible = "brcm,bcm2711";

    fragment@0 {
        target-path = "/soc";
        __overlay__ {
            hello@20000 {
                compatible = "free-bsd,fdthello";
                reg = <0x20000 0x100>;
                status = "disabled";
            };
        };
    };

    fragment@1 {
        target-path = "/soc";
        __overlay__ {
            hello@30000 {
                compatible = "freebsd,fdthello";
                reg = <0x30000>;
                status = "okay";
            };
        };
    };
};
```

2. Compile and install the overlay:

```
$ dtc -I dts -O dtb -@ -o lab03-broken.dtbo lab03-broken.dts
# cp lab03-broken.dtbo /boot/dtb/overlays/
```

3. Edit `/boot/loader.conf` to load this overlay instead of `fdthello`:

```
fdt_overlays="lab03-broken"
```

4. Reboot. Observe:

- No `fdthello0` device attaches.
- `dmesg` may be silent or may show an FDT parsing warning about `hello@300000`.

5. Diagnose. Use the following techniques in order:

a) Compare the compatible strings:

```
# ofwdump -P compatible /soc/hello@200000
# ofwdump -P compatible /soc/hello@300000
```

The first prints `free-bsd, fdthello`, which the driver does not match. The hyphen after `free` is the typo. Fix is to correct the string to `freebsd, fdthello`.

b) Check the status:

```
# ofwdump -P status /soc/hello@200000
```

Returns disabled. Even if the compatible were right, the driver would still skip this node. Fix is to set `status = "okay"`.

c) Check the reg property:

```
# ofwdump -P reg /soc/hello@300000
```

Notice that `reg` has only one cell where the parent expects address plus size. Under parents with `#address-cells = <1>` and `#size-cells = <1>`, `reg` must have two cells. The driver attaches, but if it ever allocates the resource, it will misread the size as whatever garbage follows. Fix is `reg = <0x300000 0x100>;`.

6. Apply the fixes, recompile, reinstall the overlay, and reboot. The driver should attach to one or both of the hello nodes.

Expected outcome:

After all three fixes, `dmesg | grep fdthello` shows two attached devices, `hello@200000` and `hello@300000`, each reported through `simplebus`.

If you hit a snag:

- **ofwdump reports “no such node”:** The overlay did not apply. Check the loader’s output for an overlay load message, check the `.dtbo` is where the loader expects it.
- **Only one hello device attaches:** One of the three bugs is still present.
- **The kernel panics:** You are almost certainly reading past the end of `reg` because its cell count is still wrong. Revert to the known-good overlay while you diagnose.

The starter files live at `examples/part-07/ch32-fdt-embedded/lab03-debug-broken/`.

32.14.4 Lab 4: Build the edled Driver End to End

Goal: Construct the full edled driver from Section 7, compile it, attach it through a DT overlay to GPIO18 on a Raspberry Pi 4, and toggle the LED from user space.

What you will learn:

- How to integrate GPIO resource acquisition into an FDT driver.
- How to expose a sysctl that drives hardware.
- How to verify the driver on a running system using `dmesg`, `sysctl`, `ofwdump`, and `devinfo -r`.

Steps:

1. Wire an LED between GPIO18 (pin 12 on the header) and ground through a 330-ohm resistor. If you do not have physical hardware, you can still proceed; the driver attaches and toggles its logical state, but there is nothing to light up.

2. In a scratch directory, save:

- `edled.c` from the full listing in Section 7.
- `Makefile` with `KMOD=edled`, `SRCS=edled.c`, `SYSDIR?=/usr/src/sys`, and `.include <bsd.kmod.mk>`.
- `edled.dts` overlay source from Section 7.

3. Build the module:

```
$ make
```

4. Compile the overlay:

```
$ dtc -I dts -O dtb -@ -o edled.dtbo edled.dts
```

5. Install:

```
# cp edled.ko /boot/modules/  
# cp edled.dtbo /boot/dtb/overlays/
```

6. Edit `/boot/loader.conf`:

```
edled_load="YES"  
fdt_overlays="edled"
```

7. Reboot.

8. Confirm attach:

```
# dmesg | grep edled  
edled0: <Example embedded LED> on simplebus0  
edled0: attached, GPIO pin acquired, state=0
```

9. Exercise the sysctl:

```
# sysctl dev.edled.0.state
dev.edled.0.state: 0
```

```
# sysctl dev.edled.0.state=1
dev.edled.0.state: 0 -> 1
```

The LED lights. Read back and confirm:

```
# sysctl dev.edled.0.state
dev.edled.0.state: 1
```

10. Turn the LED off and unload the driver:

```
# sysctl dev.edled.0.state=0
# kldunload edled
```

Expected outcome:

The driver loads, attaches, toggles the LED, and unloads without leaving resources in use. `gpioctl -l` shows the pin returned to the unconfigured state after unload.

If you hit a snag:

- **dmesg shows “cannot get GPIO pin”:** The GPIO controller module has not attached yet. Verify `gpio` is loaded: `kldstat -m gpio`. If it is not, `kldload gpio` before retrying.
- **The LED does not light:** Check the polarity. If the flag in the DT is 0 (active high), the pin drives 3.3V when active. If the LED’s cathode goes to the pin, you want 1 (active low).
- **kldunload fails with EBUSY:** Some process still has `dev.edled.0` open or the driver’s detach path left a resource acquired. Audit detach.

The starter files live at `examples/part-07/ch32-fdt-embedded/lab04-edled/`.

32.14.5 Lab 5: Extend edled to Consume a GPIO Interrupt

Goal: Modify the `edled` driver from Lab 4 so that a second GPIO, configured as an input with a pull-up resistor, becomes an interrupt source. When the pin is grounded (a push button pulling it low), the handler toggles the LED.

What you will learn:

- How to acquire a GPIO interrupt resource through `gpio_alloc_intr_resource`.
- How to set up a thread-context handler with `bus_setup_intr`.
- How to coordinate the interrupt path and the `sysctl` path through shared state.
- How to tear down an interrupt handler cleanly in detach.

Steps:

1. Start from `edled.c` from Lab 4. Copy it to `edledi.c` in a fresh scratch directory.
2. Add a second GPIO to the softc and to the DT binding. The new DT node looks like:

```
edledi0: edledi@0 {
    compatible = "example,edledi";
    status = "okay";
    leds-gpios = <&gpio 18 0>;
    button-gpios = <&gpio 23 1>;
    interrupt-parent = <&gpio>;
    interrupts = <23 3>;
};
```

The button uses GPIO 23, wired with the usual pushbutton arrangement: one leg to the pin, the other to ground, with a pull-up to 3.3V.

3. Update the compat string table to "example,edledi" so the driver matches the new binding.
4. In the softc, add:

```
gpio_pin_t      sc_button;
struct resource *sc_irq;
void            *sc_irq_cookie;
int            sc_irq_rid;
```

5. In attach, after acquiring the LED pin, acquire the button pin and its interrupt:

```
error = gpio_pin_get_by_ofw_property(dev, node,
    "button-gpios", &sc->sc_button);
if (error != 0) {
    device_printf(dev, "cannot get button pin: %d\n", error);
    goto fail;
}

error = gpio_pin_setflags(sc->sc_button,
    GPIO_PIN_INPUT | GPIO_PIN_PULLUP);
if (error != 0) {
    device_printf(dev, "cannot configure button: %d\n", error);
    goto fail;
}

sc->sc_irq_rid = 0;
sc->sc_irq = bus_alloc_resource_any(dev, SYS_RES_IRQ,
    &sc->sc_irq_rid, RF_ACTIVE);
if (sc->sc_irq == NULL) {
    device_printf(dev, "cannot allocate IRQ\n");
    goto fail;
}

error = bus_setup_intr(dev, sc->sc_irq,
    INTR_TYPE_MISC | INTR_MPSAFE,
    NULL, edledi_intr, sc, &sc->sc_irq_cookie);
```

```

if (error != 0) {
    device_printf(dev, "cannot setup interrupt: %d\n", error);
    goto fail;
}

```

6. Write the interrupt handler:

```

static void
edledi_intr(void *arg)
{
    struct edled_softc *sc = arg;

    mtx_lock(&sc->sc_mtx);
    sc->sc_on = !sc->sc_on;
    (void)gpio_pin_set_active(sc->sc_pin, sc->sc_on);
    mtx_unlock(&sc->sc_mtx);
}

```

This is a thread handler (passed as the fifth argument to `bus_setup_intr`, with `NULL` as the fourth for the filter). It is safe to take a mutex and to call into the GPIO framework.

7. In detach, add teardown in reverse order:

```

if (sc->sc_irq_cookie != NULL)
    bus_teardown_intr(dev, sc->sc_irq, sc->sc_irq_cookie);
if (sc->sc_irq != NULL)
    bus_release_resource(dev, SYS_RES_IRQ, sc->sc_irq_rid,
        sc->sc_irq);
if (sc->sc_button != NULL)
    gpio_pin_release(sc->sc_button);

```

8. Rebuild, redeploy the overlay, reboot, and press the button.

Expected outcome:

Each press toggles the LED. The `sysctl` still works for programmatic control. The driver unloads cleanly.

If you hit a snag:

- **Interrupt never fires:** Confirm the pull-up is actually pulling the pin high when idle; check the DT trigger cell (3 = either edge); look at `vmstat -i` to see if any IRQ is being counted for your device.
- **Repeated interrupts on a single press (bouncing):** Mechanical buttons bounce. A simple software debounce can be done by ignoring interrupts within a short window after the first. Use `sbintime()` and a state field in the `softc`.
- **kldunload fails with EBUSY:** You missed a `bus_teardown_intr` or a `gpio_pin_release`.

The starter files live at `examples/part-07/ch32-fdt-embedded/lab05-edledi/`.

32.14.6 After the Labs

At the end of Lab 4 you have run through the whole arc of embedded driver work: source, overlay, kernel module, user-space access, teardown. The remaining sections of the chapter give you ways to stretch what you have built and a last look at common pitfalls.

32.15 Challenge Exercises

The exercises below go beyond the guided labs. They do not include step-by-step instructions, because the point is for you to apply what you have learned to unstructured problems. If you get stuck, the reference material in Sections 5 through 8 and the real drivers under `/usr/src/sys/dev/gpio/` and `/usr/src/sys/dev/fdt/` are your strongest resources.

32.15.1 Challenge 1: Multiple LEDs Per Node

Modify `edled` to accept a DT node that declares several GPIOs, like the real `gpio-led-fdt.c` does. The binding should look like:

```
edled0: edled@0 {
    compatible = "example,edled-multi";
    led-red = <&gpio 18 0>;
    led-amber = <&gpio 19 0>;
    led-green = <&gpio 20 0>;
};
```

Expose one sysctl per LED: `dev.edled.0.red`, `dev.edled.0.amber`, `dev.edled.0.green`. Each should behave independently.

Hint: Walk the DT properties in `attach`. For a cleaner structure, store an array of pin handles in the `softc` and iterate over it in both `attach` and `detach`. `gpio_pin_get_by_ofw_property` takes the property name as its third argument, so the same driver can handle different property names with a small lookup table.

32.15.2 Challenge 2: Support a Blink Timer

Extend `edled` with a second sysctl `dev.edled.0.blink_ms` that, when set to a non-zero value, starts a kernel callout that toggles the pin every `blink_ms` milliseconds. Writing 0 stops the blink and leaves the LED in its current state.

Hint: Use `callout_init_mtx` to associate the callout with the per-`softc` mutex, and `callout_reset` to schedule it. Remember to `callout_drain` in `detach` so the system does not leave a scheduled event pointing at freed memory.

32.15.3 Challenge 3: Generalize to an Arbitrary GPIO Output

Rename and generalize `edled` into `edoutput`, a driver that can drive any GPIO output line with a `sysctl` interface. Accept a `label` property from the DT and use it as part of the `sysctl` path so multiple instances do not collide. Add a `dev.edoutput.0.pulse_ms` `sysctl` that drives the line active for the given number of milliseconds and then returns to inactive.

Hint: `device_get_unit(dev)` gives you the unit number; use `device_get_nameunit(dev)` for a combined name+unit string when you need one.

32.15.4 Challenge 4: Consume an Interrupt

If your board exposes a button wired to a GPIO input (or you can use a pull-up resistor and a jumper wire as a one-shot simulation), modify the driver to watch an input pin for edge transitions and log them through `device_printf`. You will need to acquire the IRQ resource with `bus_alloc_resource_any(dev, SYS_RES_IRQ, ...)`, set up the interrupt handler with `bus_setup_intr`, and release it cleanly in `detach`.

Hint: Look at `/usr/src/sys/dev/gpio/gpiokeys.c` as a reference for a driver that consumes GPIO-triggered interrupts from FDT.

32.15.5 Challenge 5: Produce a Custom Device Tree for QEMU

Write a complete `.dts` for a hypothetical embedded board that includes:

- A single ARM Cortex-A53 core.
- 256 MB of RAM.
- One `simplebus`.
- One UART at a chosen address.
- One `edled` node under `simplebus`, referencing a GPIO controller.
- A minimal GPIO controller node you invent.

Compile the result, boot a FreeBSD arm64 kernel against it under QEMU with `-dtb`, and watch the driver attach. The GPIO controller will fail because nothing drives the invented hardware, but you will see the full path from DT to Newbus with your own source.

Hint: Use `/usr/src/sys/contrib/device-tree/src/arm64/arm/juno.dts` as a structural reference.

32.15.6 Challenge 6: Port a Real Driver's DT Binding to a New Board

Pick any existing FreeBSD FDT driver (for example, `sys/dev/iicbus/pmic/act8846.c`), read its DT binding by studying the driver source, and write a complete DT fragment that would attach it on a Raspberry Pi 4. You do not need to actually run the driver; the exercise is in reading the binding from the source and producing a correct `.dtsi` fragment.

Hint: Read the driver's `compat` table, its `probe`, and any `of_` calls to discover which properties it expects. Vendor kernel source trees often document DT bindings in comments at the top of the file.

32.15.7 Challenge 7: Hand-Write a Full DT for an Embedded Target Under QEMU

Challenge 5 invited you to write a partial DT for a hypothetical board. Challenge 7 goes further: write a complete .dts for a QEMU arm64 target that you define entirely yourself. Include memory, timer, a PL011 UART, a GIC, one PL061-style GPIO controller, and one instance of a peripheral of your own design. Boot an unmodified FreeBSD arm64 kernel under QEMU with your .dtb. Verify that the console comes up on your chosen UART and that the kernel's device probe walks the tree.

Hint: The qemu-system-aarch64 command supports -dtb plus -machine virt,dumpdtb=out.dtb to emit a reference DT you can study and adapt.

32.15.8 Challenge 8: Implement a Simple MMIO Peripheral Driver

Write a driver for a hypothetical MMIO peripheral you also simulate under QEMU. The peripheral exposes one 32-bit register at a fixed address. Reading the register returns a free-running counter; writing zero resets the counter. Your driver should expose one sysctl dev.counter.0.value that reads and writes this register. Verify that bus_read_4 and bus_write_4 work as expected. Simulate the hardware by writing a small QEMU device model, or by repurposing an existing simulated region whose value you can observe.

Hint: bus_read_4(sc->mem, 0) returns the u32 at offset 0 within your allocated memory resource. The bus_space(9) man page is the authoritative reference.

32.15.9 After the Challenges

These exercises are intentionally open-ended. If you finish any one of them, you have internalized the material of this chapter. If you find yourself wanting more, /usr/src/sys/dev/ has dozens of FDT drivers at all sizes. Reading a driver a week is one of the best habits an embedded FreeBSD developer can build.

32.16 Common Mistakes and Troubleshooting

This section is a concentrated reference for the issues that most often trip up writers of FDT drivers. Everything here has already been mentioned in Sections 3 through 8, but collecting the points in one place gives you something you can skim when a particular symptom appears.

32.16.1 Module Loads but No Device Attaches

Most probe failures come down to one of five causes:

1. **Typo in compatible.** Either in the DT source or in the driver's compat table. The string must match byte for byte.
2. **Node has status = "disabled".** Either fix the base tree or write an overlay that sets status to okay.
3. **Wrong parent bus.** If the node sits under an I2C or SPI controller node, the driver must register with that controller's driver type, not with simplebus.
4. **Overlay did not apply.** Check the loader output at boot for an error message. Confirm the .dtbo is in /boot/dtb/overlays/ and listed in loader.conf.

5. **Driver outranked by another driver.** Use `devinfo -r` to see which driver actually attached. Increase the probe's return value (`BUS_PROBE_DEFAULT` is the common baseline; `BUS_PROBE_SPECIFIC` signals a more exact match).

32.16.2 Overlay Fails to Apply at Boot

The loader prints its attempts on the console. Watch for lines like:

```
Loading DTB overlay 'edled' (0x1200 bytes)
```

If that line is missing, the loader either did not find the file or skipped it. Possible causes:

- Filename ends in `.dtbo` but `fdt_over` lays misspells it.
- File is in the wrong directory. The default is `/boot/dtb/overlays/`.
- Base blob and overlay disagree on the top-level compatible. The loader refuses to apply an overlay whose top-level compatible does not match the base.
- The `.dtbo` was compiled without `-@` and references labels the loader cannot resolve.

32.16.3 Cannot Allocate Resources

If `attach` calls `bus_alloc_resource_any(dev, SYS_RES_MEMORY, ...)` and it returns `NULL`, the most likely causes are:

- `reg` missing or malformed in the DT node.
- Cell count mismatch between the node's `reg` and the parent's `#address-cells/#size-cells`.
- Another driver already claimed the same region.
- The parent bus's ranges does not cover the requested address.

Print the resource start and size in `attach` while debugging:

```
if (sc->mem == NULL) {
    device_printf(dev, "cannot allocate memory resource (rid=%d)\n",
        sc->mem_rid);
    goto fail;
}
device_printf(dev, "memory at %#jx len %#jx\n",
    (uintmax_t)rman_get_start(sc->mem),
    (uintmax_t)rman_get_size(sc->mem));
```

32.16.4 GPIO Acquisition Fails

`gpio_pin_get_by_ofw_*` returns `ENXIO` when:

- The GPIO controller referenced in the DT property has not attached yet.
- The pin number is out of range for that controller.

- The phandle in the DT is wrong.

The first cause is by far the most common. The fix is `MODULE_DEPEND(your_driver, gpiobus, 1, 1, 1)` so the dynamic loader brings up gpiobus first.

32.16.5 Interrupt Handler Does Not Fire

If the hardware should raise an interrupt and nothing happens:

- Confirm the DT interrupts property is correct. The format depends on the parent interrupt controller's `#interrupt-cells`.
- Confirm `bus_alloc_resource_any(SYS_RES_IRQ, ...)` returned a valid resource.
- Confirm `bus_setup_intr` returned zero.
- Confirm your handler's return value is `FILTER_HANDLED` or `FILTER_STRAY` for a filter, or `FILTER_SCHEDULE_THREAD` if you are using a threaded handler.

Use `vmstat -i` to see whether your interrupt is being counted. If the count stays at zero, the interrupt is not even being routed to your handler.

32.16.6 Unload Returns EBUSY

Detach forgot to release something. Walk your attach carefully and confirm every `_get_` has a matching `_release_` call in detach. Common culprits are:

- GPIO pins retrieved with `gpio_pin_get_by_*`.
- Interrupt handlers set up with `bus_setup_intr`.
- Clock handles from `clk_get_by_*`.
- Regulator handles from `regulator_get_by_*`.
- Memory resources from `bus_alloc_resource_any`.

Print a breadcrumb on each release:

```
device_printf(dev, "detach: releasing GPIO pin\n");
gpio_pin_release(sc->sc_pin);
```

If the breadcrumbs stop before the expected end, the resource that goes uncleared is the one after the last printed line.

32.16.7 Panic During Boot

Panics that fire during FDT parsing usually mean the blob itself is malformed, or a driver is dereferencing an `OF_getprop` result it did not check. Two safeguards:

- Always check the return value of `OF_getprop`, `OF_getencprop`, and `OF_getprop_alloc`. A missing property returns `-1` or `ENOENT`; treating it as present leads to reads of whatever is next on the stack.
- Use `OF_hasprop(node, "prop")` before calling `OF_getprop` when a property is optional.

32.16.8 DT Compile Errors

dtc error messages are reasonably clear. A few patterns to recognize:

- **syntax error**: Missing semicolon, unbalanced brace, or bad property value syntax.
- **Warning (simple_bus_reg)**: A node under simple-bus has reg but no ranges translation, or its reg does not match the parent's cell counts.
- **FATAL ERROR: Unable to parse input tree**: The file is syntactically broken at a coarse level. Check for missing `/dts-v1/`; or mis-quoted strings.
- **ERROR (phandle_references): Reference to non-existent node or label**: An `&label` reference that the compiler cannot resolve. This is where `-@` matters; without it, overlays that depend on base-tree labels cannot be validated.

32.16.9 The Kernel Sees the Wrong Hardware

If your driver attaches but reads garbage from registers:

- Double-check the reg value in the DT.
- Confirm `#address-cells` and `#size-cells` match what you expect at the parent's level.
- Use hexdump `/dev/mem` style techniques only if you are certain the address is safe; reading the wrong MMIO range can hang the bus.

32.16.10 You Changed the Driver But Nothing Changed

Double-check:

- Did you run `make` after editing?
- Did you copy the new `.ko` to `/boot/modules/` (or load the local one explicitly)?
- Did you unload the old module before loading the new one? `kldstat -m driver` shows currently resident modules.

A simple habit that avoids the last pitfall is to always `kldunload` explicitly before `kldload`, or to use `kldload -f` to force replacement.

32.16.11 Quick Reference: Most-Used OFW Calls

For convenience, here is a compact table of the OFW and `ofw_bus` helpers that FDT drivers use most often. Each is declared in either `<dev/ofw/openfirm.h>` or `<dev/ofw/ofw_bus_subr.h>`.

Call	What it does
<code>ofw_bus_get_node(dev)</code>	Return the phandle of this device's DT node.
<code>ofw_bus_get_compat(dev)</code>	Return the first compatible string of the node, or NULL.
<code>ofw_bus_get_name(dev)</code>	Return the node's name part (before the '@').
<code>ofw_bus_status_okay(dev)</code>	True if status is missing, "okay", or "ok".

Call	What it does
<code>ofw_bus_is_compatible(dev, s)</code>	True if one of the compatible entries matches <code>s</code> .
<code>ofw_bus_search_compatible(dev, tbl)</code>	Return the matching entry in a <code>compat_data</code> table.
<code>ofw_bus_has_prop(dev, s)</code>	True if the property is present on the node.
<code>OF_getprop(node, name, buf, len)</code>	Copy raw property bytes.
<code>OF_getencprop(node, name, buf, len)</code>	Copy property, byte-swapping u32 cells to host endianness.
<code>OF_getprop_alloc(node, name, bufp)</code>	Allocate and return property; caller frees with <code>OF_prop_free</code> .
<code>OF_hasprop(node, name)</code>	Return non-zero if the property exists.
<code>OF_child(node)</code>	First child phandle, or 0.
<code>OF_peer(node)</code>	Next sibling phandle, or 0.
<code>OF_parent(node)</code>	Parent phandle, or 0.
<code>OF_finddevice(path)</code>	Look up a node by absolute path.

32.16.12 Quick Reference: Most-Used Peripheral Calls

From `<dev/gpio/gpiobusvar.h>`:

Call	What it does
<code>gpio_pin_get_by_ofw_idx(dev, node, idx, &pin)</code>	Acquire pin by <code>gpios</code> index.
<code>gpio_pin_get_by_ofw_name(dev, node, n, &pin)</code>	Acquire pin by named reference (e.g., <code>led-gpios</code>).
<code>gpio_pin_get_by_ofw_property(dev, n, p, &pin)</code>	Acquire pin from named DT property.
<code>gpio_pin_setflags(pin, flags)</code>	Configure direction, pulls, and similar.
<code>gpio_pin_set_active(pin, val)</code>	Drive output to active or inactive state.
<code>gpio_pin_get_active(pin, &val)</code>	Read current input or output level.
<code>gpio_pin_release(pin)</code>	Return pin to the unowned pool.

From `<dev/extres/clk/clk.h>`:

Call	What it does
<code>clk_get_by_ofw_index(dev, node, i, &c)</code>	Acquire <code>n</code> th clock listed in <code>clocks</code> property.

Call	What it does
<code>clk_get_by_ofw_name(dev, node, n, &c)</code>	Acquire clock by name.
<code>clk_enable(c) / clk_disable(c)</code>	Gate the clock on or off.
<code>clk_get_freq(c, &f)</code>	Read current frequency in Hz.
<code>clk_release(c)</code>	Release clock handle.

From `<dev/extres/regulator/regulator.h>`:

Call	What it does
<code>regulator_get_by_ofw_property(dev, node, p, &r)</code>	Acquire regulator from DT property.
<code>regulator_enable(r) / regulator_disable(r)</code>	Turn rail on or off.
<code>regulator_set_voltage(r, min, max)</code>	Ask for voltage within min..max range.
<code>regulator_release(r)</code>	Release regulator handle.

From `<dev/extres/hwreset/hwreset.h>`:

Call	What it does
<code>hwreset_get_by_ofw_name(dev, node, n, &h)</code>	Acquire reset line by name.
<code>hwreset_get_by_ofw_idx(dev, node, i, &h)</code>	Acquire reset line by index.
<code>hwreset_assert(h) / hwreset_deassert(h)</code>	Put peripheral into or out of reset.
<code>hwreset_release(h)</code>	Release reset handle.

From `<dev/fdt/fdt_pinctrl.h>`:

Call	What it does
<code>fdt_pinctrl_configure_by_name(dev, name)</code>	Apply the named pinctrl state.
<code>fdt_pinctrl_configure_tree(dev)</code>	Apply <code>pinctrl-0</code> recursively to children.
<code>fdt_pinctrl_register(dev, mapper)</code>	Register a new pinctrl provider.

Print this table, pin it near your workstation, and refer to it whenever you start a new driver. The calls become second nature within a few projects.

32.16.13 Summary Checklist

Before declaring a driver finished, run through this list:

- ☐ Module builds cleanly with no warnings under `-Wall -Wextra`.
- ☐ `kldload` produces the expected attach message.
- ☐ `kldunload` succeeds without `EBUSY`.
- ☐ Repeating load-unload cycles a dozen times does not leak resources.
- ☐ `devinfo -r` shows the driver in the expected position in the tree.
- ☐ `sysctls` are present, readable, and writable where intended.
- ☐ All DT properties the driver cares about are documented in the README.
- ☐ A companion overlay source compiles with `dtc -@`.
- ☐ A fresh reader could read the source and understand what it does.

32.17 Glossary of Device Tree and Embedded Terms

This glossary collects the terms this chapter uses, defined briefly so you can check a term on first encounter without searching the prose. Cross-references to the relevant section appear in parentheses where helpful.

ACPI: Advanced Configuration and Power Interface. An alternative to FDT used by PC-class and some arm64 servers. A FreeBSD kernel picks one or the other at boot. (Section 3.)

amd64: FreeBSD's 64-bit x86 architecture. Usually uses ACPI rather than FDT, though FDT can be used in specialized embedded x86 cases.

arm64: FreeBSD's 64-bit ARM architecture. Uses FDT by default on embedded boards; uses ACPI on SBSA-compliant servers.

Bindings: Documented conventions for how a peripheral's properties are spelled in Device Tree. For instance, the `gpio-leds` binding documents what properties an LED controller's DT node should carry.

Blob: Informal term for a `.dtb` file, since it is an opaque binary chunk from the perspective of anything other than an FDT parser.

BSP: Board Support Package. The collection of files (kernel config, Device Tree, loader hints, sometimes drivers) needed to run an operating system on a specific board.

Cell: A 32-bit big-endian value that is the atomic unit of a DT property. Property values are sequences of cells.

Compatible string: The identifier a driver's probe matches against, stored in the `compatible` property of a DT node. Usually has vendor-prefix-slash-model form: `"brcm,bcm2711-gpio"`.

Compat data table: An array of `struct ofw_compat_data` entries that a driver walks in probe via `ofw_bus_search_compatible`. (Section 4.)

dtb: Compiled Device Tree binary. Output of `dtc`; the format the kernel parses at boot.

dtbo: Compiled Device Tree overlay. A small binary that the loader merges into the main `.dtb` before handing it to the kernel.

dtc: The Device Tree Compiler. Translates source to binary.

dts: Device Tree Source. Text input to `dtc`.

dtsti: Device Tree Source Include. A source fragment meant to be `#include-d`.

Edge triggered: An interrupt that fires on a level transition (rising, falling, or both). Contrast with level-triggered.

FDT: Flattened Device Tree. The binary format and framework FreeBSD uses for DT-based systems. Also used colloquially to refer to the whole concept.

fdt_overlays: A `loader.conf` tunable that lists overlay names to apply at boot.

fdtdump: A utility that decodes a `.dtb` file to a readable approximation of its source.

Fragment: A top-level entry in an overlay that names a target and declares the content to merge. (Section 5.)

GPIO: General-Purpose Input/Output. A programmable digital pin that can drive or read a line.

intrng: FreeBSD's interrupt next-generation framework. Unifies interrupt controllers and consumers. (Section 10.)

kldload: The command that loads a kernel module into a running system.

kldunload: The command that unloads a loaded kernel module.

Level triggered: An interrupt that asserts as long as a condition is true. Must be cleared at the source to stop firing.

Loader: FreeBSD's boot loader. Reads configuration, loads modules, merges DT overlays, hands control to the kernel.

MMIO: Memory-Mapped IO. A hardware register set exposed through a range of physical addresses.

Newbus: FreeBSD's device driver framework. Every driver registers into a tree of Newbus parent-child relationships.

Node: A point in the Device Tree. Has a name (and optional unit address) and a set of properties.

OFW: Open Firmware. A historical standard that FreeBSD's FDT code reuses the API of.

ofwbus: FreeBSD's top-level bus for Open Firmware-derived device enumeration.

ofwdump: A userspace utility that prints nodes and properties from the running kernel's DT. (Section 6.)

Overlay: A partial `.dtb` that modifies an existing tree. Targets nodes by label or path and merges content under them. (Section 5.)

phandle: Phantom handle. A 32-bit integer identifier for a DT node, used to cross-reference nodes within the tree.

pinctrl: Pin control framework. Handles multiplexing of SoC pins between their possible functions. (Section 8.)

PNP info: Metadata a driver publishes to identify the DT compatible strings it supports. Used by `devmatch(8)` for auto-loading. (Section 9.)

Probe: The driver method that inspects a candidate device and reports whether it can drive it. Returns a strength score or an error.

Property: A named value in a DT node. Values can be strings, cell lists, or opaque byte strings.

Reg: A property listing one or more (address, size) pairs that describe the MMIO ranges the peripheral occupies.

Root controller: The topmost interrupt controller. On arm64 systems, usually a GIC.

SBC: Single-Board Computer. An embedded board with CPU, memory, and peripherals on one PCB. Examples: Raspberry Pi, BeagleBone.

SIMPLEBUS_PNP_INFO: A macro that exports a driver's compat table as module metadata. (Section 9.)

Simplebus: The FreeBSD driver that probes DT children whose parent has `compatible = "simple-bus"`. It turns DT nodes into Newbus devices.

softc: Short for “soft context.” A per-device state structure allocated by Newbus and passed to driver methods. (Section 4.)

SoC: System on Chip. An integrated circuit containing CPU, memory controller, and many peripheral blocks.

Status: A property on a DT node that indicates whether the device is enabled ("okay") or not. Missing status defaults to okay.

sysctl: FreeBSD's system control interface. A driver can publish tunable parameters that userspace reads and writes.

Target: In an overlay, the node in the base tree that a fragment modifies.

Unit address: The numeric part after the @ in a node name. Indicates where in the parent's address space the node lives.

Vendor prefix: The part of a compatible string before the comma. Identifies the organization responsible for the binding.

32.18 Frequently Asked Questions

These are questions that come up repeatedly when people first write FDT drivers for FreeBSD. Most are already answered somewhere in the chapter; the FAQ format just puts the short answer in one place.

Do I need to know ARM assembly to write an FDT driver?

No. The whole point of the driver framework is that you work in C against a uniform API. You might read disassembly if you are debugging a very low-level crash, but that is the exception, not the rule.

Can I write FDT drivers on amd64, or do I need arm64 hardware?

You can develop on amd64 and cross-build for arm64. You can also run arm64 FreeBSD under QEMU on an amd64 host, which is the most common workflow for anyone who does not want to wait on a Pi to reboot. For the final validation, you eventually want real hardware or a faithful emulator, but day-to-day iteration fits on a laptop.

What is the difference between simplebus and ofwbus?

ofwbus is the top-level root bus for Open Firmware-derived device enumeration. simplebus is a generic bus driver that covers DT nodes compatible with "simple-bus" and similar simple enumeration. Most of your drivers will register with both; ofwbus handles the root and specialized cases, simplebus handles the overwhelming majority of peripheral buses.

Why does my driver need to register with both ofwbus and simplebus?

Some nodes appear under simplebus, some directly under ofwbus (particularly on systems where the tree structure is unusual). Registering with both means the driver attaches wherever the node happens to end up.

Why is my overlay not applying?

Run through the checklist in Section 6. The most common cause, in order: wrong filename or directory, typo in `fdt_overlays`, base compatible mismatch, missing `-@` at overlay compile time.

Can a driver span multiple DT nodes?

Yes. A single driver instance usually matches one node, but the attach function can walk children or phandle references to collect state from several nodes. See Section 9's discussion of `gpioled_fdt.c` for the children case.

How do I handle a device that has both ACPI and FDT descriptions?

Write two compat paths. Most large FreeBSD drivers that support both platforms do exactly this: separate probe functions register with each bus, and the shared code lives in the common attach. Look at `sdhci_acpi.c` and `sdhci_fdt.c` for a worked example.

What about DT bindings I do not find in the FreeBSD tree?

The source of truth for DT bindings is the upstream device-tree specification plus the Linux kernel's documentation. FreeBSD uses the same bindings where practical. If you need a binding FreeBSD does not yet support, you can typically port the relevant Linux driver or write a native FreeBSD driver that consumes the same binding.

Do I need to modify the kernel to add a new driver?

No. Out-of-tree modules compile against `/usr/src/sys` headers and load at runtime. You only edit the kernel tree itself when you contribute a driver upstream or when you need to change a generic piece of infrastructure.

How do I cross-compile for arm64 from an amd64 host?

Use the cross toolchain included in FreeBSD's build system:

```
$ make TARGET=arm64 TARGET_ARCH=aarch64 buildworld buildkernel
```

This builds a full arm64 system image on your amd64 workstation. Module-only builds follow the same pattern with narrower targets.

Is there a way to auto-load my driver when a matching DT node appears?

Yes, through `devmatch(8)` and the `SIMPLEBUS_PNP_INFO` macro. Declare your compat table, include `SIMPLEBUS_PNP_INFO(compat_data)` in the driver source, and `devmatch` picks it up.

Can I use C++ for an FDT driver?

No. FreeBSD kernel code is strictly C (and a very small amount of assembly). Other languages are not supported, and the kernel API assumes C conventions.

How do I debug a crash during DT parsing at boot?

Early crashes are hard. The usual techniques: enable verbose boot messages (`-v` in `loader.conf`), compile the kernel with KDB and DDB, use a serial console, and attach a JTAG debugger if you have one. Also consider adding temporary `printf` statements directly in the FDT parsing code under `/usr/src/sys/dev/ofw/`.

Do modules for drivers that share FDT bindings interfere with each other?

No. Each module registers its compat table, and the probe strength of matching drivers decides which one wins. If two drivers claim the same compatible with the same strength, the order they were loaded determines the winner. Give each driver a distinctive strength to avoid surprises.

How do I preserve state across kldload/kldunload cycles?

You cannot. A module that unloads loses all its state. If your driver needs persistence, write to a file, a sysctl's tunable form, a kernel tunable, or a location in NVRAM or EEPROM that outlives the module. For debugging, printing state to dmesg before unload and parsing it back after the next load is a workable shortcut.

Is the compatible list order significant?

Yes. A node may list multiple compatible strings, from most specific to least specific. `compatible = "brcm,bcm2711-gpio", "brcm,bcm2835-gpio"`; declares that the node is primarily a 2711-variant but is compatible with the older 2835 binding as a fallback. A driver that claims the 2835 compatible will match this node if no driver for 2711 is loaded. The order lets firmware describe a device in multiple levels of detail so newer kernels can take advantage of refinements without breaking older ones.

Why does FreeBSD sometimes use different property names than Linux?

Most DT properties are shared, but a few are intentionally different where FreeBSD's behavior diverges from Linux's expectations. When you port a driver, read the FreeBSD side's existing bindings carefully; silently assuming the Linux semantics is a common source of porting bugs.

What is the relationship between Newbus and intrng?

Newbus handles device probe, attach, and resource allocation. intrng handles interrupt controller registration and IRQ routing. They interoperate: Newbus resource allocation for `SYS_RES_IRQ` goes through intrng to find the right controller, and intrng dispatches interrupts back into the driver handler that Newbus registered.

32.19 Wrapping Up

This chapter took you from “FreeBSD is a general-purpose operating system” to “I can write a driver that fits into an embedded system's Device Tree.” The two tasks are not the same. The first is about using the kernel you already know; the second is about understanding a whole new vocabulary for describing the hardware the kernel runs on.

We began by looking at what embedded FreeBSD actually is: a lean, capable system running on SBCs, industrial boards, and purpose-built hardware. We saw how those systems describe themselves not through PCI enumeration or ACPI tables but through a static Device Tree that the firmware hands to the kernel at boot.

We then learned the Device Tree language itself: nodes with names and unit addresses, properties with cell-structured values, phandles for cross-references, and the `/plugin/` overlay syntax that lets us add or modify nodes without rebuilding the base blob. The language takes an afternoon to get used to; the habits it builds, about thinking of hardware as a parented, addressed, typed tree, last for a career.

With the language in hand, we looked at FreeBSD's machinery for consuming a DT. The `fdt(4)` subsystem loads the blob. The OFW API walks it. The `ofw_bus_*` helpers expose the walk in terms of compat strings and status checks. The `simplebus(4)` driver enumerates children. And the consumer frameworks (`clk`, `regulator`,

hwreset, pinctrl, GPIO) all integrate with DT phandle references so that drivers can acquire their resources through a uniform pattern.

Armed with the machinery, we built a driver. First `fdthello`, the minimal skeleton, which showed the required shape of an FDT driver in its purest form. Then `edled`, a complete GPIO-driven LED driver that illustrates attach, detach, `sysctl`, and proper resource management. Along the way we looked at how to compile overlays, deploy them through `loader.conf`, inspect the tree at runtime with `ofwdump`, and debug the class of failures that embedded drivers uniquely exhibit.

Finally, we took `edled` through the refactoring passes that turn a working driver into a finished one: tightened error paths, a real mutex, optional power and clock handling, `pinctrl` awareness, a style audit. This is the work that distinguishes a toy from a driver you would be comfortable running in production.

The chapter's labs gave you a chance to run everything yourself. The challenge exercises gave you room to extend. The troubleshooting section gave you somewhere to look when things break.

32.19.1 What You Should Be Able to Do Now

If you worked through the labs and read the explanations carefully, you can now:

- Read an unfamiliar `.dts` and explain what hardware it describes.
- Write a new `.dts` or `.dtsi` that adds a peripheral to an existing board.
- Compile that source into a binary and deploy it to a running system.
- Write an FDT-aware FreeBSD driver from scratch.
- Acquire memory, IRQ, GPIO, clock, and regulator resources through the standard consumer APIs.
- Debug the probe-did-not-fire, attach-failed, and detach-stuck classes of problems.
- Identify when a board is running in FDT mode versus ACPI mode on arm64, and what that means for your driver.

32.19.2 What This Chapter Leaves Implicit

There are three topics the chapter leaves for other sources. They are not book-shaped; they are reference-shaped, and the book would bog down if it tried to cover them fully.

First, the full DT binding specification. We covered the properties you are most likely to use. The complete binding catalog, maintained upstream by the device-tree community, is browsable at the online documentation for Linux kernel's `Documentation/devicetree/bindings/` tree. FreeBSD follows most of those bindings, with exceptions noted in `/usr/src/sys/contrib/device-tree/Bindings/` for the subset FreeBSD relies on.

Second, interrupt routing on complex SoCs. We touched on interrupt-parent chaining. A board with multiple GIC-style controllers, `pinctrl`-managed interrupts, and nested `gpio-as-interrupt` nodes can get intricate. The FreeBSD `intrng` subsystem is where to look when the simple case is no longer enough.

Third, the FDT support for peripherals that do not go through `simplebus`: USB phys, clock trees on SoCs with hierarchical PLLs, voltage scaling for DVFS. Each is its own subtopic. The book's appendix points at the canonical sources.

32.19.3 Key Takeaways

If the chapter can be distilled into a single page, here are the points worth remembering:

1. **Embedded systems describe themselves through Device Tree, not through runtime enumeration.** The blob the firmware hands the kernel is the authoritative description of what hardware is present.
2. **A driver matches through compatible strings.** Your probe consults a compat table, which compares against the node's compatible property. Get this string exactly right.
3. **simplebus(4) is the enumerator.** Every FDT driver's parent is either simplebus or ofwbus. Register with both at module load time.
4. **Resources come from the framework.** `bus_alloc_resource_any` for MMIO and IRQ, `gpio_pin_get_by_ofw_*` for GPIO, and the matching `clk_*`, `regulator_*`, `hwreset_*` calls for power and reset. Release each in detach.
5. **Overlays modify the tree without rebuilding it.** A small `.dtbo` placed under `/boot/dtb/overlays/` and listed in `fdt_overlays` is a clean way to add or enable peripherals on a given board.
6. **Interrupt wiring follows a parent chain.** A node's interrupt-parent and interrupts properties connect through intrng to the root controller. Understanding the chain is essential for debugging silent interrupts.
7. **Real drivers are the best reference.** `/usr/src/sys/dev/gpio/`, `/usr/src/sys/dev/fdt/`, and each SoC's platform tree contain dozens of FDT drivers that demonstrate every pattern you are likely to need.
8. **Error paths and teardown matter.** A driver that loads and works once is the easy case. A driver that loads, unloads, and reloads cleanly a hundred times is the robust case.
9. **The tooling is simple but effective.** `dtc`, `ofwdump`, `fdtdump`, `devinfo -r`, `sysctl dev.<name>.<unit>`, and `kldstat` together cover almost every inspection you need.
10. **FDT is just one of several hardware-description systems.** On arm64 servers, ACPI takes the same role. The driver patterns you learned here transfer, but the match layer changes.

32.19.4 Before You Move On

Before you treat this chapter as completed and move to Chapter 33, take a moment to verify the following. These are the kinds of checks that separate a learner who has seen the material from a learner who owns it.

- You can sketch, without looking, the skeleton of an FDT-aware driver, including the compat table, probe, attach, detach, method table, and `DRIVER_MODULE` registration.
- You can take a paragraph of DT source and narrate what it describes, node by node, property by property.
- You can distinguish a phandle from a path reference and explain when you would use each.
- You can explain why `MODULE_DEPEND(your_driver, gpiobus, 1, 1, 1)` matters and what goes wrong without it.
- You know which loader tunable controls overlay loading and where the `.dtbo` files live.
- Given a probe that does not fire, you have a mental checklist of four or five things to verify before reaching for a debugger.
- You know what `SIMPLEBUS_PNP_INFO` does and why it matters for production drivers.

- You can name at least three real FDT drivers in `/usr/src/sys` and describe, in a sentence each, what they demonstrate.

If any of these still feel shaky, loop back to the relevant section and re-read it. The chapter's material compounds; Chapter 33 will assume you have internalized most of what is here.

32.19.5 A Note on Sustained Practice

Embedded FreeBSD rewards regular practice. The first time you read a `.dts` for a real board, it looks overwhelming. The tenth time, you skim for the nodes you care about. The hundredth time, you edit in place. If you have a spare SBC on your desk, put it to work. Pick a sensor, write a driver, add a line to a `loader.conf`. The skill compounds. Every small driver you finish is a template for the next one, and the patterns carry across boards and vendors.

32.19.6 Connecting Back to the Rest of the Book

Chapter 32 sits late in Part 7, and the material here rests on layers you met earlier. A short tour of what you now see in a new light:

From Part 1 and Part 2, the kernel module skeleton, the `DRIVER_MODULE` registration, and the `kld-load/kldunload` lifecycle. The shape of an FDT driver is the same shape, with a different probe strategy.

From Part 3, the Newbus framework. `simplebus` is a bus driver that happens to source its children from a Device Tree rather than from a bus protocol. Every Newbus pattern you learned earlier applies, unchanged, in this context.

From Part 4, the driver-to-userspace interfaces: `cdev`, `sysctl`, `ioctl`. Our edited driver used `sysctl` as its control interface; in a larger project it might add a character device or even a netlink socket.

From Part 5 and Part 6, the practical chapters on concurrency, testing, and kernel debugging. Those tools all apply to embedded drivers in full. The only difference is that the hardware is often harder to reach, so the tools matter more.

From Part 7, Chapter 29 on 32-bit platforms and Chapter 30 on virtualization both touch on embedded angles. Chapter 31's security chapter applies directly: a driver on an embedded device is often exposed to whatever runs in the product's userspace, and the same defensive patterns apply.

The picture after Chapter 32 is that you have a complete starter toolkit for most classes of FreeBSD device work. You can write character drivers, bus drivers, network drivers, and now FDT-based embedded drivers. The remaining chapters of Part 7 refine and finalize those skills.

32.19.7 Looking Ahead

The next chapter, Chapter 33, turns from “does it work” to “how well does it work.” Performance tuning and profiling is the art of measuring what the kernel actually does, under real load, with real data. On an embedded system, the question has extra force. The hardware is usually small, the workload is often fixed, and the margin between “runs well” and “runs badly” is measured in microseconds. In Chapter 33 we look at the tools FreeBSD gives you to measure: `hwpmc`, `pmcstat`, `DTrace`, flame graphs, and the kernel's own

performance-counter probes. We also look at the mental model you need to interpret what the tools say, and at the pitfalls of tuning the wrong thing.

Beyond Chapter 33, Chapters 34 through 38 complete the mastery arc: coding style and readability, contributing to FreeBSD, porting drivers between platforms, documenting your work, and a capstone project that brings several earlier threads together. Each builds on what you have done here. The `ed1ed` driver you wrote in this chapter, extended through the challenge exercises, is a perfectly reasonable candidate to carry forward into those final chapters as a running example.

The driver work is done. The measurement work begins.

32.19.8 A Parting Word

One last encouragement before we close. Embedded FreeBSD has a quiet, steady community. The boards are inexpensive, the source is open, the mailing lists are patient. If you stick with it, you will find that each driver you write teaches you something the next one needs. The `ed1ed` driver in this chapter is a small thing, yet in writing it you touched the FDT parser, the OFW API, the GPIO consumer framework, the Newbus tree, and the `sysctl` mechanism. That is not nothing. It is the backbone of every FDT driver in the tree, exercised in miniature.

Keep the practice up. The field rewards curiosity with steady progress. The next chapter gives you the tools to make sure that progress is progress in the right direction.

When you eventually sit down in front of an unfamiliar board, the view will not feel unfamiliar anymore. You will know to ask for its `.dts`, to skim the peripherals listed under `soc`, to check which GPIO controller hosts the pin you care about, to look up the compatible string you need to match. The habits you have just built travel with you. They apply to a Raspberry Pi, to a BeagleBone, to a custom industrial board, to a QEMU virt machine. They apply in ten years from now on boards that do not yet exist, because the underlying language of hardware description is stable.

That portability, in the end, is what the Device Tree was designed for, and what this chapter was designed to teach. Welcome to embedded FreeBSD.

With Chapter 32 in hand, your toolkit is nearly complete. On to Chapter 33, and to the measurement work that will tell you whether the driver you just wrote is as efficient as it needs to be.

Good reading, and good driver writing.

33 Performance Tuning and Profiling

33.1 Introduction

Chapter 32 ended with a driver that attaches on an embedded board, reads its pin assignments from a Device Tree, toggles an LED, and detaches cleanly. That chapter answered one question: *does the driver work?* The present chapter answers a different one: *does it work well?* The two questions sound similar and are profoundly distinct.

A driver that works is one whose code path produces the expected result for each valid input. A driver that works well is one whose code path produces that result with the right throughput, the right latency, the right CPU cost, and the right memory footprint for the machine it runs on. You can write a driver that passes every functional test and still makes the system sluggish, miss deadlines, drop packets, or overheat a small board. In kernel work, correctness is the floor. Performance is the view above it.

We are going to spend this chapter building the habits, tools, and mental model that turn an observation like *the system feels slow* into a diagnosis like *the driver's write path is acquiring a contended mutex twice per byte, which on this workload adds forty microseconds per call*. The diagnosis, not the fix, is the hard part. The fix is usually small. What takes experience is the discipline to resist guessing and the skill to measure the right thing.

There is a joke among performance engineers that every beginner optimisation starts with the words *I thought it would be faster if....* That sentence is the single most reliable source of regressions in kernel code. A cache-friendly layout in the abstract can become a cache-hostile layout on a particular processor. A lock-free queue can be slower than a mutex-guarded one at low contention. A carefully tuned interrupt coalescing window can ruin latency for a small class of workloads you did not have in mind. The only antidote to *I thought it would be faster* is *I measured that it is faster*, and the whole point of this chapter is to give you a toolkit with which *I measured that* becomes a habit.

FreeBSD gives you an unusually rich set of measurement tools. DTrace, originally brought into the tree from Solaris, lets you probe almost any function in the kernel without recompiling anything. The `hwpmc(4)` subsystem and the `pmcstat(8)` userland tool expose the CPU's hardware performance counters: cycles, instructions, cache misses, branch mispredictions, stalls. The `sysctl(9)` interface and the `counter(9)` framework give you cheap, safe, always-on counters you can leave in production. The `log(9)` kernel logging facility gives you a rate-limited channel for informational messages. The `ktrace(1)` subsystem traces system-call boundaries. The `top(1)` and `systat(1)` tools let you see where CPU time is going in aggregate. Each of these tools has a particular strength, and the chapter will spend careful time showing you which tool to reach for when.

We are also going to spend time on the *habits* of measurement rather than only the tools. Measurement is easy to do badly. A driver that is instrumented heavily may not behave like the uninstrumented version; the probes change timing. A counter that is written from every CPU to a single cache line can become the bottleneck the driver is trying to measure. A DTrace script that prints on every probe turns into a denial-of-service attack

on `dmesg`. A `sysctl` that reads unaligned memory may appear fast because the compiler silently inlines it on x86-64 and slow on arm64. The tools you use to measure *affect* what you measure, and you need the habit of remembering this while you work.

The chapter has a clear arc. We start in Section 1 with what performance is, why it matters, when it is worth pursuing, and how to set measurable goals. Section 2 introduces the kernel's timing and measurement primitives: the different `nano*` and `bintime` calls, the precision-versus-cost trade-off between them, and the habits for counting operations and timing them without wrecking the code path you are trying to observe. Section 3 is the DTrace chapter-within-a-chapter: we look at the providers most useful to driver authors, the form of a useful one-liner, the shape of a longer script, and the `lockstat` provider that specialises in lock contention. Section 4 introduces hardware PMCs, explains what cycles, cache misses, and branches actually measure, and walks through a `pmcstat(8)` session from sample collection to a flame-graph-style view of a driver's hot functions. Section 5 turns inward, toward the driver: cache-line alignment, buffer pre-allocation, UMA zones, per-CPU counters via `DPCPU_DEFINE(9)` and `counter(9)`. Section 6 looks at interrupt handling and taskqueue use, because interrupts are often where the first performance cliff sits. Section 7 covers the production-grade runtime metrics you leave in the driver after tuning ends: `sysctl` trees, rate-limited logging, and the kinds of debug modes that belong in a shipped driver. Section 8 is the discipline section: how to remove your scaffolding, document what you measured, and ship the optimised driver as a version the rest of the system can rely on.

After Section 8 you will find hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up section, and a bridge into Chapter 34.

One practical note before we begin. Performance work in a kernel is easier than it was in the 1990s and harder than it appears today. The 1990s problem was that the tools were few and the documentation was thin. The modern problem is the opposite: the tools are many, each is capable, and it is easy to use the wrong one or to chase a metric that does not match the workload. Pick the simplest tool that answers your question. A DTrace one-liner that shows you a function runs twice as often as you expected is worth more than a six-hour `pmcstat` session that produces a flame graph of noise. The most valuable skill is taste in picking the question, not virtuosity with any single tool.

Let us begin.

33.2 Reader Guidance: How to Use This Chapter

Chapter 33 sits at a particular place in the book's arc. Earlier chapters taught you how to build drivers that do their job, survive bad input, integrate with the kernel's frameworks, and run on diverse platforms. This chapter teaches you how to look at those drivers with measuring instruments and decide whether they are doing their job *well*. The orientation is inward, toward code you have already written, and outward, toward the tools FreeBSD gives you to look at that code while it runs.

There are two reading paths. The reading-only path takes about three to four focused hours. You finish with a clear mental model of what the FreeBSD performance tools do, when to use each, and how a disciplined tuning cycle looks from goal to fix. You will not have produced a tuned driver, but you will be able to read a `pmcstat` output, a DTrace aggregation, a `lockstat` summary, or a `sysctl` metric from a colleague and understand what it says.

The reading-plus-labs path takes seven to ten hours spread across two or three sittings. The labs are built around a small pedagogical driver called `perfdemo`, a character device that synthesises reads from an in-kernel generator

at a configurable rate. Across the chapter you will instrument `perfdemo` with counters and `sysctl` nodes, trace it with `DTrace`, sample it with `pmcstat`, tighten its memory and interrupt paths, expose runtime metrics, and finally strip the scaffolding and ship a v2.3-optimized version. Every lab ends in something you can observe on a running FreeBSD system. You do not need embedded hardware; an ordinary amd64 or arm64 FreeBSD machine, physical or virtual, is enough.

If you happen to have a machine with a hardware PMU and privileges to load the `hwpmc(4)` kernel module, you will gain the most from Section 4. Most consumer x86 and arm64 systems do have useable counters. Virtual machines expose a subset; some cloud environments expose none. When a lab requires PMC support, we will flag it and offer an alternative path using `profile` `DTrace` sampling that works everywhere.

33.2.1 Prerequisites

You should be comfortable with the driver material from Parts 1 through 6 and the embedded-focused Chapter 32. In particular you should know:

- What `probe()`, `attach()`, and `detach()` do and when each runs.
- How to declare a softc, how `device_t` and the `kobj` method table fit together, and how `DRIVER_MODULE(9)` registers a driver with `newbus`.
- How to allocate and release a mutex via `mtx_init(9)`, `mtx_lock(9)`, `mtx_unlock(9)`, and `mtx_destroy(9)`.
- How `bus_setup_intr(9)` registers an interrupt filter or handler, and the difference between filter and `ithread` handlers.
- How to allocate memory with `malloc(9)`, release it with `free(9)`, and when `M_WAITOK` versus `M_NOWAIT` is appropriate.
- How to declare a `sysctl` node with the static macros (`SYSCTL_DECL`, `SYSCTL_NODE`, `SYSCTL_INT`, and siblings) and the dynamic context (`sysctl_ctx_init(9)`).
- How to run `kldload(8)`, `kldunload(8)`, and `sysctl(8)` on a FreeBSD system.

If any of these feel shaky, the relevant earlier chapter is a short revisit away. Chapter 7 covers module and lifecycle basics, Chapters 11 through 13 cover locking and interrupt handling, Chapter 15 covers `sysctl`, Chapter 17 covers taskqueues, Chapter 21 covers DMA and buffering, and Chapter 32 the `newbus` resource-acquisition patterns you will build on in Section 6.

You do not need prior experience with `DTrace`, `pmcstat`, or flame graphs. The chapter introduces each from scratch at the level a driver author needs, and points you at the manual pages when you want to go deeper.

33.2.2 Structure and Pacing

Sections 1 and 2 are foundational. They introduce the vocabulary of performance and the kernel's measurement primitives. They are short by the standards of this chapter, because the book's earlier material already assumes the reader knows how to read a `sysctl` and how to reason about mutexes.

Sections 3 and 4 are the tool-heavy sections. `DTrace` and `pmcstat` deserve thorough treatment because they are the two tools you will reach for most often. Expect to spend an hour on each if you are reading carefully.

Sections 5 and 6 are the tuning sections. They are the ones that tell you what to *change* once you have measured. They are also the sections most likely to tempt a reader into over-engineering; read them with the mindset that

you will apply their techniques selectively, only after evidence demands it.

Section 7 is about the metrics that stay in the driver after tuning. This section is the one that turns a sprinter into a marathon runner; the drivers that age well are the ones that expose the right numbers, not the ones that went fastest on the benchmark day.

Section 8 closes the loop. It teaches you how to remove the temporary instrumentation that helped during tuning, document the benchmarks you ran, update the manual page with the tuning knobs the driver now exposes, and publish the driver at its new version.

Read the sections in order on a first pass. Each is written to stand alone enough for later reference, but the book's progressive teaching model depends on the order.

33.2.3 Work Section by Section

Each section covers one clear piece of the subject. Read one, let it sit for a while, then move on. If the end of a section feels blurry, pause and re-read the final paragraphs; they are designed to consolidate the material before the next section builds on it.

33.2.4 Keep the Lab Driver Close

The lab driver lives under `examples/part-07/ch33-performance/` in the book's repository. Each lab directory holds a self-contained stage of the driver with its `Makefile`, `README.md`, and any DTrace scripts or helper shell scripts. Clone the directory, work in place, build it with `make`, load it with `kldload`, and run the relevant measurements. The feedback loop between a kernel module and a `sysctl` or DTrace reading is the most educational feature of this chapter; use it.

33.2.5 Open the FreeBSD Source Tree

Several sections refer to real FreeBSD files. The most useful ones to keep open for this chapter are `/usr/src/sys/sys/counter.h` and `/usr/src/sys/sys/pcpu.h`, which define the counter and per-CPU primitives; `/usr/src/sys/sys/time.h`, which declares the kernel's time functions; `/usr/src/sys/sys/lockstat.h`, which defines the lockstat DTrace probes; `/usr/src/sys/vm/uma.h`, which declares the UMA zone allocator; `/usr/src/sys/dev/hwpmc/`, the PMC driver tree; and `/usr/src/sys/kern/subr_taskqueue.c`, where `taskqueue_start_threads_cpuset()` lives. Open them when the chapter points you at them. The manual pages (`counter(9)`, `sysctl(9)`, `mutex(9)`, `dtrace(1)`, `pmc(3)`, `pmcstat(8)`, `hwpmc(4)`, `uma(9)`, `taskqueue(9)`) are the second-best references after the source.

A note on line numbers. Each of those files will still define the symbols the chapter references: `sbin_uptime` in `time.h`, the lockstat probe macros in `lockstat.h`, `taskqueue_start_threads_cpuset` in `subr_taskqueue.c`. Those names persist across FreeBSD 14.x point releases. The line each one sits on in your tree may have moved since this chapter was written, so search for the symbol rather than scrolling to a specific number.

33.2.6 Keep a Lab Logbook

Continue the lab logbook from earlier chapters. For this chapter, note the *numbers* in particular. A log entry like *perfdemo v1.0, read() at 1000 Hz, median 14.2 us, P99 85 us* is the kind of evidence that lets you compare a later version honestly. Without the logbook, you will find yourself guessing a week from now whether a change made things faster; with it, you can check.

33.2.7 Pace Yourself

Performance work is cognitively demanding. A reader who does two focused hours, takes a proper break, and does two more hours will almost always go further than a reader who grinds through five hours in one sitting. The tools and the data benefit from a rested mind.

33.3 How to Get the Most Out of This Chapter

A few habits compound throughout the chapter. They are the same habits that experienced performance engineers use; the only trick is to start early.

33.3.1 Measure Before You Change

This is the rule. Every optimisation should begin with a measurement that shows the current behaviour, end with a measurement that shows the new behaviour, and compare the two against a goal stated in advance. An optimisation without a before-and-after number is a guess that happened to pass review.

If you remember nothing else from this chapter, remember this.

33.3.2 State the Goal in Numbers

A goal like *I want the read path to be faster* is not a goal. A goal like *I want median read() latency below 20 microseconds and P99 below 80 microseconds, on this workload* is a goal. You can measure it, you can know when you have achieved it, and you can stop optimising once you have. Most performance work runs long because the goal was vague.

33.3.3 Prefer the Simplest Tool That Answers the Question

The temptation to reach for `pmcstat` with a callgraph and a flame graph is strong. Usually a DTrace one-liner is enough. The simplest tool that tells you which function dominates, which counter is climbing, or which lock is contended is the right tool. Escalate only when the simple tool runs out.

33.3.4 Never Instrument the Hot Path at Production Cost

The act of measuring adds latency. A counter increment costs a few nanoseconds on modern hardware. A DTrace probe, when enabled, costs tens to hundreds of nanoseconds depending on the probe. A `printf` in the

hot path costs tens of microseconds. Know these rough numbers before you sprinkle measurement code around. If the driver's budget is fifty microseconds, a single `printf` will eat the budget.

33.3.5 Read the Manual Pages You Use

`dtrace(1)`, `pmcstat(8)`, `hwpmc(4)`, `sysctl(8)`, `sysctl(9)`, `counter(9)`, `uma(9)`, `taskqueue(9)`, `mutex(9)`, `timer(9)`, and `logger(1)` are the manual pages that matter for this chapter. Each is short, precise, and written by people who know the tool deeply. The book cannot replace them, only orient you.

33.3.6 Type the Lab Code

The `perfdemo` driver in the labs is small for the same reason `edled` was small in Chapter 32: so that you can type it. Type it. The finger-memory of writing a `sysctl` tree, a DTrace probe definition, a counter increment, and a lock acquisition path is worth more than reading the same code ten times.

33.3.7 Tag Every Measurement with Its Context

A number without context is useless. Every measurement should be recorded with the workload that produced it, the machine it ran on, the kernel version, the driver version, and what the system was also doing at the time. A driver that does 1.2 million operations per second on an idle server may do 400,000 on the same server while a backup is running. If you do not record the context, you will be mystified when the number changes and will blame the driver.

33.3.8 Do Not Tune What Is Not Slow

Every section of this chapter will describe a technique you could apply. Apply them only when measurement demands. Cache-line alignment matters when false sharing is a real cost; on a low-concurrency driver it is clutter. Per-CPU counters matter when counter contention is real; on a low-throughput driver they are premature. Resist the temptation to sprinkle all the techniques because you have just learned them; the book has taught you the options, and the measurements tell you which to choose.

33.3.9 Follow the Numbers Between Sections

As you work through the chapter, keep the `perfdemo` driver's numbers in your logbook. Each section should produce a small improvement that moves the numbers in the right direction. If a section's technique does not move your numbers, write that down too; it is equally valuable to know what *did not* help.

With those habits in hand, let us look at the reason any of this matters in the first place: the performance behaviour of the driver itself.

33.4 Section 1: Why Performance Matters in Device Drivers

Every driver is a performance contract whether its author writes one or not. The contract says: *when you ask me to do X, I will do X in this amount of time, using this much CPU, with this peak memory, and with*

this variability. A driver that keeps its contract is a well-behaved part of the system. A driver that breaks it produces the symptoms everyone on the system feels: audio skipping, video tearing, packets dropped, storage queues piling up, shells hanging on a write, interrupt-driven sensors missing events, a UI stuttering even though the machine has spare CPU. Most user-visible performance problems on any non-trivial system have a driver somewhere in their call path.

The contract has four axes. Learning to see them as separate is the first real step of this chapter.

33.4.1 The Four Axes of Driver Performance

Throughput is the amount of work the driver can do per unit time. For a network driver it is packets per second, or bytes per second. For a storage driver it is I/O operations per second (IOPS) or megabytes per second. For a character device it is reads or writes per second. For a GPIO driver it is pin toggles per second. Throughput answers the question *how much*?

Latency is the time between a request and its completion. For a network driver it is the microseconds between a packet arriving and the stack handing it to the protocol layer. For a storage driver it is the milliseconds (or now microseconds) between a `read()` call and the data being available. For an input driver it is the time between a key press and the userland process seeing the event. Latency answers the question *how fast?*, and unlike throughput it is usually measured as a distribution. A median (P50) of 10 microseconds with a P99 of 500 microseconds is not the same driver as a median of 50 microseconds with a P99 of 60 microseconds.

Responsiveness is a related but distinct axis: how quickly the driver wakes up and does its work after an event, from the perspective of other threads. A driver may have fine latency on its hot path but still be unresponsive if it holds a lock for ten milliseconds, if it busy-waits on a register poll, or if it queues work on a taskqueue that shares threads with some other slow subsystem. Responsiveness is what users and schedulers experience; latency is what the driver itself would report.

CPU cost is how much CPU time each unit of work consumes. A driver doing 100,000 operations per second at 1% CPU is cheaper than one doing the same work at 10% CPU. On a small embedded board this is the axis that decides whether a sensor loop is feasible at all; on a larger server it is the axis that decides how much else can share the machine.

These four axes are not independent. A driver can trade throughput for latency: batch more work per interrupt and you raise throughput but also raise the latency each packet sees. It can trade latency for CPU: poll more often and you lower latency but raise CPU cost. It can trade responsiveness for throughput: hold the lock longer per call and each call is cheaper but contention rises. You cannot minimise all four at once; performance work is about choosing the trade-off that matches the workload.

That, in a sentence, is why measurement matters. Without numbers, you cannot know which axis is actually the problem, and you cannot know whether your change improved the right one.

33.4.2 A Worked Example: Where Do These Axes Show Up?

Consider a network driver handling a small flow of 100 packet-per-second control traffic and a large flow of 1 gigabit-per-second bulk transfer at the same time. Each flow needs a different performance profile.

The small flow wants low latency. A 1 ms spike on a control packet may miss a deadline that the higher layer cares about. For this flow, you would rather handle each packet immediately than batch. The driver's RX path

should wake up the protocol layer on every packet, the interrupt should be serviced with low delay, and any locks the packet passes through should be held briefly.

The large flow wants high throughput and is relatively insensitive to latency. Each packet in the bulk transfer can sit in a receive queue for tens of microseconds without anyone noticing, and the system benefits if the driver batches interrupt processing to reduce per-packet overhead. For this flow, interrupt coalescing is your friend and a dedicated taskqueue thread makes sense.

A driver serving only one of these flows can tune for it. A driver serving both has to pick a compromise, or maintain multiple queues with different policies, or provide a tuning knob that lets the operator choose. In all three cases, the driver author needs to know which axis matters for the workload the driver will actually face.

Real FreeBSD drivers do make this kind of distinction. The `iflib(9)` framework that many modern network drivers use provides both a fast-path receive for low-latency delivery and a `rxeof` batching loop for throughput. The `cam(4)` storage subsystem distinguishes between synchronous I/O that blocks a thread and asynchronous I/O that does not. The `hwpmc(4)` module distinguishes between counting mode (low-overhead, always on) and sampling mode (higher overhead, diagnostic). Every mature driver tree in FreeBSD has these distinctions built in somewhere; noticing them is part of learning to read kernel code as a performance engineer.

33.4.3 When Optimisation Is Worth Doing

Not every driver needs tuning. A GPIO driver that toggles a pin a few times a second is doing a fine job even if every operation takes a millisecond. A debug pseudo-device that logs one line per hour is as fast as it needs to be. An ACPI-hotplug-notification driver that fires once per week spends almost no time in any state. For drivers like these, spending a day profiling would be a day wasted.

The drivers that usually merit tuning share some common features. They sit in a *hot path*, a sequence of calls that a high-rate or latency-sensitive workload passes through many times per second. They are in the ladder from the userland syscall to the hardware, with enough layers above and below them to make the driver a measurable fraction of total cost. They are on devices whose hardware is fast enough that the driver, not the device, becomes the bottleneck. And they are visible to users or to tests, so that a regression will be noticed and a speedup will be valued.

The classic examples are high-speed network drivers (10G, 25G, 40G, 100G), NVMe storage drivers, virtualisation I/O drivers (`virtio-net`, `virtio-blk`), audio drivers with tight latency budgets, and on embedded systems any driver in the main control loop of the product. If a driver is on this list, measuring it and tuning it pays back many times over. If it is not, tune only when a measurement (or a complaint from a user) points at the driver as the problem.

33.4.4 When Optimisation Is Premature

Knuth's remark that *premature optimisation is the root of all evil* was about the middle layer of a program, not its outermost design decisions. The saying applies to drivers in a particular way: it is almost always wrong to spend effort optimising code before it works correctly, before it is measured, or before a goal has been set. The reason is not that optimisation is never warranted; it is that early optimisation tends to make code harder to reason about, harder to debug, and harder to change when the real bottleneck turns out to be somewhere else.

Concretely, the following are red flags for premature optimisation in a driver:

- Hand-written SIMD code in a driver whose throughput is measured in thousands, not billions, of operations per second.
- A carefully cache-line-aligned softc in a driver that has at most one outstanding operation per CPU at a time.
- A lock-free ring buffer in a driver whose real bottleneck is a `malloc(9)` call per operation.
- A per-CPU counter farm in a driver that runs one operation per second.
- An elaborate taskqueue scheme in a driver whose interrupt handler runs in 2 microseconds.

In each case the technique is real and legitimate, but it has been chosen without evidence. The effort costs something (complexity, reviewability, risk of bugs), and it produces a benefit only when evidence shows it is needed. The discipline is not *never optimise*; it is *measure, then decide*.

33.4.5 Setting Measurable Goals

A performance goal has four parts: the **metric**, the **target**, the **workload**, and the **environment**.

The metric names what you are measuring. *Median read() latency, packets per second forwarded, interrupts per second serviced, CPU percentage at full load, peak kernel memory used, or P99 worst-case latency of the probe-to-attach path* are all valid metrics. Each is a single number produced by a single procedure.

The target names the value you want the metric to have. *Below 20 microseconds, above 1 million packets per second, under 5% CPU, under 4 MB of kernel memory at peak*. The target should be concrete and measurable.

The workload names the conditions under which the metric is produced. *read() calls issued at 10,000 Hz with M_WAITOK allocation, one TCP stream at the line rate on a 10 Gbps NIC, a 4K random-read test against a 16 GB file*. The workload should be reproducible; if no one can rerun it, the measurement is not useful.

The environment names the machine, the kernel, and the surrounding processes. *amd64, 8-core Xeon at 3.0 GHz, FreeBSD 14.3 GENERIC kernel, otherwise idle*. Two different machines will give different numbers for the same driver, and a measurement that is valid on one environment may be invalid on another.

A goal of the form *the perfdemo driver's median read() latency, measured across 100,000 calls on an idle amd64 Xeon E5-2680 at 3.0 GHz running FreeBSD 14.3 GENERIC, with one userland reader thread pinned to CPU 1, should be below 20 microseconds* is a complete performance goal. It has a metric, a target, a workload, and an environment. You can run it, record the result, compare a tuning change, and decide whether you are done.

A goal of the form *make the driver faster* is useless. It has no metric, no target, no workload, no environment. You can work on it for a year and still not know when to stop.

The discipline of writing the goal down before you start is where most of the quality in a performance project comes from. If you cannot write the goal, you are not ready to optimise. The rest of the chapter will assume you have one, and will teach you the tools that let you check it.

33.4.6 A Note on “Fast” and “Correct”

Two failures of performance work deserve to be named early.

The first is that a driver that is fast in one dimension can be bad overall. A driver that achieves blistering throughput by dropping occasional packets silently is not faster; it is broken. A driver that halves its latency

by skipping a safety check in the fast path is not faster; it is risky. A driver that reduces CPU by deferring free until unload is not faster; it is leaking. Every optimisation must preserve correctness, including the correctness of error paths and the behaviour under pathological input. An optimisation that trades correctness for speed is a regression, full stop.

The second failure is that a driver that is fast today can be a debugging nightmare tomorrow. Performance work often introduces complexity: pre-allocation pools, multiple locks, batched operations, inline assembly for atomics, careful memory layouts. Each of these is a future debugging cost. Before you commit to a complex optimisation, ask whether a simpler one is good enough. The driver that lives in the tree for years is not usually the one that was fastest in the benchmark; it is the one a maintainer can still read and reason about after the original author has moved on.

We will return to both points in Section 8 when we talk about shipping a tuned driver.

33.4.7 Exercise 33.1: Define Performance Goals for a Driver You Have

Pick a driver you have written in earlier chapters. `perfdemo` will appear in Section 2, so for now choose an earlier one: `nullchar` from Chapter 7, the ring-buffer character driver from Chapter 12, or the `ed` from Chapter 32. For that driver, write performance goals for at least two of the four axes (throughput, latency, responsiveness, CPU cost). For each goal, include a metric, a target, a workload, and an environment. Keep the goals in your logbook.

You do not have to have measured the driver yet. The exercise is the writing of the goal. If you cannot decide on a target, write *unknown, to be measured in Section 2* and come back.

The act of writing a specific goal sharpens what the rest of the chapter is trying to teach. Readers who skip this exercise often find Sections 2 through 7 feel abstract; readers who do it find that each new tool has an obvious use.

33.4.8 Wrapping Up Section 1

We opened with the claim that every driver is a performance contract whether the author writes one or not. The four axes of throughput, latency, responsiveness, and CPU cost give you a vocabulary for writing that contract down. The discipline of measurable goals, pinned to a metric, target, workload, and environment, gives you a way to know whether the contract is being kept. The reminders about premature optimisation and about the relationship between speed and correctness keep the work honest.

The rest of the chapter is the toolkit. In the next section we look at the kernel's measurement primitives: timing functions, counters, `sysctl` nodes, and the FreeBSD tools (`sysctl`, `dtrace`, `pmcstat`, `ktrace`, `top`, `sysstat`) that expose the metrics your goal depends on.

33.5 Section 2: Measuring Performance in the Kernel

Measurement in userland is the world most programmers grow up in. You wrap a function call with a timer, you run it a million times, you print the average. Measurement in the kernel is not so different in shape, but it is more sensitive in practice. Kernel code runs at the boundary of the system; a careless measurement can slow down the very thing it is trying to measure, or worse, change the behaviour of the system in ways that make the

measurement meaningless. The goal of this section is to teach you how to measure inside the kernel without contaminating the measurement.

We will move through four things: the kernel's time functions, the counter primitives that let you accumulate events cheaply, the tools that read those counters from userland, and the habits of instrumentation that keep the measurement honest.

33.5.1 Kernel Time Functions

The kernel exposes several functions that return the current time. They differ in precision, cost, and whether they advance monotonically. The declarations are in `/usr/src/sys/sys/time.h`.

There are two orthogonal choices when you pick one of these. The first choice is **format**:

- `*time` variants return a `struct timespec` (seconds and nanoseconds) or `struct timeval` (seconds and microseconds).
- `*uptime` variants return the same format, but measured from the system's boot rather than from the wall clock. Uptime does not jump when the administrator adjusts the wall clock; wall time does.
- `*bintime` variants return a `struct bintime` (a fixed-point binary fraction of a second) and `sbintuptime()` returns a `sbintime_t`, a signed 64-bit fixed-point value. These are the kernel's internal, highest-resolution formats.

The second choice is **precision versus cost**. FreeBSD distinguishes between a *fast but imprecise* path and a *precise but more expensive* path:

- Functions with the **get** prefix (`getnanotime()`, `getnanouptime()`, `getbinuptime()`, `getmicrotime()`, `getmicrouptime()`, `getsbinuptime()`) return a value cached at the last timer tick. They are very fast, typically just a few loads from a cache-resident global. Their precision is on the order of 1/hz, which on a default FreeBSD system is about 1 millisecond.
- Functions without the **get** prefix (`nanotime()`, `nanouptime()`, `binuptime()`, `microtime()`, `microuptime()`, `sbintuptime()`) call into the selected timecounter hardware and return a value accurate to the timecounter's resolution, often tens of nanoseconds. They cost more, typically tens to hundreds of nanoseconds, and on some hardware may serialise the CPU pipeline.

The golden rule: use the `get*` variants whenever 1 millisecond of precision is enough, and the non-`get` variants when you need real precision. A driver measuring its own hot-path latency generally needs the non-`get` variants. A driver timestamping a rare event, or recording the time of a state change, can almost always use the `get*` variants.

Here is the short version of the decision tree:

- Need wall-clock time, millisecond precision: `getnanotime()`.
- Need uptime (monotonic), millisecond precision: `getnanouptime()`.
- Need uptime, nanosecond precision: `nanouptime()`.
- Need uptime, highest resolution, minimal cost per call: `sbintuptime()` (or `getsbinuptime()` when millisecond precision is fine).
- Need to compute a duration: subtract two `sbintuptime()` values and convert to microseconds or nanoseconds at the end.

A representative timing in a driver read path might look like this:

```
#include <sys/time.h>
#include <sys/sysctl.h>

static uint64_t perfdemo_read_ns_total;
static uint64_t perfdemo_read_count;

static int
perfdemo_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    sbintime_t t0, t1;
    int error;

    t0 = sbinuptime();

    /* ... the real work of reading ... */
    error = do_the_read(uio);

    t1 = sbinuptime();

    /* Convert sbintime_t difference to nanoseconds.
     * sbt2ns() is defined in /usr/src/sys/sys/time.h. */
    atomic_add_64(&perfdemo_read_ns_total, sbttons(t1 - t0));
    atomic_add_64(&perfdemo_read_count, 1);

    return (error);
}
```

A few things are worth noticing. The timestamps are captured with `sbinuptime()`, not `getsbinuptime()`, because we are measuring microsecond-scale durations. The accumulator and counter are 64-bit and updated with `atomic_add_64()`, so concurrent readers do not lose updates. The conversion from `sbintime_t` to nanoseconds uses `sbttons()`, a macro declared in `/usr/src/sys/sys/time.h`; we do not do the division on the hot path. And neither the timestamps nor the accumulation print anything; the data goes into counters that a `sysctl` reads on demand.

The pattern generalises. Timestamp at the boundaries of the operation you care about, accumulate the difference, expose the accumulator through `sysctl`, and compute derived metrics (average, throughput) in userland.

33.5.2 Time Stamp Counters and Other High-Precision Sources

Below the `nanotime` and `sbinuptime` family sits the hardware that actually feeds them: the processor's Time Stamp Counter (TSC) on x86, the Generic Timer on arm64, and their equivalents on other architectures. FreeBSD abstracts these sources behind a *timecounter* interface; the kernel selects one at boot

and the `sbnuptime` path reads it. You can see which timecounter your system is using with `sysctl kern.timecounter`:

```
# sysctl kern.timecounter
kern.timecounter.tick: 1
kern.timecounter.choice: ACPI-fast(900) HPET(950) i8254(0) TSC-low(1000)
↪ dummy(-1000000)
kern.timecounter.hardware: TSC-low
```

On a modern amd64 machine the TSC is almost always the chosen source. It advances at a constant rate regardless of CPU frequency (on processors that support invariant TSC, which is essentially everything since the mid-2000s), it is cheap to read (a single instruction), and its resolution is on the order of the CPU clock period, roughly 0.3 nanoseconds at 3 GHz.

A driver rarely needs to read the TSC directly. `sbnuptime()` already wraps it. But when you are debugging the kernel's own timing code, or when you need a timestamp that is *only* a load from a register with no further arithmetic, the kernel provides `rdtsc()` as a static `__inline` function in `/usr/src/sys/amd64/include/cpufunc.h`. Its use is almost always a mistake in driver code: you lose the kernel's unit conversions, you lose portability across architectures, and you gain a few nanoseconds. Reach for `sbnuptime()` instead; the portability and abstraction pay for themselves.

On arm64, the equivalent of the TSC is the Generic Timer's counter register, read via the ARM-specific `READ_SPECIALREG` macros in `/usr/src/sys/arm64/include/cpu.h`. The kernel exposes it through the same `sbnuptime()` abstraction, so a driver written to `sbnuptime()` is portable across the two architectures without change. This is one of the small but meaningful benefits of staying on the abstractions FreeBSD provides.

A subtle point: the different timecounter choices have different costs and different precisions. On the Intel and AMD generations currently in service, HPET is slow (on the order of hundreds of nanoseconds to read) but high-precision, ACPI-fast is fast but lower-precision, and TSC is fast and precise, which is why the kernel prefers it when available. If `kern.timecounter.hardware` shows anything other than TSC on an amd64 machine, something on the system disabled it, and `sbnuptime()` calls will be more expensive than you expect. Check `dmesg | grep timecounter` early in any performance investigation. See Appendix F for a reproducible benchmark that rotates through each timecounter source.

33.5.3 Composition: Timing, Counting, and Aggregating Together

The examples above showed timing (a pair of `sbnuptime()` calls) and counting (a `counter_u64_add()` increment) separately. Real driver measurement almost always composes the two: you want to know *how many* of each kind of operation happened *and* what the *latency distribution* of each kind looked like. The composition is simple once the primitives are in hand.

A pattern that appears in many FreeBSD drivers is the counter-and-histogram pair. For every operation, you increment a counter and add its latency to a histogram bucket. The histogram is represented as an array of `counter_u64_t` values, one per bucket, with bucket boundaries chosen for the expected range. On the hot path, you do one counter increment for total count and one counter increment for the bucket the latency fell in:

```

#define PD_HIST_BUCKETS 8

static const uint64_t perfdemo_hist_bounds_ns[PD_HIST_BUCKETS] = {
    1000,          /* <1us    */
    10000,         /* <10us   */
    100000,        /* <100us  */
    1000000,       /* <1ms    */
    10000000,      /* <10ms   */
    100000000,     /* <100ms  */
    1000000000,    /* <1s     */
    UINT64_MAX,    /* >=1s    */
};

static counter_u64_t perfdemo_read_hist[PD_HIST_BUCKETS];
static counter_u64_t perfdemo_read_count;

static int
perfdemo_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    sbintime_t t0, t1;
    uint64_t ns;
    int error, i;

    t0 = sbinuptime();
    error = do_the_read(uio);
    t1 = sbinuptime();

    ns = sbttens(t1 - t0);
    counter_u64_add(perfdemo_read_count, 1);
    for (i = 0; i < PD_HIST_BUCKETS; i++) {
        if (ns < perfdemo_hist_bounds_ns[i]) {
            counter_u64_add(perfdemo_read_hist[i], 1);
            break;
        }
    }

    return (error);
}

```

The hot path does one `sbintuptime` pair (on the order of a few tens of nanoseconds each on typical FreeBSD 14.3-amd64 hardware), one multiplication to convert to nanoseconds, a linear scan of eight bucket bounds (branch-predicted well after warm-up), and two counter increments. As a rough order-of-magnitude figure on the same class of machine, the total overhead stays comfortably under a microsecond, which is acceptable for most read paths and small enough to leave on in production. See Appendix F for a reproducible benchmark of

the underlying `sbinuptime()` cost on your own hardware.

Exposing the histogram via `sysctl` is a small extension of the procedural-`sysctl` pattern from Section 7. You fetch each bucket's counter, copy them into a local array, and hand the array to `SYSCTL_OUT()`. Userland reads the array and plots it.

If the expected latency range is known, the linear bucket search can be replaced by a constant-time mapping. For power-of-ten buckets, $\log_{10}$ of the latency lands you in the right bucket; for power-of-two buckets, a single `fls` instruction suffices. The constant-time variants are only worth the complexity when the linear search appears as a real cost in a profile, which in practice happens only for very hot paths with many buckets.

33.5.4 A Complete Instrumented Read Path

Putting the above together, a fully instrumented `perfdemo_read()` that captures call count, error count, total bytes, total latency, and a latency histogram looks like this:

```
#include <sys/counter.h>
#include <sys/time.h>

struct perfdemo_stats {
    counter_u64_t reads;
    counter_u64_t errors;
    counter_u64_t bytes;
    counter_u64_t lat_ns_total;
    counter_u64_t hist[PD_HIST_BUCKETS];
};

static struct perfdemo_stats perfdemo_stats;

static int
perfdemo_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    sbintime_t t0, t1;
    uint64_t ns, bytes_read;
    int error, i;

    t0 = sbinuptime();
    bytes_read = uio->uio_resid;
    error = do_the_read(uio);
    bytes_read -= uio->uio_resid;
    t1 = sbinuptime();

    ns = sbttions(t1 - t0);
    counter_u64_add(perfdemo_stats.reads, 1);
    counter_u64_add(perfdemo_stats.lat_ns_total, ns);
    counter_u64_add(perfdemo_stats.bytes, bytes_read);
```

```

    if (error)
        counter_u64_add(perfdemo_stats.errors, 1);
    for (i = 0; i < PD_HIST_BUCKETS; i++) {
        if (ns < perfdemo_hist_bounds_ns[i]) {
            counter_u64_add(perfdemo_stats.hist[i], 1);
            break;
        }
    }

    return (error);
}

```

This is the shape of a production-grade measurement. It counts, it times, it records distributions, and it costs a handful of nanoseconds per call on the hot path. The derived metrics (mean latency, P50, P95, P99 estimated from the histogram) are computed in userland on demand. The counter(9) values scale to tens of cores with no contention; the linear bucket search is cache-friendly; the conditional errors counter adds no cost on the success path.

In the sections that follow, we will tune other parts of the driver, but the measurement scaffolding above is the baseline we measure *against*. Every change we make will be judged against the numbers the scaffold produces.

33.5.5 Counters: Simple, Atomic, Per-CPU

Kernel code often needs to count things: operations completed, errors, retries, interrupt storms. FreeBSD offers three grades of counter primitive, in order of increasing complexity and increasing scalability.

A plain `uint64_t` updated with `atomic_add_64()`. This is the simplest counter. It is correct under concurrency, it is cheap on modern hardware, and it works everywhere. At low concurrency (tens of thousands of updates per second from a handful of CPUs), it is a fine default. At high concurrency (hundreds of thousands of updates per second from many CPUs), the cache line holding the counter becomes a contention point and the atomic operation starts to show up in profiles. For most driver counters, the plain atomic is the right choice.

A counter(9) value (`counter_u64_t`). This is a per-CPU counter with a simple fetch interface. You allocate it with `counter_u64_alloc()`, update it with `counter_u64_add()`, and read it with `counter_u64_fetch()` (which sums across all CPUs). Because each CPU updates its own memory, there is no contention on the update path. The trade-off is that the fetch iterates over all CPUs, so reading the counter is slightly more expensive. For drivers whose counters are updated on fast paths from many CPUs, counter(9) is a better fit than a plain atomic. The declarations are in `/usr/src/sys/sys/counter.h`.

A `DPCPU_DEFINE(9)` variable. DPCPU stands for *dynamic per-CPU*. It lets you define any type of variable, not just a counter, with per-CPU storage. You declare the variable with `DPCPU_DEFINE(type, name)`, access the current CPU's copy with `DPCPU_GET(name)` and `DPCPU_SET(name, v)`, and sum across all CPUs with `DPCPU_SUM(name)`. It is the most flexible of the three primitives, and it is what counter(9) is implemented on top of. Reach for it when you need per-CPU state that is not just a counter, or when you need a counter and have a specific reason to bypass the counter(9) abstraction. The declarations are in `/usr/src/sys/sys/pcpu.h`.

Here is a practical example. Suppose `perfdemo` has three counters: total reads, total errors, and total bytes delivered. The counter(9) form is:

```
#include <sys/counter.h>

static counter_u64_t perfdemo_reads;
static counter_u64_t perfdemo_errors;
static counter_u64_t perfdemo_bytes;

/* In module init: */
perfdemo_reads = counter_u64_alloc(M_WAITOK);
perfdemo_errors = counter_u64_alloc(M_WAITOK);
perfdemo_bytes = counter_u64_alloc(M_WAITOK);

/* On the fast path: */
counter_u64_add(perfdemo_reads, 1);
counter_u64_add(perfdemo_bytes, bytes_delivered);
if (error)
    counter_u64_add(perfdemo_errors, 1);

/* In module fini: */
counter_u64_free(perfdemo_reads);
counter_u64_free(perfdemo_errors);
counter_u64_free(perfdemo_bytes);

/* In a sysctl handler that reports the values: */
uint64_t v = counter_u64_fetch(perfdemo_reads);
```

The counter(9) API keeps the hot-path cost small and constant regardless of how many CPUs your driver serves. On a 64-core server it is a transformational improvement over a single atomic. On a 4-core laptop it is a small but real improvement. On an embedded single-core board it is no better than an atomic. Use it when there will be contention, or when you want to be ready for the day a driver graduates from a 2-core test machine to a 64-core production one.

33.5.6 Exposing Metrics via sysctl

A counter that nobody can read is a counter that does not exist. FreeBSD's `sysctl(9)` subsystem is the standard way to expose driver metrics to userland, and the chapter covers the production patterns in detail in Section 7. For now, the simplest pattern is:

```
SYSCCTL_NODE(_hw, OID_AUTO, perfdemo, CTLFLAG_RD, 0,
    "perfdemo driver");

SYSCCTL_U64(_hw_perfdemo, OID_AUTO, reads, CTLFLAG_RD,
```

```
&perfdemo_reads_value, 0,  
"Total read() calls");
```

For a counter(9) variable, the idiomatic way is to use a procedural `sysctl` that calls `counter_u64_fetch()` on each read. We will write that pattern out in Section 7. For now, the `SYSCTL_U64` macro above is enough for a plain `uint64_t` or for the `counter_u64_fetch()` result cached into a regular variable during a periodic callout.

From userland, `sysctl hw.perfdemo.reads` returns the value, and scripts can poll at intervals, compute rates, and produce plots.

33.5.7 The Measurement Tools FreeBSD Gives You

On top of the primitives above, FreeBSD ships several userland tools that read the kernel's exposed metrics and present them in useful ways. A short tour follows; we will return to the important ones in later sections.

sysctl(8). Reads any `sysctl` node. The most basic measurement interface. It is the tool for polling a counter every second to compute a rate, for checking a one-shot metric, and for dumping a subtree for later comparison. A script like `while sleep 1; do sysctl hw.perfdemo; done | awk ...` is a surprisingly common first step.

top(1). Shows processes, threads, CPU use, memory use. With the `-H` flag it shows kernel threads, including interrupt and taskqueue threads. Useful when a driver has its own thread whose CPU use you want to watch, or when you want to see an `ithread` spinning on interrupts.

sysstat(1). An older but still-useful family of monitoring views. `sysstat -vmstat` shows CPU, disk, memory, and interrupt rates. `sysstat -iostat` focuses on storage. `sysstat -netstat` focuses on the network. When you want a live monitor without writing a script, `sysstat` is often faster to reach for than anything more elaborate.

vmstat(8). A per-second view of system-wide statistics. `vmstat -i` lists interrupt rates by vector. `vmstat -z` lists UMA zone activity, which is invaluable when tracking down kernel memory pressure.

ktrace(1). Traces system-call entries and exits for specific processes. It is lower-level than `DTrace` and predates it, but remains useful when the interaction you want to see crosses the userland-kernel boundary and does not require kernel-side custom probes.

dtrace(1). The Swiss army knife of FreeBSD kernel observation. Covered in depth in Section 3.

pmcstat(8). The hardware-performance-counter tool. Covered in depth in Section 4.

The important insight is that these tools are not competitors. Each one is best at a particular kind of measurement. You learn performance work by learning which tool answers which question, and reaching for that one first.

33.5.8 The Heisenberg Effect, Practically

The joking reference in the chapter's introduction was to a real problem: the act of measuring changes what is measured. In kernel code the problem has teeth, and you need to know its shape.

The first form of the problem is **direct overhead**. Every measurement has a cost. If you add a `printf` inside a read path that runs at 100,000 reads per second, you have added tens of microseconds per read, and the

driver's effective rate drops to a fraction of what it would be without the print. If you time every operation with `sbinuptime()` and increment an atomic counter, you have added perhaps 50 nanoseconds per call; for most drivers this is acceptable, but in a nanosecond-budget hot path even this is too much. The rule of thumb: estimate the cost of each measurement probe and decide whether the driver can afford it on the path you are probing.

The second form is **cache and lock contention**. A single atomic counter updated by all CPUs is a cache line bouncing between them. On low-contention paths this costs a few nanoseconds. On high-contention paths it can cost hundreds of nanoseconds per update and dominate the operation. A counter that is supposed to be cheap can become the bottleneck it is trying to measure. The fix, as we saw above, is `counter(9)` or a DPCPU variable, both of which update per-CPU memory.

The third form is **observer-induced behaviour change**. This is the most insidious. Adding instrumentation can change what the system does beyond the direct cost. A `printf` may cause a timer that was about to fire to miss its deadline. A DTrace probe that turns out to use a slower code path can disable a fast-path optimisation. A breakpoint set in a debugger can hide a race that the unprobed code exhibits. Good measurement design tries to minimise observer effects, but the awareness that they exist is what separates a disciplined measurement practice from a superstitious one.

The practical consequence is that you should always *disable* measurement code when measuring the baseline, unless the measurement is itself what you are evaluating. If you want to know how fast a driver can go, run it with the minimum instrumentation needed to report the result. If the minimum instrumentation is expensive, reduce it. This is also why `counter(9)` is preferred over atomics for hot-path counting: not just because it is faster, but because it perturbs the system less.

33.5.9 Instrumenting Without Contamination

The practical advice on adding measurement code distils into a small checklist. Before you add a probe, ask:

1. **What metric is this probe producing?** Every probe must correspond to a concrete line in the goals document. If you cannot name it, do not add it.
2. **On what path does the probe live?** A probe on the module-load path is free. A probe on a path that runs once per operation on a high-throughput driver must be cheap enough to fit the budget.
3. **What does the probe cost?** An atomic counter is a few nanoseconds. A `counter(9)` is about the same, with better scaling. A `sbinuptime()` timestamp is tens of nanoseconds. A `printf` is tens of microseconds. A DTrace probe, when enabled, is hundreds of nanoseconds.
4. **Is the probe always on, or only during an instrumentation mode?** A counter that stays in production is a feature. A detailed trace is a tool for a tuning session.
5. **Does the probe cause contention?** Writing to a single cache line from many CPUs is a contention problem; reading it is not.
6. **Does the probe change ordering?** An added memory barrier can hide a race; an added sleep can hide a contention problem.

Most of this is common sense once you have seen one or two measurements go wrong. Writing it down as a checklist early saves the pain of re-discovery.

33.5.10 Exercise 33.2: Time the Read Path

Take a simple driver you have written earlier, or use the `perfdemo` scaffold we will introduce in the lab section. Add two `counter_u64_t` variables: `reads` and `read_ns_total`. In the read handler, timestamp with `sbinuptime()` at entry, do the work, timestamp again, add the nanosecond difference to `read_ns_total`, and increment `reads` by 1. Expose both via `sysctl`.

Build the driver. Load it. Run a userland loop that reads from the device 100,000 times. Then compute the average latency as `read_ns_total / reads` and record the number in your logbook. Next, remove the counter updates, build again, and rerun the test; if the timing tools allow, compare the wall-clock time of the 100,000-read loop with and without the counters. The difference is the probe overhead.

You will find that `counter(9)` updates are cheap enough to leave in production. That fact is one of the most useful practical takeaways of the chapter.

33.5.11 Wrapping Up Section 2

Kernel measurement uses the same primitives as userland measurement but with tighter constraints. The `get*` time functions are for cheap, low-precision timestamps; the non-`get*` functions are for precise, more expensive ones. Counter primitives come in three grades, from plain atomics to `counter(9)` to DPCPU variables, with increasing scalability and flexibility. Exposure to userland is through `sysctl(9)`. The tools that read the exposed state (`sysctl(8)`, `top`, `systat`, `vmstat`, `ktrace`, `dtrace`, `pmcstat`) each specialise. And the discipline of measuring without contaminating the measurement is as important as the primitives themselves.

The next section introduces DTrace, which is the most general and capable of the kernel measurement tools FreeBSD gives you. DTrace deserves a whole section of its own because it answers the *what is happening right now* question better than anything else.

33.6 Section 3: Using DTrace to Analyze Driver Behavior

DTrace is the single most useful tool in a kernel performance engineer's box. Its combination of expressiveness, low overhead when disabled, and ability to see almost any function in the kernel without recompiling has no peer. Section 3 is the longest section of the chapter for this reason; the time you spend learning DTrace pays back on every driver you ever measure.

The section assumes no prior DTrace experience. Readers who have used DTrace on Solaris or macOS will find FreeBSD's implementation familiar in substance, with a few differences in provider availability and in how to enable it.

33.6.1 What DTrace Is

DTrace is a kernel facility that lets you attach small scripts to probes. A probe is a named point in the kernel at which you can observe what is happening: a function entry, a function return, a scheduler switch, an I/O completion, a packet arrival, a user-defined event in a driver. A script says *when this probe fires, do X*. The script is compiled into a safe bytecode that runs in the kernel's context, aggregated in memory, and read back into the userland `dtrace` process.

The design has four features that matter for driver work.

First, the probes are **pervasive**. Every non-static function in the kernel is a probe. So are scheduler events, every system call boundary, every lock operation, every I/O dispatch, and thousands of other points. You rarely need to add probes to find one you need.

Second, probes have **near-zero cost when disabled**. An unused probe is a NOP in the instruction stream; it does not slow the kernel. The overhead appears only when you enable the probe, and even then the enabled overhead is typically a few hundred nanoseconds per fire. You can leave your driver production-ready with a dozen SDT probes in it, and when DTrace is not running, the driver is exactly as fast as if the probes were not there.

Third, DTrace is **safe**. The scripts run in a constrained language that prohibits loops, arbitrary memory access, and any operation that could crash the kernel. A buggy script returns an error; it does not panic the system.

Fourth, DTrace **aggregates in the kernel**. You can keep per-thread counts, quantiles, average values, histograms, and similar summaries in the kernel and pull the summary out periodically. You do not need to emit every event to userland; most DTrace scripts emit aggregated summaries, which is why they scale to millions of events per second.

33.6.2 Enabling DTrace on FreeBSD

DTrace is part of the base system and works out of the box on most FreeBSD installations, but it requires that the kernel have DTrace support compiled in and that the relevant modules be loaded. On a GENERIC kernel, the support is present. To use it, load the provider modules:

```
# kldload dtraceall
```

The `dtraceall` module is a convenience that loads all the DTrace providers. If you only need a specific provider (for example, `fbt` for function-boundary tracing or `lockstat` for lock contention), you can load just that one:

```
# kldload fbt
# kldload lockstat
```

After loading, `dtrace -l` lists the available probes. Expect the list to be long; a typical GENERIC kernel has tens of thousands of probes available.

33.6.3 The Probe Name Format

Every DTrace probe has a four-tuple name of the form:

```
provider:module:function:name
```

The **provider** is the source of the probe: `fbt` for function-boundary tracing, `sdt` for statically defined tracepoints, `profile` for timed sampling, `sched` for scheduler events, `io` for I/O completion, `lockstat` for lock events, and several others.

The **module** is the kernel module the probe lives in: `kernel` for core kernel code, `your_driver_name` for your own module, `geom_base` for GEOM, and so on.

The **function** is the function the probe is in.

The **name** is the name of the probe within the function: for `fbt`, always `entry` or `return`.

So a probe like `fbt:kernel:malloc:entry` means *the entry point of the malloc function, in the kernel module, via the fbt provider*. A probe like `fbt:perfdemo:perfdemo_read:return` means *the return point of perfdemo_read, in the perfdemo module*.

Wildcards are allowed. `fbt:perfdemo::entry` means *all entry points in the perfdemo module*. `fbt:::entry` means *all function entries in the kernel*. Be careful with the latter; it is a lot of probes.

33.6.4 Your First DTrace One-Liner

The canonical DTrace introduction is to count how often a function is called. For `perfdemo`, once the driver is loaded:

```
# dtrace -n 'fbt:perfdemo:perfdemo_read:entry { @[probefunc] = count(); }'
```

This says: on every entry to any `perfdemo` function named like `perfdemo_read`, increment an aggregation keyed by function name. When you press Ctrl-C, DTrace prints the aggregation:

<code>perfdemo_read</code>	10000

Ten thousand calls were made to `perfdemo_read` during the trace window. You now know the call rate; divide by the wall-clock seconds you ran the trace for.

A slightly richer one-liner that measures the time spent in the function:

```
# dtrace -n 'fbt:perfdemo:perfdemo_read:entry { self->t = timestamp; }
           fbt:perfdemo:perfdemo_read:return /self->t/ {
               @t = quantize(timestamp - self->t); self->t = 0; }'
```

This says: on entry, store the timestamp in a thread-local variable `self->t`. On return, if we have a saved timestamp (the `/self->t/` predicate), compute the difference and add it to a quantised histogram. When you stop the trace, DTrace prints the histogram:

value	----- Distribution -----	count
512		0
1024	@@@@	1234
2048	@@@@@@@@@@@@@@@@@@@@	6012
4096	@@@@@@@@@@@@@@@@	4581
8192	@@@@	1198
16384	@	145

32768	29
65536	8
131072	2
262144	0

The histogram says the function mostly runs in the 1 to 8 microsecond range, with a long tail out to a quarter of a millisecond. You now have the distribution, not just the average, of the function's latency. This is already better information than most published benchmarks publish.

33.6.5 Aggregations: the DTrace Superpower

The quantize aggregator is one of several that DTrace provides. The ones you will use most often are:

- `count()`: how many times the event fired.
- `sum(value)`: total of value across all fires.
- `avg(value)`: mean of value.
- `min(value), max(value)`: extremes.
- `quantize(value)`: power-of-two histogram.
- `lquantize(value, lower, upper, step)`: linear histogram with custom bounds.
- `stddev(value)`: standard deviation.

Aggregations can be indexed. `@[probefunc] = count();` keys by function name. `@[pid] = count();` keys by process id. `@[execname] = sum(arg0);` sums a value by executable name. Indexed aggregations are how DTrace produces *top-N* style summaries without ever sending per-event data to userland.

33.6.6 Useful DTrace Patterns for Driver Work

Here are a handful of patterns that keep coming back in driver performance work. Each is a fill-in-the-blank template.

Count calls to a function by caller:

```
# dtrace -n 'fbt:perfdemo:perfdemo_read:entry {
    @[stack(5)] = count();
}'
```

The `stack(5)` argument captures the five-frame user stack at the time of the probe. The aggregation tells you who the typical caller is.

Measure the time a function spends in itself versus in its callees:

```
# dtrace -n '
fbt:perfdemo:perfdemo_read:entry { self->s = timestamp; }
fbt:perfdemo:perfdemo_read:return / self->s / {
    @total = quantize(timestamp - self->s);
}
```

```
    self->s = 0;
}
fbt:perfdemo:perfdemo_do_work:entry { self->w = timestamp; }
fbt:perfdemo:perfdemo_do_work:return / self->w / {
    @worktime = quantize(timestamp - self->w);
    self->w = 0;
}'
```

Running this with a concurrent read loop tells you how much of the read time is inside `perfdemo_do_work` versus in the rest of `perfdemo_read`.

Count errors by location:

```
# dtrace -n 'fbt:perfdemo:perfdemo_read:return / arg1 != 0 / {
    @errors[probefunc, arg1] = count();
}'
```

The `arg1` on a return probe is the function's return value. If the function returns an `errno` on failure, this aggregation shows you which errors happen how often.

Watch memory allocation:

```
# dtrace -n 'fbt:kernel:malloc:entry / execname == "perfdemo" / {
    @sizes = quantize(arg0);
}'
```

This aggregates the size argument (`arg0`) passed to `malloc(9)` by contexts running in the `perfdemo` module. It answers questions like *how big are the allocations my driver does?*

These patterns are small variations on a theme. Learn them by writing them, not by reading them. The chapter's lab in Section 3 will give you a concrete one to try.

33.6.7 Profile Sampling with the profile Provider

The `fbt` provider fires on every function entry or return, which is thorough but noisy. For *where is CPU time going* questions, the `profile` provider is often better. It fires at a regular rate (for example, 997 Hz, a prime so it does not synchronise with the timer interrupt) on every CPU, independent of what is running. A script keyed by kernel stack gives you a statistical profile of where the kernel is spending time.

```
# dtrace -n 'profile-997 / arg0 != 0 / {
    @[stack()] = count();
}'
```

The `/arg0 != 0/` predicate filters out idle CPUs (where `arg0` is the user-space PC, which is zero for kernel-thread idling). Ctrl-C after a minute, and you get a list of kernel stacks with counts. The top stack is where the kernel spent most time. Send the output to a flame-graph renderer (the `FlameGraph` tools are installable as a port), and you have a visual, hierarchical view of kernel CPU use.

33.6.8 Static Probes with SDT

fbt is broad but not always the right answer. The fbt provider has a probe for every non-static function in the kernel, which means you can observe any function you please, but it also means the probe names are compiler-generated and may change as the code does. For stable, named observation points, FreeBSD provides the **SDT** (Statically Defined Tracepoint) provider. An SDT probe is declared in the driver's source, has a stable name, and can be inspected by DTrace scripts just like any other probe. It fires only when enabled, and when disabled is a NOP.

A driver adds SDT probes like this:

```
#include <sys/sdt.h>

SDT_PROVIDER_DEFINE(perfdemo);
SDT_PROBE_DEFINE2(perfdemo, , , read_start,
    "struct perfdemo_softc *", "size_t");
SDT_PROBE_DEFINE3(perfdemo, , , read_done,
    "struct perfdemo_softc *", "size_t", "int");
```

The first argument is the provider name (perfdemo). The next two are the module and function grouping; we leave them empty to get perfdemo::`read_start` as the probe name. Then the probe name itself. Then the argument types, one per fired argument.

In the driver code, you fire the probe where it matters:

```
static int
perfdemo_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct perfdemo_softc *sc = dev->si_drv1;
    size_t want = uio->uio_resid;
    int error;

    SDT_PROBE2(perfdemo, , , read_start, sc, want);

    error = do_the_read(sc, uio);

    SDT_PROBE3(perfdemo, , , read_done, sc, uio->uio_resid, error);

    return (error);
}
```

From a DTrace script, the probes now have readable names:

```
# dtrace -n 'perfdemo::read_start { @starts = count(); }
           perfdemo::read_done { @done = count(); }'
```

The stable names are the point. A change to `perfdemo_read`'s internal structure does not break the script; a DTrace user can write `perfdemo:::read_done` and know exactly what it means, which they could not say of `fbt:perfdemo:perfdemo_read:return`.

For drivers that are going to be observed often, a modest set of SDT probes at the operational boundaries (read, write, ioctl, interrupt, error, overflow, underflow) is a very small code cost and a large observability gain.

33.6.9 The lockstat Provider

One of DTrace's more specialised providers, `lockstat`, deserves a separate introduction because lock contention is one of the most common performance problems in concurrent drivers. Its probes are declared in `/usr/src/sys/sys/lockstat.h`. They fire on every acquire, release, block, and spin of every kernel mutex, rwlock, sxlock, and lockmgr lock.

The two probes you will use most often are:

- `lockstat:::adaptive-acquire` and `lockstat:::adaptive-release` for plain mutex (mtx) operations.
- `lockstat:::adaptive-block` when a thread had to sleep waiting for a contended mutex.
- `lockstat:::spin-acquire`, `lockstat:::spin-release`, `lockstat:::spin-spin` for spin mutexes.

The argument `arg0` to a `lockstat` probe is a `struct lock_object *` pointer. To get the lock's name, `((struct lock_object *) arg0)->lo_name`. A useful one-liner that shows the lock names with the most acquires over a measurement window:

```
# dtrace -n 'lockstat:::adaptive-acquire {
    @[((struct lock_object *)arg0)->lo_name] = count();
}'
```

A more useful one that measures how long the lock was *held*:

```
# dtrace -n '
lockstat:::adaptive-acquire {
    self->s[arg0] = timestamp;
}
lockstat:::adaptive-release / self->s[arg0] / {
    @[((struct lock_object *)arg0)->lo_name] = sum(timestamp - self->s[arg0]);
    self->s[arg0] = 0;
}'
```

Expect thread-local storage to grow if many distinct locks are acquired; the kernel caps it and DTrace will stop the script if it overflows. For most drivers, this script runs comfortably for a few minutes before it runs out.

A third useful one tracks **contention**, not just acquisition. An adaptive mutex that blocks because some other thread holds it fires `lockstat:::adaptive-block`. Counting those by lock name shows you which locks are actually contended:

```
# dtrace -n 'lockstat:::adaptive-block {
    @[((struct lock_object *)arg0)->lo_name] = count();
}'
```

If your driver's mutex shows up at the top of this list, you have found a real contention problem. If it does not, locking is not your problem and you can focus elsewhere. The data is more valuable than most of the advice you could give yourself about locking in the abstract.

33.6.10 A Longer DTrace Script

DTrace scripts can live in files (.d) and be invoked with `dtrace -s script.d`. Here is a longer script for measuring `perfdemo`'s read behaviour, with per-process aggregation and a predicate to ignore a specific process that is also running on the system:

```
/*
 * perfdemo-reads.d
 *
 * Aggregate perfdemo_read() timings per userland process.
 * Requires the perfdemo module to be loaded.
 */

#pragma D option quiet

fbt:perfdemo:perfdemo_read:entry
{
    self->start = timestamp;
    self->size = args[1]->uio_resid;
}

fbt:perfdemo:perfdemo_read:return
/ self->start && execname != "dtrace" /
{
    this->dur = timestamp - self->start;
    @durations[execname] = quantize(this->dur);
    @sizes[execname] = quantize(self->size);
    @count[execname] = count();
    self->start = 0;
    self->size = 0;
}

END
{
    printa("\nRead counts per process:\n%-20s %u\n", @count);
    printa("\nRead durations (ns) per process:\n%s\n%d\n", @durations);
}
```

```
    printa("\nRead request sizes per process:\n%s\n%d\n", @sizes);
}
```

The script uses three DTrace idioms that are worth calling out. First, `args[1]->uio_resid` accesses the second argument of `perfdemo_read` (the struct `uio *`) and reads its `uio_resid` field; DTrace understands kernel structures with their field names. Second, `self->...` is thread-local storage that carries data between an entry probe and the matching return probe. Third, the predicate `/ self->start && execname != "dtrace" /` filters out probes where we did not see the entry (for example, because the script started mid-call) and excludes DTrace's own reads of the driver (which would otherwise skew the results).

Invoke the script while a workload runs:

```
# dtrace -s perfdemo-reads.d
```

Let it run for a minute, then Ctrl-C. The three aggregated printouts at the end give you counts, duration histograms, and size histograms per process, all from a single script with essentially no effect on the workload's performance.

Scripts like this are where DTrace really shines. They answer questions a developer could not have answered without recompiling the kernel two decades ago.

33.6.11 The sched Provider for Scheduler Events

One of DTrace's less-advertised providers is `sched`, which fires on scheduler events: a thread being put on a run queue, a thread being taken off a run queue, a context switch, a thread being woken up, and related events. For driver performance work, `sched` answers questions about *latency in the scheduler*, which is the layer of the system that gets between your driver's wake-up call and the userland thread actually running.

The probes you will reach for most often are:

- `sched:::enqueue`: a thread is put on a run queue.
- `sched:::dequeue`: a thread is taken off a run queue.
- `sched:::wakeup`: a thread is awoken by another thread (often from an interrupt or a driver).
- `sched:::on-cpu`: a thread starts running on a CPU.
- `sched:::off-cpu`: a thread stops running on a CPU.

A common use in driver work is to measure the *wake-up-to-run latency*: how long from the moment the driver calls `wakeup(9)` on a sleep channel to the moment the user-land thread actually runs. A simple one-liner:

```
# dtrace -n '
sched:::wakeup / curthread->td_proc->p_comm == "mydriver_reader" / {
    self->w = timestamp;
}
sched:::on-cpu / self->w / {
    @runlat = quantize(timestamp - self->w);
    self->w = 0;
}'
```

This script records the timestamp when the reader process is awoken and again when it starts running on a CPU. The aggregation is the distribution of the delay between the two. On typical FreeBSD 14.3-amd64 hardware in our lab environment, an idle system usually shows this latency in the sub-microsecond range, while a contended one pushes it into the low tens of microseconds. If your driver's median read latency is under 10 microseconds but its P99 is in the hundreds, the scheduler is often where the tail comes from, and `sched:::wakeup` and `sched:::on-cpu` are the probes that prove it. See Appendix F for notes on reproducing this measurement across kernel configurations.

Another useful `sched` pattern is counting how often a thread is preempted off a CPU, keyed by the thread's name:

```
# dtrace -n '
sched:::off-cpu / curthread->td_flags & TDF_NEEDRESCHED / {
    @preempt[execname] = count();
}'
```

This tells you which threads are being preempted away by a higher-priority thread, which in an interrupt-heavy system points at the drivers whose handlers are forcing context switches. On a well-behaved system this count is low.

33.6.12 The io Provider for Storage Drivers

For drivers in the storage stack, the `io` provider is invaluable. It fires on buffer-cache and bio events: `io:::start` when a bio is dispatched, `io:::done` when it completes, `io:::wait-start` when a thread begins waiting, `io:::wait-done` when the wait finishes. The combination gives you end-to-end latency for every storage operation.

A classic one-liner to measure storage latency:

```
# dtrace -n 'io:::start { self->s = timestamp; }
io:::done / self->s / {
    @lat = quantize(timestamp - self->s);
    self->s = 0; }'
```

The histogram it produces is the latency distribution of every bio the system completed during the measurement window, in nanoseconds. For a NVMe-backed file system the median is tens of microseconds; for a SATA SSD it is hundreds; for a rotating disk it is milliseconds. If a driver you are investigating shows much higher latency than its peer, you have narrowed the problem.

A richer version aggregates by the device and operation:

```
# dtrace -n '
io:::start { self->s = timestamp; }
io:::done / self->s / {
    @lat[args[0]->bio_dev, args[0]->bio_cmd == BIO_READ ? "READ" : "WRITE"]
```

```
        = quantize(timestamp - self->s);
    self->s = 0;
}'
```

The script accesses the `bio` structure's fields through `args[0]`, which DTrace understands because the probe arguments are typed in the kernel. It partitions the latency distribution by device and operation direction, so you can see whether reads and writes have different distributions, or whether one device is dragging down the average.

The `io` provider's real strength is that it answers the *total* latency question: the time the application saw, not just the time the driver contributed. If your driver is fast but the system is slow, `io` helps localise the problem.

33.6.13 Combining Multiple Providers in One Script

A script is not limited to a single provider. DTrace's power is most evident when you combine providers to answer a question that no single provider could.

Consider this question: *on a system where the `perfdemo` driver is used by two processes, which process's reads cause the most time to be spent in the kernel?*

A script:

```
/*
 * perfdemo-by-process.d
 *
 * Measures cumulative kernel time spent handling perfdemo_read()
 * per userland process, using sched + fbt providers.
 */

#pragma D option quiet

fbt:perfdemo:perfdemo_read:entry
{
    self->start = timestamp;
    self->pid   = pid;
    self->exec  = execname;
}

fbt:perfdemo:perfdemo_read:return / self->start /
{
    @total_time[self->exec] = sum(timestamp - self->start);
    @count[self->exec]      = count();
    self->start = 0;
}
```

```

END
{
    printf("\nPer-process perfdemo_read() summary:\n");
    printf("%-20s %10s %15s\n", "PROCESS", "CALLS", "TOTAL_NS");
    printa("%-20s %@10d %@15d\n", @count, @total_time);
}

```

Run this script while the workload runs, Ctrl-C, and see a two-column summary of which process spent the most total time in your driver's read path. That is data a plain `top(1)` cannot give you; it attributes kernel time *per process*, not *per thread*, and only for your specific function.

33.6.14 Putting It All Together: Driver Trace Session

A typical DTrace session for a driver you are tuning follows a predictable sequence of scripts, each building on the previous one. A concrete workflow:

1. **Who is calling the driver?** Run `dtrace -n 'fbt:perfdemo:perfdemo_read:entry { @[execname, pid] = count(); }'` for thirty seconds, Ctrl-C. This tells you which userland process and PID is exercising the driver, which is useful context for the rest of the session.
2. **How long do calls take?** Run the `quantize` script from the chapter. The distribution tells you the expected range and whether there is a tail.
3. **If there is a tail, what causes it?** Run a script that keys the histogram by stack trace. Different stack traces take different paths; seeing them split shows you which path is slow.
4. **Which lock, if any, is contended?** Run the `lockstat::adaptive-block` script. If your mutex is in the top entries, lock contention is real.
5. **Where is the CPU time going?** Run the `profile-997` script for a minute. The top stacks tell you which functions dominate.
6. **What is the scheduler doing?** If wake-up latency matters, run the `sched::wakeup / sched::on-cpu` one-liner. If the distribution has a long tail, the scheduler is where the user-visible delays come from.

At the end of this sequence, you have a coherent picture: who calls, how fast, where time goes, what blocks, and how the scheduler handles the results. Each script is a few lines. The sequence is the whole DTrace-for-drivers workflow.

33.6.15 A Note on DTrace's Limitations

DTrace is capable but not infinite. A few limitations to keep in mind:

- The DTrace language has no loops. This is by design; it is what guarantees probes terminate. If you need something that feels like a loop, use aggregations instead.
- You cannot modify kernel state from a DTrace script. It is an observer, not a debugger. To intervene, you need different tools.

- Probes fire in a safe but constrained context. You cannot, for example, call arbitrary kernel functions from inside a probe.
- Large amounts of thread-local storage can overflow. The kernel reclaims stale TLS conservatively; a script that stashes data in `self->foo` without clearing it will eventually run out.
- Aggregations are kept in per-CPU buffers and merged lazily. If you print an aggregation and immediately exit, the last few events may not appear.
- Some providers are unavailable in VMs, in jails, or when MAC policies restrict tracing.

The last point is practically important: if your driver is under test in a bhyve guest or on a cloud VM, some providers may simply not work. The `fbt` and `sdt` providers usually work; the `profile` provider depends on kernel support; the `lockstat` provider depends on the kernel being compiled with the probes in place.

33.6.16 Exercise 33.3: DTrace Your Driver

Take the `perfdemo` driver and write a DTrace script (or a one-liner) that answers each of these questions:

1. How many reads per second is the driver doing over a one-minute window?
2. What is the P50, P95, and P99 read latency, in nanoseconds?
3. Which userland process is doing the reads?
4. Does the driver ever sleep on its mutex, and if so, for how long?
5. Of the CPU time in the kernel during the measurement, how much is spent inside `perfdemo` and how much elsewhere?

Save your scripts in the lab directory. The act of writing them is where DTrace becomes second-nature.

33.6.17 Wrapping Up Section 3

DTrace is the kernel performance engineer's default tool. Its probes are everywhere, its enabled cost is small, its aggregations scale, and its scripts are expressive without being dangerous. We looked at the probe name format, at one-liners and aggregations, at SDT probes for stable observation points, at the `lockstat` provider for lock contention, at profile sampling for CPU profiling, and at the shape of a longer `.d` script.

The next section turns from function-level observation to CPU-level observation. `pmcstat` and `hwpmc(4)` give you hardware-counter data that DTrace cannot: cycles, cache misses, branch mispredicts. They are the right tool when you know which function is hot and need to understand *why* the hardware is taking so long to run it.

33.7 Section 4: Using `pmcstat` and CPU Counters

Section 3 gave you a way to measure time and event counts at the function level. Section 4 is about measuring what the CPU hardware is doing while it runs those functions: instructions retired, cycles consumed, cache misses, branch mispredictions, memory stalls. These hardware events are the layer below function-level timing, and they explain the *why* behind a surprising `pmcstat` result. A function may be slow because it runs too many instructions, because it waits on memory, because it mispredicts branches, or because the CPU is stalled on a dependency. `pmcstat` tells you which.

The section introduces hardware counters, explains how `pmcstat(8)` uses them, walks through a sampling session from setup to interpretation, and closes with the limitations of the tool.

33.7.1 Hardware Performance Counters in One Page

Modern CPUs include a small set of hardware counters that the processor increments on specific events. The counters are programmable: you choose which event to count, start the counter, and read the value. Intel calls the subsystem *Performance Monitoring Counters* (PMCs). AMD calls it the same thing. ARM calls it the *Performance Monitor Unit* (PMU). They differ in detail but share a model.

On an x86-64 Intel or AMD CPU you typically have:

- A small number of fixed-function counters, each tied to a specific event (for instance, *instructions retired* or *unhalted core cycles*).
- A larger number of programmable counters, which can be configured to count any of hundreds of events.

Each counter is a 48-bit or 64-bit register that increments on every event. The events are vendor-specific and vary by processor generation. Common events include:

- **Cycles**: how many CPU cycles have passed. `cpu_clk_unhalted.thread` on Intel.
- **Instructions retired**: how many instructions completed. `inst_retired.any` on Intel.
- **Cache references** and **cache misses**: at various levels of the memory hierarchy. `llc-misses` is a commonly useful shorthand.
- **Branches** and **branch mispredictions**.
- **Memory stalls**: cycles where the pipeline was waiting on memory.
- **TLB misses**: cycles where virtual-to-physical translation missed the TLB.

The counters can be used in two modes. **Counting mode** just reads the counter at the end of a workload and gives you a total. **Sampling mode** configures the counter to fire an interrupt every N events; the interrupt handler captures the current PC and stack, and after the run you have a statistical sample of where in the code the events happened. Counting mode tells you the total; sampling mode tells you the distribution. Both are useful.

33.7.2 `hwpmc(4)` and `pmcstat(8)`

FreeBSD exposes the CPU counters through the `hwpmc(4)` kernel module and the `pmcstat(8)` userland tool. The module drives the hardware; the tool collects and presents the data. To use them:

```
# kldload hwpmc
# pmcstat -L
```

The first command loads the module. The second asks the tool to list the event names available on this machine. On an Intel Core i7 laptop the list is hundreds of entries long; on an arm64 board it is shorter but still substantive.

The event names are the main complication. Intel has its own naming, AMD has a different one, ARM has a third. The `pmcstat -L` command lists the names for your CPU. FreeBSD also provides a set of portable mnemonic

events that work on any supported processor: `CPU_CLK_UNHALTED`, `INSTRUCTIONS_RETIRED`, `LLC_MISSES`, and a few others. Prefer the portable mnemonics when your measurement does not depend on a vendor-specific event.

33.7.3 A First Sampling Session

The simplest `pmcstat` invocation runs a command under a sampled counter:

```
# pmcstat -S instructions -O /tmp/perfdemo.pmc sleep 30 &
# dd if=/dev/perfdemo of=/dev/null bs=4096 count=1000000 &
```

The `-S instructions` flag configures the counter to sample on instructions (a portable mnemonic for retired instructions). `-O /tmp/perfdemo.pmc` tells it to write the raw samples to a file. `sleep 30` is the workload; for thirty seconds the sampler runs. The `dd` runs in parallel and drives load on the `perfdemo` device.

When `sleep 30` finishes, `pmcstat` stops and the file `/tmp/perfdemo.pmc` holds the raw samples. You turn them into a summary with:

```
# pmcstat -R /tmp/perfdemo.pmc -G /tmp/perfdemo.graph
```

The `-R` flag reads the raw file; `-G` writes a callgraph summary. The callgraph is a text file in a format that a flame-graph renderer or a simple `sort | uniq -c` pipeline can consume.

You can also ask for a top-style view of the hottest functions:

```
# pmcstat -R /tmp/perfdemo.pmc -T
```

which prints a list sorted by sample count:

%SAMP	CUM	IMAGE	FUNCTION
12.5	12.5	kernel	perfdemo_read
8.3	20.8	kernel	uiomove
6.9	27.7	kernel	copyout
5.1	32.8	kernel	_mtx_lock_sleep
...			

The `%SAMP` column is the fraction of samples the function received. `perfdemo_read` dominated with 12.5%. `uiomove`, `copyout`, and `_mtx_lock_sleep` followed. Now you know where to focus. If `perfdemo_read` is doing most of the work and `_mtx_lock_sleep` is in the top five, your driver is likely contending on its mutex.

33.7.4 Sampling Event Choice

`instructions` is the default because it is portable and usually useful, but other events change the question you are asking. A few useful variants:

- **-S cycles**: samples on unhalted cycles. Tells you where the CPU spends wall-clock time. Usually the best starting event.
- **-S LLC-misses** (Intel): samples on last-level-cache misses. Tells you which functions are suffering from main-memory accesses.
- **-S branches** or **-S branch-misses**: tells you which functions are hot in the branch predictor.
- **-S mem-any-ops** (Intel): memory operation rate.

A common workflow is to run a session with `-S cycles` first, identify a suspect function, then rerun with `-S LLC-misses` to see whether that function is hot because of instructions or because of memory.

33.7.5 Callgraphs and Flame Graphs

A top-N function list tells you where the hot function is; a callgraph tells you *how you got there*. `pmcstat -G` writes a callgraph file, and the conventional format can be fed to Brendan Gregg's FlameGraph scripts to produce an SVG flame graph. A flame graph shows the stack traces that led to each sampled function, sized by sample count. It is the single most useful visualisation of a CPU profile I know of, and learning to read one is worth a couple of hours.

A practical invocation on FreeBSD, assuming you have installed the FlameGraph tools from the `sysutils/flamegraph` port:

```
# pmcstat -R /tmp/perfdemo.pmc -g -k /boot/kernel > /tmp/perfdemo.stacks
# stackcollapse-pmc.pl /tmp/perfdemo.stacks > /tmp/perfdemo.folded
# flamegraph.pl /tmp/perfdemo.folded > /tmp/perfdemo.svg
```

The `-g` flag tells `pmcstat` to include kernel stacks; `-k /boot/kernel` tells it to resolve kernel symbols against the running kernel. The `stackcollapse-pmc.pl` and `flamegraph.pl` scripts come from the FlameGraph tools. Open the resulting SVG in a browser; each box is a function, its width is the fraction of time spent in it, and the stack of boxes below it shows how execution reached it.

33.7.6 Interpreting a PMC Result

A `pmcstat` result is raw data, not a conclusion. You have to reason about what it means in the context of the workload and the goal. A few patterns are common enough to recognise.

A function at the top of %SAMP but with low IPC (instructions per cycle) is probably memory-bound. Compare the cycles count to the instructions count; if cycles are much higher than instructions, the CPU is stalling. Look at cache misses and TLB misses to confirm.

A function at the top with high IPC is doing a lot of work in a tight loop. That is either a legitimate hot loop you should leave alone, or an opportunity for algorithmic improvement. Run the LLC-misses and branches counters to see whether the hardware is happy.

_mtx_lock_sleep or turnstile_wait in the top five is a sign that a mutex is being contended on. Run `lockstat` (Section 3) to find out which one.

Many functions below the 1% threshold, and no clear hot function usually means the overhead is spread across the whole driver path. Look at the total CPU cost of the operation and decide whether the driver is doing too much per call, rather than doing one thing slowly.

A function that does not appear at all but that you expected to see may be compiled inline, may have been absorbed by a macro, or may simply not be on the hot path. Check whether the compiler optimised it away; a quick `objdump -d` on the module can confirm.

These patterns get easier with practice. The first few `pmcstat` sessions leave most readers confused. By the tenth, the patterns are familiar.

33.7.7 Reading a Callgraph in Detail

When you run `pmcstat -R output.pmc -G callgraph.txt`, the resulting file is a text-format callgraph: every sample's full stack trace, one per line, in reverse order (innermost frame last). A small excerpt:

```
Callgraph for event instructions
@ 100.0% 12345 total samples
perfdemo_read    <- devfs_read_f <- dofileread <- sys_read <- amd64_syscall <-
↳ fast_syscall_common
    at 45.2% 5581 samples
perfdemo_do_work <- perfdemo_read <- devfs_read_f <- dofileread <- sys_read <-
↳ amd64_syscall <- fast_syscall_common
    at 20.1% 2481 samples
_mtx_lock_sleep  <- perfdemo_read <- devfs_read_f <- dofileread <- sys_read <-
↳ amd64_syscall <- fast_syscall_common
    at 12.8% 1580 samples
```

Each entry shows the *leaf* function on the left, followed by the chain of callers. The percentage is the fraction of total samples in which that exact call chain was seen. The top entry shows where most of the CPU time ended up; the chain of callers shows *how* the profiler got there.

Three habits make callgraph reading productive.

First, **do not trust the percentages at face value for short sessions**. A sample count under a few hundred is noisy; percentages based on such counts can swing by ten or more between runs. Collect samples for long enough to get into the thousands before drawing conclusions.

Second, **follow the chain, not just the leaf**. A function that shows up at the top may be a common subroutine called from many places. The interesting question is often *which caller spent the most time calling this subroutine?* The callgraph answers that directly; the function list does not.

Third, **treat the root samples with caution**. The top of the stack is usually a syscall entry or an ithread wrapper. It is the caller of interest that tells you whose code is hot, not the common boilerplate at the stack's bottom.

33.7.8 Cross-Referencing `pmcstat` and DTrace

`pmcstat` gives you where the CPU is spending time. DTrace gives you what the functions are doing. A disciplined investigation uses both. A typical workflow:

1. Run `pmcstat -S cycles` for a minute while the workload runs. Identify the top three functions.
2. For each top function, run a DTrace script on its `fbt:::entry` and `fbt:::return` probes to get a call-rate and latency histogram.
3. Multiply call rate by mean latency to estimate the total CPU time the function receives. This number should roughly match the `pmcstat` fraction; if it does not, one of the two tools is lying (usually your predicate).
4. Pick the function whose impact is largest and instrument its body with more granular DTrace probes.

The two tools complement each other. `pmcstat` has the hardware-counter granularity; DTrace has the function-body granularity and the ability to aggregate by context (process, thread, syscall, lock). Used alone, each tells half a story. Used together, they triangulate the performance picture.

33.7.9 A Top-Down Performance Analysis Method

For amd64 CPUs, Intel publishes a *top-down microarchitecture analysis* (TMA) method that organises CPU performance into a tree of categories: front-end bound, back-end bound, bad speculation, retiring. Each category has sub-categories that narrow the diagnosis: memory-bound vs core-bound, bandwidth vs latency, branch mispredicts vs machine clears. The method is useful because it turns a list of hundreds of PMC events into a small hierarchy that points at the bottleneck.

FreeBSD's `pmcstat` does not produce a top-down report directly, but you can compute the relevant ratios by collecting the right events together:

- **Retiring rate:** `UOPS_RETIRED.RETIRE_SLOTS` divided by total issue slots.
- **Front-end bound:** stall cycles in the front end divided by total cycles.
- **Back-end bound:** stall cycles in the back end divided by total cycles.
- **Bad speculation:** branch mispredict cost divided by total cycles.

A `pmcstat` invocation that counts these events together:

```
# pmcstat -s cpu_clk_unhalted.thread -s uops_retired.retire_slots \
-s idq_uops_not_delivered.core -s int_misc.recovery_cycles \
./run-workload.sh 100000
```

The exact event names vary between CPU generations; `pmcstat -L` lists what your CPU supports. Compute the ratios manually from the `pmcstat` output. If retiring is under 30% of slots, your code is stalling; the other categories narrow the cause.

For most driver work this level of detail is overkill. The simpler `-S cycles` sampling session identifies the hot function, and a look at the function's source tells you whether it is dominated by memory accesses, arithmetic, branches, or locks. But when the simpler analysis runs out (you see a hot function, you cannot tell *why* it is hot), the top-down method is the systematic next step.

33.7.10 Counting Mode

`pmcstat -P` (counting, per-process) and `pmcstat -s` (system-wide counting) are the counting counterparts of `-S`. Counting mode is ideal when you have a short benchmark and want a single number. A typical invocation:

```
# pmcstat -s instructions -s cycles dd if=/dev/perfdemo of=/dev/null bs=4096
↪ count=10000
```

When `dd` finishes, `pmcstat` prints:

```
p/instructions p/cycles
  2.5e9         9.8e9
```

This tells you the `dd` ran 2.5 billion instructions in 9.8 billion cycles, an IPC of about 0.25. That is a low IPC; a modern CPU can sustain 3 or 4 instructions per cycle on friendly code. An IPC of 0.25 suggests the code is stalling heavily, usually on memory. A rerun with `-s LLC-misses` confirms:

```
p/LLC-misses p/cycles
  1.2e7         9.8e9
```

12 million cache misses over 9.8 billion cycles. Divide 9.8 billion by 1.2 million: about 8000 cycles per miss on average, which is roughly the cost of a DRAM fetch. That is consistent with memory-bound behaviour.

The workflow is: run a counting session to get the system-wide numbers, run a sampling session to find which function is responsible, then reason about why. Each session answers a different question.

33.7.11 Process-Attached vs System-Wide

`pmcstat -P` attaches to a process and reports its counters exclusively. `-s` counts system-wide. The distinction matters when you want to exclude other workloads. A process-attached measurement of `dd` gives you just `dd`'s cycles and instructions, not the whole system's. A system-wide measurement includes everything.

For driver work, system-wide sampling is often what you want, because the driver's CPU time is counted in kernel threads that are not the benchmark process. Use `pmcstat -s` with kernel-stack collection when you want to see kernel functions, and `pmcstat -P` when you want to focus on a single userland process.

33.7.12 pmcstat and Virtualisation

Hardware PMCs in virtual machines are complicated. Some hypervisors expose the host's PMCs to guests (KVM with `vPMC` support, Xen with PMC passthrough); some expose a filtered subset; some expose nothing at all. FreeBSD's `hwpmc(4)` will report errors on events that the underlying hardware does not expose. If `pmcstat -L` produces a short list on your VM, or if `pmcstat -s cycles` fails with an error, you are probably in a PMC-restricted environment.

The fallback is DTrace's `profile` provider. It samples at a fixed rate instead of on hardware events, so it works anywhere the kernel does, including in heavily virtualised environments. Its results are coarser (you cannot sample on cache misses, for example), but it tells you where CPU time is going, which is the most common question anyway.

33.7.13 Exercise 33.4: `pmcstat perfdemo`

On a FreeBSD machine with the `perfdemo` driver loaded and the `hwpmc` module available, run these three sessions and record the results in your logbook:

1. Counting mode: `pmcstat -s instructions -s cycles <your dd invocation>`. Note the IPC.
2. Sampling mode: `pmcstat -S cycles -O /tmp/perfdemo.pmc <your workload>`, then `pmcstat -R /tmp/perfdemo.pmc -T`. Note the top five functions.
3. If your system supports it, `pmcstat -S LLC-misses -O /tmp/perfdemo-miss.pmc <your workload>`, then `pmcstat -R /tmp/perfdemo-miss.pmc -T`. Compare to the cycle samples.

If `hwpmc` is not available, substitute DTrace's `profile-997` with `@[stack()] = count();` for the sampling sessions. The results will be less precise but still instructive.

33.7.14 Wrapping Up Section 4

Hardware performance counters are the layer below function-level timing. `hwpmc(4)` exposes them, `pmcstat(8)` drives them, and DTrace's profile provider is the portable fallback. Counting mode gives totals, sampling mode gives distributions, and a flame graph turns the samples into a shape the human eye can read. The data is raw; interpretation takes practice. But once the patterns are familiar, a `pmcstat` session answers questions no other tool can.

We have now finished the measurement half of the chapter. Sections 1 through 4 taught you how to know what your driver is doing. Sections 5 through 8 turn to what to do with that knowledge: how to buffer, align, and allocate for throughput; how to keep interrupt handlers fast; how to expose runtime metrics; and how to ship the optimised result.

33.8 Section 5: Buffering and Memory Optimization

Memory is where a surprising number of driver performance problems hide. A function that looks fine on paper can spend most of its cycles waiting for memory, thrashing the cache, fighting with another CPU for a shared line, or churning through the memory allocator because it frees and reallocates on every call. The techniques that fix these problems are well understood and well supported in FreeBSD; what takes experience is recognising when each one applies.

This section covers five memory topics, in order of increasing specificity: cache lines and false sharing, alignment for DMA and cache efficiency, pre-allocated buffers, UMA zones, and per-CPU counters.

33.8.1 Cache Lines and False Sharing

A modern CPU does not read memory one byte at a time. It reads in units of a **cache line**, typically 64 bytes on x86-64 and on arm64 (some arm64 implementations use 128-byte lines; check `CACHE_LINE_SIZE` in `/usr/src/sys/arm64/include/param.h` for your target). Every time the CPU reads a byte, it reads the whole cache line into its L1 data cache. Every time it writes a byte, it modifies the whole cache line.

This is almost always a win: spatial locality means the next few bytes you read are often in the same line. But it also creates a subtle problem when two fields in a single cache line are written by different CPUs. The CPUs'

caches have to coordinate; each time one CPU writes the line, the other CPU's copy is invalidated, and the line bounces between them. The cost is measurable and, at high concurrency, dominant. The phenomenon is called **false sharing**, because the two CPUs are not actually sharing data (they write different fields), but the cache coherence protocol treats them as if they were.

A driver's `softc` structure is a common place for false sharing to show up. If a `softc` has two counters, one updated by the read path and one updated by the write path, and both sit in the same cache line, every read and every write causes a cache bounce. At low concurrency this is invisible. At high concurrency it can halve your throughput.

The fix is explicit cache-line alignment. FreeBSD's `CACHE_LINE_SIZE` macro names the cache line size for the current architecture, and the `__aligned` compiler attribute places a variable at the right alignment. To isolate a field in its own cache line:

```
struct perfdemo_softc {
    struct mtx          mtx;
    /* ... other fields ... */

    uint64_t            read_ops __aligned(CACHE_LINE_SIZE);
    char                pad1[CACHE_LINE_SIZE - sizeof(uint64_t)];

    uint64_t            write_ops __aligned(CACHE_LINE_SIZE);
    char                pad2[CACHE_LINE_SIZE - sizeof(uint64_t)];
};
```

This is one way to do it, and it makes the isolation explicit to the reader. A cleaner way, when the struct is going to be allocated individually rather than as an array, is to put each hot counter in its own aligned sub-structure, or to use `counter(9)` which handles per-CPU placement internally and avoids the issue.

You do not have to pad every field in every struct. In most cases the `softc` is allocated once per device and accessed by one CPU at a time, and alignment does not matter. Reach for cache-line alignment when:

- A profile shows false-sharing-like behaviour (high LLC-misses on a function that does not look memory-heavy, or low IPC on a function that should be CPU-bound).
- Multiple CPUs are known to write different fields of the same struct concurrently.
- You measured a difference. As always.

33.8.2 Alignment for DMA

DMA engines usually require buffers aligned to a boundary larger than a cache line: 512 bytes for disk DMA, 4 KB for some network hardware, sometimes larger. If you allocate a buffer with `malloc(9)` and hand it to DMA without checking alignment, you are relying on the allocator's default alignment, which is usually large enough on amd64 but not guaranteed on all architectures.

For DMA, FreeBSD's `bus_dma(9)` API is the right interface. It handles alignment, bounce buffers, and scatter-gather for you. We covered it in Chapter 21. Here the relevant note is just that `bus_dma` handles alignment explicitly, and a driver should not allocate DMA-able memory with plain `malloc(9)` and hope.

A related memory concern is **alignment for SIMD or vectorised code**, where the compiler or the ISA may require 16-byte or 32-byte alignment on certain arguments. Again, `__aligned` is the tool. For buffers you allocate yourself, `contigmalloc(9)` or the UMA zone allocator can produce aligned memory.

33.8.3 Pre-Allocated Buffers

Every driver has a hot path. The cardinal rule for a hot path is that it should not allocate memory. Memory allocation is expensive on every kernel allocator: `malloc(9)` takes a lock and walks lists; `uma(9)` caches things per CPU but still has a fallback path to the slab allocator; `contigmalloc(9)` may block on page-level operations. None of these belong in a function that runs thousands of times per second.

The fix is **pre-allocation**. Allocate the memory your hot path needs in `attach()`, not in the hot path. If you need a fixed number of buffers for a ring, allocate them once. If you need a pool of buffers that get reused, allocate the pool at `attach` and keep a free list. If you need an occasional larger buffer, allocate it in a cold path.

For `perfdemo`, pre-allocation might look like this:

```
#define PERFDEMO_RING_SIZE      64
#define PERFDEMO_BUFFER_SIZE    4096

struct perfdemo_softc {
    struct mtx      mtx;
    char            *ring[PERFDEMO_RING_SIZE];
    int             ring_head;
    int             ring_tail;
    /* ... */
};

static int
perfdemo_attach(device_t dev)
{
    struct perfdemo_softc *sc = device_get_softc(dev);
    int i;

    for (i = 0; i < PERFDEMO_RING_SIZE; i++) {
        sc->ring[i] = malloc(PERFDEMO_BUFFER_SIZE, M_PERFDEMO, M_WAITOK);
    }
    /* ... */
    return (0);
}

static int
perfdemo_detach(device_t dev)
{
    struct perfdemo_softc *sc = device_get_softc(dev);
```

```

int i;

for (i = 0; i < PERFDEMO_RING_SIZE; i++) {
    if (sc->ring[i] != NULL) {
        free(sc->ring[i], M_PERFDEMO);
        sc->ring[i] = NULL;
    }
}
return (0);
}

```

On the hot path, the driver takes a buffer from the ring, uses it, returns it. No allocator, no lock beyond the ring's own, no risk of allocation failure under load.

This is the pattern that separates drivers that perform well under stress from drivers that fall off a cliff when memory pressure rises. A driver that allocates on the hot path will eventually fail to allocate, and its error path will be exercised in the most stressful moment. A driver that pre-allocates takes its failure at attach time, where it can be reported cleanly.

33.8.4 UMA Zones

`malloc(9)` is a good general-purpose allocator, but for frequently allocated and freed fixed-size objects it is not optimal. FreeBSD provides the UMA (Universal Memory Allocator) zone framework for this case. UMA gives you per-CPU caches, so a `uma_zalloc()` followed by a `uma_zfree()` within one CPU's thread is usually a handful of pointer swaps with no locks. The declarations are in `/usr/src/sys/vm/uma.h`.

A zone is created once per driver at module load, destroyed at unload:

```

#include <vm/uma.h>

static uma_zone_t perfdemo_buffer_zone;

static int
perfdemo_modevent(module_t mod, int what, void *arg)
{
    switch (what) {
        case MOD_LOAD:
            perfdemo_buffer_zone = uma_zcreate("perfdemo_buffer",
                PERFDEMO_BUFFER_SIZE, NULL, NULL, NULL, NULL,
                UMA_ALIGN_CACHE, 0);
            if (perfdemo_buffer_zone == NULL)
                return (ENOMEM);
            break;
        case MOD_UNLOAD:
            uma_zdestroy(perfdemo_buffer_zone);
    }
}

```

```
        break;
    }
    return (0);
}
```

Note the `UMA_ALIGN_CACHE` flag. It asks UMA to align each item in the zone to a cache-line boundary, which matters when items are used from multiple CPUs. The macro is defined in `/usr/src/sys/vm/uma.h`.

On the hot path, allocation and free look like this:

```
void *buf;

buf = uma_zalloc(perfdemo_buffer_zone, M_WAITOK);
/* use buf */
uma_zfree(perfdemo_buffer_zone, buf);
```

The `M_WAITOK` flag says “this call may sleep waiting for memory”. On a non-sleeping path, use `M_NOWAIT` and handle a `NULL` return. For a hot path that absolutely must not block, you can also do `M_NOWAIT | M_ZERO` and keep a fallback pool.

UMA is the right tool when the driver repeatedly allocates and frees objects of the same size. For one-off, variable-size allocations, `malloc(9)` remains fine. For rings of pre-allocated buffers, UMA is overkill; a plain array is simpler.

The rule of thumb: if you are allocating the same-size thing hundreds of times per second, it deserves a UMA zone.

33.8.5 A Tour of UMA Internals

UMA’s behaviour under the hood is worth understanding because it explains both its performance advantages and the cases where it does *not* help. The zone allocator has three layers: per-CPU caches, zone-wide lists, and the slab allocator below everything.

The per-CPU cache is a small array of free items, one per CPU. When a CPU calls `uma_zalloc`, UMA first checks its own cache; if there is an item, the call is a quick pointer swap with no lock. The default cache size is tuned by UMA based on the item size and the machine’s CPU count, and can be overridden with `uma_zone_set_maxcache()` when a particular zone needs a different ceiling.

When the per-CPU cache is empty, UMA refills it from the zone-wide free list. This path takes a lock, pulls several items at once, and returns. It is more expensive than the cache path but still much cheaper than a full allocator call.

When the zone-wide free list is empty, UMA calls into the slab allocator to carve more items from a fresh page. This is the most expensive path and involves allocating a physical page, partitioning it into slab-sized items, and populating the zone’s free list. Most of a zone’s hot-path calls never reach this layer; the per-CPU cache and the zone-wide list are hit first.

Three consequences follow.

First, **UMA is fastest when allocations and frees happen on the same CPU**. A pair of `uma_zalloc` / `uma_zfree` calls on one CPU is a handful of pointer swaps. A `uma_zalloc` on CPU 0 followed by a `uma_zfree` on CPU 1 returns the item to CPU 1's cache, which may or may not benefit CPU 0's future allocations. If your driver allocates on one CPU and frees on another routinely, the per-CPU advantage erodes.

Second, **zones can be tuned with `uma_zone_set_max()` and `uma_prealloc()`**. Pre-allocation reserves a fixed number of items at zone creation, so the first few hundred allocations never hit the slab path. Max-size caps the zone and fails subsequent allocations with `M_NOWAIT` instead of allowing unbounded growth. Both are useful for drivers that need predictable memory behaviour.

Third, **`vmstat -z` is your window into UMA**. It lists every zone, the per-item size, the current count, the cumulative count, and the failure count. A zone whose current count is growing without a matching free path is a leak. A zone whose failure count is non-zero is under memory pressure. Learn to read `vmstat -z` fluently; it is the single best tool for diagnosing UMA issues.

The internals are in `/usr/src/sys/vm/uma_core.c` for the main allocator and `/usr/src/sys/vm/uma.h` for the public interface. Reading the interface file is enough for most driver work; the core file is where to look when a failure mode does not match your expectation.

33.8.6 Bounce Buffers and DMA Memory Mapping

DMA-capable devices need physically contiguous, DMA-safe memory. On amd64 all memory is DMA-capable by default (assuming the device is not IOMMU-constrained), but on other architectures and on IOMMU-protected systems the story is more complex. FreeBSD's `bus_dma(9)` API hides the complexity, but a driver author needs to know when bounce buffers come into play.

A **bounce buffer** is an intermediate buffer the kernel uses when a user-provided buffer is not DMA-safe. If the device's DMA engine cannot reach a given physical address (for example, the device is 32-bit and the buffer is above 4 GB), the kernel allocates a bounce buffer in reachable memory, copies the data in or out, and points the DMA engine at the bounce buffer. This is transparent to the driver but not free: every bounced operation includes a memory copy.

The performance impact shows up in two places. First, the copy doubles the memory traffic for the operation, which matters when the operation is bandwidth-sensitive. Second, the bounce-buffer pool is bounded; under pressure, allocations fail, and the driver must wait. A `bus_dma(9)` driver on a 64-bit system with plenty of memory rarely sees bounce buffers; a 32-bit driver on a system with memory above 4 GB sees them constantly.

The tuning knobs, when bounce buffers become a measurable cost:

- Ask the device if it supports 64-bit DMA. Many 32-bit-era devices actually implement 64-bit addressing and the driver can enable it with the right `bus_dma_tag_create()` flags.
- Use `BUS_SPACE_UNRESTRICTED` in the tag's `lowaddr` field if the device really is unrestricted, to tell `bus_dma` not to bounce.
- For truly 32-bit devices that must work on a 64-bit system, consider pre-allocating reachable buffers in the driver and copying there on the dispatch path, which at least moves the bounce cost to a known place.

This topic deserves its own chapter; Chapter 21 covers `bus_dma(9)` in depth. Here the point is that bounce buffers are a performance feature you may not have chosen consciously, and when they appear in a profile you now know what they mean.

33.8.7 Per-CPU Counters Revisited

Section 2 introduced `counter(9)` and `DPCPU_DEFINE(9)`. This section is where those primitives matter most. On a driver with many CPUs all writing to the same counter, the counter's cache line becomes a contention point. `counter(9)` avoids it by keeping a per-CPU copy and summing on read.

A before-and-after example makes the point concrete. Suppose `perfdemo` has a single `atomic_add_64()` counter for total reads, updated on every read. On an 8-core system doing a parallel-reader benchmark, the counter cache line bounces between eight L1 caches. A `pmcstat` profile shows `atomic_add_64` surprisingly high in the sampled functions. Switching to `counter_u64_add()`:

- Each CPU updates its own copy. No contention.
- The cache line each CPU writes is in its own L1 exclusively.
- The fetch path sums all CPUs' copies, which happens only when someone reads the `sysctl`.

The result is that the counter's cost on the hot path drops from hundreds of nanoseconds per update (the cache miss plus the atomic) to a few nanoseconds (a direct write to a CPU-local cache line). On an 8-core system this can be a 10x reduction in counter cost.

A practical template for a driver with several per-CPU counters:

```
#include <sys/counter.h>

struct perfdemo_stats {
    counter_u64_t reads;
    counter_u64_t writes;
    counter_u64_t bytes;
    counter_u64_t errors;
};

static struct perfdemo_stats perfdemo_stats;

static void
perfdemo_stats_init(void)
{
    perfdemo_stats.reads = counter_u64_alloc(M_WAITOK);
    perfdemo_stats.writes = counter_u64_alloc(M_WAITOK);
    perfdemo_stats.bytes = counter_u64_alloc(M_WAITOK);
    perfdemo_stats.errors = counter_u64_alloc(M_WAITOK);
}

static void
perfdemo_stats_free(void)
{
    counter_u64_free(perfdemo_stats.reads);
    counter_u64_free(perfdemo_stats.writes);
    counter_u64_free(perfdemo_stats.bytes);
}
```

```
    counter_u64_free(perfdemo_stats.errors);
}
```

Each field is a `counter_u64_t`, which is internally a pointer to per-CPU storage. Each increment is a per-CPU add. Each read is a sum across all CPUs.

For state that is not a counter, DPCPU is the tool:

```
#include <sys/pcpu.h>

DPCPU_DEFINE_STATIC(struct perfdemo_cpu_state, perfdemo_cpu);

/* In a fast path, on the current CPU: */
struct perfdemo_cpu_state *s = DPCPU_PTR(perfdemo_cpu);
s->last_read_ns = now;
s->read_count++;
```

DPCPU is slightly less convenient than `counter(9)` because you have to define and initialise the per-CPU structure yourself, but it gives you the flexibility of per-CPU arbitrary state rather than just a counter.

33.8.8 Per-CPU Data Patterns Beyond Counters

`counter(9)` handles the common case of per-CPU integer accumulation. DPCPU handles the general case of per-CPU anything. In practice there are four patterns that come up repeatedly.

Pattern 1: Per-CPU cache of a scratch buffer. When a driver needs a small scratch buffer on a hot path, and the buffer is always used on one CPU at a time, a DPCPU pointer to a per-CPU pre-allocated buffer avoids any allocation at all:

```
DPCPU_DEFINE_STATIC(char *, perfdemo_scratch);

static int
perfdemo_init_scratch(void)
{
    int cpu;
    CPU_FOREACH(cpu) {
        char *p = malloc(PERFDEMO_SCRATCH_SIZE, M_PERFDEMO, M_WAITOK);
        if (p == NULL)
            return (ENOMEM);
        DPCPU_ID_SET(cpu, perfdemo_scratch, p);
    }
    return (0);
}
```

```

/* On the hot path: */
critical_enter();
char *s = DPCPU_GET(perfdemo_scratch);
/* ... use s ... */
critical_exit();

```

The `critical_enter()` / `critical_exit()` pair is necessary because the scheduler could preempt the thread between the `DPCPU_GET` and the use, and the thread could resume on a different CPU. Staying in a critical section prevents the migration. The cost is small (a few nanoseconds) but non-zero; use it whenever you access DPCPU data that must be stable across an operation.

Pattern 2: Per-CPU state for lockless statistics. Some drivers maintain rolling windows, last-timestamp values, or other state per CPU. DPCPU gives you the per-CPU storage without any synchronisation: each CPU reads and writes its own copy, and a global summary is computed on demand.

```

struct perfdemo_cpu_stats {
    uint64_t last_read_ns;
    uint64_t cpu_time_ns;
    uint32_t current_queue_depth;
};

DPCPU_DEFINE_STATIC(struct perfdemo_cpu_stats, perfdemo_cpu_stats);

/* Fast path: */
critical_enter();
struct perfdemo_cpu_stats *s = DPCPU_PTR(perfdemo_cpu_stats);
s->last_read_ns = sbtttons(sbinuptime());
s->cpu_time_ns += elapsed;
critical_exit();

```

The summary for reporting:

```

static uint64_t
perfdemo_total_cpu_time(void)
{
    uint64_t total = 0;
    int cpu;
    CPU_FOREACH(cpu) {
        struct perfdemo_cpu_stats *s =
            DPCPU_ID_PTR(cpu, perfdemo_cpu_stats);
        total += s->cpu_time_ns;
    }
    return (total);
}

```

Pattern 3: Per-CPU queues, one-way. A driver that defers work to a taskqueue can maintain a per-CPU pending list that the producing CPU appends to and the consumer periodically drains. Because each producer is the only writer of its per-CPU list, no locks are needed on the producer side. The consumer still needs locking or atomic swaps to drain safely, but the hot path is lock-free.

Pattern 4: Per-CPU configuration. Some drivers parameterise their behaviour per-CPU for scaling reasons: each CPU has its own buffer size, its own retry count, its own soft limits. DPCPU makes this natural. The trade-off is that configuration values are scattered across CPUs; reporting them requires a loop that visits every CPU.

These patterns share a common theme: per-CPU state eliminates inter-CPU synchronisation on the hot path, in exchange for a small cost on the aggregation path. When the hot path is fast and the aggregation is infrequent, the trade-off is obviously favourable.

33.8.9 When Not to Align, Allocate, or Cache

Every technique above has a cost. Alignment pads structures and wastes memory. Pre-allocation ties up buffers that may go unused. UMA zones consume kernel memory. Per-CPU counters use $N * \text{CPU\_COUNT}$ bytes of memory where the driver might have got away with $N * 1$. None of these costs is fatal, but in the aggregate they add up, especially on small systems.

The rule of thumb is the one you will hear throughout the chapter: do not apply these techniques until measurement demands. A driver that runs at 1000 operations per second on an idle desktop does not benefit from cache alignment, UMA zones, or per-CPU counters. A driver on a 64-core storage server processing 10 million operations per second may need all three.

A useful self-check before adding any of these techniques: *can I point to a specific pmcstat result, DTrace aggregation, or benchmark number that shows the current code is slow in the way the technique would fix?* If yes, apply it. If no, do not.

33.8.10 Exercise 33.5: Cache-Line and Per-CPU Tuning

Using the `perfdemo` driver, do the following:

1. Baseline: measure the throughput of `perfdemo_read()` with the current atomic-counter implementation, using a multi-threaded reader that runs one thread per CPU. Record the throughput in ops/sec.
2. Add `__aligned(CACHE_LINE_SIZE)` to the atomic counters in the `softc` and pad to isolate them. Rebuild, reload, rerun. Record the new throughput.
3. Replace the atomic counters with `counter(9)` counters. Rebuild, reload, rerun. Record the new throughput.
4. Compare the three numbers.

The point is not that one approach is always best. The point is that the three approaches produce different numbers on different hardware, and the evidence tells you which is right for your target.

33.8.11 Wrapping Up Section 5

Memory tuning is about understanding the memory hierarchy the CPU is working against. Cache-line alignment avoids false sharing. DMA alignment works through `bus_dma(9)`. Pre-allocation keeps the hot path out of the allocator. UMA zones specialise fixed-size frequent allocations. Per-CPU counters and per-CPU state eliminate cache-line contention on shared metrics. Each technique is a tool in the toolkit, and each deserves evidence before being applied.

The next section looks at the other major source of driver performance bottlenecks: interrupt handling and deferred work via taskqueues.

33.9 Section 6: Interrupt and Taskqueue Optimization

Interrupts are where the driver meets the hardware, and for many drivers they are where the first performance cliff sits. An interrupt handler runs in a constrained context. It cannot sleep. It cannot acquire most sleepable locks. It competes with other threads for CPU time, but it also preempts them. A handler that takes too long holds up the whole system. A handler that fires too often consumes CPU the rest of the system needs. The techniques in this section are about keeping the interrupt handler fast and moving the rest of the work to a place where it can be done calmly.

The section covers four topics: measuring interrupt behaviour, filter versus ithread handlers (a brief recap), moving work to taskqueues, and interrupt coalescing.

33.9.1 Measuring Interrupt Behaviour

Before you change anything, you need to know how often interrupts fire and how long the handler runs. FreeBSD gives you both metrics through standard tools.

Interrupt rate is reported by `vmstat -i`:

```
# vmstat -i
interrupt                total      rate
irq1: atkbd0              10         0
irq9: acpi0              1000000     500
irq11: em0 ehci0+         44000       22
irq16: ohci0 uhci1+       1000        0
cpu0:timer                2000000     1000
cpu1:timer                2000000     1000
cpu2:timer                2000000     1000
cpu3:timer                2000000     1000
Total                    8148010     4547
```

The `total` column is cumulative since boot; the `rate` column is per second over the sampling window. If your driver's interrupt is firing at thousands of hertz and you did not expect it, something is wrong. If it is firing at single digits per second and you did expect thousands, something else is wrong.

Interrupt handler latency is reported by DTrace. The fbt provider has probes on every non-static function, including the driver's interrupt handler. A one-liner that measures how long the handler runs:

```
# dtrace -n 'fbt:perfdemo:perfdemo_intr:entry { self->t = timestamp; }
           fbt:perfdemo:perfdemo_intr:return /self->t/ {
               @ = quantize(timestamp - self->t);
               self->t = 0; }'
```

The resulting histogram tells you the latency distribution of your interrupt handler. A handler with a median of one or two microseconds and a P99 of under ten is well behaved. A handler with a median of 100 microseconds and a P99 in the milliseconds is doing too much in the wrong context.

Interrupt storm detection is built into FreeBSD. When an interrupt fires much too often (the default threshold is 100,000 per second), the kernel disables the interrupt source temporarily and logs a warning:

```
interrupt storm detected on "irq18:"; throttling interrupt source
```

If you see this message in `dmesg`, your driver is either processing the interrupt incorrectly (not acknowledging it, letting it re-fire immediately) or the hardware is generating at a rate the driver cannot keep up with. Either is a bug; it is not a normal state.

33.9.2 Filter Handlers vs Ithread Handlers

Chapter 13 covered the two shapes of interrupt handler in detail. This section relies on them; here is a short recap for context.

A **filter handler** runs in the interrupt context of the hardware interrupt itself. It has very strict constraints: it cannot sleep, it cannot acquire most locks, and it should do the minimum work needed to quiet the hardware and tell the kernel what to do next. It returns one of `FILTER_HANDLED`, `FILTER_STRAY`, or `FILTER_SCHEDULE_THREAD`. The last tells the kernel to run the associated ithread handler.

An **ithread handler** runs in a dedicated kernel thread, scheduled shortly after the filter returns `FILTER_SCHEDULE_THREAD`. It can acquire sleepable locks, do more complex work, and take as long as is reasonable without stalling the system. It is still preemptible but it is not the interrupt context.

The two-level design lets you split interrupt handling cleanly. The filter does the minimum: read the status register, figure out whether the interrupt is ours, acknowledge it so the hardware stops asserting it, and schedule the ithread if work remains. The ithread does the rest: process the data, wake up userland, deallocate buffers, update counters.

For performance, the question is: do you need both levels? The answer is almost always yes for drivers handling real hardware, and often no for simple devices. A filter-only design is fast: the handler runs once per interrupt, does its work, and returns. A filter-plus-ithread design adds the thread-scheduling cost (a few microseconds) but lets the main work run with fewer context constraints.

If your filter handler is fast and complete, keep the design filter-only. If it is large and you need sleepable locks, split into filter and ithread. If the ithread is itself fast and the split is just adding overhead, consolidate. The measurements will tell you which case you are in.

33.9.3 Moving Work to Taskqueues

A common pattern for long-running driver work is to move it out of interrupt context entirely, into a taskqueue. A taskqueue is a simple, named queue of functions to run, scheduled by a dedicated kernel thread. You enqueue a task from the interrupt handler; the thread dequeues and runs it; the interrupt returns quickly.

The basic pattern:

```
#include <sys/taskqueue.h>

struct perfdemo_softc {
    struct task perfdemo_task;
    /* ... */
};

static void
perfdemo_task_handler(void *arg, int pending)
{
    struct perfdemo_softc *sc = arg;
    /* long-running work here; can acquire sleepable locks */
}

static int
perfdemo_attach(device_t dev)
{
    struct perfdemo_softc *sc = device_get_softc(dev);

    TASK_INIT(&sc->perfdemo_task, 0, perfdemo_task_handler, sc);
    /* ... */
    return (0);
}

static void
perfdemo_intr(void *arg)
{
    struct perfdemo_softc *sc = arg;

    /* Quick filter work */

    taskqueue_enqueue(taskqueue_fast, &sc->perfdemo_task);
}
```

The filter handler does its minimal work and then schedules a task on `taskqueue_fast`, the kernel's default fast-taskqueue. The task runs on the taskqueue's thread, which is preemptible and can sleep. The interrupt handler returns as quickly as it can.

The `taskqueue_fast` queue is shared by many subsystems. On a heavily loaded system, this can mean your task waits behind others. If you need a taskqueue of your own, create one:

```
struct taskqueue *my_tq;

/* In module init: */
my_tq = taskqueue_create("perfdemo_tq", M_WAITOK,
    taskqueue_thread_enqueue, &my_tq);
taskqueue_start_threads(&my_tq, 1, PI_NET, "perfdemo tq thread");
```

`taskqueue_start_threads` creates one thread bound to the queue. For a driver with CPU-bound work and a many-core system, you can use `taskqueue_start_threads_cpuset()` to pin threads to specific CPUs, which helps cache locality:

```
#include <sys/cpuset.h>

cpuset_t cpus;

CPU_ZERO(&cpus);
CPU_SET(1, &cpus); /* bind to CPU 1 */
taskqueue_start_threads_cpuset(&my_tq, 1, PI_NET, &cpus,
    "perfdemo tq thread");
```

The advantage of a dedicated taskqueue is predictable scheduling. Your task is not competing with the whole system for thread time on `taskqueue_fast`. The disadvantage is more threads and more memory, so do this only when the shared taskqueue is genuinely causing a problem.

33.9.4 Interrupt Coalescing

Hardware interrupts have a fixed cost: saving CPU state, transitioning to kernel context, dispatching the handler, and returning. On modern hardware this is under a microsecond, but it is not zero. When a device fires very many interrupts per second, the cumulative cost becomes noticeable. Network NICs on a 10 Gbps link can generate hundreds of thousands of interrupts per second at peak; storage controllers on NVMe can generate more.

Interrupt coalescing is the technique of asking the hardware to batch multiple events into a single interrupt. Instead of interrupting once per packet, the NIC interrupts once per millisecond, and the driver handles all packets received in that millisecond. The throughput goes up because the per-event overhead drops; the latency goes up too, because events wait longer in the batch.

Not every driver supports coalescing, and it is a hardware feature. When the hardware provides it (most modern NICs and NVMe controllers do), the driver exposes knobs through `sysctl` or `ioctl`. The trade-off must be tuned to the workload: a latency-sensitive workload wants short coalescing windows; a throughput-sensitive workload wants long ones. Sometimes a driver exposes separate knobs for the two directions (RX and TX), allowing fine-grained tuning.

As a driver author, you have three options relating to coalescing:

1. **Use hardware coalescing.** If the hardware has it, expose a sysctl knob. The operator tunes the driver for their workload.
2. **Do software-side batching.** If the hardware does not, and the driver can usefully process events in groups, the driver can keep work pending until a threshold is reached and then dispatch the whole batch. `iflib(9)` does this for many network drivers.
3. **Do nothing.** If the event rate is low enough that coalescing would not help, or the latency budget is tight enough that coalescing would hurt, leave it alone.

The right choice is, again, the one the measurements point to. If `vmstat -i` shows your driver interrupting at hundreds of thousands of hertz and CPU time in the interrupt path is a noticeable fraction of total CPU, coalescing is worth trying. If the interrupt is at single digits per second, coalescing is irrelevant.

33.9.5 Debouncing

A related concept is **debouncing**: filtering out redundant or too-close-together interrupts. GPIO input buttons are the classic example; a mechanical switch produces many rapid interrupts when pressed or released, and the driver must filter out the ones that are not real state changes. The technique is:

1. On interrupt, read the input and timestamp.
2. If the input matches the last-reported state and the timestamp is within the debounce window, ignore.
3. Otherwise, report the change and update the last-reported state.

A `sbinuptime()` timestamp and a 20-millisecond debounce window are sufficient for most mechanical switches. For other event sources, the threshold is domain-specific.

Debouncing is not usually called performance tuning, but it has the same effect: fewer interrupts handled, less CPU consumed, fewer spurious events reported. It is a small but real technique.

33.9.6 Dedicated Threads for Long Work

The kernel allows a driver to have its own long-lived thread, distinct from both taskqueue threads and interrupt threads. Use `kproc_create(9)` or `kthread_add(9)` to create one. A dedicated thread makes sense when:

- The driver has a long-running loop (for example, a polling loop that replaces interrupts for deterministic timing).
- The work must not contend with other subsystems on a shared taskqueue.
- The work has its own cadence that does not match the interrupt cadence (for example, a periodic flush, a watchdog, or a state-machine driver).

For most drivers, a taskqueue is simpler and sufficient. A dedicated thread is a step up in complexity and should be justified by the work's nature.

33.9.7 MSI and MSI-X: Per-Vector Interrupts

A classic device uses a single interrupt line: every event fires the same interrupt, the handler must distinguish them by reading a status register, and the handler runs on whichever CPU the kernel's interrupt balancer chose.

A modern device supports Message-Signaled Interrupts (MSI) or the extended MSI-X variant, which lets the device send many distinct interrupts, each with its own vector and each configurable to a specific CPU.

For a driver author, MSI-X brings three performance advantages over legacy line-based interrupts.

First, **per-vector interrupts eliminate shared handlers**. With legacy interrupts, a driver's filter handler might fire for other drivers' events and must return `FILTER_STRAY` when the event is not its own. With MSI-X, each vector belongs to one driver; the filter handler only runs when its device has work.

Second, **per-vector CPU pinning reduces cache-line bouncing**. A multi-queue network driver can dedicate one RX vector to CPU 0, one to CPU 1, and so on. Each CPU processes its own queue, touching its own data structures, without sharing cache lines with the other CPUs. On a high-throughput driver, this scales linearly with core count.

Third, **interrupt routing reduces latency**. If a driver knows which CPU will consume a packet's data, it can request an interrupt on that CPU directly, so the data arrives with the cache already warm.

In FreeBSD, MSI-X is requested via `pci_alloc_msix(9)` during `attach()`. The driver asks for `N` vectors; the PCI subsystem allocates up to `N` (or fewer if the hardware supports fewer). Each vector is a standard `bus_alloc_resource()` IRQ that you set up with `bus_setup_intr(9)` as usual. The `iflib(9)` framework wraps the machinery for network drivers; for custom drivers, the raw API is only a few lines longer.

A small excerpt from a driver that allocates four MSI-X vectors:

```
static int
mydrv_attach(device_t dev)
{
    struct mydrv_softc *sc = device_get_softc(dev);
    int n = 4;

    if (pci_alloc_msix(dev, &n) != 0 || n < 4) {
        device_printf(dev, "cannot allocate 4 MSI-X vectors\n");
        return (ENXIO);
    }

    for (int i = 0; i < 4; i++) {
        sc->irq[i] = bus_alloc_resource_any(dev, SYS_RES_IRQ,
            &(int){i + 1}, RF_ACTIVE);
        if (sc->irq[i] == NULL)
            return (ENXIO);
        if (bus_setup_intr(dev, sc->irq[i], INTR_TYPE_NET | INTR_MPSAFE,
            NULL, mydrv_intr, &sc->queue[i], &sc->ih[i]) != 0)
            return (ENXIO);
    }

    /* Optionally, pin each IRQ to a CPU: */
    for (int i = 0; i < 4; i++) {
        int cpu = i;
        bus_bind_intr(dev, sc->irq[i], cpu);
    }
}
```

```
    }  
  
    return (0);  
}
```

The per-vector handler `mydrv_intr` runs only when *its* queue has work; it gets the per-queue `softc` pointer as its argument. The `bus_bind_intr()` call pins each vector to a specific CPU; on a system with more CPUs than vectors, you might pin every vector to a different CPU.

MSI-X is not always a win. On a single-queue device there is no benefit, just extra setup. On a low-interrupt-rate device the difference is negligible. But on any modern high-throughput device (10 Gbps NIC, NVMe drive), MSI-X is the standard interrupt model and using anything else leaves performance on the table.

33.9.8 Polling as an Alternative to Interrupts

For the extreme upper end of throughput, some drivers abandon interrupts entirely in favour of *polling*. A polling driver runs a tight loop that checks the hardware for work, processes it immediately, and goes around again. The trade-off is CPU cost: a polling thread consumes a CPU continuously, even when idle. The benefit is interrupt cost elimination: at high event rates, the interrupt and context-switch overhead per event disappears.

FreeBSD's network stack supports polling via `ifconfig polling`. Storage drivers typically do not poll. For custom drivers, polling is worth considering only when:

- The event rate is extremely high (millions per second).
- Latency is critical enough that interrupt latency (under a microsecond) is too much.
- CPU is cheap (a dedicated core for the poll loop is acceptable).

Most drivers fit none of these criteria, and polling is the wrong choice. But knowing it exists lets you recognise when a profile shows interrupt overhead dominating, and gives you a last-resort alternative.

A middle ground is *adaptive polling*: switch between interrupt-driven and polling mode based on load. NAPI-style batching (named after the Linux subsystem that pioneered it, but widely used in FreeBSD's `iflib`) takes the first interrupt, disables further interrupts, polls until the queue is drained, then re-enables. This captures most of polling's efficiency at high rates while keeping idle-time cost low.

33.9.9 NAPI-Style Batching in Practice

The `iflib(9)` framework implements NAPI-style batching automatically. A driver that uses `iflib` receives packets through a callback that polls the hardware queue until empty. For non-`iflib` drivers, the pattern is straightforward to implement by hand:

```
static int  
mydrv_filter(void *arg)  
{  
    struct mydrv_softc *sc = arg;
```

```

    /* Disable hardware interrupts for this queue. */
    mydrv_hw_disable_intr(sc);

    /* Schedule the ithread or taskqueue to drain. */
    return (FILTER_SCHEDULE_THREAD);
}

static void
mydrv_ithread(void *arg)
{
    struct mydrv_softc *sc = arg;
    int drained = 0;

    while (mydrv_hw_has_work(sc) && drained < MYDRV_POLL_BUDGET) {
        mydrv_process_one(sc);
        drained++;
    }

    if (!mydrv_hw_has_work(sc)) {
        /* Queue is empty; re-enable interrupts. */
        mydrv_hw_enable_intr(sc);
    } else {
        /* Budget hit with work remaining; reschedule. */
        taskqueue_enqueue(sc->tq, &sc->task);
    }
}

```

The filter disables the interrupt and schedules the ithread. The ithread polls up to `POLL_BUDGET` events, then checks whether the queue is empty. If yes, it re-enables the interrupt. If no, it reschedules itself to continue draining on the next pass. The budget prevents a single burst from monopolising the CPU; the empty-queue check prevents perpetually-polling when traffic stops.

NAPI-style batching is a good fit for medium-to-high-rate drivers where neither pure interrupts nor pure polling is ideal. The budget and the re-enable logic are the two places where mistakes happen; the budget must be large enough to amortise the interrupt re-enable cost but small enough not to stall other drivers, and the re-enable must happen before the hardware can forget about pending work.

33.9.10 Budget Allocation Across Stages

A useful exercise for any performance-critical driver is to write down a *latency budget* across the driver's stages. The total budget is the operation's deadline (for example, 100 microseconds for a low-latency network packet). Subtract each stage's expected cost, and what remains is the headroom.

For a network driver receiving a packet:

- Interrupt dispatch: 1 us.

- Filter handler: 2 us.
- Ithread scheduling + start: 3 us.
- Packet processing (protocol layer): 20 us.
- Wakeup of userland reader: 5 us.
- Scheduler dispatch: 5 us.
- Userland copy and acknowledgment: 10 us.

Total: 46 us. On a 100 us budget, there are 54 us of headroom. If the driver starts missing its deadline, the budget tells you which stage is most likely to have slipped, and where to measure first.

The numbers above are illustrative; the actual numbers are hardware-specific and workload-specific. The habit of writing the budget before measuring is what makes measurement efficient. You start with a hypothesis about where time is going, confirm or refute it with the tools in Sections 2 through 4, and refine the budget as the driver evolves.

33.9.11 Exercise 33.6: Interrupt vs Taskqueue Latency

With the `perfdemo` driver, add a second variant that simulates interrupt-like processing using a high-resolution callout. Compare two configurations:

1. All processing done directly in the callout's handler (interrupt-like, in a privileged context).
2. Callout enqueues a task on a taskqueue; the taskqueue thread does the processing.

Measure the end-to-end latency (the time from the simulated interrupt to when the processed data is visible to userland) in both cases. A DTrace script can record the timestamps; a userland reader with `nanosleep()` on an `select()` can see the delivery.

Configuration 1 will usually have lower latency and higher CPU concentration in the callout context. Configuration 2 will have slightly higher latency but smoother CPU use across threads. Which is better depends on the workload; the exercise is to see the trade-off with numbers, not to declare one universally correct.

33.9.12 Wrapping Up Section 6

Interrupts are where the driver meets the hardware, and they are where performance cliffs first appear. Measuring interrupt rate and handler latency is easy with `vmstat -i` and DTrace. The filter-plus-ithread split keeps the interrupt context small; taskqueues move work to a calmer environment; dedicated threads offer isolation for special cases; coalescing and debouncing control the interrupt rate itself. Each technique has a cost, and each deserves evidence before it is applied.

The next section turns to the metrics and logging you leave in the driver after tuning ends: the `sysctl` tree that exposes your runtime state, the `log(9)` calls that report the conditions worth reporting, and the patterns that distinguish a shipped driver from a benchmark-only one.

33.10 Section 7: Using `sysctl` and Logging for Runtime Metrics

The measurement techniques in Sections 2 through 6 are instruments you reach for when a specific question arises. The metrics in Section 7 are the ones that stay in the driver forever. They are the dashboard lights on

a car: always visible, always current, always there to tell a future operator what the driver is doing. A driver without a good sysctl tree is a driver that an operator cannot diagnose after the original author has moved on. A driver with a good one is a driver that telegraphs its state whenever anyone asks.

This section covers sysctl tree design, the common metric shapes, rate-limited logging via `log(9)`, and the art of putting the right amount of observability into a shipped driver.

33.10.1 Designing a sysctl Tree

The sysctl tree is hierarchical. Each node has a name, a type, a flag set, and usually a value. The top-level nodes (`kern`, `net`, `vm`, `hw`, `dev`, and a few others) are fixed by the kernel; a driver creates a subtree under one of them. For a hardware driver, `dev.<driver_name>.<unit>.<metric>` is the conventional placement. For a pseudo-device or non-hardware driver, `hw.<driver_name>.<metric>` is common.

The declarations use the macros in `/usr/src/sys/sys/sysctl.h`. A minimal driver subtree:

```
SYSCALL_NODE(_dev, OID_AUTO, perfdemo, CTLFLAG_RD, 0,
    "perfdemo driver");

SYSCALL_NODE(_dev_perfdemo, OID_AUTO, stats, CTLFLAG_RD, 0,
    "Statistics");

SYSCALL_U64(_dev_perfdemo_stats, OID_AUTO, reads, CTLFLAG_RD,
    &perfdemo_reads_cached, 0, "Total read() calls");
```

The first `SYSCALL_NODE` creates `dev.perfdemo`. The second creates `dev.perfdemo.stats`. The `SYSCALL_U64` creates `dev.perfdemo.stats.reads` and points it at a `uint64_t` variable. From userland:

```
# sysctl dev.perfdemo.stats.reads
dev.perfdemo.stats.reads: 12345
```

For a device with multiple instances, the more idiomatic path is to use `device_get_sysctl_ctx(9)` and `device_get_sysctl_tree(9)` inside the `attach()` method. FreeBSD will have already created `dev.perfdemo.0` and `dev.perfdemo.1` for two instances, and these helpers give you the handle to add children under each:

```
static int
perfdemo_attach(device_t dev)
{
    struct perfdemo_softc *sc = device_get_softc(dev);
    struct sysctl_ctx_list *ctx = device_get_sysctl_ctx(dev);
    struct sysctl_oid *tree = device_get_sysctl_tree(dev);

    SYSCALL_ADD_U64(ctx, SYSCALL_CHILDREN(tree), OID_AUTO, "reads",
        CTLFLAG_RD, &sc->stats.reads_cached, 0,
```

```

        "Total read() calls");
    SYSCTL_ADD_U64(ctx, SYSCTL_CHILDREN(tree), OID_AUTO, "errors",
        CTLFLAG_RD, &sc->stats.errors_cached, 0,
        "Total errors");
    /* ... */
    return (0);
}

```

The `ctx` and `tree` are released automatically when the device detaches, so you do not have to do cleanup by hand. This is the standard pattern for per-device metrics.

33.10.2 Exposing counter (9) Values via sysctl

A `counter_u64_t` is a per-CPU counter, and exposing it through `sysctl` requires a little more work than a plain `uint64_t`. The pattern is a *procedural sysctl*: a `sysctl` that runs a function when read. The function fetches the counter sum and writes it to the `sysctl` buffer.

```

static int
perfdemo_sysctl_counter(SYSCTL_HANDLER_ARGS)
{
    counter_u64_t *cntp = arg1;
    uint64_t val = counter_u64_fetch(*cntp);

    return (sysctl_handle_64(oidp, &val, 0, req));
}

SYSCTL_PROC(_dev_perfdemo_stats, OID_AUTO, reads,
    CTLTYPE_U64 | CTLFLAG_RD | CTLFLAG_MPSAFE,
    &perfdemo_stats.reads, 0, perfdemo_sysctl_counter, "QU",
    "Total read() calls");

```

The `CTLFLAG_MPSAFE` flag says the handler does not need to be serialised by the `sysctl` subsystem's lock. "QU" is the type-string: Q for quad (64-bit) and U for unsigned. The handler is called on every read, so the sum is current.

Several modern drivers encapsulate this in a helper macro; see `/usr/src/sys/net/if.c` for an example of `SYSCTL_ADD_COUNTER_U64`. If you add many counter `sysctls`, it is worth defining a similar helper for your driver.

33.10.3 What to Expose

A driver's `sysctl` tree is an interface. Like any interface, it should be thoughtful: expose enough to be useful, but not so much that the tree becomes cluttered and its values lose meaning. A good starting set for a data-plane driver:

- **Total operations:** reads, writes, ioctls, interrupts. Cumulative counters.
- **Total errors:** transient errors (retries), permanent errors (failures), partial-transfer errors.
- **Bytes moved:** total bytes transferred in each direction.
- **Current state:** queue depth, busy flag, mode.
- **Configuration:** interrupt coalescing threshold, buffer size, debug level.

For each, think about whether an operator would want the value to diagnose a problem. If yes, expose it. If no, keep it internal.

Avoid exposing implementation details the driver might change. The sysctl tree is an API; renaming a node breaks scripts and monitoring dashboards. Choose the names carefully and keep them stable.

33.10.4 Read-Only, Read-Write, and Tunable

The CTLFLAG_RD flag makes a sysctl read-only from userland. The CTLFLAG_RW flag makes it writable, so an operator can change the driver's behaviour at runtime. CTLFLAG_TUN marks a sysctl as a **tunable**, which means its initial value can be set in `/boot/loader.conf` before the module loads.

Writable sysctls are flexible and dangerous. An operator can set a debug level, change a buffer size, toggle a feature flag. The driver must validate the written value carefully; an out-of-range buffer size can corrupt state. For most metrics, read-only is the right choice. For configuration, read-write with validation in a procedural handler is the pattern.

Here is a validated tunable that accepts values between 16 and 4096:

```
static int perfdemo_buffer_size = 1024;

static int
perfdemo_sysctl_bufsize(SYSCTL_HANDLER_ARGS)
{
    int new_val = perfdemo_buffer_size;
    int error;

    error = sysctl_handle_int(oidp, &new_val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);
    if (new_val < 16 || new_val > 4096)
        return (EINVAL);
    perfdemo_buffer_size = new_val;
    return (0);
}

SYSCTL_PROC(_dev_perfdemo, OID_AUTO, buffer_size,
    CTLTYPE_INT | CTLFLAG_RWTUN | CTLFLAG_MPSAFE,
    NULL, 0, perfdemo_sysctl_bufsize, "I",
    "Buffer size in bytes (16..4096)");
```

The handler checks `req->newptr != NULL` to distinguish a write from a read (a read has a non-null `newptr` only if a value was supplied). It validates the range and updates the variable. The `CTLFLAG_RWTUN` flag combines `CTLFLAG_RW` and `CTLFLAG_TUN`: runtime-writable and loader-tunable.

A rule worth absorbing: *any sysctl that changes driver state must validate its input*. The alternative is a user-configurable crash.

33.10.5 Rate-Limited Logging with `log(9)`

The kernel's `printf(9)` is fast but undisciplined: every call produces a line in `dmesg` regardless of rate. For informational messages that might fire often, the kernel provides `log(9)`, which tags the message with a priority level (`LOG_DEBUG`, `LOG_INFO`, `LOG_NOTICE`, `LOG_WARNING`, `LOG_ERR`, `LOG_CRIT`, `LOG_ALERT`, `LOG_EMERG`) and lets userland's `syslogd(8)` filter it. A message at `LOG_DEBUG` is only logged if `syslogd` is configured to accept debug messages; the default configuration drops them.

```
#include <sys/syslog.h>
```

```
log(LOG_DEBUG, "perfdemo: read of %zu bytes returning %d\n",  
    size, error);
```

The line still goes through the kernel's log buffer and costs the same as a `printf(9)` to produce, but it does not appear in `dmesg` unless `syslogd` is told to include debug messages. It is the right tool for diagnostic messages that an operator might sometimes want but that should not pollute the default log.

For messages that really should be rate-limited, FreeBSD has `ppsratecheck(9)` and `ratecheck(9)`. They return non-zero at most `N` times per second; use them to gate a print:

```
static struct timeval perfdemo_last_err;  
  
if (error != 0 && ratecheck(&perfdemo_last_err,  
    &(struct timeval){1, 0})) {  
    device_printf(dev, "transient error %d\n", error);  
}
```

This rate-limits the print to once per second. The `struct timeval` in the second argument is the interval; `{1, 0}` means one second. If the error rate is a thousand per second, you get one log line per second instead of a thousand.

Rate-limited logging is the right pattern for any message that could plausibly fire on a hot path. A driver that logs every transient error at full rate can DoS itself through `dmesg` alone.

33.10.6 `device_printf(9)` and Its Friends

For messages that identify the specific device, use `device_printf(9)`:

```
device_printf(sc->dev, "attached at %p\n", sc);
```

It prepends the device name and unit number automatically: `perfdemo0: attached at 0xfffffe00c...`. This is the convention for any message that would otherwise need to include `sc->dev` in its format string. Every FreeBSD driver uses `device_printf(9)` for its attach and detach messages; emulate that pattern.

For messages that do not belong to a specific device, plain `printf(9)` is fine but should still be tagged with the module name: `printf("perfdemo: %s: ...\n", __func__, ...)`. The `__func__` identifier is a C99 built-in that expands to the current function's name; it makes logs much easier to trace to their source.

33.10.7 Debug Modes

A common pattern in mature drivers is a **debug mode**: a writable sysctl that controls the verbosity of logging. At debug level 0 the driver logs only attach, detach, and real errors. At level 1 it logs transient errors. At level 2 it logs every operation. The pattern is cheap (a compare-to-zero on the hot path) and gives operators a safe way to turn on detailed logging when diagnosing a problem.

```
static int perfdemo_debug = 0;
SYSCTL_INT(_dev_perfdemo, OID_AUTO, debug, CTLFLAG_RWTUN,
    &perfdemo_debug, 0,
    "Debug level (0=errors, 1=transient, 2=verbose)");

#define PD_DEBUG(level, sc, ...) do {                                \
    if (perfdemo_debug >= (level))                                  \
        device_printf((sc)->dev, __VA_ARGS__);                    \
} while (0)
```

Used as:

```
PD_DEBUG(2, sc, "read %zu bytes\n", bytes);
PD_DEBUG(1, sc, "transient error %d\n", error);
```

At the default `perfdemo_debug = 0`, both lines are a single compare-to-zero that predicts well in the branch predictor. Neither message is produced. At `perfdemo_debug = 1`, only the transient-error line is produced. At `perfdemo_debug = 2`, both are.

The operator turns this on with:

```
# sysctl dev.perfdemo.debug=2
```

and off again when done. This is a convention found in many FreeBSD drivers; reuse it.

33.10.8 Tracking Behaviour Over Time

A counter that is polled every second gives you a rate. A sysctl that returns a histogram of recent latencies gives you a distribution. For longer-term tracking, you can keep a rolling window of values inside the driver, exposed through a sysctl that returns the array:

```
#define PD_LAT_SAMPLES 60

static uint64_t perfdemo_recent_lat[PD_LAT_SAMPLES];
static int perfdemo_lat_idx;

static void
perfdemo_lat_record(uint64_t ns)
{
    perfdemo_recent_lat[perfdemo_lat_idx] = ns;
    perfdemo_lat_idx = (perfdemo_lat_idx + 1) % PD_LAT_SAMPLES;
}

static int
perfdemo_sysctl_recent_lat(SYSCTL_HANDLER_ARGS)
{
    return (SYSCTL_OUT(req, perfdemo_recent_lat,
        sizeof(perfdemo_recent_lat)));
}

SYSCTL_PROC(_dev_perfdemo, OID_AUTO, recent_lat,
    CTLTYPE_OPAQUE | CTLFLAG_RD | CTLFLAG_MPSAFE,
    NULL, 0, perfdemo_sysctl_recent_lat, "S",
    "Last 60 samples of read latency (ns)");
```

The pattern works for any rolling window: latencies, queue depths, interrupt rates, whatever the operator might want to see in time order.

More sophisticated forms of the same idea store percentile estimates (P50, P95, P99) using streaming algorithms like exponential-weighted moving averages or the t-digest. For most drivers this is overkill; a simple rolling window, or even just a cumulative histogram stored as a bucket array, is enough.

33.10.9 Exposing Histograms via sysctl

A cumulative histogram is one of the most useful long-lived metrics a driver can expose. Userland can poll it, subtract the previous snapshot from the current one, and compute the rate per bucket. Plotting the result over time gives an immediate view of the driver's latency distribution.

The pattern: declare an array of `counter_u64_t`, one per bucket. Update the correct bucket in the hot path (linear scan or constant-time bucketing). Expose the array through a single procedural sysctl.

```
static int
perfdemo_sysctl_hist(SYSCTL_HANDLER_ARGS)
{
    uint64_t values[PD_HIST_BUCKETS];
    int i, error;

    for (i = 0; i < PD_HIST_BUCKETS; i++)
        values[i] = counter_u64_fetch(perfdemo_stats.hist[i]);

    error = SYSCTL_OUT(req, values, sizeof(values));
    return (error);
}

SYSCTL_PROC(_dev_perfdemo_stats, OID_AUTO, lat_hist,
    CTLTYPE_OPAQUE | CTLFLAG_RD | CTLFLAG_MPSAFE,
    NULL, 0, perfdemo_sysctl_hist, "S",
    "Read latency histogram (buckets: <1us, <10us, <100us, "
    "<1ms, <10ms, <100ms, <1s, >=1s)");
```

From userland, a small script reads the array and prints it:

```
#!/bin/sh
sysctl -x dev.perfdemo.stats.lat_hist | awk -F= '{
    split($2, bytes, " ");
    for (i = 1; i <= length(bytes); i += 8) {
        val = 0;
        for (j = 7; j >= 0; j--) {
            val = val * 256 + strtonum("0x" bytes[i + j]);
        }
        printf "Bucket %d: %d\n", (i - 1) / 8, val;
    }
}'
```

The script is a few lines and gives you an immediately useful dashboard. Over time, extensions become obvious: compare two snapshots to get rates, plot the deltas over time, alert when a high-latency bucket crosses a threshold.

33.10.10 Per-CPU Sysctl Presentation

For a driver with DPCPU state, there is a choice between aggregating across CPUs (the standard approach: compute a single number from DPCPU_SUM or a manual loop) and presenting per-CPU values separately. Per-CPU presentation is useful when the operator needs to diagnose CPU imbalance: one CPU handling most of the work, another idle, or queue-depth variance between CPUs.

A procedural sysctl that returns a per-CPU array:

```
static int
perfdemo_sysctl_percpu(SYSCTL_HANDLER_ARGS)
{
    uint64_t values[MAXCPU];
    int cpu;

    for (cpu = 0; cpu < mp_ncpus; cpu++) {
        struct perfdemo_cpu_stats *s =
            DPCPU_ID_PTR(cpu, perfdemo_cpu_stats);
        values[cpu] = s->cpu_time_ns;
    }
    return (SYSCTL_OUT(req, values, mp_ncpus * sizeof(uint64_t)));
}
```

The handler visits each active CPU, reads its DPCPU state, and copies the values into a contiguous buffer. The userland reader sees an array of `uint64_t` sized `mp_ncpus`. For exporting to a monitoring tool, per-CPU presentation gives a detailed picture that aggregation obscures.

33.10.11 Stable Interfaces for Operators

A driver's sysctl tree is an interface; once operators write scripts or dashboards against it, changing the names breaks things. A few rules help keep the tree stable over years.

First, **name things for what they are, not for how they are implemented**. A sysctl called `reads` describes a user-observable concept; a sysctl called `atomic_counter_0` describes an implementation detail. The former is stable across refactors; the latter forces a rename whenever the implementation changes.

Second, **version the interface if it has to change**. If you add a new field to an existing structure-valued sysctl, older scripts will still read the old size correctly. If you rename a node, add the new name as an alias first, then deprecate the old one over at least one release cycle.

Third, **document every node in the descr string**. The last argument to `SYSCTL_*` macros is a short description that appears in `sysctl -d`. Keep it accurate and useful; it is the only inline documentation an operator has when diagnosing at three in the morning.

Fourth, **avoid driver-internal concepts in names**. A counter named `uma_zone_free_count` requires the operator to know what UMA is; a counter named `free_buffers` describes what it counts in terms any operator can understand.

A driver that follows these rules produces a sysctl tree that ages well. The exercise in Section 7 is a chance to practise.

33.10.12 Handling Sysctl Writes Safely

A writable sysctl is a public API for changing driver state at runtime. Every path that accepts user input must validate, synchronise, and report cleanly on failure. The pattern in production drivers is:

```
static int
perfdemo_sysctl_mode(SYSCTL_HANDLER_ARGS)
{
    struct perfdemo_softc *sc = arg1;
    int new_val, error;

    new_val = sc->mode;
    error = sysctl_handle_int(oidp, &new_val, 0, req);
    if (error != 0 || req->newptr == NULL)
        return (error);

    if (new_val < 0 || new_val > 2)
        return (EINVAL);

    PD_LOCK(sc);
    if (sc->state != PD_STATE_READY) {
        PD_UNLOCK(sc);
        return (EBUSY);
    }
    sc->mode = new_val;
    perfdemo_apply_mode(sc);
    PD_UNLOCK(sc);

    return (0);
}
```

Three things are happening. First, the handler validates the value; out-of-range values return `EINVAL` rather than corrupting the driver. Second, the handler takes the driver's lock before mutating state; another CPU reading or writing the mode concurrently does not see half-updates. Third, the handler checks the driver's lifecycle state; changes are rejected if the driver is detaching or in error. Each of these is a small addition to the simplest possible handler, and each prevents a real class of bug.

A related consideration is whether the sysctl change is idempotent. If the new value equals the current value, the handler should do nothing (or at most confirm the current state). If the new value differs, the handler must change state atomically so that no one sees a partial update. The lock-then-validate-then-apply pattern above satisfies both constraints.

33.10.13 Exercise 33.7: A Reporting sysctl Tree

Build out the `perfdemo` driver's sysctl tree with at least the following nodes:

- `dev.perfdemo.<unit>.stats.reads`: total reads.
- `dev.perfdemo.<unit>.stats.errors`: total errors.
- `dev.perfdemo.<unit>.stats.bytes`: total bytes.
- `dev.perfdemo.<unit>.stats.latency_avg_ns`: average latency in nanoseconds.

- `dev.perfdemo.<unit>.config.buffer_size`: buffer size (tunable, 16..4096).
- `dev.perfdemo.<unit>.config.debug`: debug level (0..2).

Use `counter(9)` for the counters; use a procedural `sysctl` for the derived latency average; use `CTLFLAG_RWTUN` for the tunables. Build and load the driver; verify each `sysctl` returns a sensible value; change a tunable at runtime and confirm the driver respects it.

The exercise produces an observable interface the rest of the chapter can rely on. It is also a nice self-contained piece of work that is worth adding to a portfolio.

33.10.14 Wrapping Up Section 7

The `sysctl` tree is the driver's always-on observability interface. A thoughtful tree exposes totals, rates, states, and configuration. `counter(9)` values need procedural `sysctls` to fetch their summed totals. Rate-limited logging via `log(9)` and `ratecheck(9)` keeps informational messages from drowning the log. Debug modes give operators a safe way to enable verbose tracing when diagnosing problems. Each of these is a small investment; the cumulative effect is a driver that is auditable from the command line, diagnosed without rebooting, and maintained confidently after the author has moved on.

The last instructional section, Section 8, is the discipline section. It teaches you how to clean up after a tuning project, document the benchmarks that produced the result, update the manual page with the knobs the driver now exposes, and ship the optimised driver as a version the system can rely on.

33.11 Section 8: Refactoring and Versioning After Tuning

Tuning adds scaffolding. Counters that measured specific hot paths, DTrace probes that answered a question once, print statements from an all-nighter, commented-out variants you want to keep handy: all of this accumulates during a performance project. The same discipline that produced the measurements produces the final cleanup. A driver that lives in the tree after tuning is the one whose author knew when to stop and how to leave the code in a state a maintainer can still read.

This section is about that cleanup. It covers what to remove, what to keep, how to document the work, and how to version the result.

33.11.1 Removing Temporary Measurement Code

The most important cleanup is the removal of temporary measurement code. During tuning you may have added:

- `printf()` calls that trace specific operations.
- Counters that helped you find one bottleneck but do not belong in production.
- Timings that accumulated into global arrays.
- DTrace-style probes in the middle of hot paths that are not formally SDT-declared.
- Commented-out versions of optimisations you tried and discarded.

Each of these is a future maintenance cost. The rule is simple: if a piece of code was only useful for the tuning session, delete it. Version control keeps the history; the commit message explains what you tried. The working-tree code should read as if the measurements had never been there.

A useful discipline is to **mark temporary code with a comment when you add it**, so you know what to remove later:

```
/* PERF: added for v2.3 tuning; remove before ship. */
printf("perfdemo: read entered at %ju\n", (uintmax_t)sbinuptime());
```

When the tuning project is done, `grep` for `PERF:` and remove every line. A driver with no `PERF:` markers is one that has been cleaned up; a driver with a dozen is one where the author forgot.

33.11.2 What to Keep

Not every piece of measurement code should go. Some of it has lasting value and belongs in the shipped driver. The criteria:

- **Keep counters that tell operators what the driver is doing.** Total reads, writes, errors, bytes: these belong in the `sysctl` tree forever.
- **Keep SDT probes at operational boundaries.** They cost nothing when disabled and give any future engineer an instant way to measure the driver.
- **Keep configuration knobs that expose meaningful trade-offs.** The buffer size, the coalescing threshold, the debug level: these are interfaces to the operator.
- **Remove one-off prints and hand-written timings.** These were for one tuning session and have no place in shipped code.
- **Remove counters that are too specific to the question you were answering.** A counter named `reads_between_cache_miss_A_and_cache_miss_B` probably has no lasting value; a counter named `reads` does.

The test is: *would a future engineer benefit from this information six months from now?* If yes, keep it. If no, remove it.

33.11.3 Benchmarking the Final Driver

After the scaffolding is gone, benchmark the final driver one more time. This benchmark is the one that becomes the *published* performance of the driver; record it in your logbook and in a plain-text document in the driver's source tree. A benchmark report should include:

- The driver version (for example, `perfdemo 2.3`).
- The machine: CPU model, core count, RAM size, FreeBSD version.
- The workload: what `dd` command, what file sizes, what userland threads, what coalescing window.
- The result: throughput, latency (P50, P95, P99), CPU usage.
- Context: what else was running, any relevant `sysctl` settings.

A reader who picks up the driver months later should be able to reproduce the benchmark without asking you. That reproducibility is the purpose of the report.

33.11.4 Documenting Tuning Knobs

If the driver now exposes tunable sysctls that affect performance, document them. The right place is the driver's manual page (an .4 page under /usr/share/man/man4/) or a section at the top of the driver's source file. A manual page section looks like:

```
.Sh TUNABLES
The following tunables can be set at the
.Xr loader.conf 5
prompt or at runtime via
.Xr sysctl 8 :
.Bl -tag -width "dev.perfdemo.buffer_size"
.It Va dev.perfdemo.buffer_size
Size of the internal read buffer, in bytes.
Default 1024; valid range 16 to 4096.
Larger values increase throughput for bulk reads
but raise per-call latency.
.It Va dev.perfdemo.debug
Verbosity of debug logging.
0 logs errors only.
1 adds transient-error notes.
2 logs every operation.
Default 0; higher values should only be used
during diagnostic sessions.
.El
```

The format is arcane on a first look, but every FreeBSD manual page uses the same pattern. The existing .4 pages under /usr/src/share/man/man4/ are excellent templates; copy one whose style matches your driver and adapt.

For drivers that do not ship a manual page yet, this is the moment to write one. A driver without a manual page is underdocumented; one with a manual page is at a credibility threshold expected of base-system code.

33.11.5 Versioning

A tuned driver is a new version of the driver. Mark it with `MODULE_VERSION( )` in the driver source:

```
MODULE_VERSION(perfdemo, 3);  /* was 2 before this tuning pass */
```

The version number is consumed by `kldstat -v` and by other modules that declare `MODULE_DEPEND( )` against yours. Bumping it signals that the driver's behaviour has changed enough for consumers to care.

For a shipped driver, the convention is a major version for breaking changes, a minor version (or version suffix) for compatible additions, and a patch version for bug fixes. A pure performance tuning pass that adds no new functionality is a patch; a tuning pass that adds new sysctls is a minor; a tuning pass that changes the semantics of

existing interfaces is a major. The book's exercises call a tuned driver `v2.3-optimized`; in reality, the version scheme is the one your project uses.

Updating the changelog is part of the versioning work. A `CHANGELOG.md` or a comment in the driver source is the right place. Each entry should include:

- The version and date.
- What changed at a high level (tuning, bug fix, new feature).
- The benchmark numbers if they changed.
- Any backward-incompatible changes operators need to know about.

The habit of keeping the changelog current is the habit that makes long-lived code maintainable. Drivers without changelogs accumulate lore; drivers with them accumulate history.

33.11.6 Reviewing the Diff

Before shipping, read the whole diff of the tuning work as if you were a new maintainer reviewing the change. Look for:

- Code paths that have become harder to reason about.
- Comments that no longer match the code.
- Temporary code that survived the cleanup.
- Error paths that were changed but not retested.
- Locking that was added or removed.

This review catches the problems your own measurements did not. A piece of code that is correct but unreadable is a problem waiting to happen.

33.11.7 The Performance Report

The final deliverable of a tuning project is a short written report. Not a blog post; not a presentation; a plain document that lives with the driver. A useful template:

```
perfdemo v2.3-optimized - Performance Report
=====
```

```
Summary: v2.3 is a pure-tuning release that reduces median read
latency from 40 us to 12 us and triples throughput on a 4-core
amd64 test machine, without changing the driver's interface.
```

```
Goals (set before tuning):
```

- ```
- Median read() latency under 20 us.
- P99 read() latency under 100 us.
- Single-thread throughput above 500K ops/sec.
- Multi-thread throughput scaling linearly up to 4 CPUs.
```

```
Before (v2.2):
```

- Median read: 40 us.
- P99 read: 180 us.
- Single-thread: 180K ops/sec.
- 4-thread: 480K ops/sec (2.7x; sublinear).

After (v2.3):

- Median read: 12 us.
- P99 read: 65 us.
- Single-thread: 520K ops/sec.
- 4-thread: 1.95M ops/sec (3.75x; near-linear).

Changes applied:

1. Replaced single atomic counter with counter(9).
2. Cache-line aligned hot softc fields.
3. Pre-allocated read buffers in attach().
4. Switched to UMA zone for per-request scratch buffers.
5. Added sysctl nodes for stats and config (non-breaking).

Measurements:

All numbers from DTrace aggregations over 100,000-sample windows, 4-core amd64, 3.0 GHz Xeon, FreeBSD 14.3 GENERIC, otherwise idle. See `benchmark/v2.3/` for raw data and scripts.

Tunables introduced:

- `dev.perfdemo.buffer_size`: runtime buffer size (default 1024).
- `dev.perfdemo.debug`: runtime debug verbosity (default 0).

Risks:

Cache-line alignment increases softc memory by approximately 200 bytes per instance. Unlikely to matter on modern systems but worth noting for memory-constrained embedded targets.

Remaining work:

None for v2.3. Future tuning may investigate reducing P99 latency further if workload analysis shows a specific cause.

A report like this becomes institutional knowledge. A maintainer two years from now reading this document has everything needed to understand what was done, why, and how to reproduce it.

### 33.11.8 A/B Testing Tuning Changes

Before committing a tuning change to the tree, the responsible thing is to test it against the previous version under the same workload. An A/B test compares the two versions against a single benchmark, multiple times,

under the same system state. If the new version is measurably better *and* the difference survives the noise of multiple runs, the change is worth keeping.

A simple A/B harness:

```
#!/bin/sh
ab-test.sh <module-a-name> <module-b-name> <runs>

MODULE_A=$1
MODULE_B=$2
RUNS=$3

echo "Module A: $MODULE_A"
echo "Module B: $MODULE_B"
echo "Runs per module: $RUNS"
echo

for i in $(seq 1 $RUNS); do
 sudo kldload ./"$MODULE_A".ko
 time ./run-workload.sh 100000
 sudo kldunload "$MODULE_A"
 echo "A$i done"

 sudo kldload ./"$MODULE_B".ko
 time ./run-workload.sh 100000
 sudo kldunload "$MODULE_B"
 echo "B$i done"
done
```

Run this with `./ab-test.sh perfdemo-v22 perfdemo-v23 10`. The script alternates modules to prevent warm-up effects from biasing one in the other's favour. Ten runs each is usually enough to distinguish a 5% difference from noise.

A/B testing matters for two reasons. First, it forces you to state the comparison as *version A vs version B under workload X*, which is the shape a performance claim should have. Second, it catches regressions: if v2.3 is slower than v2.2 on some axis you did not measure, the A/B run shows it. A tuning change that improves one metric while hurting another is surprisingly common; only a disciplined comparison surfaces them.

### 33.11.9 The Benchmark Harness

A sophisticated project eventually accumulates a proper benchmark harness: a reusable script that runs a known workload, collects a known set of metrics, and writes the results in a known format. A harness is worth building when:

- You run the same benchmark more than three or four times.
- Multiple people need to reproduce the benchmark.

- The results are used in performance reports and must be comparable across runs.

The harness typically includes:

- A setup script that loads the driver, configures its sysctls, and verifies the system is idle.
- A runner script that invokes the workload for a fixed duration or a fixed number of iterations.
- A collector that captures metrics before and after, computes deltas, and writes a structured report.
- A teardown script that unloads the driver and restores any system state.
- A results archive that preserves raw and processed outputs with timestamps and run identifiers.

For `perfdemo`, the harness lives in the `lab` directory as `final-benchmark.sh`. For a production driver, it lives in the source tree alongside the driver, so anyone can reproduce the results.

The details of the harness depend on the driver. What matters is that there is *some* harness; ad-hoc benchmarks that someone has to remember how to run are ad-hoc evidence that someone has to remember how to trust.

### 33.11.10 Sharing Performance Numbers With the Project

For drivers that go into the FreeBSD base system or a significant port, the performance numbers are not a private deliverable. They become part of the project record: commit messages, mailing-list threads, release notes. The conventions for sharing are worth knowing.

**Commit messages** should summarise the change, the benchmark, and the result in the body. A good performance-related commit message looks like:

```
perfdemo: switch counters to counter(9) for better scaling
```

```
Single counters in the softc were contended on multi-CPU systems.
Switching to counter(9) reduces per-call overhead and allows the
driver to scale to higher throughput under parallel load.
```

```
Measured on an 8-core amd64 Xeon at 3.0 GHz, FreeBSD 14.3-STABLE:
Before: 480K ops/sec at 4-thread peak.
After: 1.95M ops/sec at 4-thread peak (4x).
```

```
Benchmark data and scripts are in tools/perfdemo-bench/.
```

The first line is a short summary. The body expands on what changed, why, and what the measurement showed. A reader scanning commit history can understand the significance of the change in 60 seconds.

**Mailing-list threads** announcing the change follow the same structure but can include more context: the goal of the tuning, the alternatives considered, any caveats. Link to benchmark scripts and raw data if the scale of the change warrants discussion.

**Release notes** are terser. One or two lines: *The perfdemo(4) driver now uses counter(9) for its internal statistics. This reduces overhead on multi-CPU systems and allows higher throughput under parallel load.*

Each audience gets what it needs. The pattern is that every performance claim, at every level of detail, points at a reproducible measurement.

### 33.11.11 Exercise 33.8: Ship perfdemo v2.3

Using the state of perfdemo you built across Sections 2 through 7, produce a v2.3-optimized release:

1. Remove every PERF: marker and the scaffolding it denoted.
2. Decide what stays in the sysctl tree and what was only useful during tuning.
3. Update MODULE\_VERSION( ) to 3 (or your chosen new number).
4. Update the driver's manual page (or write one if it does not exist) with the TUNABLES section.
5. Run the final benchmark and record the numbers.
6. Write the performance report.

The exercise is the entire chapter's output in a concrete form. When you finish, you have a driver that would pass review in any serious FreeBSD project, with the performance measurements that justify its state.

### 33.11.12 Wrapping Up Section 8

Tuning is only half a project. The other half is the discipline of cleaning up, documenting, and shipping. A driver with clean measurement primitives, a thoughtful sysctl tree, honest manual-page documentation, an updated version number, and a written performance report is the driver that ages well. The shortcut of skipping any of these steps is tempting, but the cost is paid by the next maintainer, which might be your future self.

The instructional portion of the chapter is complete. The next sections are the hands-on labs, the challenge exercises, the troubleshooting reference, the Wrapping Up, and the bridge into Chapter 34.

## 33.12 Putting It All Together: A Complete Tuning Session

Before the labs, a worked walkthrough that ties the eight sections into a single story. This is the shape a real tuning session takes, compressed into a few pages. The session is not fictional; it is the same pattern that produces most of the performance improvements in the FreeBSD tree.

**The driver.** perfdemo v2.0 is a working character device that produces synthetic data on read(). Its hot path takes a mutex, allocates a temporary buffer via malloc(9), fills it with pseudo-random data, copies it to userland via uiomove(9), frees the buffer, releases the mutex, and returns. It has a single atomic counter for total reads and no sysctl tree beyond what FreeBSD's device\_t gives it for free.

**The goal.** A user reports that perfdemo is slow in their production workload: they run forty concurrent reader threads, and throughput saturates at about 600,000 ops/sec across all threads on their 16-core amd64 server. They want 2 million or better. The stated goal is *median read( ) latency under 20 us and aggregate throughput above 2 million ops/sec on a 16-core amd64 Xeon running FreeBSD 14.3 GENERIC, with forty reader threads pinned across CPUs 0-15.*

**Measurement, round 1.** Before changing anything, we need numbers. We load the driver, run the user's workload, and collect baseline data.

vmstat -i does not show any unusual interrupt rates, so we rule out interrupt problems early. top -H shows the system's CPU at 65%; the driver is clearly not the only consumer, but it is a significant one. We instrument the driver minimally: one counter(9) for total reads, one for total nanoseconds of latency, both exposed via

a procedural sysctl. We run the workload for sixty seconds and record the average latency as 52 microseconds. The goal is under 20. We are 32 microseconds off.

**DTrace, round 1.** With the baseline in hand, we reach for DTrace. A one-liner to see the function-level latency distribution:

```
dtrace -n '
fbt:perfdemo:perfdemo_read:entry { self->s = timestamp; }
fbt:perfdemo:perfdemo_read:return /self->s/ {
 @lat = quantize(timestamp - self->s);
 self->s = 0;
}'
```

After a minute the histogram shows a clear shape. P50 is around 30 us; P95 is 150 us; P99 is a surprising 1.5 ms. The long tail is where the user's pain comes from.

We widen the investigation. Another one-liner:

```
dtrace -n 'lockstat:::adaptive-block {
 @[((struct lock_object *)arg0)->lo_name] = count();
}'
```

The top entry: *perfdemo\_softc\_mtx* with about 30,000 blocks during the one-minute window. Our driver's mutex is contended; forty reader threads are serialising on it.

**The first fix.** The mutex protects a counter and a pool pointer; in principle the counter could be per-CPU and the pool pointer could be lockless. We replace the atomic counter with `counter_u64_add()`, which does not require the driver's lock, and we rework the pool into a per-CPU array of buffers (one per CPU). The hot path no longer needs to take the mutex for the common case; the mutex only guards the pool's administrative paths (init, fini, resize).

We rebuild, reload, rerun. Average latency drops from 52 us to 14 us. Throughput climbs from 600K to 1.8M ops/sec. We are close to the goal but not there.

**DTrace, round 2.** With the mutex out of the way, we profile again:

```
dtrace -n 'profile-997 /arg0 != 0/ { @[stack()] = count(); }'
```

The top stack now shows most of the time in `uiomove`, `malloc`, and `free`. The allocator is the next bottleneck; every read is allocating and freeing a temporary buffer. The counter-level cost is negligible.

**The second fix.** We switch from `malloc(9)` on the hot path to a UMA zone created at attach, with `UMA_ALIGN_CACHE` for per-CPU-aligned items. The zone is sized for the expected working set; `vmstat -z` confirms the zone population stabilises a few seconds after workload start.

Rebuild, reload, rerun. Average latency drops from 14 us to 9 us. Throughput climbs from 1.8M to 2.3M ops/sec. We have met the goal: median under 20 us and throughput above 2 million.

**pmcstat, round 1.** We are inside the goal, but before declaring victory we want to know whether the driver is now well-balanced across CPUs. We run a sampling session:

```
pmcstat -S cycles -O /tmp/perfdemo.pmc ./run-workload.sh
pmcstat -R /tmp/perfdemo.pmc -T
```

The top functions are `uiomove`, `perfdemo_read`, and a couple of cache-coherence primitives from the kernel. No single bottleneck; the driver is now spending its time on the work it should be doing. Good.

A counting session:

```
pmcstat -s cycles -s instructions ./run-workload.sh
```

Prints an IPC of about 1.8. That is healthy for mostly-memory-moving code; we are not leaving hardware throughput on the table.

**Cleanup.** We read the diff. Four `PERF:` markers remain from the investigation; we remove them. Two commented-out variants exist from the second fix; we remove them. A debug-level `sysctl` that we added at one point but never used finds its way in; we remove it too.

**Sysctl tree.** The tree now has `dev.perfdemo.0.stats.reads`, `dev.perfdemo.0.stats.errors`, `dev.perfdemo.0.stats.bytes`, `dev.perfdemo.0.stats.lat_hist` (the histogram), and `dev.perfdemo.0.config.debug` (a level-0-to-2 debug verbosity). Each is documented in the `descr` string.

**Manual page.** A paragraph in the existing `.4` page describes the new tunables. The benchmark-report document describes the tuning and the numbers.

**Final numbers.** On the 16-core Xeon under the user's workload:

- Median `read()` latency: 9 us.
- P95 `read()` latency: 35 us.
- P99 `read()` latency: 95 us.
- Throughput: 2.3 million ops/sec.

**Time invested.** Roughly one engineer-day from first measurement to final report. The two fixes are small; finding them took longer than writing them. That ratio is typical.

**Lessons.** Three points stand out.

First, the investigation did not start with code changes. It started with measurement, moved through DTrace, and only then changed code. Every change was motivated by a specific observation.

Second, two fixes were enough. The mutex and the allocator were the two bottlenecks; the third-order optimisations (cache alignment on small fields, NAPI-style batching, MSI-X) were unnecessary. The chapter described them all because you have to know they exist; the session showed that you apply them selectively.

Third, the scaffolding was temporary. `PERF:` markers, commented-out variants, an unused debug level: all removed before ship. The cleaned-up driver looks simple because the tuning left little trace. That simplicity is the goal.

The labs below walk through the same shape of session, with concrete code and commands, at each stage.

## 33.13 Hands-On Labs

This chapter's labs are built around a small pedagogical driver called `perfdemo`. The driver is a character device that synthesises data on `read()` at a controlled rate, and exposes a `sysctl` tree. It is deliberately uncomplicated; the interesting part is what the labs do *with* it. Each lab takes the driver through one stage of the performance workflow: baseline measurement, DTrace tracing, PMC sampling, memory tuning, interrupt tuning, and final cleanup.

All files for the labs live under `examples/part-07/ch33-performance/`. Each lab directory has its own `README.md` with build and run instructions. Clone the directory, follow the `README` for each lab, and work through them in order.

### 33.13.1 Lab 1: Baseline `perfdemo`, Counters, and `sysctl`

**Objective:** Build the baseline `perfdemo` driver, load it, and exercise its `sysctl`-based counters. This lab is the foundation for every other lab in the chapter; take the time to get it right.

**Directory:** `examples/part-07/ch33-performance/lab01-perfcounters/`.

**Prerequisites:** A FreeBSD 14.3 system (physical, virtual, or jail with kernel build tools), the FreeBSD source tree at `/usr/src`, and root access to load kernel modules.

**Steps:**

1. Change into the lab directory: `cd examples/part-07/ch33-performance/lab01-perfcounters/`.
2. Read `perfdemo.c` to familiarise yourself with the baseline driver. Note the structure: a `module_event_handler`, a `probe/attach/detach` set, a `cdevsw` with a `read` method, a `softc`, and the `sysctl` tree under `hw.perfdemo`.
3. Build the module with `make`. If the build fails, check that `/usr/src` is populated and that you can build other kernel modules (the easiest test: `cd /usr/src/sys/modules/nullfs && make`).
4. Load the module: `sudo kldload ./perfdemo.ko`. Confirm it is loaded: `kldstat | grep perfdemo`.
5. Check the `sysctl` tree: `sysctl hw.perfdemo`. You should see:

```
hw.perfdemo.reads: 0
hw.perfdemo.writes: 0
hw.perfdemo.errors: 0
hw.perfdemo.bytes: 0
```
6. Verify the device node exists: `ls -l /dev/perfdemo`.
7. In one terminal, start a watch: `watch -n 1 'sysctl hw.perfdemo'`.
8. In another terminal, run the workload: `./run-workload.sh 100000`. The script issues 100,000 reads against `/dev/perfdemo`. It prints its wall-clock time on completion.
9. Verify the counters moved as expected. After the workload, `hw.perfdemo.reads` should be around 100,000 (a few extras from ad-hoc reads are normal).
10. Run the workload at a larger size: `./run-workload.sh 1000000`. Record the wall-clock time again. Divide `1000000 / wallclock_seconds` to get ops/sec.

11. Unload the driver: `sudo kldunload perfdemo`.

**What you should see:**

- The sysctl counters increase as the workload runs.
- The final values should match the workload's request count (within one or two operations of variance).
- The wall-clock time of the 1M-read run should be a few seconds on a modern machine.
- No kernel warnings in `dmesg`.

**What you should record in your logbook:**

- The wall-clock time and ops/sec of both workload runs.
- The machine: CPU model, core count, RAM, FreeBSD version.
- Any `dmesg` output from the module-load and module-unload events.
- The final sysctl values.

**Expected baseline numbers (for comparison):**

On an 8-core amd64 Xeon at 3.0 GHz running FreeBSD 14.3-RELEASE with the baseline driver, a 1M-read single-threaded workload completes in roughly 3 seconds, giving about 330,000 ops/sec. Your numbers will differ based on hardware, but the order of magnitude should be similar.

**Common mistakes:**

- Forgetting to load the driver before running the workload. The loader script will fail with `ENODEV` if `/dev/perfdemo` is missing.
- Running the loader script with a very small count (for example, 100) and expecting stable numbers. The noise of measurement starts to dominate below a few thousand iterations. Use 100,000 or more for baseline runs.
- Confusing `hw.perfdemo.reads` with `hw.perfdemo.bytes`. The counter for total reads is distinct from the counter for total bytes. A 100-byte read increments reads by one and bytes by 100.
- Forgetting to unload the driver before rebuilding. A stale `.ko` in the kernel can cause confusing symptoms on the next load.

**Troubleshooting:** If the module fails to load with *module version mismatch*, your kernel version does not match the one `perfdemo` was built against. Rebuild after ensuring `/usr/obj` and `/usr/src` match your running kernel.

### 33.13.2 Lab 2: DTrace perfdemo

**Objective:** Use DTrace to understand what `perfdemo`'s read path is doing, measured from outside without modifying the driver.

**Directory:** `examples/part-07/ch33-performance/lab02-dtrace-scripts/`.

**Prerequisites:** Lab 1 complete; the `perfdemo` driver loaded.

**Steps:**

1. Ensure the `perfdemo` driver is loaded (from Lab 1). If not, `cd` to `lab01-perfcounters/` and `sudo kldload ./perfdemo.ko`.

2. Load the DTrace providers: `sudo kldload dtraceall`. You can verify with `sudo dtrace -l | head` (it will list a few probes).
3. In one terminal, run the workload continuously: `while :; do ./run-workload.sh 10000; done`. Let it churn.
4. In another terminal, run the simple count one-liner:

```
sudo dtrace -n 'fbt:perfdemo:perfdemo_read:entry { @ = count(); }'
```

Let it run for 30 seconds, then Ctrl-C. You should see a number in the tens of thousands. Divide by 30 to get reads/sec, which should match what `hw.perfdemo.reads delta` shows.

5. Run the latency histogram script `read-latency.d` in this lab directory:

```
sudo dtrace -s read-latency.d
```

Let it run for 30 seconds. The histogram will look something like:

| value  | ----- Distribution ----- | count |
|--------|--------------------------|-------|
| 512    |                          | 0     |
| 1024   | @                        | 125   |
| 2048   | @@@@@                    | 520   |
| 4096   | @@@@@@@@@@@@@@@@@@@@@@@@ | 1850  |
| 8192   | @@@@@@@@@@@@@@@@@@@@     | 1320  |
| 16384  | @@@                      | 290   |
| 32768  |                          | 35    |
| 65536  |                          | 8     |
| 131072 |                          | 2     |
| 262144 |                          | 0     |

Record the P50 (the bucket that contains the median) and the P99 (the bucket that crosses 99% cumulative).

6. Run the lock-contention script `lockstat-simple.d`:

```
sudo dtrace -s lockstat-simple.d
```

Let it run for 30 seconds. Look for `perfdemo` or `perfdemo_softc_mtx` in the output. The baseline driver *will* show contention on its mutex if you run the workload with concurrency.

7. Run the profile-sampling script `profile-sample.d`:

```
sudo dtrace -s profile-sample.d
```

Let it run for 60 seconds. The output lists the top kernel stacks by sample count. `perfdemo_read` should appear among the top entries.

8. Stop the workload (Ctrl-C in its terminal).

### What you should see:

- `read-latency.d` produces a histogram with a bell-like peak around the median, and a tail to the right.

- `lockstat-simple.d` produces a list of locks touched during the measurement; if the workload is concurrent, `perfdemo_softc_mtx` appears.
- `profile-sample.d` produces a list of function stacks; `perfdemo_read`, `uiomove`, `copyout`, and `_mtx_lock_sleep` are typical entries.

**What you should record in your logbook:**

- P50 and P99 latency.
- Top three functions from `profile-sample.d`.
- The contended lock names from `lockstat-simple.d`.

**Expected results (for comparison):**

On the same 8-core Xeon, the baseline driver under 4-thread concurrent read load shows a median around 8 us, P99 around 60 us, heavy contention on `perfdemo_softc_mtx`, and top profile entries dominated by `perfdemo_read`, `uiomove`, and `_mtx_lock_sleep`.

**Common mistakes:**

- Running DTrace before the driver is loaded. The `fbt:perfdemo: probes` do not exist until `perfdemo.ko` is in the kernel.
- Writing scripts that print per-event. The DTrace buffer can drop events; always aggregate and print at the end.
- Forgetting to Ctrl-C the DTrace session at the right moment. Some aggregations only print on explicit stop.
- Running the workload at too low a rate to produce interesting data. DTrace latency histograms need at least tens of thousands of samples for clean percentile estimates.
- Forgetting to load `dtraceall`. A bare DTrace install without providers will complain about unknown providers.

**Troubleshooting:** If `dtrace -l | grep perfdemo` is empty after the driver is loaded, check that `dtraceall` is loaded (`kldstat | grep dtrace`). If the probes still do not appear, the driver may have been compiled without debug symbols; check that make used the default flags and did not strip `-g`.

### 33.13.3 Lab 3: `pmcstat perfdemo` (optional, requires `hwpmc`)

**Objective:** Sample `perfdemo` with hardware performance counters and interpret the output. This lab is richer than the others because `pmcstat` has more knobs than DTrace; plan on spending extra time.

**Directory:** `examples/part-07/ch33-performance/lab03-pmcstat/`.

**Prerequisites:** A physical or fully paravirtualised machine where PMCs are available. On most cloud VMs and on shared hypervisors, PMCs are restricted; if `pmcstat -L` lists only a handful of events or the tool refuses to start, follow the alternative path with DTrace's `profile` provider.

**Steps:**

1. Ensure `hwpmc` is loaded: `sudo kldload hwpmc` (or confirm it is already loaded with `kldstat | grep hwpmc`). Check `dmesg | tail` after loading; you should see a line like `hwpmc: SOFT/16/64/0x67<REA,WRI,INV,LOG,EV1,EV2,CAS>`.

2. Verify the tool sees events: `pmcstat -L | head -30`. You should see a mix of portable event names (cycles, instructions, cache-references, cache-misses) and vendor-specific names (for Intel, entries starting with `cpu_clk_`, `inst_retired`, `uops_issued`, and so on).
3. Run a counting session during a workload. The `-s` flag (lowercase) is for system-wide counting; use this to see the driver's contribution plus everything else the kernel is doing:

```
sudo pmcstat -s instructions -s cycles -O /tmp/pd.pmc \
 ./run-workload.sh 100000
```

After the workload finishes, `pmcstat` prints the totals:

```
p/instructions p/cycles
 3.2e9 9.5e9
```

Divide instructions by cycles to compute IPC: 3.2 billion / 9.5 billion = 0.34. An IPC below 1 on a modern CPU usually indicates stalls; likely memory or branch mispredicts.

4. Run a sampling session. The `-S` flag (uppercase) configures sampling:

```
sudo pmcstat -S cycles -O /tmp/pd-cycles.pmc \
 ./run-workload.sh 100000
pmcstat -R /tmp/pd-cycles.pmc -T
```

The `-T` output is the top-N function list. You should see something like:

| %SAMP | CUM  | IMAGE  | FUNCTION          |
|-------|------|--------|-------------------|
| 13.2  | 13.2 | kernel | perfdemo_read     |
| 9.1   | 22.3 | kernel | uiomove_faultflag |
| 8.5   | 30.8 | kernel | copyout           |
| 6.2   | 37.0 | kernel | _mtx_lock_sleep   |
| 4.9   | 41.9 | kernel | _mtx_unlock_sleep |
| ...   |      |        |                   |

Note the top five functions and their percentages.

5. Run a second sampling session, this time with LLC-misses to see where cache misses happen (requires Intel CPU):

```
sudo pmcstat -S LLC-misses -O /tmp/pd-llc.pmc \
 ./run-workload.sh 100000
pmcstat -R /tmp/pd-llc.pmc -T
```

Compare the top entries to the cycle samples. If the same functions appear in both, the time is memory-bound; if different functions appear, the cycle-hot functions are CPU-bound (arithmetic, branches).

6. If you have the FlameGraph tools installed (install them from the `sysutils/flamegraph` port: `sudo pkg install flamegraph`), generate an SVG:

```
sudo pmcstat -R /tmp/pd-cycles.pmc -g -k /boot/kernel > pd.stacks
stackcollapse-pmc.pl pd.stacks > pd.folded
flamegraph.pl pd.folded > pd.svg
```

Open `pd.svg` in a browser. The SVG is interactive; click any box to zoom into that call stack.

7. Inspect the flame graph. The bottom boxes (system call entry) should be wide and boring. Above them, your driver's functions appear as narrower stacks. The width of each box is its fraction of CPU time; the height shows call depth.

**Alternative if `hwpmc` is unavailable:** Use DTrace's profile provider:

```
sudo dtrace -n 'profile-997 /arg0 != 0/ { @[stack()] = count(); }' \
-o /tmp/pd-prof.txt
```

Let it run for a minute while the workload runs, Ctrl-C, then examine `/tmp/pd-prof.txt`. The output is similar to `pmcstat`'s callgraph, though coarser because the profile sample rate is fixed.

**What you should record in your logbook:**

- The IPC from the counting session.
- The top five functions from the sampling session, with their percentages.
- The top three functions in the LLC-misses session (if available) and whether they matched the cycle-samples list.
- A screenshot or description of the flame graph's dominant stacks.

**Expected baseline numbers (for comparison):**

On the baseline driver on an 8-core Xeon, IPC is typically 0.3 to 0.5 (memory-bound). The top function is usually `perfdemo_read` at 10-15% of cycles, with `uiomove`, `copyout`, and `_mtx_lock_sleep` following. After tuning (Labs 4 and 6), IPC should climb above 1.0 and `_mtx_lock_sleep` should disappear from the top entries.

**Common mistakes:**

- Forgetting to load `hwpmc` before running `pmcstat`. The tool will report *no device* or *no PMCs available*.
- Running the sampling session for too short a window. A few seconds of samples gives noisy data; a minute is usually enough.
- Misreading `pmcstat -T`'s output. The `%SAMP` column is the fraction of samples a function received across all CPUs; a 10% value means 10% of time, not 10% of instructions.
- Using the wrong flag: `-s` is counting, `-S` is sampling. They produce different outputs and the difference is easy to miss when reading someone else's scripts.
- Trying to sample a function that got inlined. `inst_retired.any` counts instructions retired; an inlined function's instructions are counted against the caller, not the inlined one. If you expect to see function X in the samples and it does not appear, check with `objdump -d perfdemo.ko | grep X` to see whether X was compiled as a real function.

**Troubleshooting:** If `pmcstat` hangs or prints *ENOENT*, the event name is wrong. `pmcstat -L` lists every event name the kernel knows about on your CPU; pick one from that list. If the tool crashes with a signal, `hwpmc` may not be fully initialised; unload and reload the module.

### 33.13.4 Lab 4: Cache Alignment and Per-CPU Counters

**Objective:** Measure the performance impact of cache-line alignment and the counter (9) API compared to a plain atomic, under concurrent multi-CPU load.

**Directory:** examples/part-07/ch33-performance/lab04-cache-aligned/.

**Prerequisites:** Labs 1 and 2 complete, so you know the baseline driver's behaviour and how to use DTrace.

**Steps:**

1. Build three variants of the driver, each in its own subdirectory:

- v1-atomic: single atomic counter, default layout.
- v2-aligned: single atomic counter with `__aligned(CACHE_LINE_SIZE)` and padding around it to isolate the cache line.
- v3-counter9: `counter(9)` counter instead of an atomic.

Each subdirectory has its own Makefile. Run `make` in each. The only differences between the three sources are in the `softc` layout and the counter increment lines.

2. Identify your CPU count: `NCPU=$(sysctl -n hw.ncpu)`.
3. For each variant, run the multi-threaded reader script `./run-parallel.sh <N>` with `N` equal to the number of CPUs:

```
cd v1-atomic && sudo kldload ./perfdemo.ko && ./run-parallel.sh $NCPU
sudo kldunload perfdemo
```

```
cd ../v2-aligned && sudo kldload ./perfdemo.ko && ./run-parallel.sh $NCPU
sudo kldunload perfdemo
```

```
cd ../v3-counter9 && sudo kldload ./perfdemo.ko && ./run-parallel.sh $NCPU
sudo kldunload perfdemo
```

The script spawns `N` reader threads, each pinned to a different CPU, each issuing reads as fast as it can for a fixed duration. It prints the aggregate throughput at the end.

4. Record the throughput (ops/sec) for each variant.
5. Now repeat with half and double the thread count:

```
./run-parallel.sh $((NCPU / 2))
./run-parallel.sh $((NCPU * 2))
```

Compare the three throughputs at each thread count. Half-CPU runs usually show less contention; double-CPU runs show heavy contention and scheduler effects.

6. For the clearest demonstration, run a DTrace script on each variant while the workload runs:

```
sudo dtrace -n 'lockstat:::adaptive-block /
 ((struct lock_object *)arg0)->lo_name == "perfdemo_mtx" / {
 @ = count();
 }'
```

v1-atomic should show significant blocking; v3-counter9 should show almost none.

**What you should see:**

- `v1-atomic` is the baseline. Its throughput does not scale well beyond about half the CPUs; the atomic counter's cache-line bouncing becomes a bottleneck.
- `v2-aligned` improves if the counters were previously packed with other hot fields on the same cache line. If the original softc had the atomic counter on its own line already, alignment is a no-op.
- `v3-counter9` scales near-linearly to the CPU count. Each CPU updates its own per-CPU copy; no cache-line bouncing on the counter.

**Expected results (for comparison):**

On an 8-core Xeon with 8 threads running this workload:

- `v1-atomic`: around 600K ops/sec aggregate.
- `v2-aligned`: around 680K ops/sec aggregate.
- `v3-counter9`: around 2.0M ops/sec aggregate.

At 16 threads (oversubscribed):

- `v1-atomic`: around 550K (starts dropping).
- `v2-aligned`: around 650K (also drops).
- `v3-counter9`: around 1.8M (held up by scheduler overhead, not contention).

The per-CPU counter scales; the atomics do not.

**What you should record in your logbook:**

- Throughput numbers for each variant and each thread count.
- The lock-block count for each variant from the DTrace script.
- A short note on what the numbers tell you about your hardware (how contended the CPU-interconnect is, whether hyper-threading helps or hurts).

**Common mistakes:**

- Running the parallel script with only one thread. The point of the experiment is contention; a single-thread run eliminates it and hides the effect.
- Concluding from a small difference. If the three numbers differ by less than 10%, the measurement noise could explain the difference; rerun at least three times and check variance.
- Forgetting that `UMA_ALIGN_CACHE` in UMA zones does similar work for you. The counter (9) primitive is a clean solution; you rarely need to hand-align for counters.
- Expecting linear scaling from `v1-atomic`. Atomic counters *cannot* scale past about the memory system's coherence bandwidth; once that bandwidth is saturated, adding CPUs makes throughput worse, not better.
- Forgetting to unload between runs. Loading a new variant on top of a running one does not replace the running one; `kldunload perfdemo` then `kldload ./perfdemo.ko`.

**Troubleshooting:** If the throughput numbers are inconsistent between runs, CPU frequency scaling is probably the culprit. Pin the frequency with `sysctl dev.cpu0.freq=$(sysctl -n dev.cpu0.freq_levels | awk '{print $1}' | cut -d/ -f1)` (adjust for your CPU). On systems where this is not available, disable dynamic frequency scaling in the BIOS/firmware.

### 33.13.5 Lab 5: Interrupt and Taskqueue Split

**Objective:** Compare in-interrupt-context work with taskqueue-deferred work, including behaviour under load.

**Directory:** `examples/part-07/ch33-performance/lab05-interrupt-tq/`.

**Prerequisites:** Lab 1 complete.

**Steps:**

1. Inspect the two variants in the lab directory:
  - `v1-in-callout`: a callout fires every millisecond and does its processing inline. The “interrupt handler” is the callout’s function; all work happens in that context.
  - `v2-taskqueue`: the callout enqueues a task; a taskqueue thread dequeues and processes the work. The callout itself does nothing else.
2. Build each: `make` in each subdirectory.
3. Load the first variant: `cd v1-in-callout && sudo kldload ./perfdemo.ko`.
4. Run the measurement script: `./measure-latency.sh`. It spawns a userland reader that waits for the callout’s processed data, then records the wall-clock time between the callout firing and the reader seeing the result. The script prints the median and P99 latency over 10,000 iterations.
5. Unload and load the second variant: `sudo kldunload perfdemo && cd ../v2-taskqueue && sudo kldload ./perfdemo.ko`.
6. Run the same measurement script.
7. Record median and P99 latency for each variant at idle.
8. Now repeat with artificial load on the system. In a second shell, start a CPU-intensive workload: `make -j$(sysctl -n hw.ncpu) buildworld` (if you have the world source checked out) or a simpler stressor: `for i in $(seq 1 $(sysctl -n hw.ncpu)); do yes > /dev/null & done`.
9. Rerun the measurement for each variant. The scheduler is now busy; the two variants should differ more sharply.
10. Stop the artificial load (`killall yes` or equivalent). Check that CPU usage returns to idle before declaring the test complete.

**What you should see:**

- `v1-in-callout` at idle has lower median latency but spikes when the callout’s context is preempted (which happens at taskqueue boundary).
- `v2-taskqueue` at idle has a few microseconds of added latency (the callout-to-taskqueue dispatch) but smoother behaviour.
- Under load, `v1-in-callout` latency becomes highly variable; the callout context competes with the stressor for CPU.
- Under load, `v2-taskqueue` latency is higher but smoother; the taskqueue thread’s scheduling class is more stable.

**Expected results (for comparison):**

On an 8-core Xeon:

- v1-in-callout at idle: median 8 us, P99 30 us.
- v2-taskqueue at idle: median 12 us, P99 40 us.
- v1-in-callout under load: median 15 us, P99 2000 us (spikes due to preemption).
- v2-taskqueue under load: median 20 us, P99 250 us (smoother).

The P99 improvement under load is the main reason production drivers prefer taskqueues for any significant work.

**What you should record:**

- Median and P99 latency at idle for each variant.
- Median and P99 latency under load for each variant.
- A short note on when you would use each in practice.

**Common mistakes:**

- Benchmarking only at idle. The two variants behave most differently under system load; test both states.
- Confusing callouts with real interrupts. A callout is a software timer; the lab uses it to stand in for an interrupt because real interrupt timing is hardware-specific. The conclusions transfer, but the absolute numbers depend on your scheduler.
- Forgetting to stop the stressor before declaring the test complete. Leaving yes running is rude to the next test.
- Drawing conclusions from a single measurement. Latency is distributional; a single run is a single point, not a distribution. Collect at least 10,000 measurements per configuration.

### 33.13.6 Lab 6: Ship v2.3-optimized

**Objective:** Apply the full tuning work to produce a finished `perfdemo` v2.3-optimized, complete with `sysctl` tree, manual page, and benchmark report.

**Directory:** `examples/part-07/ch33-performance/lab06-v23-final/`.

**Prerequisites:** Labs 1 through 5 complete. You should have the baseline numbers from Lab 1 and familiarity with the per-CPU counter work from Lab 4.

**Steps:**

1. Inspect the starting state of the driver in the lab directory. This is the baseline `perfdemo` with no tuning applied; comments throughout the source mark where each tuning pass will go.
2. Apply the three changes we worked through in the chapter:

**Change 1: counter(9) for all statistics.** Replace the atomic counters with `counter_u64_t`. Update the `sysctl` handlers to use procedural `sysctls` that call `counter_u64_fetch`. Mark each change with a short comment describing what was changed.

**Change 2: Cache-line alignment on hot softc fields.** Identify the fields in the `softc` that are written frequently from multiple CPUs. For each, add `__aligned(CACHE_LINE_SIZE)` and appropriate padding.

Note: if you use counter(9) for all counters, most of the cache-alignment work is already done; only non-counter hot fields (like pool pointers or state flags) need manual alignment.

**Change 3: Pre-allocated buffers.** Create a UMA zone at MOD\_LOAD time with UMA\_ALIGN\_CACHE. Use `uma_zalloc/uma_zfree` on the hot path instead of `malloc/free`. Destroy the zone at MOD\_UNLOAD.

3. Build and load: `make && sudo kldload ./perfdemo.ko`. Run a quick smoke test with `./run-workload.sh 10000` to confirm the driver works.
4. Clean up any PERF: markers from the source. Grep for them: `grep -n 'PERF:' perfdemo.c`. Each line should either be removed or the marker replaced with a permanent comment if the measurement is staying.
5. Update the `MODULE_VERSION()` macro to 3. Find the line and change:

```
MODULE_VERSION(perfdemo, 2); /* before */
MODULE_VERSION(perfdemo, 3); /* after */
```

6. Update the driver's manual page. If one does not exist, copy `/usr/src/share/man/man4/null.4` as a template and adapt it. The page should have:

- `.Nm perfdemo`
- A one-line description in `.Nd`
- A `.Sh DESCRIPTION` explaining what the driver does.
- A `.Sh TUNABLES` section documenting the sysctl knobs.
- A `.Sh SEE ALSO` referencing related pages.

Lint the page: `mandoc -Tlint perfdemo.4`. Render it: `mandoc -Tascii perfdemo.4 | less`.

7. Run the final benchmark: `./final-benchmark.sh`. The script exercises the driver across several workloads (single-thread sequential, single-thread random, multi-thread parallel) and records median and P99 latency plus throughput for each. Copy the output to your logbook.
8. Write the performance report. Use the template from Section 8 as a starting point. Fill in:
  - The “Before” numbers from Lab 1.
  - The “After” numbers from step 7.
  - The three changes applied.
  - The machine details.
  - The tunables introduced (if any).

Save the report as `PERFORMANCE.md` in the lab directory.

9. Unload the driver: `sudo kldunload perfdemo`. Confirm it unloaded cleanly with no hung threads or leaked memory (`vmstat -z | grep perfdemo` should show zero allocated, or the zone should not appear if it was destroyed).

### What you should produce:

- `perfdemo.c` with the three tuning changes applied and no PERF: markers.
- `perfdemo.4` (manual page) with a TUNABLES section.
- `PERFORMANCE.md` (benchmark report).
- Clean build, clean load, clean unload.

**Expected results (for comparison):**

The v2.3 driver on an 8-core Xeon:

- Single-thread sequential reads: median 9 us, P99 60 us, throughput 400K ops/sec.
- Multi-thread (8-thread) parallel reads: median 11 us, P99 85 us, throughput 2.8M ops/sec.

Compare to the baseline (roughly 30 us median, 330K ops/sec, 600K under 8 threads). The v2.3 is 3x on single-thread and nearly 5x on parallel.

**Common mistakes:**

- Skipping the cleanup. A driver with `PERF:` markers is not a shipped driver.
- Reporting benchmark numbers without context. Every benchmark number needs the environment it was produced in.
- Updating the version number without the matching changelog entry. The version change signals behaviour change; the changelog documents what changed.
- Writing the manual page in vague prose. The `TUNABLES` section in particular should name exact value ranges, defaults, and trade-offs.
- Not running `mandoc -Tlint`. A broken manual page is as bad as no manual page.

**33.13.7 Wrapping Up the Labs**

The labs work through one complete tuning cycle: baseline, DTrace, PMC, memory, interrupts, ship. By the time you finish Lab 6, you will have exercised every tool in the chapter at least once and have a concrete `perfdemo` artefact you can carry forward. If you have time, the challenge exercises below extend the driver in directions that are too specific for the main text but that teach the habits the chapter pointed at.

**33.13.8 A Lab Summary Table**

For quick reference, the labs at a glance:

| Lab | What it teaches              | Primary tool            | Output                           |
|-----|------------------------------|-------------------------|----------------------------------|
| 1   | Baseline measurement         | <code>sysctl(8)</code>  | Ops/sec number                   |
| 2   | Function-level profiling     | <code>dtrace(1)</code>  | Latency histogram, hot functions |
| 3   | Hardware-level profiling     | <code>pmcstat(8)</code> | IPC, PMC-hot functions           |
| 4   | Counter-contention tuning    | <code>counter(9)</code> | Scaling comparison               |
| 5   | Interrupt-context trade-offs | <code>taskqueue</code>  | Latency under load               |

| Lab | What it teaches | Primary tool                | Output              |
|-----|-----------------|-----------------------------|---------------------|
| 6   | Ship discipline | MODULE_VERSION, manual page | A clean v2.3 driver |

Each lab is scoped to one hour if you are practised with the tools, two hours if you are learning them for the first time. The full set is a solid afternoon's work; the challenge exercises extend it into a weekend's work for readers who want deeper practice.

### 33.13.9 Lab Dependencies

The labs are sequential. Lab 1 establishes the baseline numbers. Lab 2 uses those numbers as the before-and-after comparison. Lab 3 is optional (hwpmc may not be available), but its concepts flow into Lab 4. Lab 4 is where the main memory-tuning lesson is. Lab 5 is independent of the others but uses the same `perfdemo` driver. Lab 6 assumes you have absorbed Labs 1-5 and are ready to apply the full sequence.

If you are short on time, do Labs 1, 2, 4, and 6 in order. Those four are the core of the chapter.

## 33.14 Challenge Exercises

These exercises go beyond the main labs. Each is optional and can be done in any order. They are designed to stretch the ideas from the chapter in ways that generalise to real driver work.

### 33.14.1 Challenge 1: Latency Budget for a Real Driver

Pick a real FreeBSD driver that interests you. Good candidates include `/usr/src/sys/dev/e1000/` for the Intel e1000 family of Ethernet drivers (including `em` and `igb`), `/usr/src/sys/dev/nvme/` for the NVMe storage driver, `/usr/src/sys/dev/sound/pcm/` for the audio core, or `/usr/src/sys/dev/virtio/block/` for the virtio block device.

Read the driver's source and write a latency budget. For each phase of its hot path (interrupt filter, `ithread`, taskqueue handler, `softclock` callout, userland wakeup), estimate the maximum latency the driver can afford and still meet its workload's needs. A reasonable budget entry looks like:

| phase                         | target  | justification                              |
|-------------------------------|---------|--------------------------------------------|
| -----                         | -----   | -----                                      |
| PCIe read of status           | < 500ns | register read on local bus                 |
| interrupt filter              | < 2us   | must not steal <code>ithread</code> time   |
| <code>ithread</code> hand-off | < 10us  | <code>softclock</code> expects prompt wake |
| taskqueue deferred            | < 100us | reasonable for RX processing               |
| wakeup to userland            | < 50us  | scheduler-dependent                        |

Then audit the actual code: does the code on each phase justify your estimate? If the `ithread` handler takes a `MTX_DEF` sleep mutex that might block, is your budget honest?

The exercise is not about precision; the numbers above are illustrative. It is about looking at a real driver with performance eyes and reasoning about how its design fits a workload. Record your budget, your audit, and any discrepancies in your logbook. This habit, applied over many drivers, builds intuition faster than any other practice.

**Hint:** Look for explicit comments about timing in the source. Real drivers occasionally have comments of the form `/* this must complete within N us because ... */`. Those comments are a gift. Read them.

### 33.14.2 Challenge 2: Compare Three Allocators

For a driver hot path that allocates fixed-size buffers (say, 64-byte buffers), benchmark three implementations:

1. `malloc(9)` with a per-call `malloc(M_TEMP, M_WAITOK)` followed by `free(M_TEMP)`.
2. A UMA zone created with `uma_zcreate("myzone", 64, ..., UMA_ALIGN_CACHE, 0)`, with `uma_zalloc()/uma_zfree()` on the hot path.
3. A pre-allocated array of 1024 buffers plus a freelist, allocated once at attach, reused on the hot path with a simple atomic pop/push.

Wire each into a clone of `perfdemo` and run the same read workload against all three. Measure:

- Throughput (reads/second).
- Median and P99 latency (from a counter-backed histogram).
- Cache miss rate (from `pmcstat -S LLC_MISSES` or the DTrace profile provider's `LLC_MISSES` alias if available).

On a modern amd64 machine, you should see a meaningful step from 1 to 2 (roughly 1.5x to 3x throughput, depending on contention), and a smaller but real step from 2 to 3 (perhaps 10% to 30%). The shape of the histogram is often more interesting than the average: `malloc(9)` has a long tail driven by VM pressure, UMA is tighter, the preallocated ring has the tightest tail.

Write a short note explaining the trade-offs. The preallocated ring is the fastest but the most rigid (the buffer count is fixed at attach). UMA is the right default for variable workloads. `malloc(9)` is fine for rare, large, or non-hot-path allocations. Do not conclude from this exercise that `malloc(9)` is bad; it is often the correct choice for control paths.

### 33.14.3 Challenge 3: Write a Useful DTrace Script

Write a DTrace script that answers a question you actually have about a driver. Some examples:

- *How much time does my driver spend waiting on its own mutex?* Use `lockstat:::adaptive-spin` and `lockstat:::adaptive-block` filtered by the lock address.
- *What is the distribution of request sizes coming into my driver?* Capture `args[0]->uio_resid` from `fbt:myfs:myfs_read:entry` into a `quantize()` aggregation.
- *Which userland process is the heaviest consumer of my driver?* Aggregate `@[execname] = count()` on the driver's entry point.
- *What is the 99th percentile latency of the write path, broken out by request size?* Use a two-dimensional aggregation `@[bucket(size)] = quantize(latency)` where `bucket()` collapses sizes into a handful of ranges.

- *Is my driver ever called at interrupt context?* Use `self->in_intr = curthread->td_intr_nesting_level` and aggregate by that flag.

Save the script as a `.d` file in your lab directory. Annotate it with a header comment that names:

- The script's purpose (one sentence).
- The probes it uses.
- The invocation command, including any arguments.
- Sample output and how to interpret it.

A DTrace script that has the answer to a question a colleague asks is more valuable than almost anything else in an engineer's notebook. Keep a growing folder of such scripts over the years; they compound.

**Hint:** Before committing to a complex aggregation, run the probe with a `printf()` on a handful of events and confirm the variables you want to capture are actually available and contain the values you expect. Add the aggregation only once the raw probe is known to fire correctly.

### 33.14.4 Challenge 4: Instrument a Read Path Without Contaminating It

Start with a `perfdemo`-style driver where the read path runs in a tight loop at high throughput. Add enough instrumentation to answer two questions:

1. What is the P50 and P99 latency of this read path?
2. What is the distribution of request sizes?

Measure the throughput before and after instrumentation. Aim for under 5% throughput loss from instrumentation. The exercise rewards thinking about the cost of each probe. Rough cost hierarchy on modern amd64, from cheapest to most expensive:

- Static SDT probe at compile time with DTrace disabled: effectively zero cost.
- A counter(9) increment on a per-CPU slot: a few cycles.
- An `atomic_add_int()` on a shared counter: tens to hundreds of cycles under contention.
- A `sbinuptime()` call: tens of cycles.
- A `log(9)` call: hundreds to thousands of cycles plus potential lock contention.
- A `printf()` call: thousands of cycles plus a possible sleep.

Design the instrumentation accordingly. A reasonable shape: per-CPU counter(9) for counts, `DPCPU_DEFINE` histogram buckets for latency distribution, no per-call `printf()`, no shared atomics. Measure the before-and-after throughput carefully and write up what you found.

**Hint:** Compile with `-O2` and inspect the generated assembly for the hot function with `objdump -d perfdemo.ko | sed -n '/<perfdemo_read>/,/^$/p'` to confirm the instrumentation did not defeat compiler optimisations, such as pushing variables to the stack that the non-instrumented version kept in registers.

### 33.14.5 Challenge 5: Expose a Live Histogram

Extend the `perfdemo` sysctl tree with a latency histogram. Define a set of latency buckets (for example, 0 to 1us, 1 to 10us, 10 to 100us, 100us to 1ms, 1ms to 10ms, 10ms and above). For each read, measure the latency,

find its bucket, and increment a per-CPU counter for that bucket. Expose the whole bucket array as a single sysctl that returns an opaque structure.

A reasonable handler:

```
static int
perfdemo_sysctl_hist(SYSCTL_HANDLER_ARGS)
{
 uint64_t snapshot[PD_HIST_BUCKETS];
 for (int i = 0; i < PD_HIST_BUCKETS; i++)
 snapshot[i] = counter_u64_fetch(perfdemo_read_hist[i]);
 return (SYSCTL_OUT(req, snapshot, sizeof(snapshot)));
}
```

From userland, write a Python or shell script that polls the sysctl every second with `sysctl -b` and prints a live textual bar chart of the distribution. Compare the live distribution during a steady workload, during a bursty workload, and during an idle period.

The exercise demonstrates the full loop: in-kernel per-CPU counters, aggregation at read time, a binary sysctl, userland visualisation, and a continuous observation pipeline. This is the pattern real drivers use to ship latency telemetry.

**Hint:** `sysctl -b` reads the raw bytes; your userland code must unpack them using `struct.unpack` in Python or a small C program. Do not expose the buckets as a formatted string from the kernel; let the raw numbers flow out and let userland do the presentation.

### 33.14.6 Challenge 6: Tune for Two Workloads

Pick two realistic workloads for the driver. For example, *small, latency-sensitive reads at 100 per second* (latency-bound) and *large, throughput-sensitive reads at 1000 per second* (throughput-bound). Identify the driver settings that optimise each workload. Candidates include:

- Buffer size (small for latency, large for throughput).
- Coalescing threshold, if any (none for latency, yes for throughput).
- Batch size for batched operations (small for latency, large for throughput).
- Polling versus interrupts (interrupts for latency, polling for throughput).
- Debug logging level (off for both; leave on only for troubleshooting).

Write a `loader.conf`-style table showing the best settings for each workload. Explain the trade-offs: why the latency setting would hurt throughput, why the throughput setting would hurt latency, and what the cost would be of picking a middle setting.

This challenge makes concrete the point from Section 1 that one driver can be fast in different ways for different workloads. Real driver tuning often means exposing these knobs with sensible defaults and documenting the workload each corresponds to.

**Hint:** Do not guess the best settings; measure them. Run each workload against each setting and fill in a table. The winning setting is often not the one you would have guessed, especially for throughput-versus-latency trade-offs where caches and scheduler interactions surprise experienced engineers.

### 33.14.7 Challenge 7: Write the Manual Page

If `perfdemo` does not have a manual page, write one. Follow the convention of `/usr/src/share/man/man4/`: copy a simple existing page like `null(4)` or `mem(4)`, change the name, document the device, the `sysctl` knobs, the tunables, and any relevant errors.

A reasonable skeleton:

```
.Dd March 1, 2026
.Dt PERFDEMO 4
.Os
.Sh NAME
.Nm perfdemo
.Nd performance demonstration pseudo-device
.Sh SYNOPSIS
To load the driver as a module at boot time, place the following line in
.Xr loader.conf 5 :
.Pp
.Dl perfdemo_load="YES"
.Sh DESCRIPTION
The
.Nm
driver is a pseudo-device used to illustrate performance measurement and
tuning techniques in FreeBSD device drivers.
...
.Sh SYSCTL VARIABLES
.Bl -tag -width "hw.perfdemo.bytes"
.It Va hw.perfdemo.reads
Total number of reads served since load.
...
.El
.Sh SEE ALSO
.Xr sysctl 8 ,
.Xr dtrace 1
.Sh HISTORY
The
.Nm
driver first appeared as a companion to
.Em FreeBSD Device Drivers: From First Steps to Kernel Mastery .
```

Verify the formatting with `mandoc -Tlint perfdemo.4`. Render it with `mandoc -Tascii perfdemo.4 | less`.

A manual page is a small but real commitment to the rest of the system. It turns a private tool into a shared one. It also forces you to name and describe every knob, which occasionally reveals knobs that do not need to exist.

**Hint:** The mdoc language is terse but strict. Read mdoc(7) once and use a recent simple man page as a template. Do not invent mdoc macros; use only the ones documented.

### 33.14.8 Challenge 8: Profile an Unfamiliar Driver

Pick a FreeBSD driver you have not worked with. On a test system where the hardware is present (or in a VM with a compatible emulated device), run `pmcstat` or a DTrace profile during a realistic workload. Good VM-friendly targets:

- `virtio_blk` under a load generated by `dd if=/dev/vtbd0 of=/dev/null bs=1M count=1024`.
- `virtio_net` under a load generated by `iperf3`.
- `xhci(4)` if you have USB devices attached.
- `urtw(4)` or similar wireless drivers if you have the hardware.

Identify the top three functions by CPU time. For each, read the source and form a hypothesis about what the function is doing that takes the time. Record the hypothesis in your logbook. For example: *virtio\_blk\_enqueue spends most of its time in bus\_dmamap\_load\_ccb because each request copies into a bounce buffer*.

You do not have to verify the hypothesis. The exercise is about the habit of looking at an unfamiliar driver with measurement tools and reasoning about the data they produce. The hypothesis, right or wrong, sharpens the next read of the source.

**Hint:** If the top function is in common kernel code (`copyin`, `bcopy`, `memset`, `spinlocks`), that is still useful information: it tells you where the driver spends its time, even if the root cause is outside the driver itself. Follow the callers back to the driver function and form the hypothesis there.

### 33.14.9 Wrapping Up the Challenges

The challenges extend the chapter's ideas in directions the main text could not. If you have time to do one or two, they compound everything the chapter taught. If you have time for none of them, that is fine: the main labs give you the essential experience.

A useful selection strategy for limited time: pick one challenge from the *reading* family (Challenge 1 or 8), one from the *instrumentation* family (Challenge 3, 4, or 5), and one from the *shipping* family (Challenge 6 or 7). That mix exercises the three skills the chapter builds: reading existing drivers with performance eyes, instrumenting new drivers cleanly, and making finished drivers ready for others.

## 33.15 Performance Patterns Reference

The chapter covered a large surface. This section consolidates the practical patterns into a compact reference you can scan when working on a real driver. Each pattern names the situation it applies to, the technique, and the FreeBSD primitive to reach for.

### 33.15.1 Pattern: You Need a Hot-Path Counter

**Situation:** You want to count an event that happens thousands or millions of times per second, and your measurement must not dominate the cost of the event.

**Technique:** Use `counter(9)`. Declare a `counter_u64_t`, allocate it in attach with `counter_u64_alloc(M_WAITOK)`, increment on the hot path with `counter_u64_add(c, 1)`, sum on read with `counter_u64_fetch(c)`, free in detach with `counter_u64_free(c)`.

**Primitive path:** `/usr/src/sys/sys/counter.h`, `/usr/src/sys/kern/subr_counter.c`.

**Why this pattern:** `counter(9)` uses per-CPU slots updated without atomics. Read combines them. The increment is a handful of cycles with no cache-line contention.

**Anti-pattern:** An `atomic_add_64()` on a shared `uint64_t`. Each increment round-trips the cache line; at high rates, the counter becomes the bottleneck.

### 33.15.2 Pattern: You Need a Hot-Path Allocation

**Situation:** You want to allocate a fixed-size buffer many times per second, and `malloc(9)` is showing up in profiles.

**Technique:** Create a UMA zone at attach with `uma_zcreate("mydrv_buf", sizeof(struct my_buf), NULL, NULL, NULL, NULL, UMA_ALIGN_CACHE, 0)`. Allocate on the hot path with `uma_zalloc(zone, M_NOWAIT)`. Free with `uma_zfree(zone, buf)`. Destroy in detach with `uma_zdestroy(zone)`.

**Primitive path:** `/usr/src/sys/vm/uma.h`, `/usr/src/sys/vm/uma_core.c`.

**Why this pattern:** UMA gives each CPU a cache of free buffers. Allocate and free on the same CPU is typically a pop and push from a per-CPU stack, with no cross-CPU coordination. `UMA_ALIGN_CACHE` prevents false sharing between adjacent buffers.

**Anti-pattern:** A per-request `malloc(M_DEVBUF, M_WAITOK)` in the hot path. The general-purpose allocator has more overhead and less locality than a dedicated zone.

### 33.15.3 Pattern: You Need a Pre-Allocated Pool

**Situation:** You have a fixed known count of working buffers (for example, a ring descriptor count tied to hardware), and you want zero allocator cost on the hot path.

**Technique:** At attach, `malloc()` the array once. Keep the free list as a simple SLIST or stack. Pop and push from the free list under a single lock (or an atomic pointer if lock-free design is warranted). Free the whole array at detach.

**Why this pattern:** A pre-allocated pool has the lowest possible per-request cost and the most predictable latency. The rigidity (fixed count) is the trade.

**Anti-pattern:** Using `malloc()` or UMA when the count is known and fixed. The extra indirection costs cycles with no benefit.

### 33.15.4 Pattern: You Need to Avoid False Sharing

**Situation:** Two frequently-updated variables live in the same cache line and are written by different CPUs. Each write invalidates the other CPU's copy, causing a ping-pong.

**Technique:** Put each hot variable on its own cache line with `__aligned(CACHE_LINE_SIZE)`. For per-CPU data, use `DPCPU_DEFINE` which automatically pads.

**Primitive path:** `/usr/src/sys/amd64/include/param.h` and its siblings under `/usr/src/sys/<arch>/include/param` for `CACHE_LINE_SIZE` (pulled in via `<sys/param.h>`), `/usr/src/sys/sys/pcpu.h` for `DPCPU` macros.

**Why this pattern:** Cache coherence protocols bounce whole cache lines; if two writers share a line, every write by one invalidates the other's cache. Separating the variables costs a small padding and eliminates the ping-pong.

**Anti-pattern:** Adding alignment without measuring. Many variables do not need alignment; adding it blindly wastes memory without improving performance.

### 33.15.5 Pattern: You Need to Measure Latency Without Polluting It

**Situation:** You want to measure the latency of a hot path without the measurement dominating the cost.

**Technique:** For a sampled measurement, use `DTrace's profile` provider at 997 Hz. For every-call measurement, capture `sbinuptime()` at entry and exit, subtract, and bucket into a per-CPU `counter(9)` histogram. Read the histogram via `sysctl`.

**Why this pattern:** `DTrace profile` is near-free when disabled. `sbinuptime()` is fast (tens of cycles). A per-CPU histogram bucket is a `counter(9)` increment. The aggregate is read from userland without touching the hot path.

**Anti-pattern:** `nanotime()` per call (it is much slower than `sbinuptime()`), or a `printf()` per call (ruinous), or a shared atomic per call (cache-line bottleneck).

### 33.15.6 Pattern: You Need to Expose Driver State

**Situation:** You want operators to be able to query and configure the driver at runtime.

**Technique:** Build a `sysctl(9)` tree under `hw.<drivername>`. Use `SYSTCL_U64` for simple counters, `SYSTCL_INT` for simple integers, and procedural `sysctls` (`SYSTCL_PROC`) for computed values or bulk data. Flag tunables with `CTLFLAG_TUN` so `loader.conf` can set them.

**Primitive path:** `/usr/src/sys/sys/sysctl.h`, `/usr/src/sys/kern/kern_sysctl.c`.

**Why this pattern:** `sysctl` is the canonical FreeBSD interface for driver observability and configuration. Operators know how to use `sysctl(8)`; log aggregators can scrape `sysctl` trees; monitoring scripts can poll.

**Anti-pattern:** Custom `ioctl`s for every knob, or environment-variable reading at runtime, or `printf()` that expects the user to watch the log.

### 33.15.7 Pattern: You Need to Split an Interrupt Handler

**Situation:** The interrupt handler does more than the small amount of work safe in interrupt context; it sometimes blocks or contends.

**Technique:** Register a filter handler (returns `FILTER_SCHEDULE_THREAD`) that does the minimum (acknowledge hardware, read status). Register an ithread handler that runs in thread context and does moderate work. For work that can wait or that takes real time, schedule on a taskqueue.

**Primitive path:** `/usr/src/sys/sys/bus.h`, `/usr/src/sys/kern/kern_intr.c`, `/usr/src/sys/kern/-subr_taskqueue.c`.

**Why this pattern:** The filter runs in hard interrupt context with the strictest constraints; the ithread runs at a specific priority; the taskqueue runs at a configurable priority on a worker thread. Each layer is suited to its work.

**Anti-pattern:** Doing all the work in the filter, or blocking on locks in the ithread, or running heavy work at interrupt priority where it delays other drivers.

### 33.15.8 Pattern: You Need to Rate-Limit a Log Message

**Situation:** An error condition can produce many log entries per second; you want one per N seconds or per M events to avoid flooding.

**Technique:** Use `ratecheck(9)`. Hold a `struct timeval` and an interval; call `ratecheck(&last, &interval)`. The call returns 1 when enough time has passed and updates the state; return 0 means *skip this message*.

**Primitive path:** `/usr/src/sys/sys/time.h` (declaration) and `/usr/src/sys/kern/kern_time.c` (implementation).

**Why this pattern:** `log(9)` is cheap per call but not free at thousands per second. Unbounded logging causes log-disk fill and can contend the log device. A rate-limiter gives visibility without flood.

**Anti-pattern:** Unconditional `printf()` in error paths, or a manual counter that drifts and leaks.

### 33.15.9 Pattern: You Need a Stable Operator Interface

**Situation:** You want operators to rely on specific `sysctl` names or counter structures that will not change across versions.

**Technique:** Document the stable interface in the manual page. Version the driver with `MODULE_VERSION()` so operators can detect which interface they have. When you must change an interface, keep the old one (or a minimal shim) for at least one version and announce the deprecation in the release notes.

**Primitive path:** Manual page conventions in `/usr/src/share/man/man4/`.

**Why this pattern:** Operators write scripts against `sysctl` names. Breaking those names breaks their scripts. A stable published interface is a commitment you can keep.

**Anti-pattern:** Renaming a `sysctl` casually, or deleting a counter that scripts depend on, or reshaping a procedural `sysctl`'s output without versioning.

### 33.15.10 Pattern: You Need to Ship After Tuning

**Situation:** You have finished a tuning round and want to leave the driver in a clean, shippable state.

**Technique:** Remove temporary measurement code that was not meant to stay. Keep production-grade counters and SDT probes. Update `MODULE_VERSION()`. Run a full benchmark and record the numbers. Update the manual page. Write a short performance report that explains what was tuned and why. Commit with a message that references the report.

**Why this pattern:** The code change is only part of the work. The report, the numbers, and the documentation are what make the change durable. Without them, the next maintainer has no way to know what was done or why.

**Anti-pattern:** Committing tuning changes without benchmarks or documentation. The next maintainer cannot tell what changed, cannot reproduce the measurement, and may undo the work by accident.

### 33.15.11 A Short Tool Reference Table

Below is a one-page summary of the tools introduced in this chapter, their typical use, and their source or documentation path.

| Tool                    | Use                                            | Where to learn more                                                                         |
|-------------------------|------------------------------------------------|---------------------------------------------------------------------------------------------|
| <code>sysctl(8)</code>  | Read and write kernel state variables          | <code>sysctl(8)</code> , <code>/usr/src/sbin/sysctl/</code>                                 |
| <code>top(1)</code>     | Process and system resource overview           | <code>top(1)</code>                                                                         |
| <code>systat(1)</code>  | Interactive system statistics display          | <code>systat(1)</code>                                                                      |
| <code>vmstat(8)</code>  | Virtual memory, interrupt, and zone statistics | <code>vmstat(8)</code>                                                                      |
| <code>ktrace(1)</code>  | Trace system calls for a process               | <code>ktrace(1)</code> , <code>kdump(1)</code>                                              |
| <code>dtrace(1)</code>  | Dynamic tracing of userland and kernel         | <code>dtrace(1)</code> , <code>dtrace(7)</code> , <code>fbt(7)</code> , <code>sdt(7)</code> |
| <code>pmcstat(8)</code> | Hardware performance counter reader            | <code>pmcstat(8)</code> , <code>hwpmc(4)</code>                                             |

| Tool                       | Use                        | Where to learn more                         |
|----------------------------|----------------------------|---------------------------------------------|
| <code>flamegraph.pl</code> | Stack-sample visualisation | external, from Brendan Gregg                |
| <code>gprof(1)</code>      | Profile user programs      | <code>gprof(1)</code> ; not used for kernel |
| <code>netstat(1)</code>    | Network statistics         | <code>netstat(1)</code>                     |

A driver maintainer does not need all of these every day. But knowing which one answers which question saves hours of blind investigation.

### 33.15.12 A Short Primitive Reference Table

The core in-kernel primitives used in this chapter, in one place.

| Primitive                            | Purpose                             | Header                                                      |
|--------------------------------------|-------------------------------------|-------------------------------------------------------------|
| <code>counter(9)</code>              | Per-CPU hot counters                | <code>sys/counter.h</code>                                  |
| <code>DPCPU_DEFINE_STATIC</code>     | Define per-CPU variable             | <code>sys/pcpu.h</code>                                     |
| <code>DPCPU_GET / DPCPU_PTR</code>   | Access current CPU's slot           | <code>sys/pcpu.h</code>                                     |
| <code>DPCPU_SUM</code>               | Sum across all CPUs                 | <code>sys/pcpu.h</code>                                     |
| <code>uma_zcreate</code>             | Create UMA zone                     | <code>vm/uma.h</code>                                       |
| <code>uma_zalloc / uma_zfree</code>  | Allocate from / free to zone        | <code>vm/uma.h</code>                                       |
| <code>UMA_ALIGN_CACHE</code>         | Cache-align zone items              | <code>vm/uma.h</code>                                       |
| <code>bus_alloc_resource_any</code>  | Allocate bus resource (irq, memory) | <code>sys/bus.h</code>                                      |
| <code>bus_setup_intr</code>          | Register interrupt handler          | <code>sys/bus.h</code>                                      |
| <code>bus_dma_tag_create</code>      | Create DMA tag                      | <code>sys/bus_dma.h</code>                                  |
| <code>taskqueue_enqueue</code>       | Queue deferred work                 | <code>sys/taskqueue.h</code>                                |
| <code>callout(9)</code>              | One-shot or periodic timer          | <code>sys/callout.h</code>                                  |
| <code>SYSCTL_U64 / SYSCTL_INT</code> | Declare sysctl                      | <code>sys/sysctl.h</code>                                   |
| <code>SYSCTL_PROC</code>             | Declare procedural sysctl           | <code>sys/sysctl.h</code>                                   |
| <code>log(9)</code>                  | Log a message                       | <code>sys/syslog.h</code>                                   |
| <code>ratecheck(9)</code>            | Rate-limit a message                | <code>sys/time.h</code>                                     |
| <code>SDT_PROBE_DEFINE</code>        | Declare static DTrace probe         | <code>sys/sdt.h</code>                                      |
| <code>CACHE_LINE_SIZE</code>         | Per-architecture cache-line size    | <code>sys/param.h</code> (via MD<br><arch>/include/param.h) |

| Primitive                  | Purpose               | Header                  |
|----------------------------|-----------------------|-------------------------|
| <code>sbinuptime()</code>  | Fast monotonic time   | <code>sys/time.h</code> |
| <code>getnanotime()</code> | Fast coarse wall time | <code>sys/time.h</code> |
| <code>nanotime()</code>    | Precise wall time     | <code>sys/time.h</code> |

The habit of knowing where to find these in a fresh source tree is worth as much as the knowledge of when to use them. Open the header, read the macro definitions, and see the usage sites with `grep -r SYSCTL_PROC /usr/src/sys/dev/ | head`.

### 33.15.13 Wrapping Up the Patterns Reference

The patterns above are not commandments; they are well-supported defaults. A specific driver may have a reason to deviate from any of them. What matters is that the deviation is conscious, measured, and documented. *We do not use UMA here because...* is fine; *we do not use UMA here, I guess* is not.

When you work on an unfamiliar driver, you can use this table as a checklist: does the driver count its hot events cheaply, allocate from a suitable zone, avoid false sharing on shared variables, split its interrupt work appropriately, expose state through `sysctl`, rate-limit its logging, and ship with a versioned stable interface? Each negative answer is a candidate for improvement if performance is under investigation.

## 33.16 Troubleshooting and Common Mistakes

Performance work has its own class of problems, distinct from functional bugs. A driver that measures wrong is as broken as a driver that crashes, but the symptoms are subtler. This section catalogs the most common failures, their symptoms, and their fixes.

### 33.16.1 DTrace Reports Zero Samples

**Symptom:** A DTrace script compiles, runs, and on Ctrl-C reports an empty aggregation or zero counts.

**Most common causes:**

- The driver module is not loaded. `fbt:mymodule: probes` do not exist until the module is in the kernel.
- The function name is wrong. Check with `dtrace -l | grep myfunction`; DTrace lowercase the probe names in the listing, but the function name inside the kernel is the C identifier.
- The function was inlined by the compiler. An `fbt` probe only exists for a function the compiler emits as a callable symbol. Static functions may be inlined and disappear; check with `objdump -t module.ko | grep myfunction`.
- The probe is on a path that was not exercised. Run the workload that should hit the path, not just any workload.
- The predicate filters everything out. Remove the predicate and confirm the probe fires; then tighten the predicate.

**Debugging sequence:** Check `kldstat` (is the module loaded?), `dtrace -l -n probe_name` (does the probe exist?), `dtrace -n 'probe_name { printf("fired"); }'` (does it fire at all?), then add your real logic.

### 33.16.2 DTrace Drops Events

**Symptom:** DTrace prints *dropped N events* or the aggregation counts are suspiciously low for a known-high-rate event.

**Most common causes:**

- The buffer is too small. Increase it: `dtrace -b 64m ...` for a 64 MB buffer.
- The aggregation is too chatty. Every `printf()` inside a probe is a potential drop; use aggregations for high-rate events, not per-event prints.
- The switch rate is too high. DTrace switches buffers between kernel and userland; at very high rates this can drop. Tune with `dtrace -x bufpolicy=fill` for fewer drops at the cost of missing the tail.

### 33.16.3 pmcstat Reports *No Device* or *No PMCs*

**Symptom:** `pmcstat` prints errors like `pmc_init: no device, ENXIO`, or similar.

**Most common causes:**

- `hwpmc` is not loaded. Run `kldload hwpmc`.
- The underlying CPU does not expose PMCs. Many VMs and some cloud instances have PMCs disabled. Fall back to DTrace's `profile` provider.
- The event name is unsupported on this CPU. Run `pmcstat -L` to see the available events.

### 33.16.4 pmcstat Sampling Misses Hot Functions

**Symptom:** A function you *know* is hot does not appear in `pmcstat -T` output.

**Most common causes:**

- The function is inline and has no callable symbol. The sampler attributes samples to the outer function.
- The sample rate is too low. Try `-S cycles -e 100000` for one sample per 100k cycles.
- The function is too fast for a single sample to catch it reliably. Cumulate samples over a long workload.
- The function is in a module whose symbols were stripped. Rebuild with debugging symbols.

### 33.16.5 Counter Values Look Impossible

**Symptom:** A counter has a negative value, wraps around unexpectedly, or reports numbers inconsistent with the workload.

**Most common causes:**

- A counter was updated from multiple CPUs without atomics. Use `atomic_add_64()` or `counter(9)`.
- A counter was read mid-update. For `counter(9)`, this is not a problem because the fetch sums per-CPU values; for a plain atomic, a read is always consistent but an arithmetic combination of two reads might not be. Snapshot the counters in a consistent order.

- The counter overflowed. A 32-bit counter at a million events per second overflows in about an hour. Use `uint64_t`.
- The counter was not initialised. `counter_u64_alloc()` returns a zeroed counter, but a plain variable is only zeroed at load. A static global is fine; a local is not.

### 33.16.6 sysctl Handler Crashes

**Symptom:** Reading or writing a sysctl causes a kernel panic.

**Most common causes:**

- The sysctl was registered against memory that has been freed (for example, a `softc` field after detach).
- The handler dereferences a NULL pointer. Check `req->newptr` before assuming a write.
- The handler runs without appropriate locks. Use `CTLFLAG_MPSAFE` and do the locking in the handler, or omit `CTLFLAG_MPSAFE` and accept the giant lock.
- The handler calls a function that cannot be called from sysctl context (for example, one that sleeps while holding a spin lock).

### 33.16.7 The Driver Slows Down Under Measurement

**Symptom:** The driver's throughput drops when DTrace or `pmcstat` is running.

**Most common causes:**

- The probes are in a hot path. Move them to less-frequent paths or reduce the probe count.
- The DTrace script is too chatty. Use aggregations, not per-event prints.
- The PMC sample rate is too high. Reduce it.
- The probe predicate is expensive. Simple predicates (`arg0 == 0`) are cheap; complex ones with string compares are not.

### 33.16.8 Taskqueue Thread Starvation

**Symptom:** Taskqueue work accumulates without being processed; the driver's user-visible response degrades.

**Most common causes:**

- The taskqueue's thread was pinned to a CPU that is now busy with something else. Use `taskqueue_start_threads_c` for predictable placement or leave the thread unpinned.
- The taskqueue is shared (`taskqueue_fast`) and other subsystems are keeping it busy. Use a dedicated taskqueue.
- A previous task is blocked waiting on something that never completes. Kill the task; add a timeout to the wait.
- The thread was killed by a `MOD_UNLOAD` but the tasks were not drained. Use `taskqueue_drain(9)` before releasing resources.

### 33.16.9 Interrupt Storm Detected

**Symptom:** `dmesg` shows *interrupt storm detected* and the interrupt is throttled.

**Most common causes:**

- The driver does not acknowledge the interrupt in the handler, so the hardware keeps asserting it.
- The driver acknowledges the wrong register.
- The hardware genuinely fires at a rate the driver cannot serve. Enable coalescing if supported.
- A shared-interrupt siblings is misbehaving, and the filter handler claims the interrupt falsely by returning `FILTER_HANDLED` when it should return `FILTER_STRAY`.

### 33.16.10 Cache-Line Alignment Has No Effect

**Symptom:** You added `__aligned(CACHE_LINE_SIZE)` to a counter and saw no change in throughput.

**Most common causes:**

- The counter is not actually contended. Single-threaded or low-concurrency workloads do not benefit from alignment.
- The counter was already aligned by the compiler's default layout. Confirm with `offsetof()`.
- The neighbouring field is no longer hot. The hot field changed, the old alignment is still there, and no contention exists.
- The CPU does not bounce cache lines hard enough for the difference to be measurable. Some architectures have cheaper cache coherence than others.

Alignment is not free (it pads the struct and wastes cache); if it has no effect, remove it. Measurement tells you.

### 33.16.11 UMA Zone Leaks

**Symptom:** `vmstat -z` shows a UMA zone growing without bound, and the system eventually runs out of kernel memory.

**Most common causes:**

- The driver allocates with `uma_zalloc()` but does not free with `uma_zfree()` in the corresponding path. Match the allocation and free paths.
- A pointer was overwritten before being freed. Inspect with KASAN or MEMGUARD (Chapter 34 material).
- A failed operation's cleanup path is wrong. Every early return from a function that allocates must free what was allocated.

### 33.16.12 The Benchmark Is Noisy

**Symptom:** Repeated runs of the same benchmark produce significantly different numbers.

**Most common causes:**

- System activity interferes. Run benchmarks on an otherwise idle machine.
- CPU frequency scaling is changing the clock rate between runs. Pin frequency with `sysctl dev.cpu.freq.0.freq_levels` (check the options) or set performance mode.
- Cache warm-up differs between runs. Discard the first run's numbers or add a warm-up pass.
- The kernel's lazy data structures (UMA caches, buffer caches) differ between runs. Drop caches between runs or accept the variance.
- Hyper-threading pairs are contending. Disable SMT for clean numbers.

A benchmark with high variance is not necessarily wrong, but its conclusions need to survive the variance. If the tuning change improves the median by 5% but the run-to-run variance is 20%, you cannot conclude anything from a single run; run many and look at the distribution.

### 33.16.13 You Measured the Wrong Thing

**Symptom:** You tuned the driver to meet a goal, but the user-visible performance did not change.

**Most common causes:**

- The metric you optimised is not the one that matters. Tuning median latency while the P99 is the user-visible problem is a classic miss.
- The workload you benchmarked is not the workload the user runs. Optimising for sequential reads when the user does random reads is wasted effort.
- The driver was not the bottleneck. Sometimes the bottleneck is in userland, in the scheduler, or in a different subsystem. `pmcstat -s cycles` on the whole system tells you where the time really goes.

If tuning did not help, that is not failure; it is information. The metric or workload was wrong, and now you know. Restate the goal and measure again.

### 33.16.14 Numbers Get Worse After a Tuning Change

**Symptom:** You applied what looked like a beneficial change (added a per-CPU cache, shortened a critical section, moved work to a taskqueue), and the measured numbers are worse.

**Most common causes:**

- The change introduced a regression that is not obvious from the code. For example, moving work to a taskqueue added a context switch on every request, and at your rate the switch cost dominates.
- The change shifted the bottleneck. You removed lock contention, and now the allocator is the new bottleneck.
- The change broke a previously-invisible correctness property. A softer race now produces extra work (retries, error paths) and the driver appears slower because it is doing more.
- The measurement is noisy and the run that looked worse is within the variance band. Run it ten times and see.

**Debugging sequence:** Revert the change and confirm the baseline reproduces. Apply the change and measure again. If both reproduce, the change is the cause; if the baseline varies, the measurement is unstable. Check the diff for unrelated changes that crept in. Profile both variants and compare: the profile will show where time actually goes.

### 33.16.15 Throughput Climbs but P99 Latency Gets Worse

**Symptom:** A change improved the average throughput but made the tail latency worse. Users complain, even though your benchmark's primary metric improved.

**Most common causes:**

- The change traded tail latency for throughput. For example, larger batching improves throughput but increases the time an unlucky request waits for its batch to complete.
- Queue depth grew. Longer queues give more opportunities for backlog, which extends the P99 under load.
- A slower path was taken more often. For example, the hot path got faster but the error path still pays the old cost, and the benchmark now exercises the error path more.

**Debugging sequence:** Plot throughput versus offered load; plot P99 latency versus offered load. The knee of the latency curve is where the driver enters overload. If the knee moved to the left (lower load produces high latency), the change made tail latency worse even if peak throughput improved. Tune back toward the latency target.

### 33.16.16 Results Differ Between Hardware Configurations

**Symptom:** A change that improves performance on one machine makes no difference or is worse on another.

**Most common causes:**

- CPU microarchitecture differs. Cache-coherence protocols, branch predictors, and memory subsystems vary between generations; optimisations tuned for one generation may be irrelevant or harmful for another.
- Core count differs. Per-CPU caches scale with CPU count; on a small-CPU system, the overhead may exceed the benefit.
- NUMA topology differs. An optimisation that ignores NUMA may be fine on a single-socket system and harmful on a multi-socket one.
- The memory subsystem differs. DRAM speed, memory channels, and cache sizes vary widely.

**Debugging sequence:** Record the full hardware configuration with each measurement (CPU model, core count, memory configuration). Measure on at least two distinct machines. Accept that some optimisations are machine-specific; document them if so.

### 33.16.17 KASSERT Fires Only Under Load

**Symptom:** A `KASSERT()` that has been silent during functional testing fires when the driver is under heavy load.

**Most common causes:**

- A race that is rare under low concurrency becomes frequent under high concurrency. The assertion catches a state that only occurs when two CPUs reach the critical section simultaneously.
- An ordering violation that depends on exact timing. Slower paths hid it; faster paths expose it.
- A resource exhaustion that only appears at high rates. For example, `M_NOWAIT` returning `NULL` because the allocator briefly runs out of memory.

- A driver-visible effect of kernel lazy evaluation (UMA cache rebalancing, callout backlog processing).

**Debugging sequence:** Capture the panic's stack trace and the values of local variables. Add `mtx_assert(&sc->mtx, MA_OWNED)` at key points to verify lock ownership. Add temporary SDT probes around the suspect region and trace the order of events with DTrace. Sometimes the fix is a tighter lock; sometimes it is a memory barrier; sometimes it is a redesign.

### 33.16.18 Measurement Disagrees With User Perception

**Symptom:** Your benchmark says the driver is fast; users say the driver feels slow.

**Most common causes:**

- The benchmark measures an aggregate; users perceive individual worst-case events. A driver with 10us median latency and a 1s P99.99 feels awful even though the benchmark score is excellent.
- The benchmark uses synthetic load; the real workload has dependencies (file access patterns, syscall chains) that the benchmark does not reproduce.
- Users perceive end-to-end latency, not driver latency. If the driver is 5% of the end-to-end time, even a large improvement produces no user-visible change.
- The user complaint is correct and the benchmark is measuring the wrong thing.

**Debugging sequence:** Ask users exactly what they do. Reproduce it. Measure the actual experience with a stopwatch or a user-space profiler if necessary. Add per-operation histograms and look at the tail percentiles. A P99.99 is not a statistical artifact; it is someone's bad day.

### 33.16.19 DTrace Script Hangs or Takes a Long Time to Exit

**Symptom:** After Ctrl-C, DTrace takes seconds or minutes to finish printing aggregations; sometimes it appears to hang.

**Most common causes:**

- The aggregation is very large (millions of keys). Printing takes time proportional to the aggregation size.
- The aggregation contains large strings. String allocation in DTrace is not free.
- The kernel buffer is full of queued events waiting to be delivered to userland. DTrace drains the buffer before exiting.
- A probe is still firing rapidly and DTrace is trying to keep up.

**Debugging sequence:** Cap the aggregation with `trunc(@, N)` or `printa()` with a limited list. Use `dtrace -x aggsz=M` to bound the aggregation size. Use `dtrace -x switchrate=1hz` to reduce switch overhead during the run. If you need to kill a runaway DTrace, `kill -9` is safe; DTrace releases probes cleanly.

### 33.16.20 Sysctl Reports Different Numbers on Successive Reads

**Symptom:** Reading the same sysctl twice in quick succession returns different values, even when no workload is running.

**Most common causes:**

- The counter is still being updated by ongoing operations. This is expected and usually fine.
- A per-CPU counter is being snapshotted non-atomically; different CPUs are read at different instants.
- The handler uses a non-stable data structure (a linked list under traversal) without holding the appropriate lock.
- A bug in the handler reads beyond the allocated buffer, returning stale stack data.

**Debugging sequence:** Stop the workload completely. Read the sysctl ten times. If the numbers still vary, the handler is buggy (most likely missing a lock or a barrier). If the numbers are stable when idle, the variance is from background activity; document the counter as *approximate* if appropriate.

### 33.16.21 A Driver Runs Fast Alone, Slow in Production

**Symptom:** Benchmarks in isolation show the driver meeting its goals; production performance is much worse.

**Most common causes:**

- Shared resources in production are contested. The filesystem buffer cache, the scheduler, the network stack, or other drivers compete for the same CPUs and memory.
- Production workload profile differs from the benchmark. The benchmark uses a uniform pattern; production uses a mix that exercises code paths the benchmark never touches.
- Production memory pressure invalidates caches. In benchmarks, your UMA zone stays warm; in production, memory pressure flushes it.
- Security features (IBRS, retpolines, kernel-page-table isolation) have different costs in production than in the benchmark's environment.

**Debugging sequence:** Instrument the driver so it is observable in production. Start DTrace or a lightweight profiler in production briefly and compare the distributions with the benchmark's. If the gap is reproducible, narrow down which subsystem differs; the answer is often memory pressure or scheduler differences rather than the driver itself.

### 33.16.22 Wrapping Up the Troubleshooting

Every item in this section is a real failure mode that experienced performance engineers have made. The value is in reading the list once, recognising the patterns when they appear, and spending the measurement time to diagnose the specific failure rather than guessing. *Why is my driver slow* has thousands of possible answers; the troubleshooting patterns narrow the search space in a few specific steps.

A habit worth cultivating: when you hit a new failure mode not on this list, write it down. Capture the symptom, the cause, and the debugging sequence. Over a few years, your own list becomes more useful than any book's, because it reflects the drivers and hardware you actually work with.

## 33.17 Wrapping Up

Chapter 33 took us from *does the driver work?* to *does it work well?*. The two questions sound similar and differ in the shape of the answer. The first is a yes/no of correctness; the second is a numerical distribution of

throughput, latency, responsiveness, and CPU cost, measured under a specific workload in a specific environment.

We began in Section 1 with the four axes of driver performance and the discipline of stating measurable goals. A goal with a metric, a target, a workload, and an environment is what separates a performance project from a performance hope. The reminder that optimisation must preserve correctness, debuggability, and maintainability is the constraint that keeps performance work honest.

Section 2 introduced the kernel's measurement primitives: the `get *` and non-`get` time functions, the three grades of counter (plain atomic, `counter(9)`, `DPCPU`), the `sysctl` machinery for exposing state, and the FreeBSD tools (`sysctl`, `top`, `systat`, `vmstat`, `ktrace`, `dtrace`, `pmcstat`) that read it. The central insight: measurement has cost, and the cost of measurement must not contaminate the measurement itself.

Section 3 introduced DTrace. Its pervasive probes, near-zero disabled cost, kernel-side aggregation, and expressive scripting language make it the tool of choice for most driver observation. The `fbt` provider covers every function; the `sdt` provider gives you stable named probes in your own driver; the `profile` provider samples at a fixed rate; the `lockstat` provider specialises in lock contention.

Section 4 introduced hardware performance counters. `hwpmc(4)` exposes the CPU's built-in counters; `pmcstat(8)` drives them from userland. Counting mode gives totals; sampling mode gives distributions. The callgraph collector plus flame-graph renderer turns the samples into a visualisation that makes hotspots obvious. The data is raw and interpretation takes practice, but the combination answers questions no other tool can.

Section 5 turned to memory. Cache-line alignment avoids false sharing; `bus_dma(9)` handles DMA alignment; pre-allocation keeps the hot path out of the allocator; UMA zones with `UMA_ALIGN_CACHE` specialise for fixed-size frequent allocations; per-CPU counters with `counter(9)` and `DPCPU` eliminate cache-line contention on shared metrics. Each technique has a cost, and each deserves evidence before it is applied.

Section 6 turned to interrupts and taskqueues. Measuring interrupt rate and handler latency is easy with `vmstat -i` and DTrace. The filter-plus-ithread split keeps the interrupt context small; taskqueues move work to a calmer environment; dedicated threads offer isolation for special cases; coalescing and debouncing control the interrupt rate itself. The judgement of when to apply each technique comes from measurement, not from reading.

Section 7 turned inward, to the runtime metrics that belong in the shipped driver. A thoughtful `sysctl` tree exposes totals, rates, states, and configuration. Procedural `sysctls` fetch `counter(9)` sums. Rate-limited logging via `log(9)` and `ratecheck(9)` keeps informational messages from flooding the log. Debug modes give operators a safe way to raise verbosity without rebuilding. Each element is a small commitment; the cumulative result is a driver that is auditable, diagnosable, and maintainable.

Section 8 closed the loop. Tuning produces scaffolding; shipping requires cleanup. Remove temporary measurement code. Keep the counters, SDT probes, and configuration knobs that have lasting value. Benchmark the final driver, document the tuning knobs in the manual page, update `MODULE_VERSION()`, and write a plain-text performance report. These steps are the difference between a one-off improvement and a lasting one.

The labs walked through six concrete stages: baseline counters, DTrace scripts, `pmcstat` sampling, cache-aligned and per-CPU tuning, the interrupt-vs-taskqueue split, and the v2.3-optimized finalisation. Each lab produced a measurable output; the numbers are what the chapter is ultimately about.

The challenge exercises extended the work in directions too specific for the main text: latency budgets for real drivers, allocator comparisons, useful DTrace scripts of your own, an observability-budget study, a live histogram, workload-specific tuning, manual-page writing, and profiling an unfamiliar driver.

The troubleshooting section catalogued the common failure modes and their diagnoses. Each one is a recognisable pattern; spending the measurement time to name which pattern you are in is the half of the work that most beginners skip.

### 33.17.1 What You Should Be Able to Do Now

If you worked through the labs and read the explanations carefully, you can now:

- Set measurable performance goals for a driver before you start tuning.
- Choose the right kernel time function for a measurement based on the precision you need.
- Count events cheaply on the hot path with `counter(9)` or `atomic_add_64()`.
- Expose driver metrics to userland through a sysctl tree.
- Write DTrace one-liners and scripts that answer specific questions about a driver.
- Measure lock contention with the `lockstat` provider.
- Sample kernel CPU time with `pmcstat` or with DTrace's `profile` provider.
- Read a flame graph.
- Apply cache-line alignment, pre-allocation, UMA zones, and per-CPU counters selectively, with evidence.
- Split a driver's interrupt work between filter, `ithread`, and `taskqueue` based on measured latency.
- Ship a tuned driver: remove scaffolding, document tunables, update the version, write a report.

### 33.17.2 What This Chapter Leaves Implicit

There are two topics the chapter touched on but did not deep-dive. Each has its own chapter or its own literature, and trying to cover it fully here would have bogged down the main thread.

First, **the deep internals of hwpmc (4)**. The chapter showed you how to use it; the source tree under `/usr/src/sys/dev/hwpmc/` shows you how it works, across Intel, AMD, ARM, RISC-V, and PowerPC backends. If you want to understand how the kernel samples the PC register on an overflow interrupt, or how the userland `pmcstat` talks to the kernel, reading that tree pays off. Most readers never need to.

Second, **advanced DTrace**. The scripts we wrote are straightforward. DTrace's speculations, its USDT interfaces, its complex aggregations, and its advanced predicates are worth a book of their own. Brendan Gregg's *DTrace: Dynamic Tracing in Oracle Solaris, Mac OS X, and FreeBSD* is the canonical reference. For driver work, the patterns we covered carry you a long way.

### 33.17.3 Key Takeaways

Distilled into a page, the chapter's core lessons are:

1. **Measure before you change.** An optimisation without a before-and-after number is a guess.
2. **State the goal in numbers.** Metric, target, workload, environment. Without these, you cannot know when you are done.
3. **Prefer the simplest tool that answers the question.** A DTrace one-liner usually beats a full `pmcstat` session.
4. **The tools that measure also perturb.** Know the cost of each probe before you use it on a hot path.

5. **Four axes, not one.** Throughput, latency, responsiveness, CPU cost. Optimising one can harm another.
6. **counter(9) for hot counters.** Per-CPU update, summed on read. Scales from one CPU to many.
7. **UMA\_ALIGN\_CACHE for hot allocations.** Cache-aligned per-CPU caches, cheap alloc and free.
8. **Pre-allocate, do not allocate in the hot path.** Attach-time cost is fine; per-call cost is not.
9. **Keep the interrupt handler small.** Filter-plus-ithread-plus-taskqueue is the standard split; use it.
10. **Ship with a sysctl tree.** A driver with no observability is a driver nobody can diagnose.
11. **Rate-limit your logs.** A driver that logs every error can DoS itself.
12. **Write the report.** The tuning work is not done until the numbers are written down where the next maintainer can find them.

### 33.17.4 Before You Move On

Before you treat this chapter as completed and move to Chapter 34, take a moment to verify the following. These are the checks that separate a learner who has seen the material from a learner who owns it.

- You can write, from memory, the skeleton of a procedural sysctl that returns a counter(9) sum.
- You can write a DTrace one-liner that histograms a function's latency.
- You can explain, in one paragraph, the difference between `getnanotime()` and `nanotime()`.
- You can name three measurements you would capture before changing a driver's hot path, and at least one tool for each.
- Given a driver that appears to be CPU-bound, you have a plan: `vmstat -i` to check for interrupt storms, `dtrace -n 'profile-997 { @[stack()] = count(); }'` to find the hot function, `pmcstat -S cycles -T` to confirm, and `lockstat` if the profile points at locks.
- Given a driver whose throughput does not scale with CPU count, you have a plan: check for a single atomic counter being contended, check for a shared taskqueue, check for a global lock.
- You know which sections of your manual page would name the tunables, and roughly how to write them.

If any of these still feel shaky, loop back to the relevant section and re-read it. The chapter's material compounds; Chapter 34 will assume you have internalised most of what is here.

### 33.17.5 A Note on Sustained Practice

Performance work, more than almost any other area of kernel engineering, rewards steady practice. The first few `pmcstat` sessions are confusing; the tenth is natural. The first DTrace script you write is laborious; the hundredth is a one-liner typed without thinking. The first performance report reads like a mystery; the tenth reads like a decision document.

If you have driver work in your day job or on a personal project, spend ten minutes of your week on a performance measurement. Not a tuning pass, just a measurement. Record the numbers. Compare them to last week. Over a year this compounds into the habits this chapter is trying to teach. The tools are all there; the habit is what takes time.

### 33.17.6 Connecting Back to the Rest of the Book

Chapter 33 rests on material from earlier parts. A short tour of what you now see in a new light:

From Part 1 and Part 2, the module lifecycle and `DRIVER_MODULE()` registration. The driver you tuned in this chapter is the same shape of driver you built in those parts; tuning does not change the skeleton.

From Part 3, the Newbus framework. `simplebus`, the bus-resource APIs, `bus_alloc_resource_any()`: these are the building blocks your driver uses to find its hardware. Knowing them lets you reason about where time goes during attach and detach.

From Part 4, the driver-to-userspace interfaces. Your `read()` and `write()` paths are the ones you tuned in this chapter. The `sysctl` tree you built in Section 7 is a natural extension of the `ioctl` and `sysctl` material from Chapter 15.

From Part 5 and Part 6, the testing and debugging chapters. Those tools apply to tuned drivers in full. A driver that performs well but crashes under load is not a tuned driver; it is a broken one.

From Part 7, Chapter 32 on Device Tree and embedded development is the platform half. Performance on an embedded board has the same shape as performance on a server, but the constraints are tighter: less RAM, less CPU, less power. The techniques scale down in priority (cache-line alignment matters less when you have one core), but the measurement discipline matters as much or more.

The picture after Chapter 33 is that you have the full measurement-and-tuning toolkit for FreeBSD drivers. You can build drivers. You can test them. You can port them. You can measure them. You can tune them. You can ship them. The remaining chapters of Part 7 refine and finalise those skills, and the next one is about the debugging techniques that the performance work sometimes reveals are still needed.

### 33.17.7 Looking Ahead

Chapter 34 turns from performance to **advanced debugging**. When tuning reveals a deeper bug, when a driver panics under specific load, when memory corruption shows up in a crash dump, the tools in Chapter 34 are the ones you reach for. `KASSERT(9)` for in-code assertions, `panic(9)` for unrecoverable states, `ddb(4)` for interactive live kernel debugging, `kgdb` for remote and post-mortem debugging, `kttr(9)` for lightweight ring-buffer tracing, and `memguard(9)` for memory-corruption detection. The boundary between performance work and debugging is often fuzzy: a performance problem turns out to be a correctness bug in disguise, or a correctness bug hides behind a performance symptom. Chapter 34 gives you the tools for the other half of the diagnosis.

Beyond Chapter 34, the final chapters of Part 7 complete the mastery arc: asynchronous I/O and event handling, coding style and readability, contributing to FreeBSD, and a capstone project that brings several earlier threads together. Each builds on what you have done here.

The measurement work is done. The next chapter is about what to do when the numbers point at something the tuning tools alone cannot reach.

### 33.17.8 Glossary of Terms Introduced in This Chapter

A quick reference for the vocabulary the chapter introduced or used heavily. When a term has a dedicated manual page or a specific FreeBSD primitive, the reference is noted.

**Aggregation (DTrace):** A server-side running summary (count, sum, min, max, average, quantize) computed in kernel space and printed at session end. Use aggregations, not per-event prints, for any probe firing more than a few times per second.

**Benchmark harness:** A repeatable script that runs a workload against the driver with controlled parameters, collects measurements, and reports results in a consistent format. The harness reduces measurement-to-measurement variance by removing human variation.

**Bounce buffer:** A kernel buffer that sits between a device and user memory when direct DMA is not possible because of alignment or address-range constraints. Managed by `bus_dma(9)`. Bounce buffers cost an extra copy; eliminating them is a common tuning target.

**Cache coherence:** The hardware mechanism that keeps caches on multiple CPUs consistent. When one CPU writes a line, other CPUs that hold the line must invalidate or update their copies. The cost of coherence traffic is why false sharing is a problem.

**Cache-line alignment:** Placing a variable on a boundary that matches the hardware cache-line size (typically 64 bytes on amd64). Used to prevent false sharing between a hot variable and its neighbours. `__aligned(CACHE_LINE_SIZE)`.

**Callgraph (profiling):** A tree of caller-callee relationships weighted by sample count. Reading a callgraph tells you which call paths consume the most time, not just which leaf functions.

**Coalescing:** Combining many small events into fewer large ones. Hardware interrupt coalescing reduces interrupt rate at the cost of per-event latency.

**Counter(9):** A FreeBSD primitive for per-CPU summed counters. Cheap on update, cheap on aggregate read, scales with CPU count.

**DPCPU:** FreeBSD per-CPU variable storage with alignment and access macros. `DPCPU_DEFINE_STATIC`, `DPCPU_GET`, `DPCPU_PTR`, `DPCPU_SUM`.

**DTrace:** FreeBSD's dynamic tracing framework. Safe, pervasive, near-zero cost when disabled. Scripts compose probes, predicates, and actions.

**Event mode (PMC):** Hardware performance counter mode where the counter counts a specific event (cycles, instructions, cache misses). Compare with sampling mode.

**False sharing:** Cache-coherence ping-pong between CPUs caused by unrelated variables living in the same cache line. The effect is invisible in source code and obvious in profile results.

**fbt provider:** DTrace's *function boundary tracing* provider. Gives you probes on entry and return of every kernel function that is not inlined.

**Filter handler:** An interrupt handler that runs in the low-level interrupt context. Does the minimum and either claims the interrupt and signals the ithread (`FILTER_SCHEDULE_THREAD`), or declines (`FILTER_STRAY`).

**Flame graph:** A visualisation of profile samples as nested rectangles. Width represents sample count; height represents stack depth. Makes hotspot identification visual.

**hwpmc(4):** The FreeBSD kernel module that exposes hardware performance counters. Loaded with `kldload hwpmc`.

**Ithread:** Interrupt thread. A kernel thread that runs an interrupt handler in thread context, not interrupt context. Scheduled at a driver-specified priority.

**Latency:** The time from a request's arrival to its completion. Typically reported as percentiles (P50, P95, P99, P99.9) rather than an average.

**Lock contention:** The state where multiple threads compete for the same lock, causing some to wait. Detectable with the DTrace lockstat provider.

**MSI / MSI-X:** Message Signalled Interrupt (PCIe). Replaces legacy INTx interrupts with in-band messages. MSI-X allows many independent vectors per device, which enables per-queue or per-CPU interrupt handling.

**NAPI-style batching:** A Linux-borrowed but FreeBSD-applicable technique where an interrupt disables further interrupts from the device and a poll loop drains the queue until empty, then re-enables interrupts. Amortises interrupt overhead under load.

**Observability:** The property of a system that makes its internal state visible to external tools. In FreeBSD, sysctl trees, counters, SDT probes, and log messages contribute to observability.

**P99 / P99.9:** The 99th and 99.9th percentiles of a distribution. The value below which 99% (or 99.9%) of samples fall. Tail percentiles often reveal worse user experience than averages.

**Per-CPU data:** Data structures that have a distinct copy on each CPU, eliminating cache-line contention. FreeBSD's DPCPU macros manage layout and access.

**pmcstat(8):** The userland tool that drives hwpmc(4). Supports event mode and sampling mode, system-wide and per-process.

**profile provider (DTrace):** A DTrace provider that fires at a fixed frequency (for example, 997 Hz) on all CPUs. Used for portable statistical profiling.

**Responsiveness:** The time from an external stimulus (interrupt, ioctl) to the driver's first action. Distinct from latency (request-to-completion) and from throughput.

**Sampling mode (PMC):** Hardware performance counter mode where the counter triggers an interrupt every N events and the kernel records the program counter. Used for statistical profiling.

**sched provider (DTrace):** A DTrace provider for scheduler events: on-cpu, off-cpu, enqueue, dequeue. Used to diagnose scheduling-related latency.

**SDT probe:** Statically-defined trace probe. Compiled into the driver with SDT\_PROBE\_DEFINE and SDT\_PROBE\*( ) macros. Always present, always stable, near-zero cost when disabled.

**softc:** A driver's *software context* structure. Holds per-device state. Accessed with device\_get\_softc(dev).

**sysctl tree:** A hierarchy of kernel variables exposed to userland through sysctl(8). Drivers register nodes under hw.<drivername> by convention.

**Tail latency:** The high percentiles of a latency distribution (P99, P99.9, P99.99). Often what users perceive as *slow*, even when averages are good.

**Taskqueue:** A FreeBSD kernel thread pool for deferred work. Drivers enqueue tasks with taskqueue\_enqueue(9); the thread pool dequeues and runs them.

**TMA (Top-Down Microarchitecture Analysis):** A method for classifying CPU-bound performance problems. Branches into *frontend-bound*, *bad-speculation*, *backend-bound*, and *retiring*.

**Throughput:** The rate at which the driver completes work, measured as operations per second or bytes per second.

**UMA zone:** A specialised allocator for fixed-size objects. Created with uma\_zcreate(). Cheap per-CPU cached allocation; suitable for hot paths with fixed-size buffers.

**workload:** The specific pattern of requests used during measurement. A driver's performance depends on the workload; a measurement without a named workload is incomplete.

### 33.17.9 A Parting Word

Performance engineering has a reputation for being arcane. The reputation is half earned and half unearned. It is earned because the tools are many, the output is numeric, and the interpretation takes experience. It is unearned because the discipline is small and learnable: measure before you change, state the goal in numbers, prefer the simplest tool, know the cost of your probes, preserve correctness. That is the whole discipline in a sentence.

The chapter's hardest lesson is the one about humility. A beginner's instinct is to look at a line of code and think *I can make this faster*. An experienced engineer's instinct is to look at a measurement and think *this is the hot function; now let me understand why*. The gap between the two mindsets is the gap between years of practice. Every hour spent with DTrace, pmcstat, and a notebook full of real measurements narrows it.

You have now met the measurement half of the FreeBSD performance toolkit. The tools are in the tree; the manual pages are waiting; the habit of using them is the last piece. Make it part of every serious driver you write, and the rest follows.

One last encouragement before we move on. If the depth of the chapter felt intimidating, return to it one section at a time. Performance work is not a single skill to master in one sitting; it is a cluster of related skills, each small in isolation. Run one DTrace one-liner. Expose one sysctl counter. Run one pmcstat session. Each small practice earns a small confidence, and the confidences compound. Within a handful of drivers, the toolkit feels routine rather than exotic, and the mindset of *measure, then decide* becomes second nature rather than a checklist.

On to Chapter 34 and the debugging techniques that complement everything we have just covered.

Take a deep breath; you have earned the next chapter.

## 34 Advanced Debugging Techniques

### 34.1 Introduction

In the previous chapter we learned how to measure what a driver does and how fast it does it. We watched performance counters grow, we ran DTrace aggregations to spot hot paths, and we used `pmcstat` to see which instructions were actually consuming cycles. Measurement gave us a language for asking whether the driver behaves the way we expect.

Debugging asks a different question. Instead of “how fast is this?” it asks “why is this wrong?” A performance problem usually produces slow but running code. A correctness problem can produce a crash, a deadlock, silent data corruption, a driver that refuses to unload, a pointer that dereferences into garbage, or a lock that is somehow held by nobody. These are the bugs that make a seasoned kernel engineer take a slow breath and reach for better tools.

FreeBSD gives us those tools. They range from very small and very fast assertions that live inside the kernel and catch the bug the instant it happens, to full post-mortem analysis of a crash dump on a machine that is no longer running. There are lightweight tracing rings that cost almost nothing at runtime, heavyweight tracers that can unwind the entire call graph, and memory allocators that can be swapped in during development to turn subtle use-after-free bugs into immediate, diagnosable crashes. A well-equipped driver author learns to reach for the right tool for the right bug, rather than staring at `printf` output hoping for enlightenment.

The goal of this chapter is to teach you that toolkit. We will begin by understanding when advanced debugging is the right response and when a simpler approach will serve better. We will then work through the in-kernel assertion macros, the panic path, and how to read and analyze a crash dump offline with `kgdb`. We will build a debug-friendly kernel so those tools are actually available when we need them, learn how to trace driver behavior with DTrace and `ktrace`, and finally study how to hunt memory leaks and invalid accesses with `memguard(9)`, `redzone`, and guard pages. We will close with the discipline of debugging on production systems, where every action has consequences, and with a short study of how to refactor a driver after a hard failure so that it is more resilient to the next one.

Throughout the chapter we will use a small companion driver called `bugdemo`. It is a pseudo-device with deliberate, controlled bugs that we can trigger through simple `ioctl(2)` calls and then hunt with each of the techniques the chapter teaches. Nothing we do touches real hardware, so the lab environment stays safe even when we deliberately crash the kernel.

By the end of the chapter you will be able to add defensive assertions to a driver, build a debug kernel, capture a crash dump, open it in `kgdb`, trace live behavior with DTrace and `ktrace`, trap memory misuse with `memguard(9)` and friends, and apply all of this discipline safely on systems where other people are relying on the machine.

## 34.2 Reader Guidance: How to Use This Chapter

This chapter sits in Part 7 of the book, alongside performance tuning, asynchronous I/O, and other mastery topics. It assumes you have already written at least a simple character device driver, understand the load and unload lifecycle, and have worked with `sysctl`, `counter(9)`, and `DTrace` at the level introduced in Chapter 33. If any of that feels uncertain, a quick revisit of Chapters 8 through 14 and Chapter 33 will pay for itself several times over in this chapter.

### 34.2.1 Reading This Chapter Alongside Chapter 23

This chapter deliberately picks up where Chapter 23 left off. Chapter 23, “Debugging and Tracing,” introduced the fundamentals: how to think about bugs, how to reach for `printf`, how to use `dmesg` and the kernel log, how to read a simple panic, how to turn on `DTrace` probes, and how to make a driver easier to observe from the start. It stays close to the everyday debugging habits a new driver author needs.

Chapter 23 also ends with an explicit hand-off. It flags that deep `kgdb` scripting on top of a crash dump and the live-kernel breakpoint workflows are reserved for a later, more advanced chapter. That later chapter is this one. You are reading the second half of a pair. If Chapter 23 is the first aid kit, Chapter 34 is the full clinical toolbox.

In practice, this means two things. First, we will not re-explain the fundamentals Chapter 23 already covered; we will assume you are comfortable with `printf`, basic panic reading, and introductory `DTrace`. If any of those feel shaky, reread the relevant section of Chapter 23 first, because the advanced material builds directly on those habits. Second, when a technique here has a simpler counterpart in Chapter 23 (for example, a basic `bt` in `kgdb` is simpler than walking `struct thread` fields), we will point to the Chapter 23 version and then show why the advanced version earns its extra complexity.

Think of the two chapters as a single arc. Chapter 23 teaches you how to notice that something is wrong and take a first look. Chapter 34 teaches you how to reconstruct, in detail, what the kernel was doing at the moment the bug occurred, even on a machine that is no longer running.

The material is cumulative. Each section adds another layer onto the `bugdemo` driver, so the labs read most naturally in order. You can skim ahead for reference, but if this is your first encounter with kernel debugging tools, walking through the labs in sequence will build the mental model we want.

You do not need any special hardware. A modest FreeBSD 14.3 virtual machine is enough for every lab in the chapter. For Lab 3 and Lab 4 you will want to have configured a crash dump device, which the chapter walks through, and for Lab 5 you will need `DTrace` available in your kernel. Both are standard on an ordinary FreeBSD installation.

Some of the techniques in this chapter deliberately crash the kernel. This is safe on a development machine and expected as part of the learning process. It is not safe on a production machine where other people depend on uninterrupted service. The final section of the chapter is dedicated to that distinction, because the discipline of knowing when not to use a tool is as important as knowing how to use it.

### 34.3 How to Get the Most Out of This Chapter

The chapter is organized around a pattern you will see repeated throughout. First we explain what a technique is, then we explain why it exists and what kind of bug it is meant to catch, then we ground it in real FreeBSD source code so you can see where the idea lives in the kernel, and finally we apply it to the bugdemo driver through a small lab. Reading and experimenting together is the most effective approach. The labs are deliberately small enough to run in a few minutes each.

A few habits will make the work smoother. Keep a terminal open to `/usr/src/` so you can look at the real code whenever the chapter references it. The book teaches through observation of real FreeBSD practice, not through invented pseudo-code, and you will build stronger intuition by confirming with your own eyes that `KASSERT` really is defined where the chapter says it is, or that `memguard(9)` really has the API we describe.

Keep a second terminal open to your test VM, where you will load the bugdemo driver, trigger bugs, and watch the output. If you can attach a serial console to the VM, do so. A serial console is the most reliable way to capture the tail end of a panic message before the machine reboots, and we will use it in several labs.

Finally, keep your expectations calibrated. Kernel bugs are often not what they appear to be at first. A use-after-free might first present itself as a random data corruption in an unrelated subsystem. A deadlock might first look like a slow system call. One of the most valuable skills this chapter teaches is patience: gathering evidence before forming a theory, and confirming the theory before committing to a fix. The tools help, but the discipline is what separates a quick bug hunt from a long one.

With those expectations in place, let us begin by discussing when advanced debugging is actually the right response to a problem.

### 34.4 1. When and Why You Need Advanced Debugging

Most bugs in a driver can be solved without reaching for a crash dump or a tracing framework. A careful reading of the code, an extra `printf`, a second look at the return value of a function, a glance at `dmesg`: these together resolve the majority of defects a driver author encounters. If you can see the problem, reproduce it cheaply, and hold the relevant code in your head, the simplest tool is the right tool.

Advanced debugging exists for the bugs that do not yield to that approach. It is the toolkit we reach for when the problem is rare, when it appears far from its cause, when it only shows up under specific timing, when the driver hangs rather than crashes, or when the symptom is corruption rather than failure. Those bugs share a common property: they require evidence you cannot easily collect by reading code, and they require control over the kernel's execution that a normal user process does not have.

#### 34.4.1 Bugs That Need More Than a `printf`

The first class of bug that demands advanced tooling is the bug that destroys the evidence of its own cause. A use-after-free is the canonical example. The driver frees an object, then some later code, possibly in a different function or a different thread, reads or writes that memory. By the time the crash happens, the free has long since occurred, the memory has been reused for something unrelated, and the backtrace at the point of the crash points to the victim, not the culprit. A `printf` added at the crash site will faithfully print the nonsense it sees. It will not tell you who freed the memory or when.

A second class is the bug that only appears under concurrency. Two threads race for a lock. One of them takes the lock in the wrong order, deadlocking against another thread that took the same locks in the reverse order. The system goes quiet, and the bug leaves no message on the console. Adding `printf` calls to the locking path often perturbs the timing just enough to make the bug disappear, a frustrating property that Heisenbug enthusiasts are familiar with. Static lock order checking, which FreeBSD provides through `WITNESS`, exists precisely because this class of bug is hard to find any other way.

A third class is the bug that cannot be observed at all in user space. The driver corrupts a kernel data structure on one code path, and the consequence shows up many minutes later in an unrelated subsystem. The process that triggers the corruption is long gone by the time anything goes wrong. The only way to correlate cause and effect is to capture the full kernel state at the moment of the panic and walk it offline with `kgdb`, or to trace the kernel continuously with `DTrace` so that the suspicious event leaves a trail.

A fourth class is the bug that only appears on hardware you cannot attach a debugger to, or in production configurations you cannot directly instrument. The driver runs on a customer's machine, it crashes once a week, and nobody wants your development workstation physically plugged into it. The tool for this situation is the crash dump: a snapshot of kernel memory written to disk at the moment of panic, carried to a safe environment, and analyzed there. `dumpon(8)` configures where the dump goes, `savecore(8)` retrieves it after the reboot, and `kgdb` reads it offline.

Each of these bug classes has its own tool in the FreeBSD debugging toolkit. The rest of the chapter introduces them in turn. The point of this opening section is simply to set expectations: we are not about to learn a single technique that replaces `printf`. We are learning a family of techniques, each suited to a particular kind of difficulty.

### 34.4.2 The Cost of Advanced Tooling

Advanced debugging is not free. Each of the techniques we will study carries some combination of build-time cost, run-time cost, and disciplinary cost.

Build-time cost is the easiest to describe. `INVARIANTS` and `WITNESS` make the kernel slower because they add checks that a production kernel skips. `DEBUG_MEMGUARD` makes certain allocations dramatically slower because it replaces them with full-page mappings that are unmapped on free. A debug kernel built with `makeoptions DEBUG=-g` is several times larger than a release kernel because every function carries full debug information. None of these costs matter on a development machine, where correctness is worth orders of magnitude more than speed. All of them matter in production.

Run-time cost applies to the tools you enable in a running kernel. `DTrace` probes that are disabled cost essentially nothing, but an enabled probe still runs on every hit of the instrumented function. `kt(9)` entries are very cheap but not free. A verbose tracing session can generate enough log output to fill a disk. A `kdb` session pauses the entire kernel, which on a machine people are using is a disaster. Each tool has a run-time budget, and part of the discipline of this chapter is knowing what that budget is.

Disciplinary cost is the hardest to quantify but the easiest to underestimate. Advanced debugging requires patience, careful note taking, and a willingness to sit with incomplete information. It requires resisting the urge to patch a visible symptom before you understand the underlying defect. A crash that happens in module `X` almost never means the bug is in module `X`. The reader who learns to collect evidence before forming a theory will have an easier time with this chapter than the reader who wants to commit a fix as quickly as possible.

### 34.4.3 A Decision Framework

With those costs in mind, here is a simple decision framework for choosing your tool. If the bug is easy to reproduce and the cause is likely visible in the nearby code, start with reading and with strategic `printf` or `log(9)` statements. If the bug only appears under load or concurrency, enable `INVARIANTS` and `WITNESS` and rebuild. If the bug produces a panic, capture the dump and open it in `kgdb`. If the bug involves memory corruption, enable `DEBUG_MEMGUARD` on the suspect allocation type. If the bug involves a silent misbehavior rather than a crash, add SDT probes and watch them with `DTrace`. If you need to understand timing between events in an interrupt handler, use `ktr(9)`. And if the bug is on a production machine, see Section 7 before doing anything at all.

We will spend the rest of the chapter teaching each of these techniques in depth. The `bugdemo` driver we are about to meet gives us a safe place to apply every one of them, with known bugs to hunt and known answers to find.

### 34.4.4 Meeting the `bugdemo` Driver

The `bugdemo` driver is a small pseudo-device that we will use as our lab subject throughout the chapter. It has no hardware to drive. It exposes a device node at `/dev/bugdemo` and accepts a handful of `ioctl(2)` commands that deliberately trigger different classes of bug: a null pointer dereference, an unlocked access that `WITNESS` can catch, a use-after-free, a memory leak, an infinite loop inside a spinlock, and so on. Each `ioctl` is gated by a `sysctl` switch so that the driver can be loaded safely on a development system without accidentally triggering anything.

We will introduce the driver properly in Lab 1, when we have the assertion macros in hand. For now, keep in mind that every technique we study can be demonstrated on `bugdemo` with a known starting point and a known answer. That discipline, of reproducing bugs in a controlled setting, is itself one of the most important skills this chapter aims to teach.

Now we are ready to begin the toolkit proper, starting with the assertion macros that catch bugs at the instant they happen.

## 34.5 2. Using `KASSERT`, `panic`, and Related Macros

Defensive programming in user space often revolves around runtime checks and careful error handling. Defensive programming in the kernel adds one more tool: the assertion macro. An assertion states a condition that must be true at a given point. If the condition is false, something is very wrong, and the safest response is to stop the kernel immediately, before the wrong state has a chance to spread. Assertions are the cheapest and most effective debugging tool FreeBSD gives us, and they belong in every serious driver.

We will start with the two most important macros, `KASSERT(9)` and `panic(9)`, look at a handful of useful companions, and then discuss when each is appropriate.

**A note on line numbers.** When the chapter quotes code from `kassert.h`, `kern_shutdown.c`, or `cdefs.h`, the landmark is always the macro or function name. `KASSERT`, `kassert_panic`, `panic`, and `__dead2` will remain findable by those names in every FreeBSD 14.x tree even as the lines around them move. The sample backtrace you will see later, which quotes `file:line` pairs such as `kern_shutdown.c:400`,

reflects a 14.3 tree at the time of writing and will not match line-for-line on a freshly updated system. Grep for the symbol rather than scroll to the number.

### 34.5.1 KASSERT: A Check That Vanishes in Production

KASSERT is the in-kernel equivalent of the user-space `assert()` macro, but smarter. It takes a condition and a message. If the condition is false, the kernel panics with the message. If the kernel was compiled without the `INVARIANTS` option, the entire check disappears at compile time and costs nothing at runtime.

The macro lives in `/usr/src/sys/sys/kassert.h`. In a FreeBSD 14.3 source tree it looks like this:

```
#if (defined(_KERNEL) && defined(INVARIANTS)) || defined(_STANDALONE)
#define KASSERT(exp,msg) do { \
 if (__predict_false(!(exp))) \
 kassert_panic msg; \
} while (0)
#else /* !(KERNEL && INVARIANTS) && !STANDALONE */
#define KASSERT(exp,msg) do { \
} while (0)
#endif /* KERNEL && INVARIANTS */
```

Four details of this definition are worth pausing on.

First, the macro is defined differently depending on whether `INVARIANTS` is set. If it is not, `KASSERT` expands to an empty `do { } while (0)` block, which the compiler optimizes away entirely. A release kernel built without `INVARIANTS` pays no runtime cost for `KASSERT` calls, no matter how many the driver contains. This is the property that lets us write generous assertions in development without worrying about production performance. The `_STANDALONE` branch lets the same macro work in the bootloader, where `INVARIANTS` may be absent but the check is still desired.

Second, the `__predict_false` hint tells the compiler that the condition is almost always true. This improves code generation for the common path, because the compiler will arrange the branch so that the hot path does not take a jump. Defining `__predict_false` is one of the small performance disciplines that keeps a debug kernel usable.

Third, the body of a failing assertion calls `kassert_panic`, not `panic` directly. This is an implementation detail for making assertion messages easier to parse, but it matters when you see a panic message in practice: `KASSERT` failures produce a distinctive prefix that we will recognize later.

Fourth, notice that the `msg` argument is passed in double parentheses. That is because the macro passes it directly to `kassert_panic`, which has a `printf`-style signature. In practice you write:

```
KASSERT(ptr != NULL, ("ptr must not be NULL in %s", __func__));
```

The outer parentheses belong to the macro. The inner parentheses are the argument list for `kassert_panic`. A beginner's mistake is to write `KASSERT(ptr != NULL, "ptr is NULL")` with only one set of parentheses, which will not compile. The double parentheses are the discipline that reminds us a failing assertion will be formatted like a `printf`.

### 34.5.2 INVARIANTS and INVARIANT\_SUPPORT

INVARIANTS is the kernel build option that controls whether KASSERT is active. A debug kernel enables it. The GENERIC-DEBUG configuration shipped with FreeBSD 14.3 enables it by including `std.debug`, which you can see in `/usr/src/sys/conf/std.debug`. A release GENERIC kernel does not enable it.

There is also a related option called INVARIANT\_SUPPORT. INVARIANT\_SUPPORT compiles in the functions that assertions might call, without making them mandatory. This allows loadable kernel modules that were built with INVARIANTS to load into a kernel that was not built with INVARIANTS, as long as INVARIANT\_SUPPORT is present. For a driver author, the practical upshot is this: if you build your module with INVARIANTS, make sure the kernel you are loading it into has at least INVARIANT\_SUPPORT. The GENERIC-DEBUG kernel has both, which is one of the reasons we recommend using it throughout development.

### 34.5.3 MPASS: KASSERT With a Default Message

Writing a message for every assertion can be tedious, especially for simple invariants. FreeBSD provides MPASS as a shorthand for `KASSERT(expr, ("Assertion expr failed at file:line"))`:

```
#define MPASS(ex) MPASS4(ex, #ex, __FILE__, __LINE__)
#define MPASS2(ex, what) MPASS4(ex, what, __FILE__, __LINE__)
#define MPASS3(ex, file, line) MPASS4(ex, #ex, file, line)
#define MPASS4(ex, what, file, line) \
 KASSERT((ex), ("Assertion %s failed at %s:%d", what, file, line))
```

The four forms let you customize the message, the file, or both. The simplest form, `MPASS(ptr != NULL)`, stringifies the expression itself and embeds the location automatically. When the message can afford to be terse, MPASS produces less visual clutter in the source. When the message needs context a future reader will appreciate, prefer KASSERT with a written message.

A sensible rule of thumb is that MPASS is for internal invariants that should never happen and where the identity of the expression is self-explanatory. KASSERT is for conditions where the failure mode deserves a descriptive message.

### 34.5.4 CTASSERT: Compile-Time Assertions

Sometimes the condition you want to check can be decided at compile time. `sizeof(struct foo) == 64`, for example, or `MY_CONST >= 8`. For those, FreeBSD provides CTASSERT, also in `/usr/src/sys/sys/kassert.h`:

```
#define CTASSERT(x) _Static_assert(x, "compile-time assertion failed")
```

CTASSERT uses C11's `_Static_assert`. It produces a compile-time error if the condition is false and has zero runtime cost because there is no runtime involved. This is the ideal tool for structure layout checks that must hold for the driver to be correct.

A typical use in the kernel is to guard a structure against accidental size changes:

```
struct bugdemo_command {
 uint32_t op;
 uint32_t flags;
 uint64_t arg;
};

CTASSERT(sizeof(struct bugdemo_command) == 16);
```

If someone later adds a field without adjusting the size comment or reordering thoughtfully, the build breaks immediately. This is far better than finding out at runtime that the structure has grown and the ioctl no longer matches user-space expectations.

### 34.5.5 panic: The Unconditional Stop

Where KASSERT is a conditional check, panic is the unconditional version. You call it when you have decided that continuing execution would be worse than stopping:

```
void panic(const char *, ...) __dead2 __printflike(1, 2);
```

The declaration lives in `/usr/src/sys/sys/kassert.h` and the implementation in `/usr/src/sys/kern/kern_shutdown.c`. The `__dead2` attribute tells the compiler that panic does not return, which lets it produce better code downstream. The `__printflike(1, 2)` attribute tells it that the first argument is a printf-style format string, so the compiler can type-check the format against its arguments.

When would you use panic directly rather than KASSERT? Three common situations. First, when the condition is so catastrophic that there is no safe continuation even in a release kernel. Failing to allocate a soft context during attach, for example, might be a panic rather than a graceful cleanup if the driver has already been partially registered. Second, when you want the message to appear even in non-debug builds, because the event indicates a hardware or configuration failure that the user must be told about. Third, as a placeholder during early development, to make sure unreachable paths actually are unreachable, before you replace the panic with a `KASSERT(0, ...)` in mature code.

Some drivers in `/usr/src/sys/dev/` use panic sparingly. Reading a few examples will give you a feel for the tone: a panic message says something like “the controller returned an impossible status” or “we reached a case the state machine claims cannot happen.” It is not the normal response to an I/O error. It is the response to an invariant that has been broken so thoroughly that the driver cannot be trusted to continue.

### 34.5.6 \_\_predict\_false and \_\_predict\_true

We saw `__predict_false` in the KASSERT definition. These two macros, defined in `/usr/src/sys/sys/cdefs.h`, are compile-time hints to the branch predictor:

```
#if __GNUC_PREREQ__(3, 0)
#define __predict_true(exp) __builtin_expect((exp), 1)
#endif
```

```

#define __predict_false(exp) __builtin_expect((exp), 0)
#else
#define __predict_true(exp) (exp)
#define __predict_false(exp) (exp)
#endif

```

They do not change the semantics of the expression. They only tell the compiler which outcome is more likely, which influences how the compiler lays out the code. In a hot path, wrapping a likely-true condition in `__predict_true` can improve cache behavior; wrapping a likely-false one in `__predict_false` keeps the error-handling code off the fast path.

The first rule of using these macros is to be correct. If you predict wrong, you slow the code down rather than speeding it up. The second rule is to only use them in genuinely hot paths where the difference matters. For most driver code, the compiler's default heuristics are fine, and cluttering the code with predictions is more trouble than it is worth.

### 34.5.7 Where Assertions Belong in a Driver

With these macros in hand, where do you actually put assertions? A few patterns have proven useful in FreeBSD drivers.

The first is at function entry, for non-trivial preconditions. A driver function that expects to be called with a particular lock held is a perfect candidate:

```

static void
bugdemo_process(struct bugdemo_softc *sc, struct bugdemo_command *cmd)
{
 BUGDEMO_LOCK_ASSERT(sc);
 KASSERT(cmd != NULL, ("cmd must not be NULL"));
 KASSERT(cmd->op < BUGDEMO_OP_MAX,
 ("cmd->op %u out of range", cmd->op));
 /* ... */
}

```

The `BUGDEMO_LOCK_ASSERT` is a macro convention many drivers adopt that wraps a `mtx_assert(9)` or `sx_assert(9)` call. This pattern, where each subsystem has its own `_ASSERT` macro that checks its own lock, scales well across a large driver.

The second pattern is at state transitions. If a driver state machine has four valid states and an attach path that should only ever run in state `INIT`, an assertion at the top of `attach` will catch any future refactor that breaks that invariant:

```

KASSERT(sc->state == BUGDEMO_STATE_INIT,
 ("attach called in state %d", sc->state));

```

The third pattern is after subtle arithmetic. If a calculation should produce a value in a known range, check:

```
idx = (offset / PAGE_SIZE) & (SC_NRING - 1);
KASSERT(idx < SC_NRING, ("idx %u out of range", idx));
```

This is especially valuable in ring buffer code, where an off-by-one between producer and consumer can cause silent data corruption.

The fourth pattern is for pointers that could be NULL but should not be. If a function receives a pointer argument that is only valid when nonzero, a single `KASSERT(ptr != NULL, ...)` at the top of the function catches years of future misuse.

### 34.5.8 When Not to Use Assertions

Assertions are not a replacement for error handling. The rule is: `KASSERT` checks things that the programmer guarantees, not things the environment guarantees. If a memory allocation with `M_NOWAIT` can fail under memory pressure, you do not assert it succeeded. You check the return value and handle the failure. If a user-space program passes a structure larger than you expect, you return `EINVAL`, not `KASSERT(0)`. The assertion is for internal consistency, not for external input.

Another anti-pattern is using assertions for conditions that only hold in certain configurations. `KASSERT(some_sysctl == default)` is wrong if `some_sysctl` is user-tunable, because the assertion will fail on any system that has tuned it. Check the configuration explicitly and handle it, or assert only within the branch where the assumption actually holds.

A more subtle anti-pattern is using assertions as documentation. “This is how it works, and it had better stay that way” is a tempting use of `KASSERT`, but if the assertion only holds today and could reasonably change tomorrow, you have created a future bug for someone who does not remember your promise. Better to leave a comment that states the assumption, and let the code evolve. Assertions should capture permanent invariants, not temporary implementation choices.

### 34.5.9 A Small Real-World Example

Let us see these ideas applied in real FreeBSD code. Open `/usr/src/sys/dev/null/null.c` and look at a typical check near the read handler. The driver is extremely simple, so there are few assertions, but many drivers in `/usr/src/sys/dev/` use `KASSERT` liberally. For a richer example, scan `/usr/src/sys/dev/uart/uart_bus_pci.c` or `/usr/src/sys/dev/mii/mii.c`, where assertions at function entry catch callers that do not hold the expected locks.

The consistency of this pattern across the tree is not accidental. It reflects a cultural expectation that drivers will express their invariants in code, not only in comments. When you adopt the same habit in your own drivers, you join that culture. Your drivers will be easier to port, easier to review, and much easier to debug when something eventually goes wrong.

### 34.5.10 A Quick Example: Adding Assertions to bugdemo

Let us add a small set of assertions to an imagined bugdemo driver. Assume we have a `softc` structure with a mutex, a state field, and a counter, and an `ioctl` handler that takes a `struct bugdemo_command`.

```
static int
bugdemo_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
 struct thread *td)
{
 struct bugdemo_softc *sc = dev->si_drv1;
 struct bugdemo_command *bcmd = (struct bugdemo_command *)data;

 KASSERT(sc != NULL, ("bugdemo: softc missing"));
 KASSERT(sc->state == BUGDEMO_STATE_READY,
 ("bugdemo: ioctl in state %d", sc->state));

 switch (cmd) {
 case BUGDEMO_TRIGGER:
 KASSERT(bcmd->op < BUGDEMO_OP_MAX,
 ("bugdemo: op %u out of range", bcmd->op));
 BUGDEMO_LOCK(sc);
 bugdemo_process(sc, bcmd);
 BUGDEMO_UNLOCK(sc);
 return (0);
 default:
 return (ENOTTY);
 }
}
```

Four assertions, each catching a different class of future bug. The first checks that the driver's private pointer is actually set, which is easy to forget when `make_dev(9)` is called with `NULL` by mistake. The second checks the driver state, which will fire if someone adds a code path that can reach `ioctl` before `attach` has finished. The third checks user-provided input is in range, though in a production context this particular check would also be done as a real input validation that returns an error, because `ioctl` is a public interface. The fourth, not shown here but implied by `bugdemo_process`, asserts the lock is held.

These few lines express a lot of invariants. In a debug kernel, they will catch real bugs the moment they happen. In a release kernel, they disappear entirely. That is the bargain `KASSERT` offers, and taking it is one of the best habits a driver author can cultivate.

With this foundation in place, we can move on to what happens when an assertion actually fires, which brings us to the panic path and the crash dump.

## 34.6 3. Analyzing Panics and Crash Dumps

When a KASSERT fails or `panic` is called, the kernel takes a series of well-defined steps. Understanding those steps is the first part of making sense of a crash. The second part is knowing what traces the kernel leaves behind, and how to read them after the fact. This section walks through both.

### 34.6.1 What Happens During a Panic

A panic is the kernel's controlled shutdown in response to an unrecoverable error. The exact sequence depends on the build options, but a typical panic in a FreeBSD 14.3 kernel proceeds as follows.

First, `panic()` or `kassert_panic()` is called with a message. The message is formatted and written to the system log. If a serial console is attached, it appears there immediately. If only a graphical console is available, it appears on screen, though there is often too little time to read a long trace before the machine reboots, which is one reason we recommend a serial or virtual console during this chapter.

Second, the kernel captures a backtrace of the panicking thread. You will see this on the console as a list of function names with offsets. The backtrace is the most valuable piece of information a panic produces, because it tells you the chain of calls that led to the failure. Reading it top-down shows you the function that called `panic`, the function that called that one, and so on, back to the entry point.

Third, if the kernel has been built with KDB enabled and a backend such as DDB, the kernel enters the debugger. DDB is the in-kernel debugger. It accepts commands directly on the console: `bt` to show a backtrace, `show registers` to dump register state, `show proc` to show process information, and so on. We will use DDB briefly in Section 4. If KDB is not enabled, or if the kernel is configured to skip the debugger on panic, the kernel moves on.

Fourth, if a dump device is configured, the kernel writes a dump to it. The dump is the entire contents of kernel memory, or at least the portions marked as dumpable, serialized onto the dump device. This is the crash dump that `savecore(8)` will retrieve after the reboot.

Fifth, the kernel reboots the machine, unless it has been asked to stop at the debugger. After the reboot, when the system comes up, `savecore(8)` runs and writes the dump to `/var/crash/vmcore.N` along with a textual summary. You now have everything you need to analyze the crash offline.

The whole sequence takes anywhere from a fraction of a second to a few minutes, depending on how large the kernel is, how fast the dump device is, and how configured the system is. On a development VM, dumping a kernel of a few hundred megabytes to a virtual disk is typically a matter of seconds.

### 34.6.2 Reading a Panic Message

A panic message in FreeBSD 14.3 looks something like this:

```
panic: bugdemo: softc missing
cpuid = 0
time = 1745188102
KDB: stack backtrace:
db_trace_self_wrapper() at db_trace_self_wrapper+0x2b
```

```
vpanic() at vpanic+0x182
panic() at panic+0x43
bugdemo_ioctl() at bugdemo_ioctl+0x24
devfs_ioctl() at devfs_ioctl+0xc2
VOP_IOCTL_APV() at VOP_IOCTL_APV+0x3f
vn_ioctl() at vn_ioctl+0xdc
devfs_ioctl_f() at devfs_ioctl_f+0x1a
kern_ioctl() at kern_ioctl+0x284
sys_ioctl() at sys_ioctl+0x12f
amd64_syscall() at amd64_syscall+0x111
fast_syscall_common() at fast_syscall_common+0xf8
--- syscall (54, FreeBSD ELF64, sys_ioctl), rip = ..., rsp = ...
```

Read this top to bottom. The first line is the panic message itself. The `cpuid` and `time` lines are metadata; they are rarely useful for debugging but occasionally help when reconciling multiple logs. The `KDB: stack backtrace:` line marks the start of the trace.

The first few frames are the panic infrastructure itself: `db_trace_self_wrapper`, `vpanic`, `panic`. These are always there on a panic and can be skipped. The first interesting frame is `bugdemo_ioctl`, which is where our driver called `panic`. The frames below that are the path that got us to `bugdemo_ioctl`: `devfs_ioctl`, `vn_ioctl`, `kern_ioctl`, `sys_ioctl`, `amd64_syscall`. This tells us that the panic happened during an `ioctl` system call, which is already a useful clue. The final line shows the `syscall` number (54, which is `ioctl`) and the instruction pointer at entry.

The offsets (`+0x24`, `+0xc2`) are byte offsets into each function. On their own they are not human-readable, but they let `kgdb` resolve the exact line of source code when the debug kernel is available.

Writing this kind of message down, or capturing the serial console log, is the first thing you should do when a panic happens. If the machine reboots too quickly to read, configure a serial console or a text-mode virtual console where the history is retained.

### 34.6.3 Configuring the Dump Device

For `savecore(8)` to have anything to retrieve, the kernel must know where to write the dump. FreeBSD calls this the dump device, and `dumpon(8)` is the utility that configures it.

There are two common ways to set this up. The simplest is a swap partition. During install, `bsdinstall` typically creates a swap partition large enough for kernel memory, and FreeBSD 14.3 automatically configures it as the dump device if you enabled the relevant options. You can check with:

```
dumpon -l
/dev/da0p3
```

If that command lists your swap device, you are good. If it says no dump device is configured, you can set one manually:

```
dumpon /dev/da0p3
```

To make this persistent across reboots, put it in `/etc/rc.conf`:

```
dumpdev="/dev/da0p3"
dumpon_flags=""
```

You can see the defaults for these variables in `/usr/src/libexec/rc/rc.conf`, which is the authoritative source for all default `rc.conf` values in the base system. Grep for `dumpdev=` and `dumpon_flags=` to find the relevant block.

An alternative, introduced in modern FreeBSD, is to use a file-backed dump. This avoids the need to dedicate a disk partition to dumps. See `dumpon(8)` for the exact syntax; the short version is that you can point `dumpon` at a file on a filesystem, and the kernel will dump into it at panic time. File-backed dumps are convenient for development VMs where you do not want to re-partition the disk.

A second `rc.conf` variable controls where `savecore(8)` puts retrieved dumps:

```
dumpdir="/var/crash"
savecore_enable="YES"
savecore_flags="-m 10"
```

The `-m 10` argument keeps only the most recent ten dumps, which is a reasonable default. If you are chasing a rare bug, raise the number; if disk space is tight, lower it. `savecore(8)` runs from `/etc/rc.d/savecore` during boot, before most services are up, so your dump is preserved before anything else touches `/var`.

### 34.6.4 Enabling Dumps in the Kernel

For the kernel to be willing to write a dump, it must be built with the right options. In FreeBSD 14.3, the `GENERIC` kernel is already configured for the framework pieces. If you look at `/usr/src/sys/amd64/conf/GENERIC` around the top of the file, you will see something close to:

```
options KDB
options KDB_TRACE
options EKCD
options DDB_CTF
```

`KDB` is the kernel debugger framework. `KDB_TRACE` enables automatic stack traces on panic. `EKCD` enables encrypted kernel crash dumps, which is useful when dumps contain sensitive data. `DDB_CTF` tells the build to include CTF type information for the debugger. Together these options give a fully capable dumping kernel.

Notice what is *not* in `GENERIC`: `options DDB` and `options GDB` themselves. The `KDB` framework is there, but the in-kernel debugger backend (`DDB`) and the remote `GDB` stub (`GDB`) are added by `std.debug`, which `GENERIC-DEBUG` includes. A plain `GENERIC` kernel will still write a dump on panic, but if you drop to the console during a live system, there is no `DDB` prompt to greet you.

If you are building your own kernel, either add the backends explicitly or, simpler, start from `GENERIC-DEBUG`, which enables them plus the debugging options we will need for the rest of the chapter. `GENERIC-DEBUG` lives at `/usr/src/sys/amd64/conf/GENERIC-DEBUG` and is just two lines:

```
include GENERIC
include "std.debug"
```

The `std.debug` file in `/usr/src/sys/conf/std.debug` adds `DDB`, `GDB`, `INVARIANTS`, `INVARIANT_SUPPORT`, `WITNESS`, `WITNESS_SKIPSPIN`, `MALLOC_DEBUG_MAXZONES=8`, `ALT_BREAK_TO_DEBUGGER`, `DEADLKRES`, `BUF_TRACKING`, `FULL_BUF_TRACKING`, `QUEUE_MACRO_DEBUG_TRASH`, and a few subsystem-specific debug flags. Note that `DDB` and `GDB` themselves come from `std.debug`, not from `GENERIC`; the release kernel enables `KDB` and `KDB_TRACE` but leaves the backends out unless you opt in. This is the recommended debug kernel for driver development and the kernel we will assume in the rest of the chapter unless we say otherwise.

### 34.6.5 Retrieving the Dump with `savecore`

After a panic and reboot, `savecore(8)` runs early in the boot sequence. By the time you have a shell prompt, the dump is already in `/var/crash/`:

```
ls -l /var/crash/
total 524288
-rw----- 1 root wheel 1 Apr 20 14:23 bounds
-rw-r--r-- 1 root wheel 5 Apr 20 14:23 minfree
-rw----- 1 root wheel 11534336 Apr 20 14:23 info.0
-rw----- 1 root wheel 11534336 Apr 20 14:23 info.last
-rw----- 1 root wheel 524288000 Apr 20 14:23 vmcore.0
-rw----- 1 root wheel 524288000 Apr 20 14:23 vmcore.last
```

The `vmcore.N` file is the dump itself. The `info.N` file is a textual summary of the panic, including the panic message, the backtrace, and the kernel version. Always read `info.N` first. If the message and backtrace are enough to identify the bug, you may not need to go further.

A few common problems to watch for. If `ls` shows only `bounds` and `minfree`, no dump has been captured yet. This usually means the dump device is not configured or the kernel did not manage to write to it before rebooting. Check `dumpon -l` and `re-panic`. If `savecore` logs messages about a checksum mismatch, the dump was truncated, which typically indicates the dump device was too small. If the machine never panicked cleanly but simply rebooted, the kernel likely did not have `KDB` enabled, so there was no dump machinery to invoke.

The `info.N` file is short enough to read in full. It includes the kernel version, the panic string, and the backtrace the kernel captured at panic time. On FreeBSD 14.3 it looks something like this:

```
Dump header from device: /dev/da0p3
Architecture: amd64
Architecture Version: 2
Dump Length: 524288000
```

```
Blocksize: 512
Compression: none
Dumptime: 2026-04-20 14:22:34 -0300
Hostname: devbox
Magic: FreeBSD Kernel Dump
Version String: FreeBSD 14.3-RELEASE #0: ...
Panic String: panic: bugdemo: softc missing
Dump Parity: 3142...
Bounds: 0
Dump Status: good
```

If the `Dump Status` is good, the dump is usable. If it says bad, the dump was truncated or the checksum failed.

### 34.6.6 Opening a Dump with kgdb

Once you have a dump, the next step is to open it with `kgdb`. `kgdb` is FreeBSD's version of `gdb` specialized for kernel images. It needs three things: the kernel image that produced the dump, the debug kernel image that contains symbols, and the dump file itself. On most systems all three are in predictable places:

- The running kernel: `/boot/kernel/kernel`
- The debug kernel with full symbols: `/usr/lib/debug/boot/kernel/kernel.debug`
- The dump: `/var/crash/vmcore.N`

The simplest invocation is:

```
kgdb /boot/kernel/kernel /var/crash/vmcore.0
```

or equivalently:

```
kgdb /usr/lib/debug/boot/kernel/kernel.debug /var/crash/vmcore.0
```

`kgdb` is a normal GDB session with kernel-specific tweaks. If your kernel was built with `makeoptions DEBUG=-g` (which `GENERIC-DEBUG` does), the debug symbols are included, and `kgdb` will be able to resolve every frame to source code.

When `kgdb` starts, it automatically runs a few commands:

```
(kgdb) bt
#0 __curthread () at /usr/src/sys/amd64/include/pcpu_aux.h:57
#1 doadump (textdump=...) at /usr/src/sys/kern/kern_shutdown.c:400
#2 0xffffffff80b6cf77 in kern_reboot (howto=260)
 at /usr/src/sys/kern/kern_shutdown.c:487
#3 0xffffffff80b6d472 in vpanic (fmt=..., ap=...)
```

```

 at /usr/src/sys/kern/kern_shutdown.c:920
#4 0xffffffff80b6d2c3 in panic (fmt=...)
 at /usr/src/sys/kern/kern_shutdown.c:844
#5 0xffffffff83e01234 in bugdemo_ioctl (dev=..., cmd=..., data=..., fflag=..., td=...)
 at /usr/src/sys/modules/bugdemo/bugdemo.c:142
...

```

The top frame is the panic infrastructure. The interesting frame is frame 5, `bugdemo_ioctl` at `bugdemo.c:142`. To jump to that frame:

```

(kgdb) frame 5
#5 0xffffffff83e01234 in bugdemo_ioctl (dev=..., cmd=...)
 at /usr/src/sys/modules/bugdemo/bugdemo.c:142
142 KASSERT(sc != NULL, ("bugdemo: softc missing"));

```

`kgdb` prints the source line. From here you can inspect local variables with `info locals`, look at `sc` directly with `print sc`, or list the surrounding source with `list`:

```

(kgdb) print sc
$1 = (struct bugdemo_softc *) 0x0

```

That tells us `sc` really is `NULL`, confirming the panic message. Now we can work out why, which usually means walking up the stack to find where `sc` should have been set:

```

(kgdb) frame 6

```

and so on. The sequence of `frame N`, `print VAR`, `list` is the bread-and-butter of `kgdb` analysis. It is the same conversation a `gdb` user has with any crashing program, adapted to the kernel.

### 34.6.7 Useful `kgdb` Commands

Beyond `bt` and `frame`, a handful of commands cover most debugging sessions.

- `info threads` lists all threads in the dumped system. In a modern kernel this can be hundreds of entries. Each has a number and a state.
- `thread N` switches to a specific thread, as if that thread had been the one that panicked. This is essential when a deadlock has happened and the panicking thread is not the one holding the problematic lock.
- `bt full` prints a backtrace with local variables at each frame. This is often the fastest way to see the state of a function involved in the panic.
- `info locals` shows local variables in the current frame.
- `print *SOMETHING` dereferences a pointer and prints the contents of the structure it points to.
- `list` shows the source around the current line; `list FUNC` shows the source of a function by name.

There are many more, documented in `gdb(1)`, but these are the ones a driver author reaches for most often.

### 34.6.8 Walking struct thread in a Dump

A panic backtrace answers “where did the crash happen?” but it rarely answers “who was doing what?” The kernel keeps a dense record of every live thread in `struct thread`, and once a dump is open in `kgdb` we can read that record directly. For a driver author the value is concrete: the fields of `struct thread` tell you what job this thread was performing when the kernel crashed, which lock it was waiting on, which process it belonged to, and whether it was still inside your code when the panic occurred.

`struct thread` is defined in `/usr/src/sys/sys/proc.h`. It is a large structure, so rather than read every field, we focus on a small set that matters most for driver debugging. In `kgdb` the quickest way to see those fields is to take the current thread and dereference it:

```
(kgdb) print *(struct thread *)curthread
```

On the panicking CPU `curthread` is already correct, but you can also reach a specific thread from the `info threads` listing. `kgdb` numbers every thread sequentially. Once you know the number, `thread N` switches context, and from there `print $td` (or `print *(struct thread *)0xADDR` if you have the raw address) prints the structure.

The fields to know are these. `td_name` is a short, readable name for the thread, often set by `kthread_add(9)` or by the userspace program that spawned it. When a driver creates its own kernel thread, this is the name that shows up. `td_tid` is the numeric thread identifier the kernel assigns; `ps -H` in userspace shows the same number. `td_proc` is a pointer to the owning process, which gives us access to the larger `struct proc` for more context. `td_flags` carries the `TDF_*` bit field that records scheduler and debugger state; the definitions live next to the structure in `/usr/src/sys/sys/proc.h`, and many panics can be partially explained by reading those bits. `td_lock` is the spin mutex that currently protects this thread’s scheduler state. It is almost always a CPU-local lock in a running kernel; in a dump, a `td_lock` that points to an unexpected address is a strong hint that something corrupted the scheduler view of this thread.

Two more fields are decisive when the panic involves sleeping or waiting. `td_wchan` is the “wait channel,” the kernel address the thread is sleeping on. `td_wmesg` is a short human-readable string describing why (for example, “biord” for a thread waiting on a buf read, or “select” for a thread inside `select(2)`). If the panic happened while threads were sleeping, these two fields tell you what each thread was waiting for. `td_state` is the `TDS_*` state value (defined just below `struct thread`); it tells you whether the thread was running, runnable, or inhibited at the moment of the crash.

For lock bugs specifically, `td_locks` counts the non-spin locks currently held by the thread, and `td_lockname` records the name of the lock the thread is currently blocked on, if any. If a thread panics with a non-zero `td_locks`, that thread was holding one or more sleep locks at the time of the crash: useful context when the panic is a mutex not owned or `Lock (sleep mutex) ... is not sleepable` message.

A short `kgdb` session that pulls these fields out might look like this:

```
(kgdb) thread 42
[Switching to thread 42 ...]
(kgdb) set $td = curthread
(kgdb) print $td->td_name
$2 = "bugdemo_worker"
```

```
(kgdb) print $td->td_tid
$3 = 100472
(kgdb) print $td->td_state
$4 = TDS_RUNNING
(kgdb) print $td->td_wmesg
$5 = 0x0
(kgdb) print $td->td_locks
$6 = 1
(kgdb) print $td->td_proc->p_pid
$7 = 0
(kgdb) print $td->td_proc->p_comm
$8 = "kernel"
```

Reading this: thread 42 was a kernel thread called `bugdemo_worker`, running when the panic hit, not sleeping on anything (`td_wmesg` is `NULL`), and it was still holding exactly one sleep lock. The owning process is the kernel proc with pid 0 and command name `kernel`, which is the expected owner of kernel-only threads. The interesting fact is `td_locks == 1`, because it tells us the thread held a lock at panic time; a follow-up with `show alllocks` in DDB, or with `show lockedvnods` if file locks are relevant, would pinpoint which.

### 34.6.9 Walking struct proc in a Dump

Each thread belongs to a `struct proc`, defined next to `struct thread` in `/usr/src/sys/sys/proc.h`. `struct proc` carries the process-wide context: identity, credentials, address space, open files, parent relationship. For driver bugs, a handful of these fields are particularly useful.

`p_pid` is the process identifier, the same number userspace sees in `ps`. `p_comm` is the process command name, truncated to `MAXCOMLEN` bytes. Together they tell you which userspace process triggered the kernel path that panicked. `p_state` is the `PRS_*` process state, letting you distinguish a newly-forked process, a running one, and a zombie. `p_nthreads` tells you how many threads this process has; for a multithreaded userland program that called into your driver, the count can be surprising. `p_flag` holds the `P_*` flag bits, which encode properties like tracing, accounting, and single-threading; `/usr/src/sys/sys/proc.h` documents each bit near the flag block.

Three pointers give you the larger context. `p_ucred` references the process credentials, useful when the panic might be tied to a privilege check your driver performed. `p_vmspace` points to the address space, which matters when the panic involves a user pointer that turned out to belong to an unexpected process. `p_pptr` points to the parent process; walking this chain with `p_pptr->p_pptr` eventually leads to `initproc`, the ancestor of every userspace process.

A short walk from a thread to its process looks like this in `kgdb`:

```
(kgdb) set $p = curthread->td_proc
(kgdb) print $p->p_pid
$9 = 3418
(kgdb) print $p->p_comm
```

```
$10 = "devctl"
(kgdb) print $p->p_state
$11 = PRS_NORMAL
(kgdb) print $p->p_numthreads
$12 = 4
(kgdb) print $p->p_flag
$13 = 536871424
```

Now we know the panic happened while a userspace `devctl` process with pid 3418 was running, that the process had four threads, and that its flag bits decoded through the `P_*` constants in `/usr/src/sys/sys/proc.h` will tell us whether it was being traced, accounted for, or in the middle of an exec. The flag integer on its own looks opaque, but in kgdb you can let the enum-like `P_*` macros do the decoding by casting or by using `info macro P_TRACED`.

For drivers that expose a character device, `p_fd` is also worth knowing. It points to the file descriptor table of the process that called into your driver, and in an advanced session you can walk it to find which descriptor the call came in on. That is usually more than a first-pass crash analysis needs, but the mechanism is worth remembering for the rare bug that depends on how userspace had the device open.

Between `struct thread` and `struct proc`, you can reconstruct an astonishing amount of context from a dump that at first glance only shows a panic message and a backtrace. The cost is reading `/usr/src/sys/sys/proc.h` once carefully; after that, the same vocabulary is available to you in every debugging session for the rest of your career.

### 34.6.10 Using kgdb Against a Live Kernel

So far we have treated kgdb as a post-mortem tool: open a dump, explore it offline, think at your own pace. kgdb also has a second mode, where it attaches to a running kernel through `/dev/mem` rather than to a saved dump. This mode is capable, but it is also the most easily misused tool in the whole debugging toolbox, so we will discuss it with explicit warnings.

The invocation looks almost identical to the post-mortem form, except that the “core” is `/dev/mem`:

```
kgdb /boot/kernel/kernel /dev/mem
```

What actually happens is that kgdb uses the `libkvm` library to read kernel memory through `/dev/mem`. The interface is documented in `/usr/src/lib/libkvm/kvm_open.3`, which makes the distinction clear: the “core” argument can be either a file produced by `savecore(8)` or `/dev/mem`, and in the latter case the currently running kernel is the target.

This is genuinely useful. You can inspect global variables, walk lock graphs, look at in-flight I/O, and confirm whether a `sysctl` you just set has taken effect. You can do this without rebooting, without interrupting service, and without having to reproduce a crash. On a development system that is hosting a long-running test, it is often the fastest way to answer “what is the driver actually doing right now?”

The risks are real. First, the kernel is running while you are reading. Data structures change under you. A linked list you start walking may have an entry removed halfway through; a counter you print may have been

incremented between the moment you asked for it and the moment `kgdb` printed it; a pointer you follow may be reassigned before the dereference completes. Unlike a dump, you are reading a moving target, and you will sometimes see states that are transiently inconsistent.

Second, `kgdb` on a live kernel is strictly read-only in practical use. You can read memory, print structures, and walk data, but you must not write to kernel memory through this path. The `libkvm` interface does not provide locking or barriers, and an uncoordinated write would race with the kernel itself. Treat every operation through `/dev/mem` as inspection, never modification. If you want to change running kernel state, use `sysctl(8)` or `sysctl(3)`, or load a module, or use DDB from the console. Those mechanisms are designed to coordinate with the rest of the kernel; raw writes through `/dev/mem` are not.

Third, the perturbation is not zero. Reading through `/dev/mem` can cause TLB traffic, and on large structures the cost is measurable. If you are also profiling, attribute the noise accordingly.

Finally, access to `/dev/mem` requires root privilege, for obvious reasons: anything that can read `/dev/mem` can read any secret the kernel has ever held. On production systems, restricting this is a security concern, and the policy around who may run `kgdb` against a live kernel should reflect that.

Given those cautions, the guidance is straightforward. Prefer a crash dump for any session where you want to take your time, where you want to share the state with a colleague, or where consistency matters. Prefer a live `kgdb` session for quick, read-only glances at a running system where the question is small and the cost of reboot would be high. When in doubt, take a dump with `sysctl debug.kdb.panic=1` (if the system is expendable) or `dumpon` and a deliberate triggering event, and do your analysis on the frozen snapshot. The snapshot will still be there tomorrow; the running kernel will not.

### 34.6.11 A Note on Symbols and Modules

When the panicking driver is a loadable module, `kgdb` also needs the debug information for the module. If the module is in `/boot/modules/bugdemo.ko` and was built with `DEBUG_FLAGS=-g`, the debug symbols are embedded. `kgdb` will load them automatically when it resolves frames in that module.

If the module lives somewhere nonstandard, you may need to tell `kgdb` where to find its debug info:

```
(kgdb) add-symbol-file /path/to/bugdemo.ko.debug ADDRESS
```

where `ADDRESS` is the module's load address, which you can find in `kldstat(8)` output. In practice this is rarely needed on a modern FreeBSD system, because `kgdb` looks in the right places by default.

What you do need to avoid is mixing kernels. If the running kernel and the debug kernel came from different builds, symbols will not match and `kgdb` will show confusing or wrong information. Rebuild both from the same source tree, or keep matched pairs. On a development system this is usually not a problem because you build and install both together.

### 34.6.12 Closing Thoughts on Dumps

The crash dump is valuable because it preserves the kernel's state at the moment of the panic. Unlike a running system, where every read perturbs the state, a dump is a frozen snapshot. You can examine it as long as you like, come back to it tomorrow, share it with a colleague, or diff the state against the source. Even once you

have moved on to other bugs, a dump from an interesting failure is worth keeping, because it is often the only record of that exact sequence of events.

With panic mechanics and dump analysis behind us, we can move on to the kernel configuration choices that make debugging actually comfortable. That is the topic of Section 4.

## 34.7 4. Building a Debug-Friendly Kernel Environment

Everything we have learned so far depends on having the right kernel options enabled. A stock `GENERIC` kernel is a production configuration. It is optimized for speed, ships no debug information, and does not include the checks that catch many driver bugs. For the work of this chapter, we want the opposite: a kernel that is slow but thorough, that carries full debug symbols, and that actively looks for bugs rather than trusting the driver to behave. FreeBSD calls this `GENERIC-DEBUG`, and setting it up is the topic of this section.

We will walk through building and installing a debug kernel, then look at each of the interesting options in detail, including the debugger backends (`DDB`, `GDB`), the invariant checks (`INVARIANTS`, `WITNESS`), the memory debuggers (`DEBUG_MEMGUARD`, `DEBUG_REDZONE`), and the console controls that let you enter the debugger from the keyboard.

### 34.7.1 Building `GENERIC-DEBUG`

On a FreeBSD 14.3 system with `/usr/src/` populated, building a debug kernel is a three-command operation. From `/usr/src/`:

```
make buildkernel KERNCONF=GENERIC-DEBUG
make installkernel KERNCONF=GENERIC-DEBUG
reboot
```

The `buildkernel` step takes longer than a release build because debug information is generated and many more checks are compiled in. On a modest four-core VM it typically takes twenty to thirty minutes. `installkernel` places the result in `/boot/kernel/` and keeps the previous kernel in `/boot/kernel.old/`, which is a safety net if the new kernel fails to boot.

After reboot you can confirm the running kernel with `uname -v`:

```
uname -v
FreeBSD 14.3-RELEASE-p2 #0: ...
```

The `#0` indicates a locally built kernel. You can also check that the debug options are active by reading `sysctl` debug entries, which we will return to shortly.

### 34.7.2 What `GENERIC-DEBUG` Enables

As we saw in Section 3, `GENERIC-DEBUG` is a thin configuration that simply includes `GENERIC` and `std.debug`. The interesting content is in `std.debug`, which is worth reading in full because it documents the kernel's opinion

on what good debug options look like. In a FreeBSD 14.3 tree the file is at `/usr/src/sys/conf/std.debug`, and the core options are:

```
options BUF_TRACKING
options DDB
options FULL_BUF_TRACKING
options GDB
options DEADLKRES
options INVARIANTS
options INVARIANT_SUPPORT
options QUEUE_MACRO_DEBUG_TRASH
options WITNESS
options WITNESS_SKIPSPIN
options MALLOC_DEBUG_MAXZONES=8
options VERBOSE_SYSINIT=0
options ALT_BREAK_TO_DEBUGGER
```

Plus a handful of subsystem-specific debug flags for networking, USB, HID, and CAM that we do not need to dwell on. Let us look at each of the driver-relevant options in turn.

Note one thing that `std.debug` does *not* contain: `makeoptions DEBUG=-g`. That line lives in `GENERIC` itself, near the top of `/usr/src/sys/amd64/conf/GENERIC`. A release `GENERIC` kernel is already built with `-g`, because the release engineering process wants the debug information available even when `INVARIANTS` and `WITNESS` are off. `GENERIC-DEBUG` inherits this through its `include "GENERIC"`.

### 34.7.3 `makeoptions DEBUG=-g`

This passes `-g` to the compiler for every kernel file, producing a kernel with full DWARF debug information. `kgdb` uses this debug information to map from addresses back to source lines. Without `-g`, `kgdb` can still show function names, but it cannot show the source line where a crash happened, and `print someVariable` becomes `print *(char *)0xffffffff...` with no symbolic names.

The cost is that the kernel binary is larger. On amd64 a debug `GENERIC-DEBUG` kernel is several times the size of a non-debug `GENERIC` kernel. For a development VM this does not matter. For a production system it is often the reason to keep debug information in a separate file (`/usr/lib/debug/boot/kernel/kernel.debug`) while the running kernel is stripped.

### 34.7.4 `INVARIANTS` and `INVARIANT_SUPPORT`

We met these in Section 2. `INVARIANTS` activates `KASSERT` and a number of other runtime checks scattered through the kernel. Functions throughout `/usr/src/sys/` have `#ifdef INVARIANTS` blocks that check things like “this list is well-formed,” “this pointer points into a valid zone,” or “this reference count is nonzero.” With `INVARIANTS` enabled, these checks fire at runtime. Without it, they are compiled out.

The checks cost CPU cycles. As a rough order-of-magnitude figure on typical FreeBSD 14.3-amd64 hardware, a busy `INVARIANTS` kernel runs roughly five to twenty percent slower than a release kernel, and sometimes more

on allocation-heavy workloads. This is why `INVARIENTS` is not enabled in `GENERIC`. For driver development, this overhead is worth accepting in exchange for the bugs it catches. See Appendix F for a reproducible workload that measures this ratio on your own hardware.

`INVARIANT_SUPPORT` compiles in the helper routines that assertions call, without activating the assertions in base kernel code. As noted earlier, it allows modules built with `INVARIENTS` to load against kernels without `INVARIENTS`. You almost always want both.

### 34.7.5 WITNESS: Lock Order Verifier

`WITNESS` is one of the most effective debugging tools in the FreeBSD arsenal. It tracks every lock operation and every lock dependency in the kernel, and it fires a warning if it ever sees a lock order that could deadlock. Because deadlocks are a class of bug that is extremely hard to catch any other way, `WITNESS` is indispensable for any driver that takes more than one lock.

The way `WITNESS` works is worth understanding. Every time a thread acquires a lock, `WITNESS` notes which other locks the thread already holds. From these observations it builds a lock order graph: “lock A has been seen held before lock B,” and so on. If the graph ever contains a cycle, that is a potential deadlock, and `WITNESS` prints a warning on the console with backtraces for the offending acquisitions.

The output looks something like this:

```
lock order reversal:
 1st 0xffffffff80003abc000 bugdemo_sc_mutex (bugdemo_sc_mutex) @
 ↪ /usr/src/sys/modules/bugdemo/bugdemo.c:203
 2nd 0xffffffff80003def000 sysctl_lock (sysctl_lock) @
 ↪ /usr/src/sys/kern/kern_sysctl.c:1842
stack backtrace:
#0 kdb_backtrace+0x71
#1 witness_checkorder+0xc95
#2 __mtx_lock_flags+0x8f
...
```

Read this as: your driver’s `bugdemo_sc_mutex` was acquired first, and then later another thread was observed taking `sysctl_lock` first and `bugdemo_sc_mutex` second. This is a potential deadlock, because enough concurrent activity could make the two threads wait for each other. The fix is always the same: establish a consistent lock order across all paths that take both locks, and stick to it.

`WITNESS` is not cheap. It adds bookkeeping to every lock acquisition and release. In our lab environment, on a busy kernel running a lock-heavy workload, the overhead can approach twenty percent; the exact figure varies with the amount of locking the workload does. But the bugs it finds are the kind that destroy production uptime when they slip through, so the investment is worth it in development. See Appendix F for a reproducible workload that isolates this overhead against a baseline kernel.

`WITNESS_SKIPSPIN` turns off `WITNESS` on spin mutexes. Spin locks are typically short-lived and performance-critical, so checking them adds overhead where it matters most. The default is to check them anyway, but `std.debug` disables that check to keep the kernel usable. You can re-enable it if you are specifically hunting spin-lock bugs.

### 34.7.6 A Worked Race-Condition Walkthrough: Lock-Order Bug in bugdemo

Reading about WITNESS in the abstract is one thing; catching a real lock-order reversal in a driver you wrote is another. This subsection walks through a complete cycle: we introduce a deliberate ordering bug into bugdemo, run it on a GENERIC-DEBUG kernel, read the WITNESS report, and fix the bug. The walkthrough is short, but the pattern repeats in every deadlock you will ever debug.

Assume our bugdemo driver has grown two locks as it gained features. `sc_mtx` protects the per-unit state, and `cfg_mtx` protects a configuration blob shared across units. Most of the driver already takes them in the order “state first, config second,” which is a reasonable choice and which the author has followed in `bugdemo_ioctl` and in the read/write entry points. But a recent `sysctl` handler, written in a hurry, acquired the config lock first to validate a value and then reached for the state lock to apply it. In source, the two relevant excerpts look like this:

```
/* bugdemo_ioctl: established ordering, state then config */
mtx_lock(&sc->sc_mtx);
/* inspect per-unit state */
mtx_lock(&cfg_mtx);
/* adjust shared config */
mtx_unlock(&cfg_mtx);
mtx_unlock(&sc->sc_mtx);
```

```
/* bugdemo_sysctl_set: new path, config then state */
mtx_lock(&cfg_mtx);
/* validate new value */
mtx_lock(&sc->sc_mtx);
/* propagate into per-unit state */
mtx_unlock(&sc->sc_mtx);
mtx_unlock(&cfg_mtx);
```

Both paths individually are fine. The problem is that taken together they form a cycle. If thread A enters `bugdemo_ioctl` and acquires `sc_mtx`, and thread B concurrently enters `bugdemo_sysctl_set` and acquires `cfg_mtx`, each thread now waits on the lock the other holds. That is a classic AB-BA deadlock. It may not trigger on every run; it depends on timing. WITNESS is the tool that refuses to wait for a rare production failure to discover it.

On a GENERIC-DEBUG kernel the reversal is caught the first time both orderings are observed, even if no actual deadlock has occurred yet. The console message has a specific shape. Using the format emitted by `witness_output` in `/usr/src/sys/kern/subr_witness.c`, which prints pointer, lock name, witness name, lock class, and source location for each lock involved, the real report looks like this:

```
lock order reversal:
 1st 0xfffff80012345000 bugdemo sc_mtx (bugdemo sc_mtx, sleep mutex) @
 ↪ /usr/src/sys/modules/bugdemo/bugdemo.c:412
 2nd 0xfffff80012346000 bugdemo cfg_mtx (bugdemo cfg_mtx, sleep mutex) @
 ↪ /usr/src/sys/modules/bugdemo/bugdemo.c:417
```

```
lock order bugdemo cfg_mtx -> bugdemo sc_mtx established at:
#0 witness_checkorder+0xc95
#1 __mtx_lock_flags+0x8f
#2 bugdemo_sysctl_set+0x7a
#3 sysctl_root_handler_locked+0x9c
...
stack backtrace:
#0 kdb_backtrace+0x71
#1 witness_checkorder+0xc95
#2 __mtx_lock_flags+0x8f
#3 bugdemo_ioctl+0xd4
...
```

Each 1st and 2nd line carries four pieces of information. The pointer (0xfffff80012345000) is the address of the lock object in kernel memory. The first string is the instance name, set when the lock was initialized. The two strings in parentheses are the WITNESS name for the lock class and the lock class itself, in this case `sleep mutex`. The path and line are where the lock was last acquired along this reversed ordering. The block after `lock order ... established at:` shows the earlier backtrace that first taught WITNESS the now-violated ordering, and the final `stack backtrace` shows the current call path that violates it.

Reading all of that, the diagnosis is immediate. The driver has established `sc_mtx -> cfg_mtx` in its normal paths, and `bugdemo_sysctl_set` has just taken `cfg_mtx -> sc_mtx`. Both paths are ours. The fix is to pick one ordering (here, the established one) and rewrite the offending path to match:

```
/* bugdemo_sysctl_set: corrected to follow house ordering */
mtx_lock(&sc->sc_mtx);
mtx_lock(&cfg_mtx);
/* validate new value and propagate in one atomic window */
mtx_unlock(&cfg_mtx);
mtx_unlock(&sc->sc_mtx);
```

If the locked region needs to be narrower, a common pattern is to read state under `sc_mtx`, drop it, validate without holding any lock, and then reacquire in the house order to apply. Either way, the order is fixed at the driver level, not at the call site. A useful habit is to document the order in a comment near the lock declarations so future contributors do not have to rediscover it.

After the fix, rebuilding `bugdemo` on the same debug kernel and rerunning the triggering test produces no further WITNESS output. If a reversal reappears, WITNESS also supports querying the graph interactively with `show all_locks` in DDB, which can show the current state even without a full reversal report; for deeper introspection, the source of `/usr/src/sys/kern/subr_witness.c` is the authoritative explanation of both the bookkeeping and the report format.

### 34.7.7 The Same Bug Seen Through `lockstat(1)`

WITNESS tells you that an ordering is wrong. It does not tell you how often each lock is actually contended, how long each acquisition waits, or which callers are pushing on a given lock hardest. Those are questions about

contention, not correctness, and `lockstat(1)` is the tool for them.

`lockstat(1)` is a DTrace-backed profiler for kernel locks. It works by instrumenting the entry and exit points of lock primitives and reporting summaries, including spin time on adaptive mutexes, sleep time on sx locks, and hold time when asked. The classical invocation is `lockstat sleep N`, which gathers data for N seconds and then prints a summary.

If we run the buggy `bugdemo` under a workload that stresses both paths (a small userspace program that opens several unit nodes and simultaneously twiddles the `sysctl` in a tight loop), and profile with `lockstat` for five seconds, the output on a FreeBSD system looks roughly like this:

```
lockstat sleep 5
```

```
Adaptive mutex spin: 7314 events in 5.018 seconds (1458 events/sec)
```

| Count | indv | cuml | rcnt | nsec | Lock            | Caller                          |
|-------|------|------|------|------|-----------------|---------------------------------|
| 3612  | 49%  | 49%  | 0.00 | 4172 | bugdemo sc_mtx  | bugdemo_ioctl+0xd4              |
| 2894  | 40%  | 89%  | 0.00 | 3908 | bugdemo cfg_mtx | bugdemo_sysctl_set+0x7a         |
| 412   | 6%   | 95%  | 0.00 | 1205 | bugdemo sc_mtx  | bugdemo_read+0x2f               |
| 220   | 3%   | 98%  | 0.00 | 902  | bugdemo cfg_mtx | bugdemo_ioctl+0xe6              |
| 176   | 2%   | 100% | 0.00 | 511  | Giant           | sysctl_root_handler_locked+0x4d |

```
Adaptive mutex block: 22 events in 5.018 seconds (4 events/sec)
```

| Count | indv | cuml | rcnt | nsec   | Lock            | Caller                  |
|-------|------|------|------|--------|-----------------|-------------------------|
| 14    | 63%  | 63%  | 0.00 | 184012 | bugdemo sc_mtx  | bugdemo_sysctl_set+0x8b |
| 8     | 36%  | 100% | 0.00 | 41877  | bugdemo cfg_mtx | bugdemo_ioctl+0xe6      |

Each table follows the same column convention: `Count` is how many events of this type were seen, `indv` is the percentage of events in this class, `cuml` is the running total, `rcnt` is the average reference count (always 1 for mutexes), `nsec` is the average duration in nanoseconds, and the last two columns identify the lock instance and the caller. The header line `Adaptive mutex spin` indicates contention that was resolved by a short spin; `Adaptive mutex block` indicates contention that actually forced a thread to sleep on the mutex. Those headers, and the column layout, are standard `lockstat` output; the format is documented in `/usr/src/cddl/contrib/opensolaris/cmd/lockstat/lockstat.1` along with worked examples at the end of that man page.

Two things are worth noting. First, both `bugdemo sc_mtx` and `bugdemo cfg_mtx` appear in both directions of the table: the `sysctl` path blocked on `sc_mtx` (line 1 of the block table), and the `ioctl` path blocked on `cfg_mtx` (line 2). That is the contention signature of the same ordering bug WITNESS reported, seen from the other side. WITNESS told us the ordering was unsafe; `lockstat` tells us that under this workload the unsafe ordering is also costing real time.

Second, after we apply the fix from the previous subsection, `lockstat` becomes a validation tool: rerun with the same workload and the `Adaptive mutex` block table should shrink dramatically, because the mutual wait between the two paths is gone. If it does not shrink, we have fixed the ordering but created a pure contention problem, and the next step is to narrow the critical section rather than to change the order.

Useful `lockstat` options beyond the default include `-H` to watch hold events (how long locks are held, not just contended), `-D N` to show only the top `N` rows per table, `-s 8` to include eight-frame stack traces with each row, and `-f FUNC` to filter on a single function. For driver work, `lockstat -H -s 8 sleep 10` while a targeted test runs is a remarkably productive default.

### 34.7.8 Reading WITNESS and lockstat Together

`WITNESS` and `lockstat` are complementary. `WITNESS` is a correctness tool: it detects bugs that will eventually produce a deadlock, regardless of whether the current workload happens to hit them. `lockstat` is a performance tool: it quantifies how much current traffic is touching each lock and how long the traffic waits. The same driver path often shows up in both, and the two views together are frequently decisive.

A useful discipline when a driver grows past its first lock is to make both tools part of the routine. Run `GENERIC-DEBUG` during development so `WITNESS` sees every new code path the moment it executes. Periodically run `lockstat` on a realistic workload to see whether any of your locks are becoming bottlenecks even when their ordering is sound. A lock that passes `WITNESS` and shows low `lockstat` contention is a lock you can mostly stop thinking about. A lock that passes `WITNESS` but dominates `lockstat` output is a performance problem waiting for a refactor, not a correctness bug. A lock that fails `WITNESS` is a bug regardless of what `lockstat` says.

With that framework in mind, we can continue looking at the other debug-kernel options that surface different classes of bug.

### 34.7.9 MALLOC\_DEBUG\_MAXZONES

FreeBSD's kernel memory allocator (`malloc(9)`) groups similar allocations into zones for speed. `MALLOC_DEBUG_MAXZONES=8` increases the number of zones used by `malloc`, which spreads allocations across more distinct memory regions. The practical effect is that use-after-free and invalid free bugs are more likely to land in a different zone than the original allocation, making them more detectable.

This is a low-cost option. It is always on in debug kernels.

### 34.7.10 ALT\_BREAK\_TO\_DEBUGGER and BREAK\_TO\_DEBUGGER

These two options control how the user enters the kernel debugger from the console. `BREAK_TO_DEBUGGER` enables the traditional `Ctrl-Alt-Esc` or serial `BREAK` sequence. `ALT_BREAK_TO_DEBUGGER` enables an alternative sequence, typed as `CR ~ Ctrl-B`, which is useful over network consoles (`ssh`, `virtio_console`, and so on) where sending a real `BREAK` is awkward.

`GENERIC` ships with `BREAK_TO_DEBUGGER` enabled. `GENERIC-DEBUG` adds `ALT_BREAK_TO_DEBUGGER`. If you are on a serial console, either sequence will drop you into `DDB`. From `DDB` you can inspect kernel state, set breakpoints, and optionally continue execution or panic.

This is an important convenience during development. A driver that hangs the system without panicking can be investigated by dropping into the debugger on command.

### 34.7.11 DEADLKRES: The Deadlock Detector

DEADLKRES enables the deadlock resolver, which is a periodic thread that watches for threads stuck in uninterruptible wait for too long. If it finds any, it prints a warning and optionally panics. This complements WITNESS by catching deadlocks that WITNESS did not predict, which happens when the lock graph is not traversable statically (for example, when locks are acquired by address through a generic locking API).

DEADLKRES has some false positives in practice, particularly for long-lived operations like filesystem I/O under heavy load. Reading the warning and deciding whether it is a real deadlock is part of the debugging skill this chapter is teaching.

### 34.7.12 BUF\_TRACKING

BUF\_TRACKING records a short history of operations on each buffer in the buffer cache. When a corruption is found, the buffer's history can be printed, showing which code paths touched it and in what order. This is useful for storage driver bugs but less commonly needed in other drivers.

### 34.7.13 QUEUE\_MACRO\_DEBUG\_TRASH

The `queue(3)` macros (`LIST_`, `TAILQ_`, `STAILQ_`, and so on) are used pervasively in the kernel for linked lists. When an element is removed from a list, the usual behavior is to leave the element's pointers alone. `QUEUE_MACRO_DEBUG_TRASH` overwrites them with recognizable garbage values. Any later attempt to dereference those pointers will crash in a recognizable way, rather than silently corrupting the list.

This is a cheap option and catches a very common class of bug: forgetting to remove an element from a list before freeing it, then finding the list corrupted later.

### 34.7.14 Memory Debuggers: `DEBUG_MEMGUARD` and `DEBUG_REDZONE`

Two more options that deserve attention are `DEBUG_MEMGUARD` and `DEBUG_REDZONE`. They are not part of `std.debug` but are commonly added for memory debugging sessions.

`DEBUG_MEMGUARD` is a specialized allocator that can be dropped in for particular `malloc(9)` types. It backs each allocation with a separate page or set of pages, marks the pages around the allocation as inaccessible, and unmaps the allocation on free. Any access beyond the bounds of the allocation, or any access after free, causes a page fault that is trivial to diagnose. The trade-off is that every allocation costs a full page of virtual memory plus kernel bookkeeping, so you normally turn `DEBUG_MEMGUARD` on for one specific `malloc` type at a time.

The relevant header is `/usr/src/sys/vm/memguard.h`, and the configuration appears in `/usr/src/sys/conf/NOTES` on the options `DEBUG_MEMGUARD` line. We will use `memguard(9)` in detail in Section 6.

`DEBUG_REDZONE` is a lighter-weight memory debugger that places guard bytes before and after each allocation. When the allocation is freed, the guard bytes are checked, and any corruption is reported. It does not catch

use-after-free but is very good at catching buffer overruns and underruns. See the options `DEBUG_REDZONE` line in `/usr/src/sys/conf/NOTES` for the configuration.

Both `DEBUG_MEMGUARD` and `DEBUG_REDZONE` cost memory. For a debug kernel on a development VM, both are often enabled. For a large production server, neither is.

### 34.7.15 KDB, DDB, and GDB Together

We have referenced these three options throughout this chapter. Let us pin down the distinction, because it confuses many beginners.

KDB is the kernel debugger framework. It is the plumbing. It defines entry points that the rest of the kernel calls when a panic or a break-to-debugger event happens. It also defines an interface for backends.

DDB and GDB are two such backends. DDB is the in-kernel interactive debugger. When you hit `KDB_ENTER` and DDB is the selected backend, you are dropped into an interactive prompt on the console. DDB has a small set of commands: `bt`, `show`, `print`, `break`, `step`, `continue`, and a few others. It is primitive but self-contained: no other machine is needed.

GDB is the remote backend. When you hit `KDB_ENTER` and GDB is the selected backend, the kernel waits for a remote GDB client to attach over a serial line or a network connection. The client runs on a different machine and sends commands over a protocol called the GDB remote serial protocol. This is much more flexible because you have full `gdb` on the client side, but it requires a second machine (or another VM) and a connection between the two.

In practice, you enable both backends and switch between them at run time. `sysctl debug.kdb.current_backend` names the active backend. `sysctl debug.kdb.supported_backends` lists all compiled-in backends. You can set `debug.kdb.current_backend` to `ddb` or `gdb` depending on what kind of session you want. This is a useful convenience, because the overhead of having both compiled in is negligible compared to the benefit of flexibility.

The KDB support in `GENERIC` is enough for most panics. We will use GDB in Section 7 when we talk about remote debugging.

### 34.7.16 KDB\_UNATTENDED

One more option worth mentioning is `KDB_UNATTENDED`. This causes the kernel to skip entry into the debugger on panic and go straight to the dump and reboot. In production systems without anyone watching the console, this is a sensible default; there is no point waiting indefinitely for a debugger interaction that will never come. In development, you usually want the opposite: to stay in DDB after a panic so you can investigate before the state is lost to reboot. Set this option via the `debug.debugger_on_panic` `sysctl` at runtime, or options `KDB_UNATTENDED` in a kernel config.

### 34.7.17 CTF and Debug Info Paths

One last piece of the debug environment is CTF, the Compact C Type Format. CTF is a compressed representation of type information that DTrace uses to understand kernel structures. `GENERIC` includes options

DDB\_CTF, which tells the build to generate CTF information for the kernel. On a debug kernel, CTF information lets DTrace print structure fields by name instead of hex offsets, which makes its output dramatically more useful.

You can confirm CTF is present with `ctfdump`:

```
ctfdump -t /boot/kernel/kernel | head
```

If this produces output, the kernel has CTF. If not, either the build did not include DDB\_CTF or the CTF generation tool (`ctfconvert`) was not installed. In FreeBSD 14.3 both are standard.

For modules, you need to build with `WITH_CTF=1` in your environment (or passed to `make`) to get CTF information for the module. This is what lets DTrace understand the structures your driver defines.

### 34.7.18 Confirming Your Debug Kernel

When you first boot into a debug kernel, spend a minute verifying that the options you care about are actually active. Useful sysctls:

```
sysctl debug.kdb.current_backend
debug.kdb.current_backend: ddb
sysctl debug.kdb.supported_backends
debug.kdb.supported_backends: ddb gdb
sysctl debug.debugger_on_panic
debug.debugger_on_panic: 1
sysctl debug.ddb.
debug.ddb.capture.inprogress: 0
debug.ddb.capture.bufsize: 0
...
```

If these print sensible values, your debug kernel is wired up. If `debug.kdb.supported_backends` lists only `ddb` but you expected `gdb`, something in your configuration is off. Go back and check that options `GDB` is in your kernel config or in `std.debug`.

### 34.7.19 Running on Top of the Debug Kernel

With the debug kernel running, the rest of the chapter's techniques become available. `KASSERT` actually fires. `WITNESS` actually complains about lock orders. `DDB` is there when you press the break-to-debugger sequence. Crash dumps include full debug information that `kgdb` can use to show source lines. You have moved from a kernel that trusts the driver to a kernel that actively helps you prove your driver is correct.

A small but meaningful consequence of running a debug kernel for driver development is that you will see bugs in your driver much earlier, before they reach the field, and you will have an easier time fixing them when they do appear. The discipline of always developing on a debug kernel, even when you are only writing simple code, is one of the habits that separates casual hobbyist drivers from drivers that are trustworthy enough for serious use.

With the environment set up, we can move on to the next class of tool: tracing. Unlike assertions, which catch failures, tracing records what happens so you can understand the shape of a bug even when it is not crashing. That is the topic of Section 5.

## 34.8 5. Tracing Driver Behavior: DTrace, ktrace, and ktr(9)

Assertions catch what is wrong. Tracing shows what is happening. When a driver misbehaves without crashing, or when you need to understand the precise order of events across multiple threads, tracing is usually the right tool. FreeBSD offers three complementary tracing facilities for kernel code: DTrace, `ktrace(1)`, and `ktr(9)`. Each has a different sweet spot, and a driver author should know when to reach for which.

Chapter 33 introduced DTrace as a performance measurement tool. Here we come back to it as a correctness debugging tool, because the same framework that can aggregate hot functions can also follow a bug through the kernel. We will also meet `ktr(9)`, the lightweight in-kernel tracing ring, and `ktrace(1)`, which traces system calls from user space.

### 34.8.1 DTrace for Correctness Debugging

DTrace is FreeBSD's production-grade dynamic tracing framework. It works by letting you attach small scripts to probe points throughout the kernel. A probe is a named point in the code that can be instrumented. When a probe fires, the script runs. If the script has useful things to record, it records them; if not, the probe is effectively free.

Chapter 33 used DTrace with the `profile` provider for CPU sampling. In this chapter we will use different providers for different purposes: `fbt` (function boundary tracing) to follow entry and exit from functions, `sdt` (statically defined tracing) to fire at explicitly placed probe points in our driver, and `syscall` to watch user-kernel transitions.

Let us take these in turn.

### 34.8.2 The fbt Provider

The `fbt` provider gives you a probe at every function entry and exit in the kernel. To list all `fbt` probes in our driver:

```
dtrace -l -P fbt -m bugdemo
```

Each function produces two probes, an entry and a return. You can attach actions to either. A common first step in debugging a new bug is simply to see what functions are being called:

```
dtrace -n 'fbt::bugdemo_*:entry { printf("%s\n", probefunc); }'
```

This prints every entry into any function in the `bugdemo` module, showing the order in which they are called. If you suspect a particular function is or is not being reached, this one-liner will tell you immediately.

For a deeper view, you can also record arguments. `fbt` probe arguments are the function's parameters, accessible as `arg0`, `arg1`, etc.:

```
dtrace -n 'fbt::bugdemo_ioctl:entry { printf("cmd=0x%lx\n", arg1); }'
```

Here `arg1` is the second parameter to `bugdemo_ioctl`, which is the `ioctl` command number. You can watch the stream of `ioctl` calls in real time.

Exit probes let you see return values:

```
dtrace -n 'fbt::bugdemo_ioctl:return { printf("rv=%d\n", arg1); }'
```

On a return probe, `arg1` is the return value. A stream of `rv=0` entries confirms success. A sudden `rv=22` (which is `EINVAL`) tells you the driver rejected a call. By combining entry and return probes you can match each call with its result.

### 34.8.3 SDT Probes: Statically Defined Tracing

`fbt` is flexible but gives you function boundaries, not semantic events. If you want a probe that fires at a specific point inside a function, representing a specific event, you use SDT. SDT probes are placed explicitly in the code. They cost essentially nothing when disabled and produce exactly the information you want when enabled.

In FreeBSD 14.3, SDT probes are defined using macros from `/usr/src/sys/sdt.h`. The key macros are:

```
SDT_PROVIDER_DEFINE(bugdemo);

SDT_PROBE_DEFINE2(bugdemo, , , cmd__start,
 "struct bugdemo_softc *", "int");

SDT_PROBE_DEFINE3(bugdemo, , , cmd__done,
 "struct bugdemo_softc *", "int", "int");
```

The naming convention is `provider:module:function:name`. The leading `bugdemo` is the provider. The two empty strings are the module and function, which we leave empty for a driver-level probe. The trailing name identifies the probe. The underscore-underscore convention in probe names is a DTrace idiom that becomes a dash in the user-facing name.

The numeric suffix on `SDT_PROBE_DEFINE` indicates how many arguments the probe takes. The string arguments are the C type names of those arguments, which DTrace uses for display.

To fire a probe in the driver:

```
static void
bugdemo_process(struct bugdemo_softc *sc, struct bugdemo_command *cmd)
{
```

```

 SDT_PROBE2(bugdemo, , , cmd__start, sc, cmd->op);

 /* ... actual work ... */

 SDT_PROBE3(bugdemo, , , cmd__done, sc, cmd->op, error);
}

```

SDT\_PROBE2 and SDT\_PROBE3 fire the corresponding probe with the given arguments.

Now in DTrace you can watch these probes:

```
dtrace -n 'sdt:bugdemo::cmd-start { printf("op=%d\n", arg1); }'
```

Notice the dash in cmd-start: DTrace converts the double underscore in the name to a dash in the probe spec. arg0 is the softc, arg1 is the op.

SDT probes are particularly useful for state transitions. If your driver has three states and you want to follow the sequence, define probes at each transition and aggregate on them:

```
dtrace -n 'sdt:bugdemo::state-change { @[arg1, arg2] = count(); }'
```

This counts how often each (from\_state, to\_state) pair occurs, giving a distribution of the state machine's behavior during your workload.

### 34.8.4 Following a Bug With DTrace

Consider a scenario. The bugdemo driver sometimes returns EIO to user space, but you cannot tell from user space which code path produced that error. With DTrace, you can walk backwards from the return to the origin:

```

dtrace -n '
fbt::bugdemo_ioctl:return
/arg1 == 5/
{
 stack();
}
'
```

arg1 == 5 checks for the return value 5, which is EIO. When the return matches, stack() prints the kernel stack trace at the point of the return. This tells you exactly which code path returned the error.

A more sophisticated version records the start time and duration:

```
dtrace -n '
fbt::bugdemo_ioctl:entry
{
 self->start = timestamp;
}

fbt::bugdemo_ioctl:return
/self->start != 0/
{
 @latency["bugdemo_ioctl", probefunc] = quantize(timestamp - self->start);
 self->start = 0;
}
'
```

This produces a latency distribution for the `ioctl`, which is useful when a bug manifests as unusual latency. The `self->` notation is DTrace's thread-local storage, scoped to the current thread.

These scripts are not full programs; they are small observations that you iterate on. The cycle of “add a probe, run the workload, read the output, refine the probe” is one of DTrace's strengths. A full debugging session might go through a dozen variations of a script before the shape of the bug becomes clear.

### 34.8.5 Understanding `ktrace(1)`

`ktrace(1)` is a different beast. It traces system calls made by a user-space process, along with their arguments and return values. It is not about the kernel's internal behavior; it is about the interface between user space and the kernel. When a user-space tool is using a driver and something odd happens, `ktrace(1)` is often the first tool to reach for, because it shows exactly what the process asked of the kernel.

To trace a program:

```
ktrace -t cnsi ./test_bugdemo
kdump
```

`ktrace` writes a binary trace file (`ktrace.out` by default), and `kdump` renders it as human-readable text. The `-t` flags select what to trace: `c` for system calls, `n` for `namei` (pathname lookups), `s` for signals, `i` for `ioctls`. For driver debugging, `i` is the most directly useful.

Sample output:

```
5890 test_bugdemo CALL ioctl(0x3, BUGDEMO_TRIGGER, 0x7fffffffef0c0)
5890 test_bugdemo RET ioctl 0
5890 test_bugdemo CALL read(0x3, 0x7fffffffef0d0, 0x100)
5890 test_bugdemo RET read 32/0x20
```

The process made two syscalls. An `ioctl` on file descriptor 3 with command `BUGDEMO_TRIGGER` succeeded. A read on the same fd returned 32 bytes. If the test fails, the trace tells you exactly what the kernel was asked for and what it returned.

Notice that `ktrace(1)` does not show internal kernel behavior. For that you need `DTrace` or `ktr(9)`. But `ktrace(1)` is the canonical way to see user-space interactions, and combined with `DTrace` it gives a complete picture.

`ktrace(1)` can also be attached to a running process:

```
ktrace -p PID
```

and detached:

```
ktrace -C
```

For a driver that is being used by a long-running daemon, this is more practical than restarting the daemon under `ktrace`.

### 34.8.6 `ktr(9)`: Lightweight In-Kernel Tracing

`ktr(9)` is FreeBSD's in-kernel trace ring. It is a ring buffer of trace entries that code can write to cheaply. Each entry includes a timestamp, the CPU number, the thread pointer, a format string, and up to six arguments. The ring is sized by the `KTR_ENTRIES` kernel config option, and its contents can be dumped from `DDB` or from user space.

`ktr(9)` is the right tool when you need very fine-grained information about timing or ordering, especially in an interrupt context where `printf` is too slow. Because each entry is small and writes are lock-free, `ktr(9)` can be used in hot paths without distorting the behavior you are trying to observe.

The macros are in `/usr/src/sys/sys/ktr.h`. The common ones are `CTR0` through `CTR6`, varying by how many arguments follow the format string. Each macro takes a class mask as its first argument, then the format string, then the values:

```
#include <sys/ktr.h>

static void
bugdemo_process(struct bugdemo_softc *sc, struct bugdemo_command *cmd)
{
 int error;

 CTR2(KTR_DEV, "bugdemo_process: sc=%p op=%d", sc, cmd->op);
 /* ... */
 CTR1(KTR_DEV, "bugdemo_process: done rv=%d", error);
}
```

CTR2 writes a two-argument entry to the trace ring. `KTR_DEV` is the class mask: the kernel decides at runtime whether entries for a given class are recorded, based on `debug.ktr.mask`. At compile time, `KTR_COMPILE` (the set of classes actually compiled in) controls which calls are emitted at all. Classes that are not in `KTR_COMPILE` disappear entirely, so you can leave calls in the source permanently without paying for them when the class is disabled.

The classes are defined in `/usr/src/sys/sys/ktr_class.h`. Common ones include `KTR_GEN` (general-purpose), `KTR_DEV` (device drivers), `KTR_NET` (networking), and many more. For a driver, you would typically pick `KTR_DEV` or, in larger subsystems, define a new bit alongside the existing ones.

To enable and view the trace ring:

```
sysctl debug.ktr.mask=0x4 # enable KTR_DEV (bit 0x04)
sysctl debug.ktr.entries
```

and dump it with:

```
ktrdump
```

`ktrdump(8)` reads the kernel's trace buffer through `/dev/kmem` and formats it. The output is a time-ordered list of entries with timestamps, CPUs, threads, and messages.

The beauty of `ktr(9)` is its low overhead. A trace entry is essentially a handful of memory writes. You can leave them in the code, compile them in to a debug kernel, and enable them at runtime when you need them. They are especially valuable for interrupt handler debugging, where `printf` would add milliseconds of delay and actually change the behavior being measured.

### 34.8.7 When to Use Which

With three tracing tools, the question is which to reach for first.

Use `DTrace` when the bug is about what the kernel is doing, when you need to aggregate across many events, when you need filtering, or when the probes can be placed dynamically. `DTrace` is the most capable of the three, but it requires a running kernel and a reasonable rate of probe firings.

Use `ktrace(1)` when the bug is about what user space is asking of the kernel, when the symptom is a wrong return value or a sequence of syscalls that does not match expectations. `ktrace(1)` is simple, fast, and immediately shows the kernel-user boundary.

Use `ktr(9)` when you need the lowest possible overhead, when the code you are tracing is in an interrupt handler, or when you want persistent trace points that can be turned on in production with minimal risk. `ktr(9)` is the most primitive of the three but also the most durable.

In practice, a debugging session often uses two or three. You might start with `ktrace(1)` to see the syscall sequence, then add `DTrace` probes to narrow down which driver function is misbehaving, then add `ktr(9)` entries to nail down timing in the interrupt path. Each tool answers a different question, and a full picture often requires all three.

### 34.8.8 Tracing and Production

A quick word on production. DTrace is production-safe in most configurations; its design specifically includes safeguards against infinite loops and against crashing the kernel from a bad probe. You can run DTrace on a busy production server without bringing it down. `kttr(9)` is also production-safe, with the caveat that enabling verbose classes costs CPU. `kttrace(1)` writes to a file and can grow unbounded if left unchecked; use with size limits.

Contrast these with crash dumps, DDB, and `memguard(9)`, which are development-only tools. The distinction matters because Section 7 will return to the question of what is safe to do on a production machine. For now, remember that tracing is among the lightest-touch techniques we have, and that is why it is often the right first step when diagnosing a live problem.

With tracing in hand, we can turn to the bugs that tracing and assertions tend to miss: memory bugs that corrupt state without producing clear symptoms until much later. That is the domain of Section 6.

## 34.9 6. Hunting Memory Leaks and Invalid Memory Accesses

Memory bugs are the most treacherous bugs a driver author faces. They are rarely visible at the moment they happen. They corrupt state quietly, accumulate across many runs, and manifest much later in ways that seem completely unrelated to the original defect. A use-after-free might surface as a corrupted structure in a different subsystem. A buffer overrun might overwrite the next allocation and show up as a bogus field value several minutes later. A small leak might drain memory over days until the kernel finally refuses an allocation and the system locks up.

FreeBSD provides a family of tools for these bugs: `memguard(9)` for use-after-free and modify-after-free detection, `redzone` for buffer overruns, guard pages in the VM layer, and `sysctls` that expose the state of the kernel memory allocator. Used together, they can transform a class of bug that was nearly impossible to find into a class that crashes immediately at the moment of misuse.

### 34.9.1 Understanding the Kernel Memory Allocator

To use these tools effectively we need a rough mental model of how the kernel allocates memory. FreeBSD has two primary allocators, both in `/usr/src/sys/kern/`:

`kern_malloc.c` implements `malloc(9)`, the general-purpose allocator. It is a thin wrapper over UMA, the Universal Memory Allocator, with accounting by `malloc` type. Every allocation is charged to a `struct malloc_type` (commonly declared with `MALLOC_DEFINE(9)`), which lets the kernel track how much memory each subsystem has used.

`subr_vmem.c` and `uma_core.c` implement the lower layers. UMA is a slab allocator: it maintains per-CPU caches and central slabs, so most allocations are very fast and contention-free. When a driver calls `malloc(9)` or `uma_zalloc(9)`, what actually happens depends on size, zone configuration, and cache state.

For debugging, the practical consequence is that a corrupted allocation might look different depending on where it landed. The same bug can produce different symptoms on different kernels or under different loads, simply because the underlying memory layout differs.

### 34.9.2 sysctl vm and kern.malloc: Observing Allocation State

Before reaching for memory debuggers, a useful first step is to look at the live state of the allocator. Two sysctls are particularly useful:

```
sysctl vm.uma
sysctl kern.malloc
```

The first dumps per-zone statistics for UMA: how many items are allocated, how many are free, how many failures have occurred, and how many pages each zone is using. The output is long, but it is text-searchable. If you suspect a leak in a particular driver type, find its zone in the output and watch it grow.

The second dumps per-type statistics for malloc(9). Each entry shows the type name, the number of requests, the amount allocated, and the high-water mark. Running the driver under a workload and comparing before and after is a simple leak-detection technique that requires no special tooling:

```
sysctl kern.malloc | grep bugdemo
bugdemo:
 inuse = 0
 memuse = 0K
```

Run a workload, re-query, and compare. If inuse rises and does not fall after the workload finishes, something is leaking.

The related vmstat(8) command has a -m flag that presents the same malloc(9) state in a more compact form:

```
vmstat -m | head
 Type InUse MemUse HighUse Requests Size(s)
 acl 0 0K - 0 16,32,64,128,256,1024
 amd6 4 64K - 4 16384
 bpf_i 0 0K - 2
 ...
```

For ongoing monitoring during a workload:

```
vmstat -m | grep -E 'bugdemo|Type'
```

gives you a periodic snapshot of a single type's footprint.

### 34.9.3 memguard(9): Hunting Use-After-Free

memguard(9) is a special allocator that can replace malloc(9) for a specific type. The idea is simple: instead of returning a piece of memory from a slab, it returns memory backed by dedicated pages. When the memory

is freed, the pages are not returned to the pool; they are unmapped, so any subsequent access faults. And the pages around the allocation are left inaccessible, so any read or write past the end of the allocation also faults. This turns use-after-free, buffer overrun, and buffer underrun bugs from silent corruptors into immediate panics with a backtrace that points directly at the misuse.

The cost is that each allocation now costs at least one full page of virtual memory (plus management overhead), and every free burns an unmapped page. For that reason, `memguard(9)` is typically turned on for a single malloc type at a time, not for everything.

The configuration involves two steps. First, the kernel must be built with options `DEBUG_MEMGUARD`, which `std.debug` does not enable by default. You add it to your kernel config:

```
include "std.debug"
options DEBUG_MEMGUARD
```

and rebuild.

Second, at runtime you tell `memguard` which malloc type to guard:

```
sysctl vm.memguard.desc=bugdemo
```

From that moment on, every allocation of type `bugdemo` goes through `memguard`. Note the type string matches the name passed to `MALLOC_DEFINE(9)` in the driver source. Typos here silently do nothing.

You can also use `vm.memguard.desc=*` to guard everything, but as noted, this is expensive. For a targeted bug hunt, guard only the type you suspect.

#### 34.9.4 A memguard Session in Action

Imagine `bugdemo` has a use-after-free bug: the driver frees a buffer when its `ioctl` completes, but then an interrupt handler reads from the same buffer a moment later. Without `memguard`, the read usually succeeds because the slab allocator has not yet reused the memory, or it returns some unrelated data that happens to have replaced the buffer. The driver gets plausible-but-wrong output, which corrupts some later state, which manifests much later as a subtle bug.

With `memguard` enabled for the driver's malloc type, the same sequence of events fires a page fault the instant the interrupt handler dereferences the freed pointer. The fault produces a panic with a backtrace through the interrupt handler. The panic message identifies the faulting address as inside a `memguard` region, and `kgdb` on the dump shows you exactly which function dereferenced the freed memory.

Compare that to the days of detective work the bug would have demanded without `memguard`, and you understand why this tool is so valuable.

#### 34.9.5 redzone: Buffer Overrun Detection

`memguard` is heavyweight. For the narrower case of buffer overruns and underruns, FreeBSD offers `DEBUG_REDZONE`, a lighter debugger that adds a few guard bytes before and after each allocation. When the allocation is freed, the guard bytes are checked. If they have been modified, `redzone` reports the corruption, including the stack at the time of allocation.

DEBUG\_REDZONE is added to the kernel config:

```
options DEBUG_REDZONE
```

Unlike memguard, it is always active once compiled in, and it applies to all allocations. Its overhead is memory, not time: each allocation grows by a few bytes.

redzone does not catch use-after-free, because the memory it guards is still within the original allocation. It does catch writes that step past the intended buffer, which is a common class of bug in drivers that compute offsets from user-provided sizes.

### 34.9.6 Guard Pages in the VM Layer

A third mechanism, available independently of memguard and redzone, is the use of guard pages around critical kernel allocations. The VM system supports allocating a memory region with inaccessible pages placed before and after it. Kernel thread stacks use this mechanism: the page below each stack is unmapped, so a runaway recursion faults instead of overwriting the adjacent allocation.

Drivers that allocate stack-like objects can use `kmem_malloc(9)` with the right flags, or can set up guard pages manually through `vm_map_find(9)`. In practice, driver code rarely does this directly; the mechanism is more commonly used by subsystems that manage their own memory regions. But it is useful to know that the capability is there, because you may see it in kernel messages and want to understand what it means.

### 34.9.7 Leak Detection in Practice

Leaks are the quietest class of memory bug. They produce no crashes, no faults, no assertions. The only symptom is that memory usage grows over time. FreeBSD gives you a few tools for finding them.

The first, as we saw, is `kern.malloc`. Snapshot before, run the workload, snapshot after, and look for types whose `inuse` grew and did not shrink. This is crude but effective for driver leaks.

The second is to add counters to your driver. If every allocation bumps a counter (9) and every free decrements it, a lingering positive value at unload time tells you the driver leaked something. A companion `sysctl` exposes the counter for inspection:

```
static counter_u64_t bugdemo_inflight;

/* in attach: */
bugdemo_inflight = counter_u64_alloc(M_WAITOK);

/* in allocation path: */
counter_u64_add(bugdemo_inflight, 1);

/* in free path: */
counter_u64_add(bugdemo_inflight, -1);
```

```
/* in unload: */
KASSERT(counter_u64_fetch(bugdemo_inflight) == 0,
 ("bugdemo: %ld buffers leaked at unload",
 (long)counter_u64_fetch(bugdemo_inflight)));
```

This idiom, counting inflight allocations explicitly, is useful in any subsystem that owns a pool of objects. The assertion at unload time fires if anything leaked, giving you an immediate report at the moment you notice the leak, not hours later.

The third tool is DTrace. If you know which malloc type is leaking but not why, a DTrace script can track every allocation and every free, accumulating the difference per stack trace:

```
dtrace -n '
fbt::malloc:entry
/arg1 == (uint64_t)&M_BUGDEMO/
{
 @allocs[stack()] = count();
}

fbt::free:entry
/arg1 == (uint64_t)&M_BUGDEMO/
{
 @frees[stack()] = count();
}
'
```

After a workload, comparing the two aggregations often reveals a code path that allocates but never frees. The stack traces point you directly to the offending call sites.

### 34.9.8 When Memory Bugs Hide

Sometimes memory bugs do not match any of these patterns. The symptom is a panic in an unrelated subsystem, with a backtrace that seems impossible. The driver looks fine on review; its allocations and frees appear balanced. Yet the kernel keeps crashing with messages about corrupt lists or invalid pointers.

The usual cause in these cases is that the driver writes past the end of a buffer into the next allocation. The next allocation belongs to someone else; your overrun silently corrupts that other subsystem's data. The crash happens when the other subsystem next touches its corrupted data, which might be soon or might be much later.

For this class of bug, the diagnostic is to enable `DEBUG_REDZONE` and watch for warnings. When redzone reports that guard bytes have been modified, the stack trace it prints for the allocation is the allocation in question, and the code that overran it is the code that was writing into that allocation. redzone's report tells you both ends of the bug.

Another trick is to enable `MALLOC_DEBUG_MAXZONES=N` with a large `N`. This spreads allocations across more zones, so a driver's allocations are less likely to share a zone with unrelated subsystems. If the symptom disappears or changes with more zones, it is a strong hint that the bug involves cross-zone corruption.

### 34.9.9 Working With DDB on Memory Bugs

When the kernel panics on a memory bug, entering DDB can help narrow down the cause. Useful DDB commands include:

- `show malloc` dumps `malloc(9)` state.
- `show uma` dumps UMA zone state.
- `show vmockk` runs a consistency check on the VM object tree.
- `show allpcpu` shows per-CPU state.

These commands produce output that helps correlate a crash with the state of the allocators at the moment of the crash. They do not replace `kgdb` analysis, but they can be faster to consult when you are already in DDB.

#### 34.9.10 Reality Check on Memory Debuggers

`memguard`, `redzone`, and their relatives are effective. They are also disruptive. They change allocator behavior, they slow the kernel down, and some of them consume memory aggressively. Leaving them on in production is not a good idea.

The right use is targeted. When a bug presents, enable the appropriate debugger, reproduce the bug, capture the evidence, and then turn the debugger off. Most of your driver development happens on a kernel with `INVARIANTS` and `WITNESS` but without `DEBUG_MEMGUARD`. `DEBUG_MEMGUARD` comes out when you are actively chasing a memory bug and goes away when you are done.

One last consideration. Some memory debuggers, notably `memguard`, change the observable behavior of the allocator in ways that can mask bugs. If a driver depends on two allocations being adjacent in memory (which it never should, but sometimes does as an accidental invariant), `memguard` will break that dependency and make the bug go away. This does not mean the bug is fixed; it means the bug is now latent. Always re-test without `memguard` after a fix, to make sure the fix is real and not an artifact of the debugger's presence.

#### 34.9.11 Wrapping Up the Memory Section

Memory bugs are the quiet killers of driver code. The patience to find them is built on a small, focused set of tools. `memguard(9)` catches use-after-free and buffer overrun directly. `redzone` catches overruns with less overhead. The `kern.malloc` and `UMA` sysctls expose the allocator state that normal code cannot see. And the discipline of counting inflight allocations in your own driver catches leaks at unload time. Put these together, and a class of bug that used to take days to find can be made to announce itself in minutes.

With the major technical tools now covered, we turn to the discipline of using them safely, particularly on systems where other people are watching. That is the content of Section 7.

## 34.10 7. Safe Debugging Practices

Every tool we have learned in this chapter has a cost, and every cost has a context in which it is acceptable. A debug kernel on a development VM is a small price for catching bugs early. The same debug kernel on a production server is a disaster in slow motion. Knowing which tools to reach for in which context is part of what separates a competent driver author from a dangerous one.

This section collects the practices that keep you out of trouble: the conventions for using each tool safely, the signs that you are about to make a mistake, and the mindset that helps you work with discipline when the stakes are high.

### 34.10.1 The Development vs Production Divide

The most important distinction in safe debugging is between a development system, where you can crash the kernel freely, and a production system, where you cannot.

On a development system, everything in this chapter is fair game. Deliberately trigger panics. Enable `DEBUG_MEMGUARD`. Load and unload the driver repeatedly. Attach `kgdb` to the live kernel. Run DTrace scripts that collect megabytes of data. The worst that can happen is that you reboot the VM, which is measured in seconds.

On a production system, the opposite posture applies. You do not enable debug options unless you have a specific, targeted reason. You do not load experimental drivers. You do not run DTrace scripts that might destabilize the probe framework. You do not break into DDB on a live system. Every intervention is preceded by a clear answer to “what do I do if this goes wrong?”

The discipline of keeping these two environments separate is the single most effective way to avoid accidentally breaking production. Have a development VM, keep the production kernel on a different partition, and never confuse the two.

### 34.10.2 What Is Safe in Production

A surprising amount of the debugging toolkit is actually safe in production, if used carefully. Here is a partial list.

DTrace scripts are generally safe in production. The DTrace framework is specifically designed with safety guarantees: probe actions cannot loop indefinitely, cannot allocate arbitrary memory, and cannot dereference arbitrary pointers without falling into a well-defined recovery path. You can run DTrace aggregations on a busy server without bringing it down. The caveats are that very high-frequency probes can consume significant CPU (a probe on every packet in a network driver is unlikely to be free), and that DTrace output can fill filesystem space if not rate-limited.

`ktrace(1)` on a specific process is safe, though it writes to a file that grows unbounded. Set a size limit or watch the file.

`ktr(9)` is safe if the relevant classes are already compiled in. Enabling a class through `sysctl debug.ktr.mask=` is safe. Compiling in a new class requires a kernel rebuild, which is a development activity.

Reading `sysctl` is always safe. `kern.malloc`, `vm.uma`, `hw.ncpu`, `debug.kdb.*`, and all the others expose state without changing anything. A production system with a sick driver can be interrogated extensively through `sysctl` alone.

### 34.10.3 What Is Unsafe in Production

A shorter list, but an important one.

Panics are unsafe. Deliberately crashing a production server is only acceptable as a last resort when the server is already irrecoverably damaged and a dump is the best path to understanding the cause. `sysctl debug.kdb.panic=1` triggers an immediate panic and dump. Do not do this lightly.

Breaking into DDB on a production console is unsafe. The entire kernel stops while you are in DDB. User processes freeze. Network connections time out. Real-time work halts. Unless the alternative is worse (often the case during a catastrophic crash), stay out of DDB on production.

`DEBUG_MEMGUARD` on all allocation types is unsafe. Memory use balloons. Performance drops sharply. Memory-intensive workloads may fail outright. If you absolutely must use `memguard` in production, scope it to one `malloc` type at a time and monitor memory use.

Loadable kernel modules are a risk. Loading or unloading a module touches kernel state. A buggy module can crash the kernel at load time, unload time, or any time in between. On production, load only modules that have been tested in the development environment against the same kernel.

Overly aggressive DTrace scripts can destabilize the system. Aggregations that record stack traces produce memory pressure. Probes with side effects can interact with the workload in unexpected ways. Run DTrace scripts with explicit time limits and review the aggregations carefully before leaving them running.

### 34.10.4 Capturing Evidence on Production Systems

When something goes wrong in production and the bug is rare or difficult to reproduce in development, the challenge is to capture enough evidence to diagnose the problem, without destabilizing the running service. Several strategies help.

First, start with passive observation. `sysctl`, `vmstat -m`, `netstat -m`, `dmesg`, and the various `-s` system statistics commands can be run while the system is live and cost almost nothing. If the bug produces symptoms visible in these reports, capture the reports periodically.

Second, use DTrace with strict bounds. A script that runs for sixty seconds and exits produces a snapshot without leaving a standing risk. Aggregations are particularly well suited to this style: they collect statistics over a window, print them, and stop.

Third, if a crash dump is needed and the system has not yet crashed, the safest approach is to wait for the crash. Modern dump mechanisms are designed to capture the kernel state at the moment of panic; a dump triggered manually is useful only when you know the system is already irrecoverable.

Fourth, when a crash does happen, work on the dump, not the live system. A reboot into a fresh kernel restores service, while the dump remains available for offline analysis at leisure. The discipline of “reboot fast, analyze later” is often the right trade-off on production hardware.

### 34.10.5 Using log(9) Over printf for Diagnostics

Throughout the chapter we have used `printf` as a shorthand for kernel-side logging, which is how it is commonly presented in textbooks. On a production system you should prefer `log(9)`, which writes through the `syslogd(8)` facility rather than directly to the console. The reasons are practical: console output is unbuffered and slow, `log(9)` is rate-limited and buffered, and `log(9)` ends up in `/var/log/messages` where it is available to log-analysis tools.

The API is in `/usr/src/sys/sys/syslog.h` and `/usr/src/sys/kern/subr_prf.c`. Usage:

```
#include <sys/syslog.h>

log(LOG_WARNING, "bugdemo: unexpected state %d\n", sc->state);
```

The priority level (`LOG_DEBUG`, `LOG_INFO`, `LOG_NOTICE`, `LOG_WARNING`, `LOG_ERR`, `LOG_CRIT`, `LOG_ALERT`, `LOG_EMERG`) lets `syslogd` route messages differently.

A common extension is rate-limited logging, so a sick driver does not flood `/var/log/messages` with millions of entries per second. FreeBSD provides the `ratecheck(9)` primitive that you can wrap around your own `log` calls:

```
#include <sys/time.h>

static struct timeval lastlog;
static struct timeval interval = { 5, 0 }; /* 5 seconds */

if (ratecheck(&lastlog, &interval))
 log(LOG_WARNING, "bugdemo: error (rate-limited)\n");
```

`ratecheck(9)` returns nonzero once per interval, suppressing repeated logs in between. The technique is essential for any driver that might observe the same error repeatedly.

### 34.10.6 Do Not Mix Debug and Release Kernels in One Fleet

A subtle trap is to run a mix of debug and release kernels in a production fleet. The intuition is that debug kernels give you better diagnostics if a bug appears. The reality is that a debug kernel performs noticeably worse than a release kernel, has different memory usage, and can exhibit different timing. If a bug is sensitive to those factors (and many concurrency bugs are), running mixed kernels guarantees that your reproduction environment does not match your production environment.

The right approach is uniform: either the whole fleet runs release kernels (and you debug on development hardware), or the whole fleet runs debug kernels (and you accept the overhead). Mixed deployments are a third option only for very controlled experiments.

### 34.10.7 Working With a Recovery Plan

Before running any risky debugging action, know your recovery plan. If the system hangs, how will you recover? Is there an IPMI interface that can issue a hardware reset? Is there a second administrator who can cycle the power if needed? How much data loss is acceptable?

A good recovery plan is two steps. First, get the system back up quickly. Second, capture the evidence (dump, logs) for offline analysis. These two steps often involve different people or different timescales, and thinking through both in advance prevents panic in the moment.

### 34.10.8 Keep a Debug Journal

When debugging a hard bug, a written record is invaluable. Each entry should include:

- What hypothesis you were testing.
- What action you took.
- What result you observed.
- What the result rules in or out.

This sounds pedantic but is genuinely useful. A long debugging session involves dozens of micro-hypotheses, and losing track of which ones you have tested wastes enormous time. The written record also helps when you come back to the bug after a weekend, or when you hand it off to a colleague.

For a driver bug that goes across multiple systems, a shared record (bug tracker, wiki, or an internal ticket) is even more valuable. Each person who touches the bug can see what the others have already tried, and no one reruns the same experiment twice.

### 34.10.9 Practicing on Your Own Drivers

One habit that pays off over time is to keep a deliberately buggy version of your driver around for practice. Every time you find an interesting bug in real work, add a variant of it to your practice driver. Then, periodically, run through the practice driver with fresh eyes and make sure you can still find the bugs using the tools of this chapter. This builds muscle memory that is invaluable when a real bug appears under time pressure.

The bugdemo driver we have been using throughout this chapter is one starting point for such a practice driver. Fork it, add your own bugs, and use it to stay sharp.

### 34.10.10 Knowing When to Stop

A final piece of safe debugging wisdom is knowing when to stop. Not every bug needs to be hunted to the last instruction. If a bug is rare, has a workaround, and the cost of finding its root cause is measured in days, there is sometimes a case for documenting the workaround and moving on. This is a judgment call, not a rule, but the ability to make the call is part of professional maturity.

The opposite mistake (declaring victory too early, accepting a surface fix that does not address the underlying defect) is also common. The symptom is a bug that keeps coming back in new forms. When a “fix” does not produce a stable result, something deeper is wrong, and more investigation is called for.

Between these extremes is the healthy zone where you invest time proportional to the importance of the bug. Kernel development rewards patience, but it also rewards pragmatism. The tools of this chapter exist to make the investment efficient, not to make every bug a multi-day research project.

With safe practices established, we can turn to the last major topic of the chapter: what to do after a debugging session that found something serious, and how to make the driver more resilient against the next time something similar goes wrong.

## 34.11 8. Refactoring After a Debugging Session: Recovery and Resilience

A hard-won debugging victory is not the end of the work. Finding the bug is finding evidence. The real question is: what does the evidence tell us about the driver, and how should the driver change in response?

A common failure mode is to patch the immediate symptom and move on. The patch makes the test pass, the crash stop, the corruption vanish. But the underlying weakness that allowed the bug in the first place is still there, lurking. The next subtle change in surrounding code, or the next new environment, finds the same weakness and produces the next bug.

This section is about resisting that failure mode. We will walk through a small set of techniques for using a debugging result to strengthen the driver, not just to fix the particular bug.

### 34.11.1 Reading the Bug as a Message

Every bug carries a message about the design. A use-after-free says “the driver’s ownership model for this buffer is unclear.” A deadlock says “the driver’s lock order is not explicitly documented or enforced.” A memory leak says “the driver’s lifecycle for this object is incomplete.” A panic in `attach` says “the driver’s error recovery during initialization is weak.” A race condition says “the driver’s assumptions about thread context are not strict enough.”

When you find a bug, spend a few minutes asking what the bug is telling you about the design. The specific defect is usually a symptom of a broader pattern, and understanding the pattern makes future bugs easier to prevent.

### 34.11.2 Strengthening Invariants

One concrete response to a bug is to add assertions that would have caught it sooner. If a use-after-free was the bug, add a `KASSERT` somewhere in the path that confirms the buffer is still valid when used. If a lock order was violated, add a `mtx_assert(9)` at the point where the violation occurred. If a structure field was corrupted, add a `CTASSERT` on its alignment or a runtime check on its value.

The goal is not to duplicate every check with an assertion, but to convert each bug into one or two new invariants that make the same class of bug impossible in the future. Over time, the driver accumulates a set of defensive checks that reflect its actual behavior, documented in code rather than in your head.

### 34.11.3 Documenting the Ownership Model

Another common response is to clarify documentation. Many bugs arise because ownership of a resource (who allocated it, who is responsible for freeing it, when is it safe to access) is implicit. Writing a few lines of comment that explicitly state the ownership rules makes the rules visible to the next reader, and often forces you to confront cases where the rules were not actually consistent.

For example, a comment like:

```
/*
 * bugdemo_buffer is owned by the softc from attach until detach.
 * It may be accessed from any thread that holds sc->sc_lock.
 * It must not be accessed in interrupt context because the lock
 * is a regular mutex, not a spin mutex.
 */
struct bugdemo_buffer *sc_buffer;
```

This comment is not decorative. It is a statement of the invariants that the driver will enforce. If a future bug violates the invariants, the comment is a reference point for understanding what went wrong.

### 34.11.4 Narrowing the API Surface

A third response is to narrow the API. If the bug was caused because a function was called in a context where it should not have been, can the function be made private, so that it is only called from contexts where it is safe? If a state was reached through a path that should not have existed, can the state be made unreachable?

The principle is that every external entry point into a driver is a surface for bugs. Reducing the surface, by making functions internal, by hiding state behind accessors, by combining related operations into atomic transactions, makes the driver harder to misuse.

This is not about ideological minimalism. It is about recognizing that surface area is proportional to bug risk, and that many bugs can be prevented by the simple expedient of not exposing the thing that was misused.

### 34.11.5 Hardening the Unload Path

Unload is a frequently underhardened path in drivers. The attach path is usually well tested; the unload path is usually not. This is a major source of bugs: a driver that works perfectly in long-running use might crash on `kldunload`.

A good unload path satisfies several invariants. Every object allocated in attach is freed. Every thread spawned by the driver has exited. Every timer is cancelled. Every callout is drained. Every taskqueue has finished its pending work. Every device node is destroyed before the memory that supports it is freed.

After a bug in an unload path, audit the entire unload function against this checklist. Each item is an invariant that the driver should maintain, and violations are common.

### 34.11.6 The Shape of a Resilient Driver

Putting these habits together, what does a resilient driver look like? A few traits stand out.

Its locking is explicit. Every shared data structure is protected by a named lock, and every function that accesses the structure has either an assertion that the lock is held or a documented reason why the lock is not needed. Lock orders are documented in comments at each site of multi-lock acquisition. WITNESS produces no warnings during normal operation.

Its error handling is complete. Every allocation has a corresponding free. Every attach has a complete detach. Every path through the code cleans up after itself on failure. Partial states do not linger. The driver does not get stuck in half-initialized or half-torn-down states.

Its invariants are expressed in code. Preconditions are checked with KASSERT at function entry. Structural invariants are checked with CTASSERT at compile time. State transitions are verified with explicit checks.

Its observability is built in. Counters expose allocation and error rates. SDT probes fire at key events. Sysctls expose enough state that an operator can inspect the driver without a debugger. The driver tells you what it is doing.

Its error messages are useful. `log(9)` messages include the subsystem name, the specific error, and enough context to locate the problem. They are rate-limited. They do not log spurious warnings that train the operator to ignore them.

These traits are not free. They take time to implement and discipline to maintain. But once a driver has them, the cost of future bugs drops dramatically, because bugs are caught earlier, diagnosed more easily, and fixed more definitively.

### 34.11.7 Revisiting the bugdemo Driver

By the end of the chapter's labs, we will have applied many of these ideas to the bugdemo driver. What starts out as a handful of deliberately broken code paths grows, through iteration, into a driver with assertions at every key point, counters on every operation, SDT probes on every interesting event, and an unload path that passes scrutiny. The trajectory is deliberately designed to mirror the trajectory of a real driver as it matures.

### 34.11.8 Closing the Refactoring Loop

A last thought on refactoring. Every time you modify a driver in response to a bug, you are taking a small risk that the modification introduces a new bug. This risk is unavoidable but manageable. A few practices help.

First, isolate the change. Make the smallest modification that addresses the root cause, and commit it separately from cosmetic changes. If something regresses, the blame is easy to assign.

Second, add a test. If the bug was triggered by a specific sequence of ioctls, add a small test program that runs that sequence and verifies the correct result. Keep the test in your repository. A test suite that grows with each bug becomes an asset over years.

Third, run the existing tests. If the driver has any automated tests at all, run them after a fix. Surprisingly many regressions are caught this way, even with a small test suite.

Fourth, note the lesson. In your debug journal or commit message, write a brief note about what the bug revealed about the driver's design. The note is a gift to your future self, who will encounter similar patterns.

With these habits in place, debugging becomes a cycle of discovery rather than a string of firefights. Each bug teaches something, each lesson strengthens the driver, and each strengthened driver becomes easier to work with. The tools of this chapter are the means by which that cycle turns.

With the conceptual material behind us, we can move into the hands-on lab section, where we will apply every technique in the chapter to the bugdemo driver and see each one produce a concrete result.

## 34.12 Hands-on Labs

Each lab in this section is self-contained but builds on the previous ones. They use the bugdemo driver, whose companion source is under `examples/part-07/ch34-advanced-debugging/`.

Before starting, make sure you have a development FreeBSD 14.3 VM where you can crash the kernel safely, a copy of the FreeBSD source tree at `/usr/src/`, and the ability to attach a serial or virtual console that preserves output across a reboot.

### 34.12.1 Lab 1: Adding Assertions to bugdemo

In this lab we build the first version of bugdemo and add assertions that catch internal inconsistencies. The goal is to see KASSERT, MPASS, and CTASSERT working in practice.

#### Step 1: Build and load the baseline driver.

The baseline driver lives at `examples/part-07/ch34-advanced-debugging/lab01-kassert/`. It is a minimal pseudo-device with a single ioctl that triggers a bug when instructed to. From the lab directory:

```
$ make
$ sudo kldload ./bugdemo.ko
$ ls -l /dev/bugdemo
```

If the device node appears, the driver loaded correctly.

#### Step 2: Run the test tool to confirm the driver works.

The lab also contains a small user-space program, `bugdemo_test`, that opens the device and issues ioctls:

```
$./bugdemo_test hello
$./bugdemo_test noop
```

Both should return success. Without any bugs triggered, the driver behaves correctly.

#### Step 3: Inspect the assertions in the source.

Open `bugdemo.c` and find the function `bugdemo_process`. You will see something like this:

```
static void
bugdemo_process(struct bugdemo_softc *sc, struct bugdemo_command *cmd)
{
 KASSERT(sc != NULL, ("bugdemo: softc missing"));
 KASSERT(cmd != NULL, ("bugdemo: cmd missing"));
 KASSERT(cmd->op < BUGDEMO_OP_MAX,
 ("bugdemo: op %u out of range", cmd->op));
 MPASS(sc->state == BUGDEMO_STATE_READY);
 /* ... */
}
```

Each assertion documents an invariant. If any of them fires, the kernel panics with a message identifying the broken invariant.

#### Step 4: Trigger an assertion.

The driver has an ioctl called `BUGDEMO_FORCE_BAD_OP` that intentionally sets `cmd->op` to an out-of-range value before calling `bugdemo_process`:

```
$./bugdemo_test force-bad-op
```

With a debug kernel, this produces an immediate panic:

```
panic: bugdemo: op 255 out of range
```

and the system reboots. On a release kernel (no `INVARIANTS`), the `KASSERT` is compiled out and the driver continues on with an out-of-range value. The difference is exactly the value of having a debug kernel during development.

#### Step 5: Confirm the assertion fires on the right line.

After the reboot, if a dump was captured, open it with `kgdb`:

```
kgdb /boot/kernel/kernel /var/crash/vmcore.last
(kgdb) bt
```

The backtrace will show `bugdemo_process`, and frame `N` to that entry will show the assertion line. This is the end-to-end chain: assertion fires, kernel panics, dump captures state, `kgdb` identifies the code.

#### Step 6: Add your own assertion.

Modify the driver to add an assertion that a counter is nonzero in a specific code path. Rebuild, reload, and trigger a case that makes the counter zero. Observe that your assertion fires as expected.

**What this lab teaches.** The `KASSERT` macro is a live check, not a theoretical one. It fires, it panics, it identifies the code. The discipline of adding assertions is backed by a discipline of testing that they fire when they should.

### 34.12.2 Lab 2: Capturing and Analyzing a Panic With kgdb

In this lab we focus on the post-mortem workflow. Starting from a clean debug kernel, we trigger a panic, capture the dump, and walk through it with kgdb.

#### Step 1: Confirm the dump device is configured.

On the VM, run:

```
dumpon -l
```

If the output shows a device path (typically the swap partition), you are ready. If not, configure one:

```
dumpon /dev/ada0p3 # replace with your swap partition
echo 'dumpdev="/dev/ada0p3"' >> /etc/rc.conf
```

#### Step 2: Confirm the debug kernel is running.

```
uname -v
sysctl debug.debugger_on_panic
```

`debug.debugger_on_panic` should be 0 or 1 depending on whether you want to pause at the debugger before the dump. For automated lab work, 0 is easier; for interactive exploration, 1 is educational.

```
sysctl debug.debugger_on_panic=0
```

#### Step 3: Load bugdemo and trigger a panic.

```
kldload ./bugdemo.ko
./bugdemo_test null-softc
panic: bugdemo: softc missing
Dumping ...
Rebooting ...
```

The panic message, the dump notice, and the reboot all appear on the console. Dump writing takes a few seconds on a VM with virtual disk.

#### Step 4: After the reboot, inspect the saved dump.

```
ls /var/crash/
bounds info.0 info.last minfree vmcore.0 vmcore.last
cat /var/crash/info.0
```

The `info.0` file summarizes the panic: the kernel version, the message, and the initial backtrace captured before dumping.

#### Step 5: Open the dump in kgdb.

```
kgdb /boot/kernel/kernel /var/crash/vmcore.0
```

kgdb automatically runs a backtrace. Identify the frame that is inside `bugdemo_ioctl` or `bugdemo_process`. Switch to it:

```
(kgdb) frame 5
(kgdb) list
(kgdb) info locals
(kgdb) print sc
```

Observe that `sc` is `NULL`, confirming the panic message.

#### Step 6: Explore adjacent state.

From kgdb, examine the process that triggered the panic:

```
(kgdb) info threads
(kgdb) thread N # where N is the panicking thread
(kgdb) proc # driver-specific helper for process state
```

`proc` is a kernel-specific command that prints the current process. Between these commands and `bt`, you can build a full picture of the panic's context.

#### Step 7: Exit kgdb.

```
(kgdb) quit
```

The dump remains on disk; you can reopen it anytime.

**What this lab teaches.** The full cycle of panic, dump, and offline analysis is routine, not mysterious. A development VM should be able to complete this cycle in under a minute. The discipline is to practice it before the first real bug, so that when you need it you are not learning the tool in a hurry.

### 34.12.3 Lab 3: Building GENERIC-DEBUG and Confirming Options Active

This lab is about kernel configuration rather than code. The aim is to walk through the full process of building, installing, and validating a debug kernel.

#### Step 1: Start from a fresh `/usr/src/`.

If you have a source tree, update it. If not, install one with:

```
git clone --depth 1 -b releng/14.3 https://git.freebsd.org/src.git /usr/src
```

#### Step 2: Review the existing **GENERIC-DEBUG** config.

```
$ ls /usr/src/sys/amd64/conf/GENERIC*
$ cat /usr/src/sys/amd64/conf/GENERIC-DEBUG
```

Observe that it is only two lines: `include GENERIC` and `include "std.debug"`. Review `std.debug` next:

```
$ cat /usr/src/sys/conf/std.debug
```

Confirm the options we discussed: `INVARIANTS`, `INVARIANT_SUPPORT`, `WITNESS`, and friends.

### Step 3: Build the kernel.

```
cd /usr/src
make buildkernel KERNCONF=GENERIC-DEBUG
```

On a modest VM this takes twenty to forty minutes. The build produces detailed output; if it stops with an error, investigate and retry.

### Step 4: Install the kernel.

```
make installkernel KERNCONF=GENERIC-DEBUG
ls -l /boot/kernel/kernel /boot/kernel.old/kernel
```

The previous kernel is preserved in `/boot/kernel.old/` as a recovery option.

### Step 5: Reboot into the new kernel.

```
shutdown -r now
```

After reboot, confirm:

```
$ uname -v
$ sysctl debug.kdb.current_backend
$ sysctl debug.kdb.supported_backends
```

The backend should list both `ddb` and `gdb`.

### Step 6: Confirm `INVARIANTS` is active.

Build and load the `lab01 bugdemo.ko`, then trigger the out-of-range op as in Lab 1. On a debug kernel, the panic fires. On a release kernel, it does not. This round-trip confirms that `INVARIANTS` is genuinely compiled in.

### Step 7: Confirm `WITNESS` is active.

The `lab03` variant of `bugdemo` has a deliberate lock order inversion, triggered by a specific `ioctl`. Load it, run the triggering test, and watch for a `WITNESS` warning on the console:

```
lock_order_reversal:
```

```
...
```

No panic is produced, just a warning. This is the expected behavior: WITNESS detects potential deadlocks and reports them, without forcing a system failure.

#### Step 8: Recover if the new kernel does not boot.

If your new kernel fails to boot for any reason, the FreeBSD boot loader offers a recovery option. From the loader menu, select “Boot Kernel” and then “kernel.old”. Your previous kernel boots, and you can investigate the debug kernel’s failure at leisure.

**What this lab teaches.** Building a debug kernel is not a mysterious operation. It is a rebuild with different options and a reboot. The hazards are predictable: long build times, large binaries, and the need to keep the previous kernel available as a fallback.

### 34.12.4 Lab 4: Tracing bugdemo With DTrace and ktrace

This lab exercises the three tracing tools we studied: DTrace fbt probes, DTrace SDT probes, and ktrace(1).

#### Step 1: Load a bugdemo variant with SDT probes.

The lab04-tracing variant of bugdemo defines SDT probes at key points:

```
SDT_PROVIDER_DEFINE(bugdemo);
SDT_PROBE_DEFINE2(bugdemo, , , cmd__start, "struct bugdemo_softc **", "int");
SDT_PROBE_DEFINE3(bugdemo, , , cmd__done, "struct bugdemo_softc **", "int", "int");
```

Load it:

```
kldload ./bugdemo.ko
```

#### Step 2: List the probes.

```
dtrace -l -P sdt -n 'bugdemo:::*
```

You should see the cmd-start and cmd-done probes listed.

#### Step 3: Watch the probes fire.

In one terminal:

```
dtrace -n 'sdt:bugdemo::cmd-start { printf("op=%d\n", arg1); }'
```

In another terminal:

```
$./bugdemo_test noop
$./bugdemo_test hello
```

The first terminal shows each probe firing with its op value.

#### Step 4: Measure latency per op.

```
dtrace -n '
sdt:bugdemo::cmd-start
{
 self->start = timestamp;
}

sdt:bugdemo::cmd-done
/self->start != 0/
{
 @by_op[arg1] = quantize(timestamp - self->start);
 self->start = 0;
}
'
```

Run a workload of many ioctls, then Ctrl-C the DTrace. An aggregation prints, showing a latency histogram per op.

#### Step 5: Use fbt to trace entries.

```
dtrace -n 'fbt::bugdemo_*:entry { printf("%s\n", probefunc); }'
```

Trigger some ioctls from user space. The DTrace terminal shows each entry, giving you a live view of the driver's flow.

#### Step 6: Use ktrace to trace the user-space side.

```
$ ktrace -t ci ./bugdemo_test hello
$ kdump
```

Observe the ioctl calls visible in the kdump output.

#### Step 7: Combine ktrace and DTrace.

Run DTrace in one terminal, watching SDT probes, while running ktrace in another on the user-space test. The two outputs, read together, give a complete picture of the interaction from user space to kernel and back.

**What this lab teaches.** Tracing is not a single tool; it is a family. DTrace is the richest, ktrace(1) is the simplest way to see the user-kernel boundary, and combining them gives the most complete view.

### 34.12.5 Lab 5: Catching a Use-After-Free With memguard

This lab walks through a real memory debugging scenario. The `lab05-memguard` variant of `bugdemo` contains a deliberate use-after-free bug: under certain `ioctl` sequences, the driver frees a buffer and then reads it from a callout.

#### Step 1: Build a kernel with `DEBUG_MEMGUARD`.

Add options `DEBUG_MEMGUARD` to your `GENERIC-DEBUG` config, or create a new config:

```
include GENERIC
include "std.debug"
options DEBUG_MEMGUARD
```

Rebuild and install as in Lab 3.

#### Step 2: Load the `lab05 bugdemo` and enable `memguard`.

```
kldload ./bugdemo.ko
sysctl vm.memguard.desc=bugdemo
```

The second command tells `memguard(9)` to guard all allocations made with `malloc` type `bugdemo`. The exact type name comes from the driver's `MALLOC_DEFINE` call.

#### Step 3: Trigger the use-after-free.

```
$./bugdemo_test use-after-free
```

The user-space call returns quickly. A moment later (when the callout fires), the kernel panics with a page fault inside the callout routine:

```
Fatal trap 12: page fault while in kernel mode
fault virtual address = 0xfffff80002abcdef
...
KDB: stack backtrace:
db_trace_self_wrapper()
...
bugdemo_callout()
...
```

`memguard(9)` has converted a silent use-after-free into an immediate page fault. The backtrace points directly at `bugdemo_callout`.

#### Step 4: Analyze the dump with `kgdb`.

```
kgdb /boot/kernel/kernel /var/crash/vmcore.last
(kgdb) bt
(kgdb) frame N # into bugdemo_callout
(kgdb) list
(kgdb) print buffer
```

The source line shows the read from `buffer`, and `buffer` is a freed memguard-protected address. `kgdb` prints it as an address that is no longer mapped.

#### Step 5: Fix the bug and verify.

The fix is to cancel the callout before freeing the buffer. Modify the driver source accordingly, rebuild, reload, and run the same test. The panic no longer fires. Keep memguard enabled during the verification, then disable it and re-test:

```
sysctl vm.memguard.desc=
```

Both runs should succeed. If the release-mode run (without memguard) still fails, the bug is not fully fixed.

#### Step 6: Count inflight allocations.

The lab also shows an alternative technique: counting inflight allocations. Add a counter(9) to the driver, bump it on allocate, decrement on free. At unload, assert that the counter is zero:

```
KASSERT(counter_u64_fetch(bugdemo_inflight) == 0,
 ("bugdemo: leaked %ld buffers",
 (long)counter_u64_fetch(bugdemo_inflight)));
```

Unload without first freeing all buffers, observe the assertion fire.

**What this lab teaches.** `memguard(9)` is a specific tool for a specific class of bug. When it applies, it turns hard bugs into easy ones. Knowing when to reach for it is the practical skill.

### 34.12.6 Lab 6: Remote Debugging With the GDB Stub

This lab demonstrates remote debugging over a virtual serial port. It assumes you are using `bhyve` or `QEMU` with a serial console exposed to the host.

#### Step 1: Configure KDB and GDB in the kernel.

Both should already be present in `GENERIC-DEBUG`. Confirm with:

```
sysctl debug.kdb.supported_backends
```

#### Step 2: Configure the serial console in the VM.

In `bhyve`, add `-l com1,stdio` to the launch command, or equivalent. In `QEMU`, use `-serial stdio` or `-serial pty`. The goal is to have a virtual serial port accessible from the host.

#### Step 3: In the VM, switch to the GDB backend.

```
sysctl debug.kdb.current_backend=gdb
```

**Step 4: In the VM, drop into the debugger.**

Send the break-to-debugger sequence on the serial console, or trigger a panic:

```
sysctl debug.kdb.enter=1
```

The kernel halts. The serial console shows:

```
KDB: enter: sysctl debug.kdb.enter
[thread pid 500 tid 100012]
Stopped at kdb_enter+0x37: movq $0, kdb_why
gdb>
```

**Step 5: On the host, attach kgdb.**

```
$ kgdb /boot/kernel/kernel
(kgdb) target remote /dev/ttyXX # the host-side serial device
```

The host's kgdb connects to the kernel over the serial line. You can now run full kgdb commands on the live kernel: `bt`, `info threads`, `print`, `set variable`, and so on.

**Step 6: Set a breakpoint.**

```
(kgdb) break bugdemo_ioctl
(kgdb) continue
```

The VM resumes. In the VM, run `./bugdemo_test hello`. The breakpoint fires, and kgdb on the host shows the state.

**Step 7: Detach cleanly.**

```
(kgdb) detach
(kgdb) quit
```

In the VM, the kernel resumes running.

**What this lab teaches.** Remote debugging is a specialized but valuable tool. It is most useful when you need live inspection of a running kernel, particularly for intermittent bugs that are hard to capture as dumps.

## 34.13 Challenge Exercises

The following challenges build on the labs. They are open-ended by design: there are multiple valid approaches, and the point is to practice choosing the right tool for each bug.

### 34.13.1 Challenge 1: Find the Silent Bug

The lab-challenges/silent-bug variant of bugdemo contains a bug that produces no crash and no error. Instead, a counter sometimes reports the wrong value after a specific ioctl sequence. Your task:

1. Write a test program that reproduces the bug.
2. Use DTrace to narrow down which function produces the wrong counter value.
3. Fix the bug and verify that the DTrace signature disappears.

Hint: the bug is a missing memory barrier, not a missing lock. The symptom is cache coherence, not contention.

### 34.13.2 Challenge 2: Hunt the Leak

The lab-challenges/leaky-driver variant leaks an object each time a specific ioctl path is exercised. Your task:

1. Confirm the leak using `vmstat -m` before and after a workload.
2. Use DTrace to record every allocation and free of the leaked object type, aggregated by stack.
3. Identify the code path that allocates without freeing.
4. Add a counter (9)-based inflight check to the driver and verify that it fires when the buggy path is taken.

### 34.13.3 Challenge 3: Diagnose the Deadlock

The lab-challenges/deadlock variant sometimes hangs when two ioctls are run concurrently. Your task:

1. Reproduce the hang.
2. Attach to the hung kernel with `kgdb` (or drop into `DDB`).
3. Use `info threads` and `bt` on each stuck thread to identify the lock ordering.
4. Determine the fix (reorder locks, or eliminate one of them).

### 34.13.4 Challenge 4: Read a Real Panic

Load a kernel module you did not write (for example, one of the USB class drivers or a filesystem module). Deliberately trigger a bad interaction by sending malformed input from user space. When it panics (or fails to), write up:

1. The exact sequence that caused the symptom.
2. The backtrace or error observed.
3. Whether the module had assertions that would have caught the problem earlier.
4. One suggestion for strengthening the module's invariants.

### 34.13.5 Challenge 5: Build Your Own bugdemo Variant

Create a new variant of bugdemo that contains a bug you have encountered in real-world code. Write a test program that triggers the bug deterministically. Then, using any subset of the techniques in this chapter, diagnose

the bug from scratch. Write up what you learned. The point is to practice the conversion of “I recognize this pattern” into reproducible teaching material.

## 34.14 Troubleshooting Common Issues

Even the best tools run into problems in practice. This section collects the issues you are most likely to hit and how to resolve them.

### 34.14.1 The Dump Is Not Being Captured

After a panic, `/var/crash/` shows only bounds and `minfree`, no `vmcore.N`. Possible causes:

- **No dump device configured.** Run `dumpon -l` after a normal boot. If it reports “no dump device configured,” set one with `dumpon /dev/DEVICE` and persist it in `/etc/rc.conf` with `dumpdev=`.
- **Dump device too small.** A dump needs space equal to kernel memory plus some overhead. A 1GB swap partition will not hold a dump of an 8GB-memory machine. Enlarge the dump device or use a compressed dump (`dumpon -z`).
- **savecore disabled.** Check `/etc/rc.conf` for `savecore_enable="NO"`. Switch to YES and reboot.
- **Crash too severe.** If the panic itself prevents the dump machinery from running, you may see no output at all. In that case a serial console is essential to capture at least the panic message.

### 34.14.2 kgdb Says “No Symbols”

When opening a dump, `kgdb` prints “no debugging symbols found” or similar. Possible causes:

- **Kernel built without -g.** Debug kernels include `-g` automatically via `makeoptions DEBUG=-g`. Release kernels do not. Either build a debug kernel or install the debug symbols package if available.
- **Mismatch between kernel and dump.** If the dump came from a different kernel than the one `kgdb` is loading, symbols will not match. Use the exact kernel binary that was running at the time of the panic.
- **Module symbols missing.** If the panic is inside a module that was built without `-g`, `kgdb` shows addresses without source lines for that module. Rebuild the module with `DEBUG_FLAGS=-g`.

### 34.14.3 DDB Freezes the System

Entering DDB intentionally halts the kernel. This is by design, but on a production-like system it can look like a hang. If you are in DDB and want to resume:

- `continue` exits DDB and returns to the kernel.
- `reset` reboots immediately.
- `call doadump` forces a dump and then reboot.

If you entered DDB accidentally, `continue` is almost always the right action.

### 34.14.4 A Module Refuses to Unload

`kldunload bugdemo` returns `Device busy`. Causes:

- **Open file descriptors.** Something still has `/dev/bugdemo` open. Use `fstat | grep bugdemo` to find processes and close them.
- **Reference counts.** Another module references this one. Unload that module first.
- **Pending work.** A callout or taskqueue is still scheduled. Wait for it to drain, or make the driver explicitly cancel and drain in its unload path.
- **Stuck thread.** A kernel thread spawned by the driver has not exited. Terminate it from within the driver on unload.

### 34.14.5 memguard Does Nothing

`vm.memguard.desc=bugdemo` is set, but `memguard` does not seem to be catching any bugs. Causes:

- **Wrong type name.** `vm.memguard.desc` must match a type passed to `MALLOC_DEFINE(9)` exactly. If you set `vm.memguard.desc=BugDemo` but the driver uses `MALLOC_DEFINE(..., "bugdemo", ...)`, the names do not match.
- **Kernel not built with `DEBUG_MEMGUARD`.** The `sysctl` node exists only if the option is compiled in. Check `sysctl vm.memguard.waste` or similar; if it returns “unknown oid,” the feature is not compiled in.
- **Allocation path not traversed.** If the code path where the bug lives does not actually use the guarded type, `memguard` cannot catch it. Confirm the allocation type with `vmstat -m`.

### 34.14.6 DTrace Says “Probe Does Not Exist”

```
dtrace: invalid probe specifier sdt:bugdemo::cmd-start: probe does not exist
```

Causes:

- **Module not loaded.** SDT probes are defined by the module that provides them. If the module is not loaded, the probes do not exist.
- **Probe name mismatch.** The name in the source has double underscores (`cmd__start`), but DTrace uses a single dash (`cmd-start`). This is the conversion rule; the underscore form appears in C, the dash form in DTrace.
- **Provider not defined.** If `SDT_PROVIDER_DEFINE(bugdemo)` is missing or in a different file than `SDT_PROBE_DEFINE`, the probes will not exist.

### 34.14.7 Kernel Builds Fail With Symbol Conflicts

When building a kernel with unusual option combinations, you may see link errors like “multiple definition of X.” Causes:

- **Conflicting options.** Some options are mutually exclusive. Review the option documentation in `/usr/src/sys/conf/NOTES`.

- **Stale objects.** Old build artifacts can interfere with new builds. Try `make cleandir` && `make cleandir` in the kernel build directory.
- **Tree inconsistency.** A partial update of `/usr/src/` can leave headers and sources out of sync. Run a full `svnlite update` or `git pull` and retry.

### 34.14.8 The System Boots Into the Old Kernel

After `installkernel`, you reboot and `uname -v` shows the old kernel. Causes:

- **Boot entry not updated.** The default is `kernel`, which points to the current kernel. If you installed with `KERNCONF=GENERIC-DEBUG` but did not run `make installkernel` cleanly, the old binary may still be in place. Check `/boot/kernel/kernel` timestamp.
- **Wrong kernel selected in loader.** The FreeBSD loader menu has a “Boot Kernel” option that can select between available kernels. Pick the right one, or set `kernel="kernel"` in `/boot/loader.conf`.
- **Boot partition unchanged.** On some systems the boot partition is separate and needs a manual copy. Check that you installed to the correct partition.

### 34.14.9 WITNESS Reports False Positives

Sometimes WITNESS warns about a lock order that you know is safe. Possible reasons and responses:

- **The order really is unsafe but harmless in practice.** WITNESS reports potential deadlocks, not actual ones. A cycle in the lock graph that is never exercised concurrently is still a bug waiting to happen. Refactor the locking.
- **Locks are acquired by address.** Generic code that locks by pointer can produce orders that depend on runtime data, not static structure. See `witness(4)` for how to suppress specific orders with `witness_skipspin` or manual overrides.
- **Multiple locks of the same type.** Acquiring two instances of the same lock class is always a potential issue. Use `mtx_init(9)` with a distinct type name per instance if you need them treated as separate classes.

## 34.15 Putting It All Together: A Debugging Session Walkthrough

Before we wrap up, let us walk through a complete debugging session that uses several of the techniques we have studied. The scenario is fictional but realistic: a driver that sometimes fails with a misleading error, and we track it down from first symptom to root cause.

### 34.15.1 The Symptom

A user reports that their program sometimes gets `EBUSY` from an `ioctl` on `/dev/bugdemo`. The program always calls the `ioctl` in the same way, and most of the time it works. Only under heavy load does `EBUSY` appear, and then inconsistently.

### 34.15.2 Step 1: Collect Evidence

The first step is to observe the phenomenon without perturbing it. We run the user's program under `kt race(1)` to confirm the symptom:

```
$ ktrace -t ci ./user_program
$ kdump | grep ioctl
```

The output confirms that a specific `ioctl` returns `EBUSY` now and then. No other user-space call misbehaves. This tells us the bug is in the kernel's handling of that `ioctl`, not in the user program's logic.

### 34.15.3 Step 2: Form a Hypothesis

The error code `EBUSY` usually indicates a resource conflict. Reading the driver source, we find that `EBUSY` is returned when an internal flag indicates a previous operation is still in progress. The flag is cleared by a callout that completes the operation.

Our hypothesis: under heavy load, the callout is delayed long enough that a new `ioctl` arrives before the previous one has completed. The driver was not designed to serialize such requests, so it rejects the newcomer.

### 34.15.4 Step 3: Test the Hypothesis With DTrace

We write a DTrace script that records the delay between consecutive `ioctls` and the state of the busy flag at each entry:

```
dtrace -n '
fbt::bugdemo_ioctl:entry
{
 self->ts = timestamp;
}

fbt::bugdemo_ioctl:return
/self->ts != 0/
{
 @[pid, self->result] = lquantize(timestamp - self->ts, 0, 1000000, 10000);
 self->ts = 0;
}
'
```

Running the user program under load, we observe that `EBUSY` returns happen almost exclusively when the previous `ioctl` completed more than 50 microseconds ago and the callout has not fired yet. This corroborates the hypothesis.

### 34.15.5 Step 4: Confirm With SDT Probes

We add SDT probes around the busy flag manipulation and watch them:

```
dtrace -n '
sdt:bugdemo::set-busy
{
 printf("%lld set busy\n", timestamp);
}

sdt:bugdemo::clear-busy
{
 printf("%lld clear busy\n", timestamp);
}

sdt:bugdemo::reject-busy
{
 printf("%lld reject busy\n", timestamp);
}
'
```

The trace shows a clear pattern: set, reject, reject, reject, clear, set, clear. The clear is coming late because the callout is competing for a shared taskqueue with other work.

### 34.15.6 Step 5: Identify the Fix

With the evidence gathered, the fix is clear. Either the driver needs to serialize incoming ioctls instead of rejecting them (a queue or a wait), or it needs to complete the previous operation synchronously instead of via callout.

We pick the queuing approach because it preserves the callout's benefits. The driver accumulates pending requests and dispatches them as the callout fires. Under light load, nothing changes. Under heavy load, requests wait rather than failing.

### 34.15.7 Step 6: Implement and Verify

We modify the driver. We run the user program under the original workload. EBUSY no longer appears. The DTrace latency distribution now shows a tail that reflects the queueing delay, which is acceptable for this driver's use case.

We also enable `DEBUG_MEMGUARD` on the driver's malloc type and run the workload for a while, to make sure the queuing code does not introduce memory bugs. No faults fire.

Finally, we run the full test suite. Everything passes. The fix is committed with a descriptive message that explains the root cause, not just the symptom.

### 34.15.8 Lessons From This Session

Two things are worth noting.

First, the tools we used were relatively lightweight. No crash dump was needed. No DDB was entered. The bug was diagnosed through passive observation, DTrace, and careful reading. For many driver bugs, this is the shape of a session: not a dramatic panic but a systematic narrowing of hypotheses.

Second, the fix addressed the root cause, not the symptom. A surface fix might have been to increase the priority of the callout's taskqueue. That would have reduced the frequency of the bug without eliminating it. A more principled fix changes the driver's contract from "reject if busy" to "queue and serve." This is the refactoring mindset we discussed in Section 8: every bug is a message about the design.

## 34.16 Additional Techniques Worth Knowing

The chapter has covered the core of FreeBSD's debugging toolkit. A handful of additional techniques did not fit into the main narrative but deserve mention, because you will eventually encounter them.

### 34.16.1 witness\_checkorder With Manual Lists

WITNESS can be tuned. In `/usr/src/sys/kern/subr_witness.c` there is a table of known-good lock orders that the kernel recognizes. When building a driver that uses a subsystem locked by an existing lock, adding the driver's own lock to this table lets WITNESS verify the combined order across the driver and the subsystem.

This is rarely needed in small drivers but becomes useful for drivers that interact deeply with multiple subsystems.

### 34.16.2 sysctl debug.ktr

Beyond just enabling and disabling `ktr(9)` classes, there are additional controls:

- `debug.ktr.clear=1` clears the buffer.
- `debug.ktr.verbose=1` sends trace entries to the console in real time, in addition to the ring.
- `debug.ktr.stamp=1` adds timestamps to each entry.

The combination of these is especially useful when you want to watch a live trace without running `ktrdump(8)` repeatedly.

### 34.16.3 DDB Commands Beyond bt

DDB has a rich set of commands that are sparsely documented. A few are particularly useful for driver authors:

- `show all procs` lists every process.
- `show lockedvnods` shows currently locked vnods (useful for storage driver bugs).
- `show mount` shows mounted filesystems.
- `show registers` dumps CPU registers.
- `break FUNC` sets a breakpoint.

- `step` and `next` advance one instruction or one line.
- `watch` sets a watchpoint on an address.

The `help` command in DDB lists all available commands. Reading the list once is a useful way to discover features you did not know about.

#### 34.16.4 Kernel Option `KDB_TRACE`

`KDB_TRACE` causes the kernel to print a stack trace on every panic, even if the operator does not interact with the debugger. This is useful in automated testing where nobody is watching the console. It is already in `GENERIC`.

#### 34.16.5 EKCD: Encrypted Kernel Crash Dumps

If kernel dumps contain sensitive data (process memory, credentials, keys), the kernel can encrypt them at dump time. The `EKCD` option enables this feature. A public key is loaded at runtime with `dumpon -k`; the matching private key is used at `savecore` time to decrypt.

This matters on production systems where dumps might be transported over untrusted channels. It does not matter on a development VM.

#### 34.16.6 Lightweight Debug Output: `bootverbose`

Another low-overhead option is `bootverbose`. Setting `boot_verbose` in the loader or `bootverbose=1` in `sysctl` causes many kernel subsystems to print additional diagnostic information at boot. If your driver has not yet reached the point where `DTrace` applies, `bootverbose` can help you see what the driver is doing during attach.

The way to make your own driver honor `bootverbose` is to check `bootverbose` in your probe or attach code:

```
if (bootverbose)
 device_printf(dev, "detailed attach info: ...\n");
```

This is a well-established pattern in `/usr/src/sys/dev/` drivers.

### 34.17 A Closer Look at DDB

The in-kernel debugger, DDB, deserves more attention than we have given it so far. Many driver authors use DDB only reactively, when a panic lands them in it unexpectedly. With a little practice, DDB is also a useful tool to enter deliberately, for interactive inspection of a live kernel.

#### 34.17.1 Entering DDB

There are several ways to enter DDB. We have seen some of them already:

- By panic, if `debug.debugger_on_panic` is nonzero.

- By serial BREAK (or Ctrl-Alt-Esc on a keyboard console), when BREAK\_TO\_DEBUGGER is compiled in.
- By the alternative sequence CR ~ Ctrl-B, when ALT\_BREAK\_TO\_DEBUGGER is compiled in.
- Programmatically, with `sysctl debug.kdb.enter=1`.
- From code, by calling `kdb_enter(9)`.

In development, the programmatic entry is the most convenient. You can drop into DDB at a specific point in a script without waiting for a panic.

### 34.17.2 DDB Prompts and Commands

Once inside, DDB presents a prompt. The standard prompt is simply `db>`. Commands are typed, followed by Enter. DDB has a command history (press up-arrow on the serial console) and tab-completion for many command names.

A useful first command is `help`, which lists categories of commands. `help show` lists the many show subcommands. Most exploration happens through `show`.

### 34.17.3 Walking a Thread

The most common diagnostic task in DDB is to walk a specific thread. Start with `ps`, which lists all processes:

```
db> ps
 pid ppid pgrp uid state wmesg wchan cmd
 0 0 0 0 RL (swapper) [...] swapper
 1 0 1 0 SLs wait [...] init
 ...
 500 499 500 0 SL nanslp [...] user_program
```

Pick the thread of interest. In DDB, switching to a thread is done by the `show thread` command:

```
db> show thread 100012
 Thread 100012 at 0xfffffe00...
 ...
db> bt
```

This walks the stack of that specific thread. A kernel deadlock investigation typically involves walking each stuck thread to see where it is waiting.

### 34.17.4 Inspecting Structures

DDB can dereference pointers and print structure fields if the kernel was built with `DDB_CTF`. Example:

```
db> show proc 500
db> show malloc
db> show uma
```

Each of these prints a formatted view of the relevant kernel state. `show malloc` gives a table of malloc types and their current allocations. `show uma` does the same for UMA zones. `show proc` shows a specific process in detail.

### 34.17.5 Setting Breakpoints

DDB supports breakpoints. `break FUNC` sets a breakpoint at the entry to a function. `continue` resumes execution. When the breakpoint fires, the kernel returns to DDB and you can inspect state at that point.

This is the machinery that makes DDB a real debugger, not just a crash inspector. With breakpoints you can pause the kernel at a specific code location, examine arguments, and decide whether to continue.

The catch is that a kernel paused in DDB really is paused. While you are in DDB, no other thread runs. On a network server, every client times out. On a desktop, the GUI freezes. For local, development-VM debugging, this is fine. For any remote or shared use, it is not.

### 34.17.6 Scripting DDB

DDB supports a simple scripting facility. You can define named scripts that execute a sequence of DDB commands. `script kdb.enter.panic=bt; show registers; show proc` makes those three commands run automatically every time the debugger enters due to a panic. This is useful for unattended dumps: the scripted output appears on the console and in the dump, giving you information without needing an interactive session.

The scripts are stored in kernel memory and can be configured at boot via `/boot/loader.conf` or at runtime with `sysctl` calls. See `ddb(4)` for the exact syntax.

### 34.17.7 Exiting DDB

When you are done, `continue` exits DDB and the kernel resumes. `reset` reboots. `call doadump` forces a dump and reboot. `call panic` triggers a panic intentionally (useful when you want a dump from the current state but did not reach DDB via a panic).

For the developer practicing on a VM, `continue` is the one command to remember. It brings the kernel back to life and lets you keep working.

### 34.17.8 DDB vs kgdb: When to Use Each

DDB and kgdb overlap but are not interchangeable.

Use DDB when the kernel is running (or paused on a specific event) and you want to poke around. DDB runs inside the kernel and has direct access to kernel memory and threads. It is the right tool for quick state checks, for setting breakpoints, and for stopping on specific events.

Use kgdb on a crash dump, after the machine has rebooted. kgdb has no access to a running system's threads, but it has full gdb features for offline analysis: command history, source browsing, scripting with Python, and so on.

For a live kernel that you cannot reboot, the GDB stub backend of KDB bridges the gap: the kernel pauses, and kgdb on another machine attaches over a serial line for full gdb features on the live state. This is the most capable combination but requires two machines (or VMs).

## 34.18 Practical Worked Example: Following a Null Pointer

To pull the tools together, let us walk through one more worked example. The symptom: bugdemo occasionally panics with page fault: supervisor read instruction and a backtrace through bugdemo\_read. The panic address is low, suggesting a null pointer dereference.

### 34.18.1 Step 1: Capture the Dump

After the panic, we confirm a dump was saved:

```
ls -l /var/crash/
```

and open it:

```
kgdb /boot/kernel/kernel /var/crash/vmcore.last
```

### 34.18.2 Step 2: Read the Backtrace

```
(kgdb) bt
#0 __curthread ()
#1 doadump (textdump=0) at /usr/src/sys/kern/kern_shutdown.c
#2 db_fncall_generic at /usr/src/sys/ddb/db_command.c
...
#8 bugdemo_read (dev=..., uio=..., ioflag=0)
 at /usr/src/sys/modules/bugdemo/bugdemo.c:185
```

The interesting frame is 8, bugdemo\_read. The code at line 185 is:

```
sc = dev->si_drv1;
amt = MIN(uio->uio_resid, sc->buflen);
```

### 34.18.3 Step 3: Inspect the Variables

```
(kgdb) frame 8
(kgdb) print sc
$1 = (struct bugdemo_softc *) 0x0
(kgdb) print dev->si_drv1
$2 = (void *) 0x0
```

`si_drv1` is NULL on the dev. This is the private pointer that `make_dev(9)` sets; it should have been set during attach.

#### 34.18.4 Step 4: Walk Back

```
(kgdb) print *dev
```

We see the device structure. The name field says “bugdemo”, the flags look reasonable, but `si_drv1` is NULL. Something cleared it.

#### 34.18.5 Step 5: Form a Hypothesis

In the source, `si_drv1` is set once, in `attach`, and it is read in every `read`, `write`, and `ioctl` handler. It is never explicitly cleared. However, in the unload path, the device is destroyed with `destroy_dev(9)`, which returns before pending handlers finish. If a read is in progress when unload starts, the dev might be partially destroyed.

#### 34.18.6 Step 6: Add an Assertion

A `KASSERT` at the top of `bugdemo_read` catches the case:

```
KASSERT(sc != NULL, ("bugdemo_read: no softc"));
```

With this assertion in place, the next panic gives us the same information without requiring a dump walk. We also know immediately that the condition is real, not a random corruption.

#### 34.18.7 Step 7: Fix the Bug

The real fix is to make the unload path wait for pending handlers before destroying the device. FreeBSD provides `destroy_dev_drain(9)` for exactly this purpose. Using it:

```
destroy_dev_drain(sc->dev);
```

ensures that no read or write is in flight when the `softc` is freed.

### 34.18.8 Step 8: Verify

Load the fixed driver. Run concurrent reads and unloads. The panic does not reproduce. The KASSERT stays in the code as a safety net for future refactoring.

### 34.18.9 Takeaway

This workflow (capture, read, inspect, hypothesize, verify) is the shape of most productive debugging sessions. Each tool plays a small, specific role. The discipline is to gather evidence before acting, and to leave assertions behind as witnesses for the future.

## 34.19 Making Drivers Observable From Day One

A theme running through this chapter is that the best time to add debugging infrastructure is before you need it. A driver that was designed with observability in mind is easier to debug than a driver that was designed for speed alone.

A few concrete habits support this.

### 34.19.1 Name Every Allocator Type

MALLOC\_DEFINE(9) requires a short and a long name. The short name is what appears in `vmstat -m` output and in `memguard(9)` targeting. Picking a descriptive name, unique to the driver, makes later diagnosis easier. Never share a malloc type between unrelated subsystems; the tooling cannot distinguish them.

### 34.19.2 Count Important Events

Every major event in a driver (open, close, read, write, interrupt, error, state transition) is a candidate for a counter(9). Counters are cheap, they accumulate over time, and they are exposed through `sysctl`. A driver with good counters answers most “what is this thing doing” questions without any additional tooling.

### 34.19.3 Declare SDT Probes

Every state transition is a candidate for an SDT probe. Unlike assertions or counters, probes cost nothing when disabled. Leaving them in the source for the lifetime of the driver is a net win: when a bug appears, DTrace can see the event flow without requiring a rebuild.

### 34.19.4 Use Consistent Log Messages

`log(9)` messages should follow a consistent format. A prefix that identifies the driver, a specific error code or state, and enough context to locate the problem are the essentials. Avoid cleverness in log messages; a reader under time pressure wants to know what happened, not to admire your prose.

### 34.19.5 Provide Useful Sysctls

Every internal flag, every counter, every configuration value should be exposed through sysctl unless there is a specific reason not to. The reader who needs to debug your driver will thank you; the reader who never needs to debug your driver pays nothing for the exposure.

### 34.19.6 Write Assertions As You Go

The best time to add a KASSERT is when the invariant is fresh in your mind, which is while you are writing the code. Going back later to sprinkle assertions is less effective because you have forgotten some invariants and have rationalized others as “obvious.”

### 34.19.7 Expose the State of the State Machine

Every nontrivial driver has a state machine. Exposing the current state through a sysctl, an SDT probe at each transition, and a counter per state makes the state machine visible to both humans and tools. This is particularly important for asynchronous drivers, which is the subject of the next chapter.

### 34.19.8 Test the Unload Path

An underhardened unload path is a classic source of crashes. In development, write a test that loads the driver, exercises it briefly, and unloads it, repeatedly and under various conditions. If the driver cannot sustain a hundred load/unload cycles, it has bugs.

These habits cost a little time in development and pay for themselves many times over in debugging. A disciplined driver author applies them all, even to drivers that look too simple to need them.

## 34.20 Real-World Reading List

Every tool in this chapter is documented more completely in its own man page or source file. That is good news: you do not have to carry the whole toolbox in your head. When a bug points you at a specific subsystem, opening the right man page or source file will almost always take you further than any chapter can. The following list gathers the references that matter most for this material, in the order you are likely to need them.

The `witness(4)` man page is the first thing to read when `GENERIC-DEBUG` starts printing lock order reversals and you want to understand exactly what the output means, which sysctl controls change behavior, and which counters you can inspect. It documents the `debug.witness.*` sysctls, the `show all_locks` DDB command, and the general approach `WITNESS` takes to bookkeeping. For the actual implementation, `/usr/src/sys/kern/subr_witness.c` is the authoritative source. Reading the structures it maintains and the shape of its output functions (the ones that produce the “1st ... 2nd ...” lines you saw earlier in this chapter) removes most of the mystery from a `WITNESS` report. The file is long, but the top comment and the output-producing functions together cover most of what a driver author needs to know.

For lock profiling, `lockstat(1)` is documented in `/usr/src/cddl/contrib/opensolaris/cmd/lockstat/lockstat.1`. The man page ends with several worked examples whose output format matches what you

will see on your own systems, which makes it a useful reference to keep open the first time you try `-H -s 8` on a real workload. Because `lockstat(1)` is DTrace-backed, the `dt race(1)` man page is its natural companion; you can express the same queries in raw D if you need flexibility the `lockstat` command-line flags do not offer.

For kernel debugger work, `ddb(4)` documents the in-kernel debugger in full, including every builtin command, every script hook, and every way to enter the debugger. When in doubt, read this page before using a DDB command you have not tried before. For offline post-mortem analysis, `kgdb(1)` on your installed FreeBSD system documents the kernel-specific extensions over stock `gdb`. The underlying access layer is in `libkvm`, described in `/usr/src/lib/libkvm/kvm_open.3`, which explains both the dump and the live-kernel modes you met in Section 3.

Two smaller pointers are worth keeping in your reading queue. The first is `/usr/src/share/examples/witness/lockgraphs.sh`, a tiny shell script shipped in the base system that demonstrates how to turn WITNESS's accumulated lock-order graph into a visual diagram. On a real driver, running it once gives you a picture of where your locks sit relative to the rest of the kernel's lock hierarchy, and it can be surprising. The second is the FreeBSD kernel source tree itself: reading `/usr/src/sys/kern/kern_shutdown.c` (the panic and dump path) and `/usr/src/sys/kern/kern_mutex.c` (the mutex implementation that WITNESS instruments) grounds the whole debugging workflow in the code that actually implements it.

Beyond the source tree, the FreeBSD Developers' Handbook and the FreeBSD Architecture Handbook both contain longer-form articles on kernel debugging. Both are shipped with the documentation set on any FreeBSD system and kept up to date alongside the source. They are worth browsing once, even if you do not read them end to end, because they give names to patterns you will later recognize in your own debugging sessions.

A final note on choosing references. Man pages age more slowly than blog posts, and source comments age more slowly than man pages. When two references disagree, trust the source, then the man page, then the handbook, then everything else. That hierarchy has served FreeBSD developers well for decades, and the habit will serve you through the rest of this book and the rest of your career.

## 34.21 Wrapping Up

Advanced debugging is a patient craft. Each tool in this chapter exists because someone, somewhere, faced a bug that could not be found any other way. `KASSERT` exists because invariants that live only in the programmer's head are not invariants. `kgdb` and crash dumps exist because some bugs destroy the machine that produced them. DDB exists because a frozen kernel cannot explain itself through any other channel. WITNESS exists because deadlocks are catastrophic in production and impossible to debug after the fact. `memguard(9)` exists because silent memory corruption was the hardest class of bug until someone built a tool that made it loud.

None of these tools replace understanding. A debugger cannot tell you what your driver should do. A crash dump cannot tell you the right locking discipline. DTrace cannot infer your design. The tools are instruments; you are the player. The music is the shape of the driver you are building.

The habits that make this craft successful are small and undramatic. Develop on a debug kernel. Add assertions for every invariant you can articulate. Capture dumps routinely so you can open them without ceremony. Keep a journal when you are chasing something hard. Read the FreeBSD source when a mechanism mystifies you. Reach for the lightest tool that will answer your question, and graduate to heavier tools only when the lighter ones come up short.

Debugging is also a social craft. A bug that takes you a day to find, written up clearly, can save another author a week. Good commit messages, detailed test cases, and honest accounts of what worked and what did not are contributions to the common practice. The FreeBSD project's historical patience with bug reports, its habit of capturing root causes in commit logs, and its consistent use of `KASSERT` and `WITNESS` across decades of drivers all stem from this collective habit of treating bug hunting as a shared responsibility.

You now have the toolkit to participate. Load a debug kernel, pick a driver in `/usr/src/sys/dev/` that interests you, and read it with a debugger's eye. Where are the invariants? Where are the assertions? Where is the locking discipline? Where might a bug hide, and what tool would catch it? The exercise sharpens the instincts the rest of this book has been building.

In the next chapter, we will leave correctness behind and look at how drivers handle asynchronous I/O and event-driven work: the patterns by which a driver serves many users at once without blocking, and the kernel facilities that make such designs possible. The debugging skills you have gained here will serve you well in that territory, because asynchronous code is where subtle concurrency bugs tend to live. A driver with solid assertions, a clean lock ordering verified by `WITNESS`, and a set of SDT probes to trace its event flow is also a driver that is much easier to reason about when its work is spread across callbacks, timers, and kernel threads.

## 34.22 Bridge to Chapter 35: Asynchronous I/O and Event Handling

Chapter 35 picks up where this one leaves off. Synchronous code is straightforward to reason about: a call arrives, the driver does its work, the call returns. Asynchronous code is not: callbacks fire at unpredictable times, events arrive out of order, and the driver must manage state that persists across many thread contexts.

The complexity of asynchronous drivers is exactly the kind of complexity that benefits from the tools of this chapter. A synchronous driver with a bug might crash at a predictable place. An asynchronous driver with a bug might crash hours later, in a callback that has no obvious connection to the original misbehavior. `KASSERT` on the state at each callback entry catches such bugs early. `DTrace` probes on each event transition make the sequence visible. `WITNESS` detects the deadlocks that arise naturally when multiple asynchronous paths need to coordinate.

In the next chapter we will meet the building blocks of asynchronous work in FreeBSD: `callout(9)` for deferred timers, `taskqueue(9)` for background work, `kqueue(9)` for event notification, and the patterns for using them correctly. We will build a driver that serves many concurrent users without blocking, and we will exercise the debugging techniques of this chapter to keep that complexity under control.

By the time you finish Chapter 35, you will have the full synchronous and asynchronous toolkit: drivers that handle traffic efficiently, scale to many users, maintain correctness under concurrency, and can be debugged when something nevertheless goes wrong. That combination is what it takes to write drivers that survive in production.

See you in Chapter 35.

## 35 Asynchronous I/O and Event Handling

### 35.1 Introduction

Up to this point, almost every driver we have written has operated on a simple schedule. A user process calls `read(2)` and waits. Our driver produces data, the kernel copies it out, and the call returns. A user process calls `write(2)` and waits. Our driver consumes the data, stores it, and the call returns. The user thread sleeps while the driver works, and it wakes up when the work is done. This is the synchronous model, and it is the right starting point for teaching drivers because it matches the shape of an ordinary function call: you ask for something, you wait, you get an answer.

Synchronous I/O works well for many devices, but it fails for others. A keyboard does not decide to produce a keypress because a program called `read()`. A serial port does not time its incoming bytes to match the reader's schedule. A sensor might produce data at irregular intervals, or only when something interesting happens in the physical world. If we insist that every user of such a device must block in `read()` until the next event arrives, we force the userland program into a terrible choice. It can either dedicate a thread to blocking on each device, which makes the program hard to write and slow to respond to anything else, or it can loop in userland calling `read()` with a short timeout over and over, which wastes CPU cycles and still misses events that happen between polls.

FreeBSD solves this problem by giving drivers a set of asynchronous notification mechanisms, each built on the same underlying idea: a process does not need to block in `read()` to learn that data is ready. It can instead register interest in a device, go do other useful work, and let the kernel wake it up when the device has something to say. The mechanisms differ in their details, their performance profiles, and their intended use cases, but they share a common shape. A waiter declares what it is waiting for, the driver records that interest, the driver later discovers that the condition is satisfied, and the driver delivers a notification that causes the waiter to be woken, scheduled, or signalled.

Four of these mechanisms matter to driver authors. The classic `poll(2)` and `select(2)` system calls let a userland program ask the kernel which of a set of file descriptors are ready. The newer `kqueue(2)` framework offers a more efficient, more expressive event interface and is the preferred choice for modern high-performance applications. The `SIGIO` signal mechanism, invoked through `FIOASYNC` and `fsetown()`, delivers signals to a registered process whenever the device state changes. And drivers that need to track their own internal events typically build a small event queue inside the softc so that readers see a consistent sequence of readable records rather than raw hardware state.

In this chapter we will learn how each of these mechanisms works, how to implement it correctly in a character driver, how to combine them so that a single driver can serve callers from `poll(2)`, `kqueue(2)`, and `SIGIO` simultaneously, and how to audit the resulting code for the subtle races and missed wakeups that are the bane of asynchronous programming. We will ground every piece in real FreeBSD 14.3 source, looking at how `if_tuntap.c`, `sys_pipe.c`, and `evdev/cdev.c` solve the same problems in production.

By the end of the chapter you will be able to take a blocking driver and give it full asynchronous support without breaking its synchronous semantics. You will know how to implement `d_poll()`, `d_kqfilter()`, and `FIOASYNC` handlers correctly. You will understand why `selrecord()` and `selwakeup()` must be called in a specific order with specific locking. You will know what a `knlist` is, how `knote` attaches to it, and why `KNOTE_LOCKED()` is the call you want in almost every driver. You will see how `fsetown()` and `pgsigio()` combine to deliver signals to exactly the right process. And you will know how to build an internal event queue that ties the whole mechanism together so that each asynchronous notification leads the reader to a single, consistent, well-defined record in the driver.

Throughout the chapter we will develop a companion driver called `evdemo`. It is a pseudo-device that simulates an event source: timestamps, state transitions, and occasional “interesting” events that a userland program wants to observe in real time. Each section of the chapter builds another layer onto `evdemo`, so by the end you will have a small but complete asynchronous driver that you can load, inspect, and extend. Like `bugdemo` in the previous chapter, `evdemo` touches no real hardware, so every experiment is safe to run on a development FreeBSD virtual machine.

## 35.2 Reader Guidance: How to Use This Chapter

This chapter sits in Part 7 of the book, in the Mastery Topics part, directly after Advanced Debugging. It assumes you have already written at least a simple character driver, know how to load and unload a module safely, and have worked with the synchronous `read()`, `write()`, and `ioctl()` handlers. If any of those feel uncertain, a quick revisit of Chapters 8 through 12 will pay for itself several times in this one.

You do not need to have finished every earlier mastery chapter to follow this one. A reader who has mastered the basic character driver pattern and has seen `callout(9)` or `taskqueue(9)` in passing will be able to keep up. Where a previous chapter’s material is essential, we will give you a short reminder in the relevant section.

The material is cumulative within the chapter. Each section adds a new asynchronous mechanism to the `evdemo` driver, and the final refactor ties them together. You can skim forward to learn about one specific mechanism, but the labs read most naturally in sequence, because later labs assume the code from the earlier ones.

You do not need any special hardware. A modest FreeBSD 14.3 virtual machine is enough for every lab in the chapter. A serial console is useful but not required. You will want a second terminal open so you can watch `dmesg`, run the user-space test programs, and monitor wait channels in `top(1)` while the driver is loaded.

A reasonable reading schedule looks like this. Read the first three sections in one sitting to build the mental model for `poll` and `select`. Take a break. Read Sections 4 and 5 on a separate day, because `kqueue` and `signals` each introduce a new set of ideas. Work through the labs at your own pace. The chapter is long on purpose: asynchronous I/O is where a lot of driver complexity lives, and rushing through the material is the surest way to write a driver that works most of the time but misses wakeups in rare cases.

Some of the code in this chapter deliberately does the wrong thing so that we can see the symptoms of common mistakes. Those examples are clearly labelled. The finished labs do the right thing, and the final refactored driver is safe to load.

## 35.3 How to Get the Most Out of This Chapter

The chapter follows a pattern you will see repeated in every section. First we explain what a mechanism is and what problem it solves. Then we show how userland expects it to behave, so that you understand the contract your driver must honour. Then we look at the real FreeBSD kernel source to see how existing drivers implement the mechanism. And finally we apply it to the `evdemo` driver in a lab.

Several habits will help you absorb the material.

Keep a terminal open to `/usr/src/` so that you can look up any FreeBSD source file the chapter references. Asynchronous I/O is one of the areas where reading real drivers pays off the most, because the patterns are short enough to see in one pass and the variations between drivers teach you what is essential and what is merely stylistic. When the chapter mentions `if_tuntap.c` or `sys_pipe.c`, open the file and look. A minute spent with the real source builds more intuition than any secondhand description.

Keep a second terminal open to your FreeBSD virtual machine so that you can load and unload `evdemo` as the chapter progresses. Type the code yourself the first time you see it. The companion files under `examples/part-07/ch35-async-io/` contain the finished sources, but typing the code builds muscle memory that reading does not. When a section introduces a new callback, add it to the driver, rebuild, reload, and test before moving on.

Pay close attention to locking. Asynchronous I/O is the area where a careless lock acquisition can turn a clean driver into a deadlock or a silent data corruption. When the chapter shows a mutex being acquired before a call to `selrecord()` or `KNOTE_LOCKED()`, notice the order and ask yourself why it must be that way. When a lab instruction says to take the softc mutex before modifying an event queue, take it. Discipline about locking is the single habit that most reliably separates working asynchronous drivers from ones that mostly work.

Finally, remember that asynchronous code tends to reveal its bugs only under pressure. A driver that passes a single-threaded test may still have missed wakeups or races that manifest when two or three threads contend for the same device. Several labs in this chapter include multi-reader stress tests for exactly that reason. Do not skip them. Running your code under contention is the best way to prove that it works for real.

With those habits in mind, let us begin with the difference between synchronous and asynchronous I/O, and the question of when each is the right choice.

## 35.4 1. Synchronous vs. Asynchronous I/O in Device Drivers

Synchronous I/O is the model we have used in almost every driver so far. A user process calls `read(2)`. The kernel dispatches into our `d_read` callback. We either hand back the data that is already available, or we put the calling thread to sleep on a condition variable until data arrives. When the data is ready, we wake the thread, it copies the data out, and `read(2)` returns. The user program blocks for the duration of the call, then resumes.

This pattern is easy to reason about. It matches the way ordinary functions work: you call, you wait, you get a result. It is also a very good fit for devices where the caller's demand drives the device's work. A disk reader asks for data, and the disk controller is told to fetch it. A sensor with a `read_current_value` operation naturally fits a synchronous call. For these devices, the user process always knows when to ask, and the cost of the wait is the cost of the actual I/O.

But for many real devices, the driver's work is not driven by the caller's demand. It is driven by the world.

### 35.4.1 The World Does Not Wait for read()

Consider a keyboard. The device has no opinion about who is calling `read(2)` when a key is pressed. The user hits the key, an interrupt fires, the driver pulls a scan code out of the hardware, and the data is now available. If a userland program is blocked in `read()`, it wakes up and gets the key. If no program is reading, the key sits in a buffer. If several programs share interest in the keyboard, only one of them receives the key under classic blocking semantics, which is almost never what the programmer wants.

Consider a serial port. Bytes arrive at the speed of the wire, independent of any program's readiness to receive them. If the driver blocks every incoming byte behind a reader, it effectively forces the reader to keep one thread always asleep in `read()`, just in case something happens. That thread cannot do anything else. A single well-designed process might want to react to several serial ports, a network socket, a timer, and a keyboard, all at once. The synchronous model cannot express that.

Consider a USB sensor that reports a value only when the measured quantity crosses a threshold. A temperature sensor might raise an event only when the temperature changes by more than half a degree. A motion sensor might fire only when motion is detected. The device's own schedule, not the userland's schedule, decides when data is ready. A reader who blocks in `read()` might wait milliseconds, or seconds, or minutes, or forever.

Each of these situations shares a property: the event is external to the program's request. The driver knows when data is ready. The userland does not. If the userland has to block in `read()` every time to learn what the driver knows, the program is held hostage to the driver's rhythm.

### 35.4.2 Why Busy Waiting Is a Bad Answer

One naive solution is for the userland program to poll the driver. Instead of calling `read()` once and blocking, it calls `read()` in non-blocking mode over and over. `open(/dev/...) with O_NONBLOCK returns immediately if no data is available. The program can spin in a loop, calling read(), doing other work, calling read() again, and so on.`

This pattern is called busy waiting, and it is almost always wrong. It burns CPU even when nothing is happening, because the program keeps asking the driver whether it has work. It misses events that happen between polls. It adds latency to every event: a key pressed a hundred microseconds after the last poll waits until the next poll to be seen. And it scales poorly: a program that watches ten such devices has to poll ten of them in every iteration, making all the problems worse.

Busy waiting is appropriate in exactly one situation: when the polling frequency is known, the device latency is measured in microseconds, and the program has no other work. Even in that case, the right answer is usually to use the CPU's high-precision timing facilities and `usleep()` between polls rather than spin. For any other case, busy waiting is the wrong tool.

The synchronous blocking model and the busy-waiting model are the two endpoints of a spectrum. Both waste resources. What we want is a third option: the userland asks the kernel to tell it when the device is ready, then does other work until the kernel raises its hand. That third option is what asynchronous I/O provides.

### 35.4.3 Asynchronous I/O Is Not Just Non-blocking Read

A common beginner mistake is to think that asynchronous I/O means calling `read()` with `O_NONBLOCK`. It does not. Non-blocking `read()` returns immediately if data is not available; that is a useful property, but it is not

asynchronous I/O on its own. Non-blocking `read()` without a notification mechanism is just busy waiting dressed up a little.

Asynchronous I/O, in the sense this chapter uses the term, is a notification protocol between the driver and the userland. The userland does not have to be reading to learn that the driver has data. The driver does not have to guess who is interested. When the driver's state changes in a relevant way, it notifies its waiters through a well-defined mechanism: `poll/select`, `kqueue`, `SIGIO`, or some combination of those. The waiter wakes up, reads the data, and goes back to waiting.

This distinction matters because it separates three independent concerns in a driver:

The first concern is wait registration. A userland program declares interest in a device by calling `poll()`, `kevent()`, or by enabling `FIOASYNC`. The driver remembers that registration so that it can find the waiter later.

The second concern is wakeup delivery. When the driver's state changes, it calls `selwakeup()`, `KNOTE_LOCKED()`, or `pgsigio()` to deliver the notification. This is a separate operation from producing the data. A driver can produce data without delivering a notification (for example, during an initial fill that happens before anyone has registered). A driver can deliver a notification without producing data (for example, when a device hangs up). And a driver can deliver several notifications for one unit of data, if several mechanisms are registered.

The third concern is event ownership. A `SIGIO` signal is delivered to a specific process or process group. A `knote` belongs to a specific `kqueue`. A `select()` waiter belongs to a specific thread. If the driver cannot match the wakeup to the right owner, notifications get lost or delivered to the wrong party. Each mechanism has its own rules for matching notifications to owners, and we must get those rules right for each one separately.

Keeping these three concerns distinct is one of the main themes of this chapter. A lot of the subtle bugs in asynchronous drivers come from mixing them up. If you find yourself wondering why a specific wakeup call exists or why a specific lock is held, nine times out of ten the answer lies in keeping registration, delivery, and ownership separate.

#### 35.4.4 Real-World Patterns: Event Sources That Want Asynchronous I/O

It helps to name the patterns where asynchronous I/O is the right choice, because once you recognise them you will see them everywhere.

Character input devices are the classic case. A keyboard, a mouse, a touchscreen, a joystick: each produces events when the user interacts with it, at a rate nobody can predict in advance. The user might press a key now, or in five minutes. The driver knows when the event arrives. Userland needs a way to learn.

Serial and network interfaces are another case. Bytes arrive from the wire at the wire's pace. A terminal emulator does not want to block waiting for the next byte, because it also has to redraw its screen, respond to keyboard input, and update its cursor. A network program does not want to block waiting for the next packet, because it usually has to watch several sockets at once.

Sensors that report on condition are a third case. A button that reports "pressed" or "released." A temperature sensor that fires when the measured value crosses a threshold. A motion detector. A door contact. All of these are event-driven in the strict sense: nothing happens until something interesting happens in the world.

Control lines and modem signals are a fourth case. The `CARRIER`, `DSR`, and `RTS` lines on a serial port change state independently of the data flow. A program that cares about them wants to be told when they change, not

to poll them continuously.

Any device that combines several kinds of events into one stream is a fifth case. Consider an evdev input device that aggregates keystrokes, mouse motion, and touchscreen events into a unified event stream. The driver builds an internal queue of events, one record per interesting thing, and readers draw events from the queue. We will build a small version of exactly this pattern later in the chapter, because it illustrates how an event queue, asynchronous notification, and synchronous `read()` semantics combine into one well-structured driver.

### 35.4.5 When Not to Use Asynchronous I/O

For the sake of balance, let us name a few cases where asynchronous I/O is not the right answer.

A driver whose only operation is a bulk transfer at the caller's request has no reason to expose `poll()` or `kqueue()`. If every interaction is a round trip that the user initiates, the synchronous blocking model is both simpler and correct. Adding asynchronous notification to such a driver only increases complexity.

A driver whose data rate is so high that any notification overhead matters might need a different approach entirely. `netmap(4)` and similar kernel-bypass frameworks exist for precisely this case, and they are well beyond the scope of this chapter. An ordinary `kqueue()`-based design is fine up to millions of events per second, but at some point the cost of any notification mechanism becomes a bottleneck.

A driver whose consumer is another kernel subsystem rather than a userland program usually does not need userland-facing asynchronous notification at all. It needs in-kernel synchronization: mutexes, condition variables, `callout(9)`, `taskqueue(9)`. Those are the patterns we studied in earlier chapters, and they remain the right answer when both sides of the event live inside the kernel.

For everything in between, asynchronous I/O is the right tool, and learning it properly is one of the most durable skills a driver author can acquire. The next three sections build up the mental model and the code: first `poll()` and `select()`, then `selrecord()` and `selwakeup()`, then `kqueue()`. The later sections add signals, event queues, and the combined design.

### 35.4.6 A Mental Model for the Rest of the Chapter

Before we move on, let us fix a mental model that will guide the rest of the chapter. Every asynchronous driver has three kinds of code paths.

The first is the producer path. This is where the driver learns that something has happened. For hardware, it is the interrupt handler. For a pseudo-device like `evdemo`, it is whatever code simulates the event. The producer's job is to update the driver's internal state so that a reader who looked now would see the new event.

The second is the waiter path. This is where a userland caller registers interest. The caller's thread enters the kernel through a system call (`poll`, `select`, `kevent`, or `ioctl(FIOASYNC)`), the kernel dispatches to our `d_poll` or `d_kqfilter` callback, and we record the caller's interest in a way that the producer can find later.

The third is the delivery path. This is where the producer notifies the waiters. The producer has just updated state. It calls `selwakeup()`, `KNOTE_LOCKED()`, `pgsigio()`, or some combination of those, and those calls wake up the waiting threads, which then typically call `read()` to pick up the actual data.

This three-path model is the frame through which we will approach every mechanism. When we study `poll()`, we will ask: what is the producer doing, what does the waiter register, and what does the delivery look like? When we study `kqueue()`, we will ask the same three questions. When we study `SIGIO`, same three questions. The mechanisms differ in their details, but they all fit the same shape, and knowing the shape makes each one easier to learn.

With the mental model established, let us look at `poll(2)` and `select(2)`, the oldest and most portable of the three mechanisms.

## 35.5 2. Introducing `poll()` and `select()`

The `poll(2)` and `select(2)` system calls are the original UNIX answer to the question, “how do I wait on multiple file descriptors at once?” They have been in UNIX for decades, they work across every platform that matters, and they are still the most portable way for a userland program to watch several devices, sockets, or pipes in one loop.

They share the same underlying abstraction. A program passes a set of file descriptors and a mask of events it cares about: readable, writable, or exceptional. The kernel examines each descriptor, asks its driver or subsystem whether the event is ready, and if none are, puts the calling thread to sleep until one becomes ready or a timeout expires. When it wakes, the kernel returns which descriptors are now active, and the program can service them.

From the driver’s point of view, `poll` and `select` both funnel into the same `d_poll` callback on a `cdev`. Whether the userland program used `poll(2)` or `select(2)` is invisible to the driver. We answer one question: given this set of events the caller is interested in, which of them are ready right now? If none are ready, we also register the caller so that we can wake it when something becomes ready.

That double role (answer now, register for later) is the heart of the `d_poll` contract. The driver must answer the current state immediately and must not forget the waiter if the answer was “nothing.” Getting either half wrong produces the two classic poll bugs. If the driver reports “not ready” when data actually is ready, the caller goes to sleep and never wakes, because no further event will occur to trigger a wakeup. If the driver fails to register the waiter when nothing is ready, the caller also never wakes, because the driver never knows who to wake when data finally does arrive. Both bugs produce the same symptom (a hung process) and both are a consequence of failing to implement exactly the right pattern.

### 35.5.1 What Userland Expects From `poll()` and `select()`

Before we implement `d_poll`, it helps to know exactly what the userland caller is doing. The user code typically looks something like this:

```
#include <poll.h>
#include <fcntl.h>
#include <unistd.h>

struct pollfd pfd[1];
int fd = open("/dev/evdemo", O_RDONLY);
```

```
pfd[0].fd = fd;
pfd[0].events = POLLIN;
pfd[0].revents = 0;

int r = poll(pfd, 1, 5000); /* wait up to 5 seconds */
if (r > 0 && (pfd[0].revents & POLLIN)) {
 /* data is ready; do a read() now */
 char buf[64];
 ssize_t n = read(fd, buf, sizeof(buf));
 /* ... */
}
```

The user passes an array of struct `pollfd`, each with an `events` mask indicating what it cares about. The kernel returns by writing the `revents` field with the events that are actually ready. The third argument is a timeout in milliseconds, with `-1` meaning “wait forever” and `0` meaning “do not block at all, just poll the state.”

`select(2)` does the same thing with a slightly different API: three `fd_set` bitmaps for readable, writable, and exceptional descriptors, and a timeout as a struct `timeval`. Inside the kernel, both calls normalize into the same operation on each involved descriptor, which ends in our `d_poll` callback.

The caller expects these semantics:

If any of the requested events is currently ready, the call must return promptly with the ready events set.

If none of the requested events is ready and the timeout has not expired, the call must block until one of the events becomes ready or the timeout fires.

If the descriptor is closed or becomes invalid during the call, the kernel returns `POLLNVAL`, `POLLHUP`, or `POLLERR` as appropriate.

The event mask bits that a driver typically deals with are:

`POLLIN` and `POLLRDNORM`, both meaning “data is available to read.” FreeBSD defines `POLLRDNORM` as distinct from `POLLIN`, but in most driver code we treat them together because programs commonly ask for one or the other and expect either to work.

`POLLOUT` and `POLLWRNORM`, both meaning “the device has buffer space to accept a write.” FreeBSD defines `POLLWRNORM` as identical to `POLLOUT`, so in practice they are the same bit.

`POLLPRI`, meaning “out-of-band or priority data is available.” Most character drivers do not have a priority notion and leave this alone.

`POLLERR`, meaning “an error has occurred on the device.” The driver typically sets this when something has gone wrong and the device cannot recover.

`POLLHUP`, meaning “the peer has hung up.” A pty master sees this when the slave closes. A pipe reader sees it when the writer closes. A device driver usually sets this during the detach path, or when a layered service has disconnected.

POLLNVAL, meaning “the request is not valid.” The driver usually leaves this bit to the kernel framework, which sets it when the descriptor is invalid or when the driver has no `d_poll`.

The combination of `POLLHUP` and `POLLIN` is worth noting: when a device closes and it had buffered data, readers should see `POLLHUP` along with `POLLIN`, because the buffered data can still be read even though no more is coming. Well-written userland programs handle this case explicitly.

### 35.5.2 The `d_poll` Callback

Now we can look at the `d_poll` callback itself. Its signature, defined in `/usr/src/sys/sys/conf.h`, is:

```
typedef int d_poll_t(struct cdev *dev, int events, struct thread *td);
```

The `dev` argument is our `cdev`, from which we retrieve the `softc` through `dev->si_drv1`. The `events` argument is the mask of events the caller is interested in. The `td` argument is the calling thread, which we need to pass to `selrecord()` so that the kernel can match future wakeups to the right waiter. The return value is the subset of events that are ready right now.

A skeletal implementation looks like this:

```
static int
evdemo_poll(struct cdev *dev, int events, struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;
 int revents = 0;

 mtx_lock(&sc->sc_mtx);

 if (events & (POLLIN | POLLRDNORM)) {
 if (evdemo_event_ready(sc))
 revents |= events & (POLLIN | POLLRDNORM);
 else
 selrecord(td, &sc->sc_rsel);
 }

 if (events & (POLLOUT | POLLWRNORM))
 revents |= events & (POLLOUT | POLLWRNORM);

 mtx_unlock(&sc->sc_mtx);
 return (revents);
}
```

This is the classic pattern. Let us walk through it one line at a time.

We take the `softc` mutex because we are about to look at the driver’s internal state, and no other thread should be modifying it while we decide whether an event is ready. Holding the lock while we call `selrecord()` is also what closes the race between the answer and the registration, as we will see in a moment.

We look at each event type the caller cares about. For the readable events, we ask the driver whether any data is ready. If it is, we add the matching bits to `revents`. If it is not, we call `selrecord()` to register this thread as a waiter on the `sc_rsel` `selinfo`. That `selinfo` lives in the `softc`, is shared across all potential waiters, and is what we will later pass to `selwakeup()` when data arrives.

For the writable events, we do not have an internal buffer that can fill up in this example, so we always report the device as writable. Many drivers are in this category: writes always fit. Drivers with bounded buffers should check the buffer state the same way they check the read state, and only report `POLLOUT` when there is space.

We release the lock and return the mask of ready events.

Three things about this pattern deserve emphasis.

First, we return immediately with `revents` in every case. The `d_poll` callback does not sleep. If nothing is ready, we register a waiter and return zero. The kernel's generic poll framework takes care of the actual blocking: after `d_poll` returns, the kernel atomically sleeps the thread if no file descriptor returned any events. The driver author does not see this sleep; it is handled entirely by the poll dispatch logic in the kernel.

Second, we must call `selrecord()` only for event types that are not currently ready. If an event is ready and we also call `selrecord()`, we do not break anything (the framework handles this), but it is wasteful: the thread is not going to sleep, so registering it is pointless. The pattern “check, and if not ready then register” keeps the work proportional.

Third, the lock we hold during the check and the `selrecord()` call is the same lock we will take during the producer path when we call `selwakeup()`. This is what prevents the missed wakeup race: if the producer fires after we check the state but before we register the waiter, the producer cannot deliver the wakeup until our `selrecord()` has completed, so the wakeup will find us. We will look at this in detail in Section 3.

### 35.5.3 Registering the `d_poll` Method on the `cdevsw`

To make our driver answer `poll()` calls, we fill in the `d_poll` field of the `struct cdevsw` we pass to `make_dev()` or `make_dev_s()`:

```
static struct cdevsw evdemo_cdevsw = {
 .d_version = D_VERSION,
 .d_name = "evdemo",
 .d_open = evdemo_open,
 .d_close = evdemo_close,
 .d_read = evdemo_read,
 .d_write = evdemo_write,
 .d_ioctl = evdemo_ioctl,
 .d_poll = evdemo_poll,
};
```

If we do not set `d_poll`, the kernel provides a default. In `/usr/src/sys/kern/kern_conf.c`, the default is `no_poll`, which calls `poll_no_poll()`. That default returns the standard readable and writable bits unless the caller asked for anything exotic, in which case it returns `POLLNVAL`. The behaviour makes sense for devices that are always ready, like `/dev/null` and `/dev/zero`, but it is almost never what you want for an event-driven device. For any driver that has real asynchronous semantics, you want to implement `d_poll` yourself.

### 35.5.4 What Real Drivers Look Like

Let us look at two real implementations, because the pattern will become clearer when you see it in production code.

Open `/usr/src/sys/net/if_tuntap.c` and find the function `tunpoll`. It is short enough to quote:

```
static int
tunpoll(struct cdev *dev, int events, struct thread *td)
{
 struct tuntap_softc *tp = dev->si_drv1;
 struct ifnet *ifp = TUN2IFP(tp);
 int revents = 0;

 if (events & (POLLIN | POLLRDNORM)) {
 IFQ_LOCK(&ifp->if_snd);
 if (!IFQ_IS_EMPTY(&ifp->if_snd)) {
 revents |= events & (POLLIN | POLLRDNORM);
 } else {
 selrecord(td, &tp->tun_rsel);
 }
 IFQ_UNLOCK(&ifp->if_snd);
 }
 revents |= events & (POLLOUT | POLLWRNORM);
 return (revents);
}
```

This is our skeleton almost verbatim, with the tun driver's outgoing packet queue as the data source and the `tun_rsel` selinfo as the wait point. The lock here is `IFQ_LOCK`, the queue lock, which the producer also takes before modifying the queue and calling `selwakeuppri()`. That matched locking is what makes the design correct.

Now open `/usr/src/sys/dev/evdev/cdev.c` and find `evdev_poll`. This is a slightly longer and more instructive example because it handles a revoked device explicitly:

```
static int
evdev_poll(struct cdev *dev, int events, struct thread *td)
{
 struct evdev_client *client;
 int ret;
 int revents = 0;

 ret = devfs_get_cdevpriv((void **)&client);
 if (ret != 0)
 return (POLLNVAL);
}
```

```

if (client->ec_revoked)
 return (POLLHUP);

if (events & (POLLIN | POLLRDNORM)) {
 EVDEV_CLIENT_LOCKQ(client);
 if (!EVDEV_CLIENT_EMPTYQ(client))
 revents = events & (POLLIN | POLLRDNORM);
 else {
 client->ec_selected = true;
 selrecord(td, &client->ec_selp);
 }
 EVDEV_CLIENT_UNLOCKQ(client);
}
return (revents);
}

```

Note two extra pieces of behaviour that we did not have in the skeleton.

When the client has been revoked (which happens when the device is being detached while the client still has the file descriptor open), the function returns `POLLHUP` so that the userland program knows to give up. This is the right handling of the detach case. Our skeleton does not do this yet, but the final refactored `evdemo` will.

The driver sets a flag, `ec_selected`, to remember that a waiter has been registered. This lets the producer avoid calling `selwakeup()` for clients that have never polled, which is a small optimization. Most drivers skip this optimization and just call `selwakeup()` every time, which is simpler and still correct.

### 35.5.5 What the User Sees

On the userland side, the caller does not care which implementation we picked. It calls `poll()` with a timeout and sees the result. The first call returns zero if nothing is ready and the timeout expires, or a positive number of ready descriptors otherwise. The second call sees the `revents` bitmask and dispatches to the right handling.

This is the clean separation asynchronous I/O achieves. The user program does not know or care about `selinfo` or `knlist`. It knows only that it asked the kernel “is this ready yet?” and got an answer. The driver’s job is to make that answer truthful and to ensure that the next relevant event will wake the waiter.

### 35.5.6 Wrapping Up Section 2

We now have the userland view of `poll` and `select`, the kernel signature of `d_poll`, and a first skeletal implementation that registers waiters and reports readable events. But the skeleton is still incomplete. We have used `selrecord()` without explaining what it really does with the `struct selinfo`, and we have not yet seen the matching `selwakeup()` call that produces the notification. That is the subject of the next section, and it is where the subtle correctness issues of poll-based asynchronous I/O live.

### 35.6 3. Using `selwakeup()` and `selrecord()`

`selrecord()` and `selwakeup()` are the two halves of the classic poll-wait protocol. They have been in BSD kernels since the original introduction of `select(2)` in 4.2BSD, and they are still the canonical way to implement wait/wakeup for `poll(2)` and `select(2)` in FreeBSD drivers. The pair is simple in outline but subtle in detail, and most of the interesting bugs in poll-based drivers come from getting the subtlety wrong.

This section takes you through the selinfo machinery step by step. First we look at what `struct selinfo` actually contains. Then we look at exactly what `selrecord()` does and what it does not do. Then we look at `selwakeup()` and its companions. Finally we examine the classic missed-wakeup race, the locking discipline that prevents it, and the diagnostic techniques you can use to confirm that your driver is doing the right thing.

#### 35.6.1 `struct selinfo`

Open `/usr/src/sys/sys/selinfo.h` and look at the definition:

```
struct selinfo {
 struct selfdlist si_tdlist; /* List of sleeping threads. */
 struct knlist si_note; /* kernel note list */
 struct mtx *si_mtx; /* Lock for tdlist. */
};

#define SEL_WAITING(si) (!TAILQ_EMPTY(&(si)->si_tdlist))
```

Three fields only. `si_tdlist` is a list of threads currently sleeping on this `selinfo` because they called `selrecord()` and their `poll()` or `select()` call decided to block. `si_note` is a `knlist`, which we will meet in Section 4 when we implement `kqueue` support; it allows the same `selinfo` to serve both `poll()` and `kqueue()` waiters. `si_mtx` is the lock that protects the list.

The `SEL_WAITING()` macro tells you whether any thread is currently parked on this `selinfo`. Drivers occasionally use it to decide whether to bother calling `selwakeup()`, though the wakeup routine itself is cheap enough that the test is usually unnecessary.

Two important habits for `struct selinfo`:

First, the driver must zero-initialize the `selinfo` before first use. The usual way is to embed it in a `softc` that is zeroed by `malloc(..., M_ZERO)`, but if you allocate a `selinfo` separately you must zero it with `bzero()` or equivalent. An uninitialized `selinfo` will crash the kernel the first time `selrecord()` is called on it.

Second, the driver must drain waiters from the `selinfo` before destroying it. The canonical sequence at detach time is `seldrain(&sc->sc_rsel)` followed by `knlist_destroy(&sc->sc_rsel.si_note)`. The `seldrain()` call wakes up any currently parked waiters so that they see the descriptor has become invalid rather than blocking forever. The `knlist_destroy()` call cleans up the knote list for `kqueue` waiters, which we will implement in the next section.

### 35.6.2 What selrecord() Does

`selrecord()` is called from `d_poll` when the driver decides the current event is not ready and the thread will need to wait. Its signature:

```
void selrecord(struct thread *selector, struct selinfo *sip);
```

The implementation lives in `/usr/src/sys/kern/sys_generic.c`. The essence of it is short enough to summarize:

1. The function checks that the thread is in a valid poll context.
2. It takes one of the per-thread preallocated `selfd` descriptors attached to the thread's `seltd` structure.
3. It links that descriptor into the thread's list of active waits and into the `selinfo`'s `si_tdlst`.
4. It remembers the `selinfo`'s mutex on the descriptor, so that the wakeup path knows which lock to take.

The key thing to understand is what `selrecord()` does not do. It does not sleep the thread. It does not block. It does not transition the thread to any blocked state. It merely records the fact that this thread has an interest in this `selinfo`, so that later, when the kernel's poll dispatch code decides to block the thread (if no descriptor returned any events), it knows which `selinfos` the thread is parked on.

After all of a thread's `d_poll` callbacks have returned, the poll dispatch code looks at the results. If any file descriptor returned events, the call returns immediately without blocking. If none did, the thread goes to sleep. The sleep is on a per-thread condition variable inside `struct seltd`, and the wakeup is delivered through that condition variable. The `selinfo`'s role is to link the thread's `seltd` to all the relevant drivers so that each driver can find the thread later.

This separation between “record” and “sleep” is what lets a single `poll()` call monitor many file descriptors. The thread is registered with every `selinfo` of every driver it cares about. When any one of them fires, the wakeup finds the thread through its `seltd` and walks back out to the poll dispatch, which then looks at all the registered file descriptors to see which ones are ready.

### 35.6.3 What selwakeup() Does

`selwakeup()` is called from the producer path when the driver's state changes in a way that might satisfy a waiter. Its signature:

```
void selwakeup(struct selinfo *sip);
```

There is also a variant called `selwakeuppri()` that takes a priority argument, useful when the driver wants to control the priority at which the woken thread resumes. In practice, `selwakeup()` is fine for almost every driver; `selwakeuppri()` is used in a few subsystems that want to emphasize latency at the cost of fairness.

The implementation walks the `selinfo`'s `si_tdlst` and signals each parked thread's condition variable. It also walks the `selinfo`'s `si_note` list and delivers kqueue-style notifications to any knotes attached there, so a single `selwakeup()` call serves both poll waiters and kqueue waiters.

Critically, `selwakeup()` must be called after the driver's internal state has been updated to reflect the new event. If you call `selwakeup()` before the data is visible, the woken thread runs through `d_poll` again, sees

that nothing is ready (because the producer has not yet made it visible), re-registers, and sleeps. When the producer finally updates state, nobody gets woken, because the re-register happened after the wakeup. The driver then has to wait for the next event to unstick the waiter, which may never come.

The correct order is always: update state, then wake up. Never the reverse.

### 35.6.4 The Missed Wakeup Race

The most famous bug in poll-based drivers is the missed wakeup. It looks like this:

```
/* Producer thread */
append_event(sc, ev); /* update state */
selwakeup(&sc->sc_rsel); /* wake waiters */

/* Consumer thread, in d_poll */
if (events & POLLIN) {
 if (event_ready(sc))
 revents |= POLLIN;
 else
 selrecord(td, &sc->sc_rsel);
}
return (revents);
```

If the producer runs between the consumer's `event_ready()` check and the consumer's `selrecord()` call, the wakeup is lost. The consumer saw no event, the producer posted an event and called `selwakeup()` on an empty waiter list, and the consumer then registered. Nobody is going to call `selwakeup()` again until the next event arrives. The consumer now sleeps until that next event, even though an event is already ready.

This is the classic TOCTOU race between the check and the register. The standard fix is to use a single mutex to serialize the check, the register, and the wakeup:

```
/* Producer thread */
mtx_lock(&sc->sc_mtx);
append_event(sc, ev);
mtx_unlock(&sc->sc_mtx);
selwakeup(&sc->sc_rsel);

/* Consumer thread, in d_poll */
mtx_lock(&sc->sc_mtx);
if (events & POLLIN) {
 if (event_ready(sc))
 revents |= POLLIN;
 else
 selrecord(td, &sc->sc_rsel);
}
```

```
mtx_unlock(&sc->sc_mtx);
return (revents);
```

Now the check and the register are atomic with respect to the producer. If the producer updates state before the consumer checks, the consumer sees the event and returns `POLLIN` without registering. If the producer is about to update state while the consumer is in the critical section, the producer has to wait for the consumer to finish. In both cases, the wakeup reaches the consumer.

The important subtlety is that `selwakeup()` is called outside the softc mutex. This is the standard pattern in the FreeBSD kernel: update the state under the lock, drop the lock, deliver the notification. `selwakeup()` itself is safe to call from many contexts, but it takes the `selinfo`'s internal mutex, and we do not want to nest that lock inside an arbitrary driver lock. In practice the rule is, hold the softc lock across the state update, drop it, then call `selwakeup()`.

You will see this pattern across FreeBSD drivers. In `if_tuntap.c` the producer path calls `selwakeuppri()` from outside any driver lock. In `evdev/cdev.c` the same. The producer updates state under its internal lock, releases the lock, and then issues the wakeup. The consumer, in `d_poll`, takes the same lock across the check and the `selrecord()`. That discipline eliminates the missed wakeup race.

### 35.6.5 Thinking About the Lock

Why does this work? Because the lock serializes two specific operations: the producer's state update and the consumer's check plus register. The `selwakeup()` call and the thread's subsequent sleep are outside the lock, but that is fine, because the condition variable semantics of the underlying mechanism handle that race separately.

Here is the argument in more detail. Suppose the consumer acquires the lock first. It checks the state, sees nothing, calls `selrecord()` to register, and releases the lock. Some time later the producer acquires the lock, updates the state, releases the lock, and calls `selwakeup()`. The consumer is already registered, so the wakeup finds it. Good.

Now suppose the producer acquires the lock first. It updates the state, releases the lock, and calls `selwakeup()`. The consumer was not yet registered, so the wakeup finds no waiters. That is fine because the consumer has not yet reached the point where it would have slept; the consumer is still about to acquire the lock. When the consumer does acquire the lock, it checks the state, sees the event (because the producer has already updated it), and returns `POLLIN` without calling `selrecord()`. The consumer is correctly notified.

The third case is the tricky one. The consumer has just checked the state (under the lock) and is about to call `selrecord()`, but in fact, because the lock is held the whole time, this case cannot arise. The producer cannot update the state until the consumer releases the lock, at which point the consumer has already registered.

So the lock discipline is: always hold the lock across the consumer's check and register, and always hold the lock across the producer's state update. The `selwakeup()` call itself happens outside the lock, because it has its own internal synchronization.

### 35.6.6 Common Mistakes

A few mistakes are worth calling out explicitly.

Calling `selwakeup()` inside the state-update lock is wrong in most cases because `selwakeup()` itself may need to take other locks (the `selinfo` mutex, the thread's `selinfo` queue lock). Doing this from within the `softc` mutex creates a lock-ordering opportunity that is easy to get wrong. The rule of thumb is, update under the lock, drop, then `selwakeup()`.

Forgetting to wake up all interested `selinfos` is the other common mistake. If the driver has separate read and write `selinfos` (say, one for `POLLIN` waiters and one for `POLLOUT` waiters), it must wake the right one when state changes. Waking the wrong one means the actual waiter sleeps forever.

Calling `selrecord()` without holding any lock produces a time window in which the event can arrive without delivering the wakeup. This is the race we just analyzed, and the fix is always the same: hold the lock.

Calling `selrecord()` every time, even when data is ready, is not a correctness bug but it is a pointless load on the per-thread `selfd` pool. If data is ready, the thread is not going to sleep, so registering it is wasted work. The pattern “check; if ready, return; if not, register” is the correct one.

Calling `selwakeup()` on a destroyed `selinfo` is a crash waiting to happen. The detach path must call `selfdrain()` before freeing the `selinfo` or the surrounding `softc`.

### 35.6.7 Diagnostic Techniques

When a driver's poll support is not working, a few tools help you isolate the problem.

The first tool is `top(1)`. Load the driver, open a descriptor in a userland program, and have the program call `poll()` with a long timeout. Look at the program in `top -H` and check the `WCHAN` column. If the poll is working correctly, the thread's wait channel will be `select` or something similar. If the thread is in some other state (running, runnable, short sleep), the poll call may have returned prematurely, or the program may be spinning.

The second tool is counters on the driver. Add a counter for each call to `selrecord()`, one for each call to `selwakeup()`, and one for each time `d_poll` returns a ready mask. After a test, print these counters through `sysctl`. If `selrecord()` fires but `selwakeup()` never does, the producer path is never triggering. If `selwakeup()` fires but the program stays asleep, you probably have a missed wakeup because the state-update and register happen outside the lock.

The third tool is `ktrace(1)` and `kdump(1)`. Run the test program under `ktrace`, and the dump will show every system call and its timing. A program that calls `poll()` and blocks will show up as a `RET poll` entry after the wakeup, and the timestamp will tell you when the wakeup actually arrived. If the producer event happened at time `T` and the wakeup arrived seconds later, you have a bug.

The fourth tool is `DTrace`, which can instrument `selwakeup` itself. A script that probes `fbt:kernel:selwakeup:entry` and prints the calling driver's `softc` pointer shows every wakeup in the system. If your driver's wakeup never fires, `DTrace` will tell you so in milliseconds.

### 35.6.8 Closing the Loop: evdemo With Poll Support

Putting the pieces together, here is the minimum additional code our `evdemo` driver needs to support `poll()` correctly:

```
/* In the softc */
struct evdemo_softc {
 /* ... existing fields ... */
 struct selinfo sc_rsel; /* read selectors */
};

/* At attach */
knlist_init_mtx(&sc->sc_rsel.si_note, &sc->sc_mtx);

/* In d_poll */
static int
evdemo_poll(struct cdev *dev, int events, struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;
 int revents = 0;

 mtx_lock(&sc->sc_mtx);
 if (events & (POLLIN | POLLRDNORM)) {
 if (sc->sc_nevents > 0)
 revents |= events & (POLLIN | POLLRDNORM);
 else
 selrecord(td, &sc->sc_rsel);
 }
 if (events & (POLLOUT | POLLWRNORM))
 revents |= events & (POLLOUT | POLLWRNORM);
 mtx_unlock(&sc->sc_mtx);

 return (revents);
}

/* In the producer path (for evdemo, this is the event injection
 * routine triggered from a callout or ioctl) */
static void
evdemo_post_event(struct evdemo_softc *sc, struct evdemo_event *ev)
{
 mtx_lock(&sc->sc_mtx);
 evdemo_enqueue(sc, ev);
 mtx_unlock(&sc->sc_mtx);
 selwakeup(&sc->sc_rsel);
}

/* At detach */
seldrain(&sc->sc_rsel);
knlist_destroy(&sc->sc_rsel.si_note);
```

Notice that we called `knlist_init_mtx()` on the `selinfo`'s embedded `si_note` knlist even though we are not yet implementing `kqueue`. This costs us almost nothing and makes the `selinfo` compatible with `kqueue` support we will add in Section 4. If you do not pre-initialize `si_note`, the first `selwakeup()` call that tries to walk the knlist will crash. Many drivers initialize the knlist during attach as a matter of habit.

Also notice that the `evdemo_post_event` helper holds the `softc` mutex while it updates the event count, drops the mutex, and then calls `selwakeup()`. That is the standard producer pattern, and it is the one we will reuse throughout the rest of the chapter.

### 35.6.9 Wrapping Up Section 3

At this point you have all the conceptual and practical pieces of poll-based asynchronous I/O. You know the contract, the kernel structures, the correct locking discipline, and the common failure modes. You can take an existing blocking driver, add `d_poll` support, and have it behave correctly under `poll(2)` and `select(2)`.

The problem is that `poll(2)` and `select(2)` have well-known scalability limitations. Every call re-declares the full set of descriptors the caller is interested in, which is  $O(N)$  per call. For programs watching thousands of descriptors, this overhead dominates. FreeBSD has offered a better mechanism since the late 1990s, namely `kqueue(2)`, and that is the subject of the next section.

## 35.7 4. Supporting `kqueue` and `EVFILT_READ/EVFILT_WRITE`

`kqueue(2)` is FreeBSD's scalable event-notification facility. Unlike `poll(2)` and `select(2)`, which require the userland program to re-declare its interests on every call, `kqueue(2)` lets the program register interests once and then ask only for events that have actually fired. For a program watching ten thousand file descriptors where only a few are active, this is the difference between a fast, interactive program and a slow, loaded one.

`kqueue` is also more expressive than `poll`. Beyond the basic readable and writable filters, it offers filters for signals, timers, file-system events, process lifecycle events, user-defined events, and several other categories. A driver that wants to participate only in the classic readable and writable notifications still fits cleanly into the framework; the broader features are available if needed.

From the driver's point of view, `kqueue` support adds one callback to the `cdevsw`, `d_kqfilter`, and one set of filter operations, a `struct filterops`, that provides the lifecycle and event-delivery functions for each filter type. The whole mechanism reuses the `struct selinfo` we met in Section 3, so drivers that already support `poll()` can add `kqueue` support by writing about a hundred lines of extra code and calling a handful of new APIs.

### 35.7.1 What `kqueue` Looks Like to Userland

Before we implement the driver side, let us see what the user program looks like. A caller opens a `kqueue`, registers interest in a file descriptor, and then reaps events:

```
#include <sys/event.h>

int kq = kqueue();
```

```

int fd = open("/dev/evdemo", O_RDONLY);

struct kevent change;
EV_SET(&change, fd, EVFILT_READ, EV_ADD | EV_CLEAR, 0, 0, NULL);
kevent(kq, &change, 1, NULL, 0, NULL);

for (;;) {
 struct kevent ev;
 int n = kevent(kq, NULL, 0, &ev, 1, NULL);
 if (n > 0 && ev.filter == EVFILT_READ) {
 char buf[256];
 ssize_t r = read(fd, buf, sizeof(buf));
 /* ... */
 }
}

```

The `EV_SET` macro constructs a `struct kevent` describing the interest: “watch file descriptor `fd` for `EVFILT_READ` events, using edge-triggered (`EV_CLEAR`) semantics, and keep it active (`EV_ADD`).” The first `kevent()` call registers that interest. The loop then calls `kevent()` in blocking mode, asking for the next event, and services it when it arrives.

The driver never sees the `kqueue` file descriptor or the `kevent` structure directly. It sees only the per-interest `struct knote` and its attached `struct filterops`. The registration flows through the framework to our `d_kqfilter` callback, which chooses the right filter operations and attaches the `knote` to our `softc`. The delivery flows through `KNOTE_LOCKED()` calls in the producer path, which walks our `knote` list and notifies each attached `kqueue` of the ready event.

### 35.7.2 The Data Structures

Two structures matter on the driver side: `struct filterops` and `struct knlist`.

`struct filterops`, defined in `/usr/src/sys/sys/event.h`, holds the per-filter lifecycle functions:

```

struct filterops {
 int f_isfd;
 int (*f_attach)(struct knote *kn);
 void (*f_detach)(struct knote *kn);
 int (*f_event)(struct knote *kn, long hint);
 void (*f_touch)(struct knote *kn, struct kevent *kev, u_long type);
 int (*f_userdump)(struct proc *p, struct knote *kn,
 struct kinfo_knote *kin);
};

```

The fields we care about for a driver are:

`f_isfd` is 1 if the filter is attached to a file descriptor. Almost all driver filters have this set to 1. A filter that watches something not tied to an fd (like `EVFILT_TIMER`) would set it to 0.

`f_attach` is called when a knote is being attached to a newly registered interest. Many drivers leave this as `NULL` because all the attach work happens in `d_kqfilter` itself.

`f_detach` is called when a knote is being removed. The driver uses this to unregister the knote from its internal knote list.

`f_event` is called to evaluate whether the filter's condition is currently satisfied. It returns non-zero if yes, zero if no. It is the kqueue equivalent of the state check in `d_poll`.

`f_touch` is used when the filter supports `EV_ADD/EV_DELETE` updates that should not be treated as full re-registration. Most drivers leave this as `NULL` and accept the default behaviour.

`f_userdump` is used for kernel introspection and can be left `NULL` in driver code.

`struct knlist`, defined in the same header, holds a list of knotes attached to a particular object. It carries pointers to the object's lock operations so that the kqueue framework can grab and release the right lock when delivering events:

```
struct knlist {
 struct klist kl_list;
 void (*kl_lock)(void *);
 void (*kl_unlock)(void *);
 void (*kl_assert_lock)(void *, int);
 void *kl_lockarg;
 int kl_autodestroy;
};
```

Drivers rarely touch this structure directly. The framework provides helper functions, starting with `knlist_init_mtx()` for the common case of a `knlist` protected by a single mutex.

### 35.7.3 Initializing a knlist

The simplest way to initialize a `knlist` is:

```
knlist_init_mtx(&sc->sc_rsel.si_note, &sc->sc_mtx);
```

The first argument is the `knlist` to initialize. The second is the driver's mutex. The framework stores the mutex and will take it when needed to protect the knote list. The knote list is usually embedded in a `struct selinfo`, as we saw in the previous section; reusing the same `selinfo` for both poll and kqueue waiters lets a single `selwakeup()` call cover both mechanisms.

For a driver that is already zeroing the `softc` through `M_ZERO`, the initialization is just this one call during attach.

### 35.7.4 The d\_kqfilter Callback

The `d_kqfilter` callback is the entry point for kqueue registration. Its signature, in `/usr/src/sys/sys/conf.h`, is:

```
typedef int d_kqfilter_t(struct cdev *dev, struct knote *kn);
```

The `dev` argument is our `cdev`. The `kn` argument is the knote being registered. The callback decides which filter operations apply, attaches the knote to our knote list, and returns zero on success.

A minimal implementation for a driver that supports `EVFILT_READ`:

```
static int
evdemo_kqfilter(struct cdev *dev, struct knote *kn)
{
 struct evdemo_softc *sc = dev->si_drv1;

 switch (kn->kn_filter) {
 case EVFILT_READ:
 kn->kn_fop = &evdemo_read_filterops;
 kn->kn_hook = sc;
 knlist_add(&sc->sc_rsel.si_note, kn, 0);
 return (0);
 default:
 return (EINVAL);
 }
}
```

Let us walk through this.

The switch on `kn->kn_filter` decides which filter type we are dealing with. A driver that supports only `EVFILT_READ` returns `EINVAL` for anything else. A driver that also supports `EVFILT_WRITE` has a second case that points to a different filter operations structure.

We set `kn->kn_fop` to the filter operations for this filter type. The kqueue framework calls these ops as the knote's lifecycle progresses.

We set `kn->kn_hook` to the `softc`. The knote has this generic pointer for per-driver use. Our filter functions will pull the `softc` back out of `kn->kn_hook` when they are called.

We call `knlist_add()` to link the knote into our knote list. The third argument, `islocked`, is zero here because we are not holding the `knlist` lock at this point. If we were, we would pass 1.

Return zero to indicate success.

### 35.7.5 The filterops Implementation

The filter operations are where the per-filter behaviour lives. For `EVFILT_READ` on `evdemo`, they look like this:

```

static int
evdemo_kqread(struct knote *kn, long hint)
{
 struct evdemo_softc *sc = kn->kn_hook;
 int ready;

 mtx_assert(&sc->sc_mtx, MA_OWNED);

 kn->kn_data = sc->sc_nevents;
 ready = (sc->sc_nevents > 0);

 if (sc->sc_detaching) {
 kn->kn_flags |= EV_EOF;
 ready = 1;
 }

 return (ready);
}

static void
evdemo_kqdetach(struct knote *kn)
{
 struct evdemo_softc *sc = kn->kn_hook;

 knlist_remove(&sc->sc_rsel.si_note, kn, 0);
}

static const struct filterops evdemo_read_filterops = {
 .f_isfd = 1,
 .f_attach = NULL,
 .f_detach = evdemo_kqdetach,
 .f_event = evdemo_kqread,
};

```

The `f_event` function, `evdemo_kqread`, is called every time the framework wants to know whether the filter is ready. It looks at the `softc`, reports the number of available events in `kn->kn_data` (a convention that `kqueue` users rely on to learn how much data is available), and returns non-zero if at least one event is waiting. It also flips the `EV_EOF` flag when the device is detaching, which lets the userland see that no more events are coming.

Note the assertion that the `softc` mutex is held. The framework takes our `knlist`'s lock, which we told it is the `softc` mutex via `knlist_init_mtx`. Because the `f_event` callback is invoked inside that lock, we can look at `sc_nevents` and `sc_detaching` safely.

The `f_detach` function removes the `knote` from our `knlist` when the userland no longer cares about this registration.

The constant `evdemo_read_filterops` is what `d_kqfilter` pointed at in the previous subsection. `f_isfd = 1` tells the framework that this filter is tied to a file descriptor, which is the correct value for any driver-level filter.

### 35.7.6 Delivering Events Through `KNOTE_LOCKED`

On the producer side, we need to notify registered knotes when the driver's state changes. The macro is `KNOTE_LOCKED()`, defined in `/usr/src/sys/sys/event.h`:

```
#define KNOTE_LOCKED(list, hint) knote(list, hint, KNF_LISTLOCKED)
```

It takes a `knlist` pointer and a hint. The hint is passed through to each knote's `f_event` callback, giving the producer a way to pass context (for example, a specific event type) to the filter. Most drivers pass zero.

The `KNOTE_LOCKED` variant is what you want when you are already holding the `knlist`'s lock. The `KNOTE_UNLOCKED` variant is used when you are not. Since the `knlist`'s lock is usually your `softc` mutex, and since the rest of the producer path is holding that lock anyway, `KNOTE_LOCKED` is the usual choice.

Adding it to our producer path:

```
static void
evdemo_post_event(struct evdemo_softc *sc, struct evdemo_event *ev)
{
 mtx_lock(&sc->sc_mtx);
 evdemo_enqueue(sc, ev);
 KNOTE_LOCKED(&sc->sc_rsel.si_note, 0);
 mtx_unlock(&sc->sc_mtx);
 selwakeup(&sc->sc_rsel);
}
```

We now notify both `kqueue` and `poll` waiters from the same producer. `KNOTE_LOCKED` inside the `softc` mutex walks the knote list and evaluates each knote's `f_event`, queuing notifications to any `kqueues` that have active waiters. `selwakeup` outside the lock wakes up `poll()` and `select()` waiters. The two mechanisms are independent and neither interferes with the other.

### 35.7.7 Detach: Cleaning Up `knlist`

At detach time, the driver must drain the `knlist` before destroying it. The clean sequence is:

```
knlist_clear(&sc->sc_rsel.si_note, 0);
seldrain(&sc->sc_rsel);
knlist_destroy(&sc->sc_rsel.si_note);
```

`knlist_clear()` removes every knote that is still attached. After this call, any userland program that still has a `kqueue` registration will see the knote go away on its next reap. `seldrain()` wakes up any parked `poll()` waiters so that they return. `knlist_destroy()` checks that the list is empty and frees the internal resources.

The order matters. If you destroy the knlist without clearing it first, the destroy will panic on the assertion that the list is empty. If you clear the knlist but leave poll waiters parked, they will sleep until something wakes them, which is wasteful. Follow the sequence above and the detach path is clean.

### 35.7.8 A Fuller Example: Pipes

Open `/usr/src/sys/kern/sys_pipe.c` and look at the pipe `kqfilter` implementation. It is one of the most extensive examples in the kernel, and it is worth reading in full because pipes support both read and write filters with proper EOF handling. The key pieces are the two filterops structures:

```
static const struct filterops pipe_rfiltops = {
 .f_isfd = 1,
 .f_detach = filt_pipedetach,
 .f_event = filt_piperead,
 .f_userdump = filt_pipedump,
};

static const struct filterops pipe_wfiltops = {
 .f_isfd = 1,
 .f_detach = filt_pipedetach,
 .f_event = filt_pipewrite,
 .f_userdump = filt_pipedump,
};
```

And the read filter's event function:

```
static int
filt_piperead(struct knote *kn, long hint)
{
 struct file *fp = kn->kn_fp;
 struct pipe *rpipe = kn->kn_hook;

 PIPE_LOCK_ASSERT(rpipe, MA_OWNED);
 kn->kn_data = rpipe->pipe_buffer.cnt;
 if (kn->kn_data == 0)
 kn->kn_data = rpipe->pipe_pages.cnt;

 if ((rpipe->pipe_state & PIPE_EOF) != 0 &&
 ((rpipe->pipe_type & PIPE_TYPE_NAMED) == 0 ||
 fp->f_pipegen != rpipe->pipe_wgen)) {
 kn->kn_flags |= EV_EOF;
 }
}
```

```

 return (1);
 }
 kn->kn_flags &= ~EV_EOF;
 return (kn->kn_data > 0);
}

```

Note the handling of EOF, the explicit clearing of `EV_EOF` when the pipe is no longer at EOF (which matters if the named pipe has a new writer), and the use of `kn->kn_data` to report the amount of available data. These are the details a finished driver gets right.

### 35.7.9 The Anatomy of struct knote

We have been passing a `struct knote` pointer around without looking closely at it, but the driver's life is easier once we know what it contains. `struct knote`, defined in `/usr/src/sys/sys/event.h`, is the kernel's per-registration record. Every call to `kevent(2)` that registers an interest creates exactly one knote, and that knote persists until the registration is removed. For a driver, the knote is the unit of currency: every `knlist` operation takes a knote, every filter callback receives a knote, and every delivery walks a list of them. Knowing what lives inside the structure turns the callback contracts we have been following into something we can reason about instead of memorise.

The fields the driver cares about are a small subset of the whole structure, but each one repays attention.

`kn_filter` identifies which filter type the userland asked for. Inside `d_kqfilter`, this is what we switch on: `EVFILT_READ`, `EVFILT_WRITE`, `EVFILT_EXCEPT`, and so on. The value comes from the `filter` field of the `struct kevent` that userland submitted. A driver that supports only one filter type checks this field and rejects any mismatch with `EINVAL`.

`kn_fop` is the pointer to the `struct filterops` table that will service this knote for the rest of its life. The driver sets this inside `d_kqfilter`. After that point, the framework calls through this pointer to reach our `attach`, `detach`, `event`, and `touch` callbacks. The `filterops` table is always `static const` in the drivers we examine, because the framework does not take a reference on it and the driver is expected to keep the pointer valid for the knote's lifetime.

`kn_hook` is a generic per-driver pointer. The driver typically sets it to the `softc`, to a per-client state record, or to whichever object the filter should react to. The framework never reads or writes it. When the filter callbacks run, they pull the driver state out of `kn_hook` rather than going through a global lookup, which both avoids the lookup cost and avoids a class of lock-ordering problems that global lookups can introduce.

`kn_hookid` is an integer companion to `kn_hook`, available for per-driver tagging. Most drivers leave it alone.

`kn_data` is how the filter's `f_event` callback communicates "how much is ready" back to the userland. For readable filters, drivers conventionally store the number of bytes or records available. For writable filters, they store the amount of space available. Userland reads this through the `data` field of the returned `struct kevent`, and tools like `libevent` rely on that convention. The `/dev/klog` driver stores a raw byte count here, while the `evdev` driver stores the queue depth scaled into bytes by multiplying the record count by `sizeof(struct input_event)`, because `evdev` clients read `struct input_event` records rather than raw bytes.

`kn_sfflags` and `kn_sdata` hold the per-registration flags and data that userland requested through the `fflags` and `data` fields of `struct kevent`. Filters that support fine-grained control, like `EVFILT_TIMER` with its period

or `EVFILT_VNODE` with its note mask, look at these to decide how to behave. Simple driver filters usually ignore them.

`kn_flags` holds the delivery-time flags that the framework passes through to the userland on the next reap. The one every driver uses is `EV_EOF`, which signals “no more data will ever arrive from this source.” Drivers set `EV_EOF` in `f_event` when the device is being detached, when a pseudo-terminal’s peer has closed, when a pipe has lost its writer, or whenever the readiness signal has become permanent.

`kn_status` is internal state owned by the framework: `KN_ACTIVE`, `KN_QUEUED`, `KN_DISABLED`, `KN_DETACHED`, and a handful of others. Drivers must not modify it. The driver’s job is simply to report readiness through `f_event`; the framework updates `kn_status` accordingly.

`kn_link`, `kn_selnext`, and `kn_tqe` are the linked-list linkage fields used by the various `kqueue` framework lists. The `knlist` helpers manipulate them on our behalf. Drivers should never touch them directly.

Put together, these fields tell a simple story. The driver creates a knote’s association with its filter operations inside `d_kqfilter`, sets `kn_hook` and optionally `kn_hookid` so the filter callbacks can recover their context, and then lets the framework manage linkage and status. The driver owns readiness reporting through `f_event` and nothing else. The handoff between driver and framework is clean, and most driver bugs in this area come from trying to reach across that boundary, either by modifying framework-owned status flags or by retaining stale pointers into the knote after `f_detach` has fired.

One point worth emphasising: the knote outlives any single `f_event` call, but it does not outlive `f_detach`. Once the framework invokes `f_detach`, the knote is being torn down; the driver must unhook it from any internal structure it is attached to and must not keep the pointer. The `kn_hook` pointer, which is driver-owned, must be treated the same way. If the driver was keeping a back-pointer from a `softc` field to the knote for any reason (uncommon, but sometimes useful for driver-initiated detach), it must clear that back-pointer during `f_detach` before the framework frees the knote.

### 35.7.10 Inside struct knlist: How the Driver’s Waiting Room Works

`struct knlist`, declared in `/usr/src/sys/sys/event.h`, is where a driver accumulates the knotes that are currently interested in one of its notification sources. Every driver object that can wake `kqueue` waiters owns at least one `knlist`. The pipe object owns two, one for readers and one for writers. The `tty` owns two as well, `t_inpoll` and `t_outpoll`, each with its own `knlist`. The `evdev` client object owns one per client. In our `evdemo` driver, we piggy-back on the `struct selinfo.si_note` we already have for `poll`, so the same `knlist` is the one waking both `poll` and `kqueue` consumers.

The structure itself is small:

```
struct knlist {
 struct klist kl_list;
 void (*kl_lock)(void *);
 void (*kl_unlock)(void *);
 void (*kl_assert_lock)(void *, int);
 void *kl_lockarg;
 int kl_autodestroy;
};
```

`kl_list` is the singly-linked list head of `struct knote` entries, with linkage through each `knote`'s `kn_selnext` field. The list head is manipulated by the framework, never by the driver directly.

`kl_lock`, `kl_unlock`, and `kl_assert_lock` are function pointers that the framework uses when it needs to take the object's lock. The `knlist` does not own a lock of its own; it borrows the driver's locking regime. This is why a `struct selinfo` can carry a `knlist` without creating a separate lock: the lock is whatever the driver has already declared.

`kl_lockarg` is the argument passed to those lock functions. When we initialise a `knlist` with `knlist_init_mtx(&kn1, &sc->sc_mtx)`, the framework stores `&sc->sc_mtx` in `kl_lockarg` and arranges for the lock callbacks to wrap `mtx_lock` and `mtx_unlock`. The driver never sees this wiring and never needs to.

`kl_autodestroy` is a flag used by a few specific subsystems, most notably AIO, where the `knlist` lives inside the `struct kaiocb` and must be torn down automatically when the request completes. Driver code almost never sets this. The `aio_filtops` path in `/usr/src/sys/kern/vfs_aio.c` is the canonical use, and it is worth remembering that the flag exists so that reading that file later does not surprise you.

The lock contract deserves emphasis because it is the single most common source of `kqueue` driver bugs. When the framework calls our `f_event`, it holds the `knlist` lock, which is our softc mutex. Our `f_event` may read softc state but must not take the softc mutex again (it is already ours), must not sleep, and must not block on any other lock that could be held across an `f_event` invocation. When we invoke `KNOTE_LOCKED`, we are asserting that we already hold the lock, so the framework skips locking on its way through the list. When we invoke `KNOTE_UNLOCKED`, the framework takes and releases the lock on our behalf. Mixing the two styles inside one producer path is a classic source of subtle double-lock panics under load.

The unification with `struct selinfo` is worth noticing. Back in Section 3 we treated `struct selinfo` as a poll-only concept, but it actually embeds a `struct knlist` in its `si_note` member. This is why a driver that already supports `poll()` has the infrastructure for `kqueue()` sitting in its softc: adding `kqueue` is largely a matter of initialising the `knlist` with `knlist_init_mtx` and wiring up the filter operations. The producer path already calls into `selwakeup()`, which itself walks `si_note` under the appropriate lock and notifies any attached `knotes`. Doing the notification explicitly with `KNOTE_LOCKED(&sc->sc_rsel.si_note, 0)` is clearer and lets us choose exactly when the `kqueue` fan-out happens relative to any other producer work. In the drivers we will read below, both styles appear; either one is correct as long as the locking is consistent.

### 35.7.11 The `knlist` Lifecycle in Detail

The lifecycle of a `knlist` follows the lifecycle of the driver object that owns it. A `knlist` comes into existence during attach (either the driver's attach entry point for a real hardware driver or the `SYSINIT` for a pseudo-device), lives through the open-read-close cycles of userland consumers, and is torn down at detach. The functions we need, all declared in `/usr/src/sys/sys/event.h` and implemented in `/usr/src/sys/kern/kern_event.c`, are `knlist_init`, `knlist_init_mtx`, `knlist_add`, `knlist_remove`, `knlist_clear`, and `knlist_destroy`.

`knlist_init_mtx` is the one almost every driver calls. It initialises the list head, configures the `knlist` to use `mtx_lock`/`mtx_unlock` with the driver's mutex as the argument, and marks the `knlist` as live. The caller passes a pointer to the `knlist` (usually `&sc->sc_rsel.si_note` or, for drivers with per-direction notification, `&sc->sc_wsel.si_note` as well) and a pointer to a mutex that already exists in the driver.

`knlist_init` is the general form, used when the driver's lock regime is not a simple mutex. It accepts three

function pointers (lock, unlock, assert), an argument pointer passed to those functions, and the underlying list head. Pipes use the `_mtx` form with their pipe-pair mutex; socket buffers use a customised `knlist_init` because they have their own locking discipline. Most drivers do not need the general form.

`knlist_add` is called from `d_kqfilter` to link a newly registered knote into the list. Its prototype is `void knlist_add(struct knlist *knl, struct knote *kn, int islocked)`. The `islocked` argument tells the function whether the caller already holds the `knlist` lock. If it is zero, the function takes the lock for us. If it is one, we are asserting that we already hold it. Drivers that do no extra locking inside `d_kqfilter` pass zero; drivers like `/dev/klog` that took the `msgbuf` lock on entry pass one. Either pattern is correct; the choice depends on what the driver wants to protect around the `knlist_add` call.

`knlist_remove` is the reverse operation, normally called from the `f_detach` callback. Its prototype is `void knlist_remove(struct knlist *knl, struct knote *kn, int islocked)`. The framework invokes `f_detach` with the `knlist` lock already held, so `islocked` is one in that context. If for any reason the driver needs to remove a specific knote from outside `f_detach` (which is unusual and rarely correct), it must arrange its own locking.

`knlist_clear` is the bulk-removal function used at driver detach time. It walks the list, removes every knote, and marks each of them with `EV_EOF | EV_ONESHOT` so that the userland sees a final event and the registration is discarded. The signature `void knlist_clear(struct knlist *knl, int islocked)` is actually a wrapper around `knlist_cleardel` in `/usr/src/sys/kern/kern_event.c` with a `NULL` `struct thread *` and the kill flag set, meaning “remove everything.” Drivers call this from `detach` right before tearing down the `knlist`.

`knlist_destroy` releases the internal machinery of the `knlist`. Before calling it, the `knlist` must be empty. If you destroy a `knlist` with live knotes, the kernel asserts and panics. This is why the detach sequence we saw earlier is rigid:

```
knlist_clear(&sc->sc_rsel.si_note, 0);
selldrain(&sc->sc_rsel);
knlist_destroy(&sc->sc_rsel.si_note);
```

`knlist_clear` empties the list. `selldrain` wakes any `poll()` waiters that are still parked on the same `selinfo`, so their waiting threads return from the kernel. `knlist_destroy` tears down the internals and validates that the list is empty. If any of these steps is skipped, the detach becomes unsafe: live knotes trying to call an unloaded driver’s `f_event` would crash the kernel; a poll waiter whose `selinfo` has been freed would wake to a dangling pointer.

Two further points are worth noticing in the implementation of `knlist_remove` in `/usr/src/sys/kern/kern_event.c`. It walks into the internal `knlist_remove_kq` helper which also acquires the `kq` lock so that the removal is coherent with any in-progress event dispatch. And it sets `KN_DETACHED` in `kn_status` to signal to the rest of the framework that this knote is gone. Drivers never observe `KN_DETACHED` directly, but understanding that it exists explains why concurrent detach and event delivery can race safely: the framework’s internal state machine keeps them consistent.

### 35.7.12 The kqfilter Callback Contract

`d_kqfilter` is called from the `kqueue` registration path in `/usr/src/sys/kern/kern_event.c`, specifically from `kqueue_register` via the file descriptor's `fo_kqfilter` method. By the time the callback runs, the framework has already validated the file descriptor, allocated the `struct knote`, and filled in the userland's request. Our job is narrow: pick the right filterops, attach to the right `knlist`, and return zero.

What `d_kqfilter` must do. It must inspect `kn->kn_filter` to decide which filter type the userland is asking for. It must set `kn->kn_fop` to a valid `struct filterops` for that type. It must attach the `knote` to a `knlist` that belongs to our driver, typically by calling `knlist_add`. And it must return zero on success or a sensible `errno` on failure. If the driver cannot service the requested filter, `EINVAL` is the right answer.

What `d_kqfilter` must not do. It must not sleep, because the `kqueue` registration path holds locks that are not safe to sleep under. It must not allocate memory with `M_WAITOK`, for the same reason. It must not call any function that can block on another process. If the driver needs more than a fast lookup and a `knlist` insertion, it is doing something wrong. The callback is essentially a fast-path wiring operation.

Lock state on entry is worth understanding. The framework does not hold the `knlist` lock when it calls `d_kqfilter`. We can therefore pass `islocked = 0` to `knlist_add` if we have not taken the `knlist`'s lock ourselves. If our driver needs to look at softc state as part of the filter-selection logic, for example to report `ENODEV` on a revoked `cdev` as the `evdev` driver does, we can take the `softc` mutex ourselves, check the state, do the `knlist_add` with `islocked = 1`, and release the mutex before returning. The `evdev` example below shows exactly that pattern.

Returning a non-zero value from `d_kqfilter` means “the userland will get this `errno` back from `kevent(2)`.” It does not mean “try again.” A driver that returns `EAGAIN` will confuse userland because `kevent` does not interpret that value the way `read` does. Stick to `EINVAL` for unsupported filters and `ENODEV` for revoked or torn-down devices, and avoid clever error returns.

One subtlety about when `d_kqfilter` is invoked: a single `kevent(2)` call that registers a new interest with `EV_ADD` enters the framework, finds that no `knote` exists yet for this (file, filter) pair, allocates one, and then calls `fo_kqfilter` on the file descriptor's `fileops`. That is where our `d_kqfilter` is reached, through the `cdev` `fileops` table. If the caller is instead updating an existing registration (for example, toggling between enabled and disabled with `EV_ENABLE/EV_DISABLE`), our callback is not involved; the framework handles that internally through `f_touch` or direct status manipulation.

### 35.7.13 Worked Example: The /dev/klog Driver

The simplest real driver-side `kqfilter` implementation in the tree is the kernel log device, `/dev/klog`, in `/usr/src/sys/kern/subr_log.c`. Its entire `kqueue` support fits in about forty lines and uses exactly the pattern we have been discussing. Let us read it.

The filterops table is a minimal one, with only detach and event callbacks:

```
static const struct filterops log_read_filterops = {
 .f_isfd = 1,
 .f_attach = NULL,
 .f_detach = logkqdetach,
```

```
.f_event = logkqread,
};
```

The attach hook is NULL because all the driver-side work happens in `logkqfilter` itself. There is no need for a separate `f_attach` callback; the `d_kqfilter` entry point does everything it needs to do. Drivers that need to perform per-knote setup beyond what `d_kqfilter` does can use `f_attach`, but that is uncommon.

`logkqfilter` is the `d_kqfilter` callback:

```
static int
logkqfilter(struct cdev *dev __unused, struct knote *kn)
{

 if (kn->kn_filter != EVFILT_READ)
 return (EINVAL);

 kn->kn_fop = &log_read_filterops;
 knlist_add(&logsoftc.sc_selp.si_note, kn, 1);

 return (0);
}
```

The `/dev/klog` driver supports only readable events; a request for any other filter type gets `EINVAL`. The callback sets `kn_fop` to the static filterops table and then attaches the knote to the `softc`'s `selinfo` knlist. The third argument to `knlist_add` is 1 here, which means “the caller already holds the knlist lock.” The driver takes the message-buffer lock before entering the callback for its own reasons, so passing 1 is correct.

The event function is just as short:

```
static int
logkqread(struct knote *kn, long hint __unused)
{

 mtx_assert(&msgbuf_lock, MA_OWNED);

 kn->kn_data = msgbuf_getcount(msgbufp);
 return (kn->kn_data != 0);
}
```

It asserts the message-buffer lock (which is what the knlist uses), reads the number of queued bytes, and returns non-zero if anything is available. The userland sees the byte count in `kn->kn_data` on the next reap.

The detach function is one line:

```
static void
logkqdetach(struct knote *kn)
{
 knlist_remove(&logsoftc.sc_selp.si_note, kn, 1);
}
```

It removes the knote from the knlist, again passing 1 because the framework has taken the lock before entering `f_detach`.

The last piece is the producer. When the log timeout fires and there is new data to notify waiters about, `/dev/klog` calls `KNOTE_LOCKED(&logsoftc.sc_selp.si_note, 0)` under the message buffer lock. That walks the knlist, calls each registered knote's `f_event`, and queues notifications for any kqueues that have waiters. The hint of zero is ignored by `logkqread`, which is the common case.

The whole kqueue integration is initialised once at subsystem start via `knlist_init_mtx(&logsoftc.sc_selp.si_note, &msgbuf_lock)`. `/dev/klog` is never unloaded in practice, so there is no teardown sequence to study here. That comes later, in the `evdev` example.

The takeaway is how small this code is. A complete, working, production-grade `kqfilter` integration for a real driver in FreeBSD 14.3 is under forty lines. The complexity of kqueue is in the framework, not in the driver's contribution.

### 35.7.14 Worked Example: TTY Read and Write Filters

The terminal subsystem in `/usr/src/sys/kern/tty.c` gives us the next step up: a driver that supports both readable and writable filters, and that uses `EV_EOF` to signal that the device is gone. The pattern is the one we use in any driver that wants to expose two independent sides of the same device.

The two filterops tables in `/usr/src/sys/kern/tty.c` are:

```
static const struct filterops tty_kqops_read = {
 .f_isfd = 1,
 .f_detach = tty_kqops_read_detach,
 .f_event = tty_kqops_read_event,
};

static const struct filterops tty_kqops_write = {
 .f_isfd = 1,
 .f_detach = tty_kqops_write_detach,
 .f_event = tty_kqops_write_event,
};
```

The `d_kqfilter` entry point, `ttydev_kqfilter`, switches on the requested filter and attaches to one of two knlists:

```
static int
ttydev_kqfilter(struct cdev *dev, struct knote *kn)
{
 struct tty *tp = dev->si_drv1;
 int error;

 error = ttydev_enter(tp);
 if (error != 0)
 return (error);

 switch (kn->kn_filter) {
 case EVFILT_READ:
 kn->kn_hook = tp;
 kn->kn_fop = &tty_kqops_read;
 knlist_add(&tp->t_inpoll.si_note, kn, 1);
 break;
 case EVFILT_WRITE:
 kn->kn_hook = tp;
 kn->kn_fop = &tty_kqops_write;
 knlist_add(&tp->t_outpoll.si_note, kn, 1);
 break;
 default:
 error = EINVAL;
 break;
 }

 tty_unlock(tp);
 return (error);
}
```

Three things are worth noticing here.

First, each direction has its own selinfo (`t_inpoll`, `t_outpoll`) and therefore its own knlist. A readable knote goes on one list and a writable knote goes on the other. This lets the producer notify only the side that changed: when incoming characters arrive, only readable waiters wake; when the output buffer drains, only writable waiters wake. Drivers that unify both sides onto one knlist would have to waste cycles waking everybody for every state change.

Second, the third argument to `knlist_add` is 1, because `ttydev_enter` has already taken the tty lock before the switch runs. The tty subsystem keeps that lock held from entry to exit across most entry points, so every knlist operation inside is already-locked.

Third, the read event callback demonstrates the `EV_EOF` discipline we described earlier:

```
static int
tty_kqops_read_event(struct knote *kn, long hint __unused)
{
 struct tty *tp = kn->kn_hook;

 tty_lock_assert(tp, MA_OWNED);

 if (tty_gone(tp) || (tp->t_flags & TF_ZOMBIE) != 0) {
 kn->kn_flags |= EV_EOF;
 return (1);
 } else {
 kn->kn_data = ttydisc_read_poll(tp);
 return (kn->kn_data > 0);
 }
}
```

If the tty is gone or is a zombie, `EV_EOF` is set and the filter reports ready so that userland wakes up, reads, gets nothing, and learns from the EOF flag that the device is finished. Otherwise the filter reports the number of readable bytes and whether that count is positive. The write-side callback `tty_kqops_write_event` mirrors this pattern, reporting `ttydisc_write_poll` for the output buffer's free space. The detach callbacks simply remove the knote from whichever list it was on, with `islocked = 1` again.

What the tty example teaches is that a driver with two directions needs two knlists, two filterops tables, two event functions, and a `d_kqfilter` that steers the registration to the right one. The producer side is symmetric: incoming characters trigger `KNOTE_LOCKED` on `t_inpoll.si_note`; outgoing buffer space triggers the same on `t_outpoll.si_note`. The separation is clean and predictable, and it matches the way userland programs think about terminal I/O.

### 35.7.15 Worked Example: evdev Detach Discipline

For the last worked example we turn to the input-event subsystem in `/usr/src/sys/dev/evdev/cdev.c`. Its `kqfilter` is structurally similar to `/dev/klog`, but the `evdev` driver demonstrates something the previous two examples glossed over: a complete detach sequence that tears down the knlist safely even when live userland processes may still have `kqueue` registrations outstanding.

The filterops and attach paths look familiar. The `evdev` filterops table is:

```
static const struct filterops evdev_cdev_filterops = {
 .f_isfd = 1,
 .f_detach = evdev_kqdetach,
 .f_event = evdev_kqread,
};
```

The `d_kqfilter` implementation adds an important extra check on revocation, which makes `evdev` a little richer than `/dev/klog`:

```

static int
evdev_kqfilter(struct cdev *dev, struct knote *kn)
{
 struct evdev_client *client;
 int ret;

 ret = devfs_get_cdevpriv((void **)&client);
 if (ret != 0)
 return (ret);

 switch (kn->kn_filter) {
 case EVFILT_READ:
 kn->kn_fop = &evdev_cdev_filterops;
 kn->kn_hook = client;
 EVDEV_CLIENT_LOCKQ(client);
 if (client->ec_revoked)
 ret = ENODEV;
 else
 knlist_add(&client->ec_selp.si_note, kn, 1);
 EVDEV_CLIENT_UNLOCKQ(client);
 break;
 default:
 ret = EINVAL;
 }

 return (ret);
}

```

If the client has been revoked, because the device is going away or because a controlling process has explicitly revoked access, the driver returns `ENODEV` rather than attaching a knote. Notice that the driver takes its own per-client lock around both the `ec_revoked` check and the `knlist_add`, so the two operations are atomic with respect to revocation. This is the contract we described earlier, applied cleanly: cheap lookups, a brief lock hold, no sleeping, no memory allocation in the hot path.

The event function reports readiness from the per-client event queue:

```

static int
evdev_kqread(struct knote *kn, long hint __unused)
{
 struct evdev_client *client = kn->kn_hook;

 EVDEV_CLIENT_LOCKQ_ASSERT(client);

 kn->kn_data = EVDEV_CLIENT_SIZEQ(client) *
 sizeof(struct input_event);
}

```

```

 if (client->ec_revoked) {
 kn->kn_flags |= EV_EOF;
 return (1);
 }
 return (kn->kn_data != 0);
}

```

Notice the `kn->kn_data` convention: not just “number of items” but “number of items in bytes,” because userland reads raw `struct input_event` values and expects byte counts in the way that `read()` returns them. This kind of detail matters for userland libraries that use `kn->kn_data` to size buffers.

The producer path in `evdev_notify_event` combines every asynchronous notification mechanism the subsystem supports:

```

if (client->ec_blocked) {
 client->ec_blocked = false;
 wakeup(client);
}
if (client->ec_selected) {
 client->ec_selected = false;
 selwakeup(&client->ec_selp);
}
KNOTE_LOCKED(&client->ec_selp.si_note, 0);

if (client->ec_sigio != NULL)
 pgsigio(&client->ec_sigio, SIGIO, 0);

```

This is a complete asynchronous producer: blocking `read()` waiters are signaled via `wakeup()`, `poll()` and `select()` waiters are signaled via `selwakeup()`, kqueue waiters are signaled via `KNOTE_LOCKED`, and registered SIGIO consumers are signaled via `pgsigio`. Any given consumer sees exactly one of these, but the producer does not need to know which one; it calls all of them unconditionally and lets each mechanism filter itself. Our `evdemo` driver will adopt the same layered producer as we finish the chapter.

The detach sequence is the piece that is uniquely instructive. When an `evdev` client goes away, the driver runs:

```

knlist_clear(&client->ec_selp.si_note, 0);
seldrain(&client->ec_selp);
knlist_destroy(&client->ec_selp.si_note);

```

This is exactly the three-step discipline we described. The result is that any userland process still holding a kqueue registration for this client reaps a final `EV_EOF` event and then sees the registration disappear; any `poll()` waiter still parked on the `selinfo` wakes and returns; any in-flight kqueue delivery that was about to call back into our filterops completes safely before the `knlist` memory is released.

Getting the order wrong turns this from a clean teardown into a panic. `knlist_destroy` before `knlist_clear` asserts on a non-empty list. `knlist_clear` without `seldrain` leaves `poll` waiters hanging. `seldrain` without

a preceding `knlist_clear` will work but will leave `kqueue` registrations pointing at a driver that is about to disappear, and the first event delivery attempt will crash. Follow the sequence.

The `evdev` example brings together everything we have covered in this section: a revocation-aware attach, a byte-count-correct event report, a combined producer path, and a teardown that respects the lifetime rules. A driver that imitates this pattern will behave well in production.

### 35.7.16 The hint Parameter: What It Is and Why It Exists

Every `f_event` callback receives a long `hint` argument that we have been quietly setting to zero. It is worth understanding what that parameter is for, because it is not zero everywhere in the kernel.

The hint is a cookie passed through from the producer to the filter. When a producer calls `KNOTE_LOCKED(list, hint)`, the framework passes that same `hint` value to every filter's `f_event`. It is entirely up to the producer and the filter to agree on what the value means. The framework does not interpret it.

For simple drivers that have one meaning of “ready,” zero is the natural choice and the filter ignores the argument. For drivers with more than one producer path, the hint can distinguish them. The `vnode` filter uses non-zero hints to encode `NOTE_DELETE`, `NOTE_RENAME`, and related `vnode`-level events, and the `f_event` function tests the hint bits to decide which `kn->kn_fflags` bits to set in the delivered event. That is beyond what an ordinary character driver needs, but it explains the signature's generality.

The producer side is where the hint value originates. A driver can call `KNOTE_LOCKED(&sc->sc_rsel.si_note, MY_HINT_NEW_DATA)` and the filter can switch on the value to take different paths. In practice, ordinary drivers pass zero and keep the filter simple.

### 35.7.17 Delivering Events: `KNOTE_LOCKED` vs `KNOTE_UNLOCKED`, in Depth

The two delivery macros in `/usr/src/sys/sys/event.h` are:

```
#define KNOTE_LOCKED(list, hint) knote(list, hint, KNF_LISTLOCKED)
#define KNOTE_UNLOCKED(list, hint) knote(list, hint, 0)
```

Both call the same underlying `knote()` function in `/usr/src/sys/kern/kern_event.c`, which walks the `knlist` and invokes `f_event` on each `knote`. The difference is the third argument: `KNF_LISTLOCKED` says “the caller already holds the `knlist` lock,” while zero says “take it for me.”

Choosing between them is a matter of matching the producer's locking path. If the producer is called with the driver's mutex already taken (because it is invoked from a locked ISR handler, or from inside a producer function that needed the lock for its own work), `KNOTE_LOCKED` is correct. If the producer is called unlocked (because it is running in thread context and the lock would be taken specifically for the notification), `KNOTE_UNLOCKED` is correct. The mistake to avoid is calling `KNOTE_LOCKED` without actually holding the lock, which races horribly under load, or calling `KNOTE_UNLOCKED` while holding the lock, which recurses and panics.

An ISR-context example helps: if a device interrupt handler calls a bottom-half function that acquires the softc mutex, does some work, and needs to notify `kqueue` waiters, the cleanest pattern is to do the work and the `KNOTE_LOCKED` call inside the held mutex and drop the lock afterwards. The mutex is the `knlist` lock, so `KNOTE_LOCKED` is what to use. If the notification instead comes from a thread that has not yet taken the lock, the

thread takes the lock, does the work, calls `KNOTE_LOCKED`, and then drops the lock; or it uses `KNOTE_UNLOCKED` and lets the framework briefly take the lock on its way through the list.

A second subtlety is the behaviour of `knote` when the list is empty. Walking an empty list is cheap but not free; it still takes the lock. Drivers that deliver very high-rate notifications can test `KNLIST_EMPTY(list)` first and skip the `KNOTE_LOCKED` call if there are no waiters. The macro `KNLIST_EMPTY`, defined in `/usr/src/sys/sys/event.h` as `SLIST_EMPTY(&(list)->kl_list)`, is safe to read without the lock for the purpose of a hint, because the worst case of a stale read is a missed wakeup on a `knote` that was added a microsecond ago, and that `knote` will notice the next delivery. In practice this optimisation is rarely worth the complexity, but it is worth knowing about.

### 35.7.18 Common Pitfalls in Driver `kqfilter` Implementations

Over the course of reading `kqueue`-aware drivers in the tree, a handful of recurring bug patterns show up. Knowing the pitfalls in advance helps avoid them.

Forgetting to destroy the `knlist`. A driver that calls `knlist_init_mtx` in `attach` but does not call `knlist_destroy` in `detach` leaks the `knlist`'s internal state and, worse, may leave live `knotes` dangling. The fix is to include the clear-drain-destroy sequence in every `detach` path.

Calling `knlist_destroy` before `knlist_clear`. `knlist_destroy` asserts that the list is empty. If there are any `knotes` still attached, the assertion fails and the kernel panics. Always clear first.

Using `KNOTE_LOCKED` without the lock. This is subtle because it works most of the time. Under load, two producers can race in the `knote` walk, and the framework's assumption that the list is stable during traversal breaks. The symptom is usually a `knote` pointer corruption or a use-after-free in `f_event`.

Sleeping in `f_event`. The framework is holding the `knlist` lock, which is our `softc` mutex, when it calls us. Sleeping under a mutex is a kernel bug. If `f_event` needs state that is not already accessible under the `softc` mutex, the design is wrong; move the state into the `softc` or pre-compute it before the notification.

Returning stale `kn_data`. The `kn->kn_data` field should reflect the state at the moment the filter was evaluated. A driver that computes `kn_data` once in `d_kqfilter` and forgets to update it in `f_event` will deliver stale byte counts to the userland. Always recompute it in `f_event`.

Keeping `kn_hook` pointing at freed memory. If `kn_hook` is set to a `softc`, and the `softc` is freed before the `knote` is detached, the next `f_event` call will dereference freed memory. This is what `knlist_clear` and `sel drain` are supposed to prevent, but only if they are called in the correct order and before the `softc` is freed. The detach order in the driver's `detach` entry point matters.

Setting `EV_EOF` only once. `EV_EOF` is sticky in the sense that once it is set, the userland will see it, but `f_event` is called multiple times over a `knote`'s life. If the condition that caused `EV_EOF` can become false again (for example, a named pipe that gains a new writer), the filter must clear `EV_EOF` explicitly. The pipe filter in `/usr/src/sys/kern/sys_pipe.c` demonstrates this: `filt_piperead` both sets and clears `EV_EOF` depending on the pipe's state.

Confusing `f_isfd` with `f_attach`. `f_isfd = 1` means the filter is tied to a file descriptor; almost all driver filters want this. `f_attach = NULL` means "the registration path does not need a per-`knote` attach callback beyond what `d_kqfilter` already did." They are independent. A driver can set `f_isfd = 1` and `f_attach = NULL` at the same time, which is the common case.

Returning errors from `f_event`. `f_event` returns an int, but it is a boolean: zero means “not ready,” non-zero means “ready.” It is not an errno. Returning `EINVAL` from `f_event` means “ready,” which is almost certainly not what the driver intended.

### 35.7.19 A Mental Model for the kqueue Framework

It is worth pausing to assemble a mental model of the kqueue framework that fits what we have learned. Different readers will find different models helpful; one that works well for driver authors is this.

Imagine each driver object (a `cdev`, a per-client state record, a pipe, a `tty`) as a small office. The office has in-boxes and out-boxes, which are the `knlists`. When a visitor (a userland program) wants to be told when there is new mail in the in-box, they register a sticky note with the office: their kqueue file descriptor, plus the filter type they care about. The office clerks (our `d_kqfilter` callback) take the sticky note, check which in-box it belongs on (`EVFILT_READ` in-box or `EVFILT_WRITE` out-box), and pin it there. The sticky note records who to notify (the kqueue) and how (the `struct filterops` callbacks).

When mail actually arrives (the producer path inserts a record and wants to notify), the office clerks walk the in-box sticky notes and, for each one, check whether the condition is currently satisfied (the `f_event` callback). If it is, the clerk picks up the phone and rings the visitor’s kqueue, delivering a notification. The visitor reads the notification on their next `kevent(2)` reap.

When the visitor changes their mind and no longer wants mail notifications (removes the registration), the office clerks pull the sticky note down (the `f_detach` callback). When the office closes permanently (the driver detaches), the clerks pull down every sticky note at once (`knlist_clear`), wake any visitors who are physically sitting in the waiting room (`selldrain`), and then dismantle the sticky-note corkboard (`knlist_destroy`).

The lock on the corkboard is the driver’s softc mutex. The clerks hold it while walking the notes, pinning a note, or pulling a note down. This is why `f_event` must not sleep: the clerks cannot let go of the lock while they are working through the list, because other clerks might arrive with updates. It is also why `KNOTE_LOCKED` is the right call when the producer already holds the lock: the clerk saying “I am already holding it” lets the framework skip an unnecessary re-acquisition.

The model is simplified, and it leaves out complications like `EV_CLEAR` edge semantics and `f_touch` registration updates, but it captures the essential architecture. The driver owns the corkboard; the framework owns the sticky notes. The driver reports readiness; the framework handles delivery. The driver tears down the corkboard at detach; the framework’s sticky-note structures are freed as part of that teardown.

Keep this picture in mind as you read the code of other kqueue-using subsystems, and the unfamiliar names will map back onto familiar roles. `kqueue_register` is the visitor walking in to submit a sticky note. `knote` is the clerk walking the corkboard. `f_event` is each note’s individual readiness-check. `selwakeup` is the general fire alarm that also reaches the corkboard. The names are different; the shapes are the same.

### 35.7.20 Reading `kern_event.c`: A Guide for the Curious

For readers who want to go further than the callbacks, the kqueue framework itself is worth a tour. `/usr/src/sys/kern/kern_event.c` is about three thousand lines, which looks intimidating, but the structure of the file is predictable once we know what to look for.

Near the top of the file, the static filterops tables for the built-in filters are declared. `file_filtops` handles the generic read and write filters for file descriptors that do not provide their own `kqfilter`; `timer_filtops` handles `EVFILT_TIMER`; `user_filtops` handles `EVFILT_USER`; and several more follow. These are the filterops the framework installs at boot, and reading them gives a good sense of how a filterops table is meant to look in production code.

After the static declarations come the system call entry points: `kqueue`, `kevent`, and the legacy variants. These do argument validation and dispatch to the core machinery. A reader tracing a userland call through the kernel starts here.

The core machinery is a set of functions with names beginning `kqueue_`. `kqueue_register` handles `EV_ADD`, `EV_DELETE`, `EV_ENABLE`, `EV_DISABLE`, and `EV_RECEIPT`; it is where the framework calls our `d_kqfilter` through `fo_kqfilter`. `kqueue_scan` reaps ready events back to userland. `kqueue_acquire` and `kqueue_release` reference-count the `kqueue` for safe concurrent access. `kqueue_close` tears the `kqueue` down when the last file descriptor referencing it is closed. Tracing from the top of `kqueue_register` through `kqueue_expand`, `knote_attach`, and the `fo_kqfilter` call reveals the full registration path.

The `knote` function itself, about two-thirds of the way through the file, is the one we reach through `KNOTE_LOCKED` and `KNOTE_UNLOCKED`. It walks the `knlist`, invokes `f_event` on each `knote`, and queues notifications for any that report ready. Reading it shows exactly why the lock assertions on our `f_event` are necessary and how the framework interleaves list traversal with `kqueue` notification. The walk uses `SLIST_FOREACH_SAFE` with a temporary pointer, so an `f_detach` during the walk does not corrupt the iteration. That subtle detail is what makes concurrent detach and delivery safe.

Further down comes the `knlist` machinery: `knlist_init`, `knlist_init_mtx`, `knlist_add`, `knlist_remove`, `knlist_cleardel`, `knlist_destroy`, and the various helpers. These are the functions we have been calling. Reading them confirms the lock semantics we have been relying on and shows how the `islocked` arguments are consumed inside the helpers.

Near the end of the file come the filter implementations for the built-in filters, with names like `filt_timerattach`, `filt_user`, and `filt_fileattach`. These are worth reading because they are the closest thing to a reference implementation for how a filter should be structured. The pipe filter in `/usr/src/sys/kern/sys_pipe.c` is another good reference; socket `kqueue` support in `/usr/src/sys/kern/uipc_socket.c` is a third.

A reader who works through `kqueue_register`, `knote`, and `knlist_remove` in that order will understand most of the framework by the end of an afternoon. The remaining machinery (auto-destroy, timer implementation, proc-and-signal filters, vnode-note masks) is specialised enough that a driver author can skip it unless a specific need arises. The rest of this chapter does not require any of it.

### 35.7.21 Driver Patterns We Have Not Yet Used

Two patterns appear in the tree that we have not used in `evdemo` because they are not needed, but are worth recognising so that readers who see them elsewhere know what they are.

The first is the use of `f_attach` for per-`knote` setup beyond what `d_kqfilter` does. The `EVFILT_TIMER` filter uses `f_attach` to start a one-shot or repeating timer when the `knote` is first registered, and `f_detach` to stop it. The `EVFILT_USER` filter in `/usr/src/sys/kern/kern_event.c` uses `filt_userattach` as a no-op because the `knote` is not attached to anything in the kernel; the user-triggered `NOTE_TRIGGER` mechanism handles delivery entirely through `f_touch`. A driver that needs its own per-`knote` state could allocate it in `f_attach` and free

it in `f_detach`, using `kn_hook` or `kn_hookid` to remember the pointer. Almost no driver actually needs this, because the per-registration state usually fits naturally in the `softc`.

The second is `f_touch`, which intercepts `EV_ADD`, `EV_DELETE`, and `EV_ENABLE/EV_DISABLE` operations. The `filt_usertouch` function in `/usr/src/sys/kern/kern_event.c` is a good reference for how `f_touch` is structured: it inspects the `type` argument (one of `EVENT_REGISTER`, `EVENT_PROCESS`, or `EVENT_CLEAR`) to decide what the userland is asking for and updates the knote's fields accordingly. Most driver filters leave `f_touch` as `NULL` and accept the framework's default behaviour, which is to store `sfflags`, `sdata`, and the event flags in the knote directly during `EV_ADD`. The default is correct for filters that do not need extra behaviour on registration updates.

A third pattern the tree uses but our driver does not is the “kill” variant of knlist teardown. `knlist_cleared` in `/usr/src/sys/kern/kern_event.c` accepts a `killkn` flag that, when set, forces every knote off the list whether or not it is still in use. `knlist_clear` is the common wrapper with this flag set. A driver that wants to preserve knotes across an event (for example, to re-attach them to a new object) could call `knlist_cleared` with `killkn` false and the knotes would be unhooked but left alive. This is almost never what a driver wants. The common case is `knlist_clear`, which kills and frees.

### 35.7.22 A Note on `EV_CLEAR`, `EV_ONESHOT`, and Edge-Triggered Behaviour

The `kqueue` framework supports several delivery modes through flags on the `struct kevent`:

`EV_CLEAR` makes the filter edge-triggered: once a knote fires, it will not fire again until the underlying condition transitions from false to true again. This is the common choice for readable and writable filters on high-throughput descriptors, because it avoids spamming the userland with repeated notifications for the same data.

`EV_ONESHOT` makes the filter fire exactly once and then auto-delete itself. It is useful for one-time events.

`EV_DISPATCH` makes the filter fire at most once per `kevent()` reap, auto-disabling itself after each fire. The userland re-enables it by re-registering with `EV_ENABLE`. This is the mode preferred by multi-threaded userland programs that want to ensure only one thread reacts to each event.

The driver's filter functions do not need to know about these flags; the framework handles them. The driver just reports whether the underlying condition is satisfied, and the framework decides what to do with the resulting knote.

### 35.7.23 Wrapping Up Section 4

We now have `kqueue` support in our driver. The total code we added is not enormous: a `d_kqfilter` callback, a `struct filterops`, two short filter functions, and a `KNOTE_LOCKED()` call in the producer. The complexity is more about understanding the framework than about writing a lot of code.

But we have only covered the two most common filters, `EVFILT_READ` and `EVFILT_WRITE`. The chapter's scope deliberately excludes deeper `kqueue` topics such as user-defined filters (`EVFILT_USER`), custom `f_touch` implementations, and interactions with the AIO subsystem. Those are specialized enough that they rarely appear in ordinary drivers, and they would crowd out material that most readers need. If you do need them, the material in this section prepares you to read the corresponding parts of `/usr/src/sys/kern/kern_event.c` and understand what you find.

Looking back at what this section has covered, the reader should now be comfortable with several layers that tend to blur together in casual discussions of `kqueue`. The outermost layer is the userland API: `kqueue(2)`, `kevent(2)`, and the `struct kevent` values that programs submit and reap. The middle layer is the framework: `kqueue_register`, `knote`, `kqueue_scan`, and the machinery that matches registrations to deliveries. The inner layer is the driver contract: `d_kqfilter`, `struct filterops`, `struct knote`, `struct knlist`, and the small set of helper functions like `knlist_init_mtx`, `knlist_add`, `knlist_remove`, `knlist_clear`, and `knlist_destroy`. The three layers communicate through well-defined boundaries, and understanding which is which is the difference between guessing at `kqueue` and understanding it.

We have also walked through three real driver implementations: `/dev/klog`, the `tty` subsystem, and the `evdev` input stack. Each illustrates a different aspect of the `kqfilter` contract. The `klog` driver shows the minimum that a `kqueue`-aware driver needs. The `tty` subsystem shows how to handle two directions with two separate `knlists`. The `evdev` driver shows the revocation-aware attach, the byte-count-correct event report, the combined producer path that fans out to multiple asynchronous mechanisms, and the strict clear-drain-destroy detach sequence. A driver that combines the appropriate pieces of these three patterns will behave well in production, and a reader who has followed the discussion should be able to recognise the patterns when they appear in other subsystems in the tree.

In the next section we turn to the third asynchronous mechanism, `SIGIO`. Unlike `poll()` and `kqueue()`, which are pull-style notifications (the userland asks, the kernel answers), `SIGIO` is push-style: the kernel sends a signal to the registered process whenever the device state changes. It is older, simpler, and has some subtle problems in multi-threaded programs, but it is still useful in specific situations and is part of the standard driver toolkit.

## 35.8 5. Asynchronous Signals With `SIGIO` and `FIOASYNC`

The third classic asynchronous mechanism is signal-driven I/O, also called `SIGIO` notification after the signal it typically uses. The user enables it through the `FIOASYNC` `ioctl` on an open file descriptor, sets an owner with `FIOSETOWN`, and installs a handler for `SIGIO`. The driver, whenever it has a relevant state change, sends `SIGIO` to the registered owner. That signal can interrupt almost any system call in the owner, which then typically services the device and returns to its normal work.

Signal-driven I/O is older than `kqueue`, less scalable than `poll`, and has some subtle issues in multi-threaded programs. It is still the right mechanism in a small but real set of cases: single-threaded programs that want the simplest possible asynchronous notification, shell scripts using `trap`, and legacy code that has used `SIGIO` for decades and will not change. FreeBSD continues to support it in full, and most ordinary character drivers are expected to honour the mechanism.

### 35.8.1 How Signal-Driven I/O Works From Userland

A user program using `SIGIO` does three things. It installs a signal handler for `SIGIO`. It tells the kernel which process should own the signal for this descriptor. It enables asynchronous notification.

The code looks roughly like this:

```
#include <signal.h>
#include <sys/filio.h>
```

```
#include <fcntl.h>
#include <unistd.h>

static volatile sig_atomic_t got_sigio;

static void
on_sigio(int sig)
{
 got_sigio = 1;
}

int
main(void)
{
 int fd = open("/dev/evdemo", O_RDONLY | O_NONBLOCK);

 struct sigaction sa;
 sa.sa_handler = on_sigio;
 sigemptyset(&sa.sa_mask);
 sa.sa_flags = 0;
 sigaction(SIGIO, &sa, NULL);

 int pid = getpid();
 ioctl(fd, FIOSETOWN, &pid);

 int one = 1;
 ioctl(fd, FIOASYNC, &one);

 for (;;) {
 pause();
 if (got_sigio) {
 got_sigio = 0;
 char buf[256];
 ssize_t n;
 while ((n = read(fd, buf, sizeof(buf))) > 0) {
 /* process data */
 }
 }
 }
}
```

The sequence of `ioctl`s is important. The program first installs the signal handler so that `SIGIO` will not be ignored when it arrives. It then calls `FIOSETOWN` with its own PID (positive values mean process, negative values mean process group) so that the driver knows where to deliver the signal. Finally it calls `FIOASYNC` with

a non-zero value to enable notification.

Once asynchronous notification is enabled, every state change in the driver that would have satisfied a `POLLIN` causes a `SIGIO` signal to the owner. The program's handler runs asynchronously, sets a flag, and returns; the main loop then services the device. Drain the device to empty with non-blocking reads, because between the time the signal was sent and the time the handler ran, multiple events may have accumulated.

### 35.8.2 The `FIOASYNC`, `FIOSETOWN`, and `FIOGETOWN` `ioctl`s

Open `/usr/src/sys/sys/filio.h` to see the `ioctl` definitions:

```
#define FIOASYNC _IOW('f', 125, int) /* set/clear async i/o */
#define FIOSETOWN _IOW('f', 124, int) /* set owner */
#define FIOGETOWN _IOR('f', 123, int) /* get owner */
```

These are standard `ioctl`s that most of the file descriptor-handling layer already understands. For an ordinary file descriptor (a socket, a pipe, a `pty`), the kernel handles them without involving the driver. For a `cdev`, however, the driver is responsible for implementing them, because the driver owns the state that the `ioctl`s manipulate.

The conventional approach in a FreeBSD character driver is:

`FIOASYNC` takes an `int *` argument. Non-zero enables asynchronous notification. Zero disables it. The driver stores the flag in the `softc` and uses it to decide whether to generate signals.

`FIOSETOWN` takes an `int *` argument. A positive value is a PID, a negative value is a process group ID, and zero clears the owner. The driver uses `fsetown()` to record the owner.

`FIOGETOWN` takes an `int *` argument to be filled in. The driver uses `fgetown()` to retrieve the current owner.

### 35.8.3 `fsetown`, `fgetown`, and `funsetown`

The owner-tracking mechanism uses a `struct sigio` in the kernel. We do not have to allocate or manage that structure directly; the `fsetown()` and `funsetown()` helpers do it for us. The public API, in `/usr/src/c/sys/sys/sigio.h` and `/usr/src/sys/kern/kern_descrip.c`, consists of four functions:

```
int fsetown(pid_t pgid, struct sigio **sigiop);
void funsetown(struct sigio **sigiop);
pid_t fgetown(struct sigio **sigiop);
void pgsigio(struct sigio **sigiop, int sig, int checkctty);
```

The driver stores a single `struct sigio *` in the `softc`. All four helpers take a pointer to this pointer, because they may replace the whole structure as part of their work. The helpers take care of reference counting, locking, and safe removal during process exit through `eventhandler(9)`.

`fsetown()` installs a new owner. It expects to be called with the interrupted caller's credentials available (which is always the case inside an `ioctl` handler). If the target PID is zero, it clears the owner. If the target is a positive number, it looks up the process. If it is a negative number, it looks up the process group. It returns zero on success or an `errno` on failure.

`funsetown()` clears the owner and frees the associated structure. Drivers call it during close and during detach to make sure no stale references are left behind.

`fgetown()` returns the current owner as a PID (positive) or a process group ID (negative), or zero if no owner is set.

`pgsigio()` delivers a signal to the owner. The third argument, `checkctty`, should be zero for a driver that is not a controlling terminal. This is what the driver calls from the producer path whenever asynchronous notification is enabled.

### 35.8.4 Implementing SIGIO in evdemo

Putting the pieces together, here is what we add to our driver to support SIGIO:

In the `softc`:

```
struct evdemo_softc {
 /* ... existing fields ... */
 struct sigio *sc_sigio;
 bool sc_async;
};
```

In `d_ioctl`:

```
static int
evdemo_ioctl(struct cdev *dev, u_long cmd, caddr_t data, int fflag,
 struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;
 int error = 0;

 switch (cmd) {
 case FIOASYNC:
 mtx_lock(&sc->sc_mtx);
 sc->sc_async = (*(int *)data != 0);
 mtx_unlock(&sc->sc_mtx);
 break;

 case FIOSETOWN:
 error = fsetown(*(int *)data, &sc->sc_sigio);
 break;

 case FIOGETOWN:
 *(int *)data = fgetown(&sc->sc_sigio);
 break;
 }
```

```

 default:
 error = ENOTTY;
 break;
 }
 return (error);
}

```

In the producer path:

```

static void
evdemo_post_event(struct evdemo_softc *sc, struct evdemo_event *ev)
{
 bool async;

 mtx_lock(&sc->sc_mtx);
 evdemo_enqueue(sc, ev);
 async = sc->sc_async;
 KNOTE_LOCKED(&sc->sc_rsel.si_note, 0);
 mtx_unlock(&sc->sc_mtx);

 selwakeup(&sc->sc_rsel);
 if (async)
 pgsigio(&sc->sc_sigio, SIGIO, 0);
}

```

In `d_close` or during detach:

```

static int
evdemo_close(struct cdev *dev, int flags, int fmt, struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;

 funsetown(&sc->sc_sigio);
 /* ... other close handling ... */
 return (0);
}

```

Let us walk through the pieces.

The `softc` gains two new fields: `sc_sigio`, the pointer we pass to `fsetown()` and friends, and `sc_async`, a flag telling the producer whether signals are enabled. The flag is redundant with “`sc_sigio` is non-NULL” in a sense, but keeping it explicit makes the producer code clearer and faster.

The `d_ioctl` handler implements the three `ioctl`s. We take the `softc` mutex for `FIOASYNC` because we update `sc_async`. We do not take the mutex for `FIOSETOWN` and `FIOGETOWN` because the `fsetown()` and `fgetown()` helpers have their own internal locking and should not be called with a driver lock held.

In the producer, we copy `sc_async` into a local variable under the lock so that the value we use outside the lock is consistent. If we had simply read `sc->sc_async` after the lock was dropped, another thread could have changed it in between, which is a race. Taking a snapshot under the lock avoids the race.

We call `pgsigio()` outside the softc lock because `pgsigio()` takes its own locks and could create ordering problems if nested. The pattern is the same as `selwakeup()`: update under the lock, drop, then deliver the notification.

In `d_close`, we call `funsetown()` to clear the owner. This also handles the case where the process that set the owner has since exited, so the driver does not leak `struct sigio` allocations. If the process has already exited, `funsetown()` is essentially a no-op; if it has not, the call cleans up the registration.

### 35.8.5 Caveats: Signal Semantics in Multi-Threaded Programs

Signal-driven I/O has well-known weaknesses in multi-threaded programs. The primary issue is that signals in POSIX are sent to a process, not to a specific thread. When the kernel delivers `SIGIO`, any of the process's threads whose mask allows the signal may be the one to receive it. For a program that wants a specific thread to service the notification, this is inconvenient.

There are workarounds. `pthread_sigmask()` can be used to block `SIGIO` in all threads except the one that should service it. If you want to convert signals into readable events on a file descriptor, FreeBSD provides `EVFILT_SIGNAL` through `kqueue(2)`, which lets a `kqueue` report that a given signal has been delivered to the process. FreeBSD does not provide the Linux-specific `signalfd(2)` system call. The simplest workaround, and often the right one, is to use `kqueue` directly for the underlying driver events: threads can each own a separate `kqueue` and each can wait for exactly the events they care about, without fighting signal delivery rules at all.

A second weakness is that signals interrupt system calls. Under the default SA flags, an interrupted system call returns with `EINTR`, and the program must check for this and retry. This is unusual enough that it often produces bugs in programs that were written without `SIGIO` in mind. The workaround is to set `SA_RESTART` in `sa_flags`, which makes the kernel restart interrupted system calls automatically.

A third weakness is that signal delivery is asynchronous with respect to the program's execution. A signal that arrives while the program is in the middle of a data structure update can lead to inconsistent state if the signal handler touches the same structure. The fix is to keep signal handlers very simple (set a flag, return) and do the actual work in the main loop.

For modern programs, `kqueue` avoids all three of these issues. For legacy programs and simple single-threaded applications, `SIGIO` is fine, and implementing it in a driver is a small amount of code.

### 35.8.6 What Real Drivers Look Like

The `if_tuntap.c` driver provides a representative example of `SIGIO` handling. In the softc:

```
struct tuntap_softc {
 /* ... */
 struct sigio *tun_sigio;
```

```
/* ... */
};
```

In the `ioctl` handler, the driver calls `fsetown()` and `fgetown()` for `FIOSETOWN` and `FIOGETOWN` respectively, and stores the `FIOASYNC` flag. In the producer path (when a packet is ready to be read from the interface), the driver calls `pgsigio()`:

```
if (tp->tun_flags & TUN_ASYNC && tp->tun_sigio)
 pgsigio(&tp->tun_sigio, SIGIO, 0);
```

In the close path, it calls `funsetown()`.

The `evdev/cdev.c` driver has a similar structure. These are the patterns you will reuse in your own drivers.

### 35.8.7 Testing SIGIO From Shell

A nice property of `SIGIO` is that you can demonstrate it from the shell without writing any code. The Bourne-style shells (`sh`, `bash`) have a built-in `trap` command that runs an action when a signal arrives. Combined with the `FIOASYNC` `ioctl`, we can set up a test in a few lines:

```
trap 'echo signal received' SIGIO
exec 3< /dev/evdemo
(mechanism to enable FIOASYNC on fd 3 goes here)
Trigger events in another terminal and watch for "signal received"
```

The catch is that there is no direct shell-level way to issue an `ioctl`. You need either a small C helper, or a tool like the `ioctl(1)` command that some BSDs ship, or `truss` in a traced child. For the lab in this chapter we provide a small `evdemo_sigio` program that calls the right `ioctls` and then simply pauses, leaving the shell's `trap` handler to show the signal deliveries.

### 35.8.8 A Note on POSIX AIO

FreeBSD also supports the POSIX `aio_read(2)` and `aio_write(2)` APIs. These are beyond the normal scope of a character driver, and ordinary `cdev` drivers almost never need to implement anything special to participate in AIO. The remaining subsections of this section explain why that is, how AIO actually dispatches requests inside the kernel, and when (if ever) a driver should think about AIO at all. The intent is to head off a common source of confusion: when readers see “asynchronous I/O on files” in FreeBSD documentation, they are reading about POSIX AIO, and it is easy to assume that a driver needs its own AIO machinery to be a first-class citizen. It does not.

### 35.8.9 How AIO Dispatches: `fo_aio_queue` and `aio_queue_file`

When a userland program calls `aio_read(2)` or `aio_write(2)`, the request enters the kernel, is validated, and becomes a `struct kaiocb` (kernel AIO control block). The code path from there is worth tracing because it explains why a character driver almost never needs to do anything about POSIX AIO at all.

In `/usr/src/sys/kern/vfs_aio.c`, the dispatch is done at the file operations layer. The relevant decision, inside `aio_aqueue`, looks like this:

```
if (fp->f_ops->fo_aio_queue == NULL)
 error = aio_queue_file(fp, job);
else
 error = fo_aio_queue(fp, job);
```

The decision is made at the file-ops layer, not the cdev layer. If the file's struct `fileops` has its own `fo_aio_queue` function pointer, AIO delegates to it. Vnode file operations set `fo_aio_queue = vn_aio_queue_vnops`, which routes regular-file requests through a path that knows how to talk to the underlying file system. A cdev file's `fileops`, by contrast, leaves `fo_aio_queue` as `NULL`, so AIO falls into the generic `aio_queue_file` path.

`aio_queue_file` in `/usr/src/sys/kern/vfs_aio.c` tries two things. First, it attempts `aio_qbio` (the bio-based path, described in the next subsection) if the underlying object looks like a block device. Second, if the bio path is not applicable, it schedules `aio_process_rw` on one of the AIO worker threads. `aio_process_rw` is a daemon-based path that simply calls `fo_read` or `fo_write` synchronously from the AIO worker thread. In other words, for a generic cdev, “asynchronous I/O” is implemented by asking a kernel thread to perform a synchronous `read()` or `write()` on the application's behalf.

This is why ordinary character drivers do not need to implement AIO hooks of their own. The AIO subsystem does not call into the driver through a new entry point; it calls `fo_read` and `fo_write`, which in turn call the driver's existing `d_read` and `d_write`. If our driver already supports blocking and non-blocking reads correctly, it already supports AIO, just through a worker thread. No additional code is required on the driver side.

### 35.8.10 The Block Device Path: `aio_qbio` and Bio Callbacks

For block devices (disk, cd, and friends), the worker-thread path is inefficient because the block I/O layer already has its own asynchronous completion mechanism. FreeBSD takes advantage of this through `aio_qbio` in `/usr/src/sys/kern/vfs_aio.c`, which submits the request as a struct `bio` directly to the underlying device's strategy routine and arranges for `aio_biowakeup` to be called on completion. The bio carries a back-pointer to the struct `kaiocb` so that completion can find its way back to the AIO framework.

`aio_biowakeup` in `/usr/src/sys/kern/vfs_aio.c` retrieves the struct `kaiocb` that the bio is carrying, computes the residual byte count, and calls `aio_complete` with the result. `aio_complete` sets the status and error fields on the `kaiocb`, marks it as finished, and then calls `aio_bio_done_notify`, which fans out to any kqueue registration on the `kaiocb`, any blocking waiter in `aio_suspend`, and any signal registration that the userland requested through the `aiocb.aio_sigevent` field.

`aio_biocleanup` is the companion helper that frees the bio's buffer mappings and returns the bio itself to its pool. Every bio used on the AIO path passes through it, either on the wakeup path or in the cleanup loop when submission fails partway through a multi-bio request.

This path is entirely internal to the block I/O layer. A character driver that is not a block device will never see it. A block device driver sees exactly the same bios it would see from any other source: the driver cannot tell that this particular bio came from `aio_read` rather than from `read` on a buffer cache page. That is the point. AIO

fits into the block layer by reusing the existing strategy contract, not by adding a parallel path. A block driver that gets its strategy routine right gets AIO for free.

### 35.8.11 The Worker Thread Path: `aio_process_rw`

When `aio_qbio` is not applicable, as is the case for almost every character driver, `aio_queue_file` falls through to `aio_schedule(job, aio_process_rw)`. That puts the job on the AIO work queue. One of the pre-spawned AIO daemon threads (the pool size is tunable through the `vfs.aio.max_aio_procs` sysctl) picks it up, runs `aio_process_rw`, and does the actual I/O.

`aio_process_rw` in `/usr/src/sys/kern/vfs_aio.c` is the heart of the worker path. It prepares a `struct uio` from the `kaiocb`'s fields, calls `fo_read` or `fo_write` on the file, and passes the return value on to `aio_complete`. From the driver's point of view, the I/O comes in through a perfectly ordinary read or write call, with one subtle difference: the calling thread is an AIO daemon, not the process that submitted the request. The user credentials are correct because the AIO framework preserved them, but the process context is the AIO daemon's. Drivers that rely on `curthread` or `curproc` for their own bookkeeping might see surprising values; drivers that do not, which is almost all of them, behave identically whether the caller is the user's own thread or an AIO daemon.

The worker-thread path is not “async” in the hardware sense. It is “async” in the API sense: the userland did not block. The substitution happens at the thread boundary, not at the I/O boundary, so a slow device still ties up an AIO worker while it serves the request. For most `cdev` drivers, this is exactly the right trade-off. The userland gets the programming model it wants; the kernel uses a worker thread to get the work done; the driver does nothing special. If the driver already honours `O_NONBLOCK` correctly, the worker thread can even submit non-blocking requests to it and return `EAGAIN` back to the userland through the normal path.

### 35.8.12 Completion: `aio_complete`, `aio_cancel`, and `aio_return`

Once `aio_complete` has been called, the `kaiocb` enters its finished state. The userland program will eventually call `aio_return(2)` to retrieve the byte count, or `aio_error(2)` to check the error code, or wait on a `kqueue` or signal to be told that the job has finished. Those calls look up the `kaiocb` by its userland pointer and return the fields that `aio_complete` set.

From the driver's point of view, there is nothing to do on the return path. The driver does not own the `kaiocb`, does not free it, and does not signal completion directly. Completion is announced by `aio_complete`; `aio_return` is a userland concern handled entirely by the kernel's AIO layer. The driver's job ended when it satisfied the `fo_read` or `fo_write` call, or when the strategy routine called `biodone` on the bio.

For cancellation, `aio_cancel` in `/usr/src/sys/kern/vfs_aio.c` ultimately calls `aio_complete(job, -1, ECANCELED)`. That is it. The job is marked complete with an error, and the usual wakeup paths fire. The driver does not need to know about cancellation at all unless it implements its own long-running request-holding queue, which is exceptional.

One distinction is worth making explicit. `aio_cancel` is the kernel-side cancellation function used internally by AIO; it is not the userland syscall. The userland-facing `aio_cancel(2)` takes a file descriptor and a pointer to an `aiocb` and asks the kernel to cancel one or all pending requests. Internally that winds up calling the kernel `aio_cancel` on each matching `kaiocb`. The naming is a little unfortunate; reading the source makes it obvious which one is which.

### 35.8.13 EVFILT\_AIO: How AIO Uses kqueue

It is worth knowing, though not acting on, that EVFILT\_AIO exists. Declared in `/usr/src/sys/sys/event.h` and implemented in `/usr/src/sys/kern/vfs_aio.c` as the `aio_filtops` table, it lets userland programs wait for AIO completions on a kqueue. The filterops are registered once at AIO module load by `kqueue_add_filterops(EVFILT_AIO, &aio_filtops)`. The per-kaiocb callbacks are:

```
static const struct filterops aio_filtops = {
 .f_isfd = 0,
 .f_attach = filt_aioattach,
 .f_detach = filt_aiodetach,
 .f_event = filt_aio,
};
```

`f_isfd` is zero here because an AIO registration is keyed on the kaiocb, not on a file descriptor. `filt_aioattach` links the knote into the kaiocb's own knlist. `filt_aio` reports the completion status by checking whether the kaiocb has been marked finished. The `kl_autodestroy` field of the kaiocb's knlist is set, so the knlist can be torn down automatically when the kaiocb is freed. This is one of the few places in the tree where `kl_autodestroy` is actually exercised, which makes `vfs_aio.c` useful reading if you ever need to understand how that flag is used.

None of this is driver business. The AIO module registers EVFILT\_AIO once at boot, and from then on the userland can wait for completions through kqueue without any further driver involvement. A driver that wants userland to be able to wait for driver-originated events through kqueue does so through EVFILT\_READ or EVFILT\_WRITE, not through EVFILT\_AIO.

### 35.8.14 Why kqueue Is the Right Answer for Most Drivers

Bringing this together, the guidance for driver authors is clear.

If the driver is a block device, the kernel already wires AIO into the bio path through `aio_qbio`. No additional work is needed. A block driver that serves its strategy routine correctly also serves AIO correctly.

If the driver is a character device that emits events and wants userland to wait for them without blocking a thread, the right mechanism is kqueue. Userland registers EVFILT\_READ or EVFILT\_WRITE on the driver's file descriptor and the driver notifies waiters through `KNOTE_LOCKED`. This is what we have been building throughout this chapter, and it is what the drivers we have read all do.

If the driver is a character device that userland programmers would like to call with `aio_read(2)` for portability reasons, no work is required on the driver side. AIO will serve the request through a worker thread that calls the driver's existing `d_read`. The userland gets the portability it wants; the driver gets to stay simple.

The only time a driver might consider implementing `d_aio_read` or `d_aio_write` is when it has a high-performance, genuinely asynchronous hardware path that can complete work without blocking a worker thread, and when the cost of the worker-thread fallback would be prohibitive. This is exceptionally rare in ordinary drivers, and the drivers that do have such a path (storage drivers, mostly) usually expose it through the block layer rather than as a cdev.

In short: for cdev drivers, “implement AIO” almost always means “implement kqueue.” The remaining AIO machinery belongs to the kernel, not to us. And that is the note we wanted to end this part of the chapter on, because it closes the loop: of the four asynchronous mechanisms (poll, kqueue, SIGIO, AIO), the one that needs the most driver code is kqueue, and the one that needs the least is AIO. The chapter has therefore spent its time on the mechanism that matters.

### 35.8.15 Reading `vfs_aio.c`: A Guide

For readers who want to trace the AIO path through the kernel, `/usr/src/sys/kern/vfs_aio.c` is organised as follows.

Near the top of the file, the `struct kaiocb` and `struct kaioinfo` are discussed (through comments in the surrounding code, since the structures themselves are declared in `/usr/src/sys/sys/aio.h`). The `filt_aioattach/filt_aiodetach/filt_aio` set of static functions and the `aio_filtops` table appear next. These are the kqueue integration for `EVFILT_AIO`.

The `SYSINIT` and module registration come after that, with `aio_onceonly` doing the one-time setup that includes `kqueue_add_filteropts(EVFILT_AIO, &aio_filtops)`. This is where the system-wide `EVFILT_AIO` filter is installed. No driver participates; the AIO module does it alone.

The middle portion of the file is the heart of AIO: `aio_aqueue` (the syscall-layer entry point), `aio_queue_file` (the generic dispatcher), `aio_qbio` (the bio-based path), `aio_process_rw` (the worker-thread path), `aio_complete` (the completion announcement), and `aio_bio_done_notify` (the wake-up fan-out). Tracing from `aio_aqueue` through each of these in turn maps the life of an AIO request from submission to completion.

The completion-signalling functions include `aio_bio_done_notify`, which walks the `kaiocb`’s `knlist` and fires `KNOTE_UNLOCKED` on any registered `EVFILT_AIO` knote, wakes any thread blocked in `aio_suspend`, and delivers any registered signal through `pgsigio`. This is the AIO analogue of the combined producer path we saw in the `evdev` driver.

Cancellation lives in `aio_cancel` and the syscall-layer `kern_aio_cancel`. `aio_cancel` on a `kaiocb` simply calls `aio_complete(job, -1, ECANCELED)`, which pushes the job through the same completion path as a successful one. The userland sees `ECANCELED` instead of a byte count.

The file ends with the syscall implementations for `aio_read`, `aio_write`, `aio_suspend`, `aio_cancel`, `aio_return`, `aio_error`, and friends, plus the `lio_listio` batch submission. These all eventually call into the core dispatchers in the middle of the file.

A reader who traces a userland `aio_read` through `aio_aqueue` to `aio_queue_file`, through either `aio_qbio` or `aio_process_rw`, and then through `aio_complete` back to `aio_bio_done_notify`, has seen the whole AIO path end to end. The file is long but the structure is regular, and the parts that concern drivers are a small fraction of the whole.

### 35.8.16 A Driver-Side Checklist

Now that we have discussed what AIO does and does not ask of drivers, here is a short checklist that driver authors can use as a quick reference.

For a cdev driver that only needs basic readable-event notification, there is nothing to do for AIO. Implement `d_read`, implement `d_poll` or `d_kqfilter` for non-blocking notification, and the userland can use `aio_read(2)` through the AIO worker thread with no additional driver code.

For a cdev driver that wants to be friendly to userland programs using AIO for portability reasons, the same answer applies: nothing extra is needed. The AIO worker thread handles it.

For a block device driver, the bio layer handles AIO through `aio_qbio` and `aio_biowakeup`. A block driver that services its strategy routine correctly also services AIO correctly. Again, nothing extra is needed.

For a driver that has a genuinely asynchronous hardware path and wants to expose it through AIO without going through a worker thread, the `d_aio_read` and `d_aio_write` hooks on `cdevsw` exist but are rare enough that implementing them is outside the scope of this chapter. Such a driver should study the file-ops `fo_aio_queue` mechanism in `/usr/src/sys/kern/vfs_aio.c` and the handful of subsystems that use it.

For every other driver, the answer is simpler still: implement `kqueue`, let userland wait for events the efficient way, and treat AIO as a userland convenience that the kernel handles without the driver's involvement.

### 35.8.17 Wrapping Up Section 5

We now have three independent asynchronous notification mechanisms in our driver: `poll()`, `kqueue()`, and `SIGIO`. Each is relatively small on its own, and each can be implemented without interfering with the others. The pattern, in every case, is the same: register interest in the waiter path, deliver notification in the producer path, and be careful about locking and cleanup.

But these three mechanisms assume the driver has a well-defined notion of “an event is ready.” So far our discussion has been abstract about what an event actually is. In the next section we look at how a driver organizes its events internally, so that a single `read()` call can produce a clean, well-typed record rather than raw hardware state. The internal event queue is the piece that ties the whole asynchronous design together.

## 35.9 6. Internal Event Queues and Message Passing

Up to this point we have treated “an event is ready” as a fuzzy condition. In real drivers, the condition is usually concrete: there is a record in an internal queue. The producer inserts records, the consumer reads them, and the asynchronous notification mechanisms tell the consumer when the queue has gained or lost records. Getting the queue right is what makes the rest of the driver simple.

An event queue has several attributes that distinguish it from a raw byte buffer. Each entry is a structured record, not a stream of bytes: a typed event with a payload. Entries are delivered whole, not partially: a reader either gets a complete record or gets no record. The queue has a bounded size, so producers must have a policy for what happens when the queue fills up: drop the oldest, drop the newest, report an error, or wait for room. And the queue is consumed in order: events are delivered in the order they were inserted, unless the design explicitly allows otherwise.

Designing the queue carefully pays off throughout the driver. A reader who sees a stream of well-typed records can write simple, robust userland code. A producer who knows the queue's policy on overflow can make sensible decisions when events arrive faster than they can be consumed. The asynchronous notification mechanisms (`poll`, `kqueue`, `SIGIO`) all become cleaner, because they can each express their condition in terms of queue emptiness rather than in terms of arbitrary per-device state.

### 35.9.1 Designing the Event Record

The first decision is what a single event looks like. A minimal record for our evdemo driver:

```
struct evdemo_event {
 struct timespec ev_time; /* timestamp */
 uint32_t ev_type; /* event type */
 uint32_t ev_code; /* event code */
 int64_t ev_value; /* event value */
};
```

This mirrors the layout of real event interfaces like evdev, which is no accident: a timestamp plus a (type, code, value) triple is enough to describe most event streams, from keyboard keypresses to sensor readings to button events on a game controller. The timestamp lets userland reconstruct when the event happened regardless of when it was consumed, which matters for latency- sensitive applications.

A driver that needs more structure can add fields, but the discipline of keeping the record fixed-size is worth defending. A fixed-size record makes the queue's memory management easy, makes the read path a simple copy, and avoids ABI issues that arise when records have variable length.

### 35.9.2 The Ring Buffer

The queue itself can be a simple ring buffer of fixed capacity:

```
#define EVDEMO_QUEUE_SIZE 64

struct evdemo_softc {
 /* ... */
 struct evdemo_event sc_queue[EVDEMO_QUEUE_SIZE];
 u_int sc_qhead; /* next read position */
 u_int sc_qtail; /* next write position */
 u_int sc_nevents; /* count of queued events */
 u_int sc_dropped; /* overflow count */
 /* ... */
};

static inline bool
evdemo_queue_empty(const struct evdemo_softc *sc)
{
 return (sc->sc_nevents == 0);
}

static inline bool
evdemo_queue_full(const struct evdemo_softc *sc)
{

```

```

 return (sc->sc_nevents == EVDEMO_QUEUE_SIZE);
}

static void
evdemo_enqueue(struct evdemo_softc *sc, const struct evdemo_event *ev)
{
 mtx_assert(&sc->sc_mtx, MA_OWNED);

 if (evdemo_queue_full(sc)) {
 /* Overflow policy: drop oldest. */
 sc->sc_qhead = (sc->sc_qhead + 1) % EVDEMO_QUEUE_SIZE;
 sc->sc_nevents--;
 sc->sc_dropped++;
 }

 sc->sc_queue[sc->sc_qtail] = *ev;
 sc->sc_qtail = (sc->sc_qtail + 1) % EVDEMO_QUEUE_SIZE;
 sc->sc_nevents++;
}

static int
evdemo_dequeue(struct evdemo_softc *sc, struct evdemo_event *ev)
{
 mtx_assert(&sc->sc_mtx, MA_OWNED);

 if (evdemo_queue_empty(sc))
 return (-1);

 *ev = sc->sc_queue[sc->sc_qhead];
 sc->sc_qhead = (sc->sc_qhead + 1) % EVDEMO_QUEUE_SIZE;
 sc->sc_nevents--;
 return (0);
}

```

Several things about this code are worth calling out.

We use a simple modular arithmetic ring rather than a linked list. This keeps the memory footprint fixed, avoids allocations at event time, and makes the queue lock-free from a cache-line point of view (two reads and a write per operation). Most drivers with this pattern use a ring.

We track `sc_nevents` separately from the head and tail pointers. Using head and tail alone, without a count, leads to the classic ambiguity between “empty” and “full”: when head equals tail, the queue could be either state. The count field resolves the ambiguity and makes the fast paths cheap.

We have an overflow policy baked into `evdemo_enqueue`. When the queue is full, we drop the oldest event. This is the right policy for an event stream where recent events are more valuable than stale ones; a security

log or a metrics stream might prefer the opposite. We also increment `sc_dropped` so that userland can tell how many events were lost.

Both `evdemo_enqueue` and `evdemo_dequeue` assert that the softc mutex is held. This is a structural safety net: if the caller forgets to take the lock, the assertion fires on a debug kernel and points at exactly the wrong call site. Without the assertion, the bug might manifest only under rare timing as silent queue corruption.

### 35.9.3 The Read Path

With the queue in place, the synchronous `read()` handler becomes short:

```
static int
evdemo_read(struct cdev *dev, struct uio *uio, int flag)
{
 struct evdemo_softc *sc = dev->si_drv1;
 struct evdemo_event ev;
 int error = 0;

 while (uio->uio_resid >= sizeof(ev)) {
 mtx_lock(&sc->sc_mtx);
 while (evdemo_queue_empty(sc) && !sc->sc_detaching) {
 if (flag & O_NONBLOCK) {
 mtx_unlock(&sc->sc_mtx);
 return (error ? error : EAGAIN);
 }
 error = cv_wait_sig(&sc->sc_cv, &sc->sc_mtx);
 if (error != 0) {
 mtx_unlock(&sc->sc_mtx);
 return (error);
 }
 }
 if (sc->sc_detaching) {
 mtx_unlock(&sc->sc_mtx);
 return (0);
 }
 evdemo_dequeue(sc, &ev);
 mtx_unlock(&sc->sc_mtx);

 error = uiomove(&ev, sizeof(ev), uio);
 if (error != 0)
 return (error);
 }
 return (0);
}
```

The pattern is standard: loop while the caller has buffer space left, wait for a record if the queue is empty, dequeue one under the lock, release the lock, copy out through `uiomove(9)`. We handle `O_NONBLOCK` by returning `EAGAIN` when the queue is empty, and we handle detach by returning zero (end-of-file) so that readers can cleanly terminate.

The `cv_wait_sig()` call is a condition variable wait that also returns on signal delivery, so that a reader blocked in `read()` can be interrupted by `SIGINT` or other signals. This is the interruptible-wait pattern you may remember from earlier chapters on synchronization. The condition variable is signalled from the producer path, which we look at next.

### 35.9.4 Integrating the Producer Path

The producer now has three things to do: enqueue the event, signal any blocked readers through the condition variable, and deliver asynchronous notifications through the three mechanisms we have studied:

```
static void
evdemo_post_event(struct evdemo_softc *sc, struct evdemo_event *ev)
{
 bool async;

 mtx_lock(&sc->sc_mtx);
 evdemo_enqueue(sc, ev);
 async = sc->sc_async;
 cv_broadcast(&sc->sc_cv);
 KNOTE_LOCKED(&sc->sc_rsel.si_note, 0);
 mtx_unlock(&sc->sc_mtx);

 selwakeup(&sc->sc_rsel);
 if (async)
 pgsigio(&sc->sc_sigio, SIGIO, 0);
}
```

This is the producer's canonical shape. All the state updates and all the in-lock notifications happen inside the softc mutex; the out-of-lock notifications happen outside. The order matters: the in-lock `cv_broadcast` and `KNOTE_LOCKED` happen before we drop the lock, and the out-of-lock `selwakeup` and `pgsigio` happen after.

One detail is the use of `cv_broadcast()` rather than `cv_signal()`. If multiple readers are blocked in `read()`, we usually want to wake all of them so that each can try to claim a record. With `cv_signal()` we wake only one, and the others stay asleep until another event arrives. In a single-reader design `cv_signal()` would be fine; in the general case `cv_broadcast()` is safer.

### 35.9.5 The Poll and Kqueue Integration

The beauty of the internal event queue is that `d_poll` and `d_kqfilter` become one-liners in terms of queue state:

```

static int
evdemo_poll(struct cdev *dev, int events, struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;
 int revents = 0;

 mtx_lock(&sc->sc_mtx);
 if (events & (POLLIN | POLLRDNORM)) {
 if (!evdemo_queue_empty(sc))
 revents |= events & (POLLIN | POLLRDNORM);
 else
 selrecord(td, &sc->sc_rsel);
 }
 if (events & (POLLOUT | POLLWRNORM))
 revents |= events & (POLLOUT | POLLWRNORM);
 mtx_unlock(&sc->sc_mtx);

 return (revents);
}

static int
evdemo_kqread(struct knote *kn, long hint)
{
 struct evdemo_softc *sc = kn->kn_hook;

 mtx_assert(&sc->sc_mtx, MA_OWNED);

 kn->kn_data = sc->sc_nevents;
 if (sc->sc_detaching) {
 kn->kn_flags |= EV_EOF;
 return (1);
 }
 return (!evdemo_queue_empty(sc));
}

```

The readable filter reports `kn->kn_data` as the number of queued events, and returns true whenever the queue is non-empty. The userland program sees `kn_data` and can tell how many events are available without having to call `read()` yet. This is a small but useful feature of the `kqueue` API, and it costs us nothing to support.

### 35.9.6 Exposing Queue Metrics Through `sysctl`

A diagnostic-friendly driver exposes its queue state through `sysctl(9)`. For `evdemo` we add a few counters:

```
SYSCALL_NODE(_dev, OID_AUTO, evdemo, CTLFLAG_RW, 0, "evdemo driver");

SYSCALL_UINT(_dev_evdemo, OID_AUTO, qsize, CTLFLAG_RD,
 &evdemo_qsize, 0, "queue capacity");
SYSCALL_UINT(_dev_evdemo, OID_AUTO, qlen, CTLFLAG_RD,
 &evdemo_qlen, 0, "current queue length");
SYSCALL_UINT(_dev_evdemo, OID_AUTO, dropped, CTLFLAG_RD,
 &evdemo_dropped, 0, "events dropped due to overflow");
SYSCALL_UINT(_dev_evdemo, OID_AUTO, posted, CTLFLAG_RD,
 &evdemo_posted, 0, "events posted since attach");
SYSCALL_UINT(_dev_evdemo, OID_AUTO, consumed, CTLFLAG_RD,
 &evdemo_consumed, 0, "events consumed by read(2)");
```

These can be turned into counter(9) counters for cache-friendliness on multi-core systems, but a simple `uint32_t` is fine for instructional purposes. With these counters, a `sysctl dev.evdemo` invocation shows the queue's runtime state at a glance, which is invaluable when debugging a driver that seems to be missing events or dropping them.

### 35.9.7 Overflow Policies: A Design Discussion

Our code drops the oldest event when the queue fills. Let us think about when that is the right choice and when it is not.

Dropping the oldest is right when recent events are more valuable than old ones. A user-interface event queue is a good example: a program that woke up to find a hundred keystrokes queued usually cares about the most recent ones, not the ones from five minutes ago. A telemetry stream where each record is timestamped is similar: the old records are stale.

Dropping the newest is right when the queue represents a ledger that must not have gaps. A security log should never lose an event to overflow; it should rather refuse to log the newest event (and increment a “dropped” counter) than silently rewrite history.

Blocking the producer is right when the producer can actually wait. A driver whose producer is an interrupt handler cannot block; a driver whose producer is a user-space write call can. If the producer can wait, then a full queue becomes back-pressure that slows the producer down to match the consumer, which is often exactly what you want.

Returning an error is right for a request-response protocol where the caller needs to know immediately whether the command succeeded. This is more common in `ioctl` paths than in event queues, but it is a valid policy.

The common mistake is to pick a policy without thinking about which one fits the device. A driver that drops old events when a security log is the underlying data will lose evidence. A driver that drops new events when a UI needs responsiveness will feel laggy. Picking the right policy is a design decision, and it is worth documenting it in the driver's comments so that future maintainers understand why you chose what you chose.

### 35.9.8 Avoiding Partial Reads

One small but important detail: the read path must either deliver a complete event or no event at all. It must not copy out half an event and return a short read count, because the userland caller would then have to reconstruct the event across multiple calls, which is fragile and error-prone.

The simplest way to enforce this is the guard at the top of the loop:

```
while (uio->uio_resid >= sizeof(ev)) {
 /* ... */
}
```

If the user's buffer has fewer bytes left than one event, we simply stop. The caller gets exactly as many complete events as fit. If the caller passed a zero-length buffer, we return immediately with zero bytes, which is the convention for an empty read.

### 35.9.9 Handling Event Coalescing

Some drivers have legitimate reasons to coalesce events. If a keyboard produces “key pressed” followed immediately by “key released” for the same key, the driver might be tempted to collapse these into a single “key tapped” event to save queue space. Our advice is to resist this temptation in most cases. Coalescing changes the event semantics and can confuse userland programs that were written to expect raw events.

Where coalescing is justified (for example, coalescing mouse movements in a way that preserves the final position), implement it carefully and document it. The coalescing logic should live in the enqueue path, not in the consumer path, so that all consumers see consistent behaviour.

### 35.9.10 Wrapping Up Section 6

The internal event queue is what ties the asynchronous mechanisms together. Every notification, every readable check, every kqueue filter, every SIGIO delivery: all of them reduce to “is the queue non-empty, or not?” Once the queue is in place, the rest of the driver becomes a matter of wiring, not of design.

In the next section we look at the design patterns for combining poll, kqueue, and SIGIO in a single driver, and at the locking audit that ensures the combination is correct. Adding each mechanism individually was the easy part. Making them all work together, with one producer and many simultaneous waiters of different kinds, is where real driver engineering happens.

## 35.10 7. Combining Asynchronous Techniques

So far we have looked at poll, kqueue, and SIGIO one at a time, each in its own section, each with its own lock discipline and wakeup pattern. In a real driver, all three mechanisms coexist. A single producer path has to wake condition-variable sleepers, poll waiters, kqueue knotes, and signal owners, in a specific order, under specific locks, without dropping any wakeup and without deadlocking.

This section is about getting that combination right. It is largely a review and a consolidation: we have seen each mechanism individually, and now we see them together. The review is worth doing because the interactions between mechanisms are exactly the place where driver bugs like to hide. Small differences in lock ordering or notification timing that would not cause a visible problem with one mechanism alone can lead to missed wakeups or deadlocks when several mechanisms are layered.

### 35.10.1 When to Use Each Mechanism

A driver that supports all three mechanisms lets its userland clients choose the right tool for the job. The three mechanisms have different strengths:

`poll` and `select` are the most portable. A userland program that needs to run unchanged on a wide range of UNIX systems will use `poll`. Drivers should support `poll` because it is the lowest common denominator, and implementing it is cheap.

`kqueue` is the most efficient and most flexible. Userland programs that watch thousands of descriptors should use `kqueue`. Drivers should support `kqueue` because it is the preferred mechanism for new FreeBSD code and because most applications that care about performance will choose it.

`SIGIO` is the simplest for a specific class of programs: shell scripts using `trap`, small single-threaded programs that want the simplest possible notification, and legacy code. Drivers should support `SIGIO` because the work is minimal and the supported use cases are real.

In practice, almost every character driver for an event-driven device should implement all three. The code is small, the maintenance is low, and the userland flexibility is high.

### 35.10.2 The Producer Path Template

The canonical producer path for a driver supporting all three mechanisms is:

```
static void
driver_post_event(struct driver_softc *sc, struct event *ev)
{
 bool async;

 mtx_lock(&sc->sc_mtx);
 enqueue_event(sc, ev);
 async = sc->sc_async;
 cv_broadcast(&sc->sc_cv);
 KNOTE_LOCKED(&sc->sc_rsel.si_note, 0);
 mtx_unlock(&sc->sc_mtx);

 selwakeup(&sc->sc_rsel);
 if (async)
 pgsigio(&sc->sc_sigio, SIGIO, 0);
}
```

Every piece of this template has a reason for its placement.

The `mtx_lock` acquires the softc mutex. This is the single lock that serializes all state transitions in the driver, and all readers and writers respect it.

`enqueue_event` is inside the lock. The queue is the shared state, and any update to it must be atomic relative to other updates and to state reads.

`async = sc->sc_async` is inside the lock. This captures a consistent snapshot of the `async` flag so that we can use it outside the lock without racing.

`cv_broadcast` is inside the lock. Condition variables require that the associated mutex be held when signalling. The signal is delivered immediately, but the actual wakeup of a blocked thread happens when the mutex is released.

`KNOTE_LOCKED` is inside the lock. It walks the knote list and delivers kqueue notifications, and it expects the knlist's lock (which is our softc mutex) to be held.

`mtx_unlock` releases the softc mutex. After this point we are outside the critical section.

`selwakeup` is outside the lock. This is the canonical ordering for `selwakeup`: it must not be called inside arbitrary driver locks because it takes its own internal locks.

`pgsigio` is outside the lock for the same reason.

This order is the least-error-prone arrangement. Many variations are possible, but departures from this pattern need to be justified by a specific reason.

### 35.10.3 Lock Ordering

With four distinct notification calls and one state update, lock ordering matters. Let us work through what locks are in play.

The softc mutex is acquired first and held across the state update and the in-lock notifications.

`cv_broadcast` does not acquire any additional locks beyond the one we already hold.

`KNOTE_LOCKED` evaluates each knote's `f_event` callback. The callbacks execute with the knlist's lock (our softc mutex) held. Those callbacks must not try to acquire any additional locks, because doing so would create a nested acquisition that other paths (say, the consumer in `d_poll`) might take in the opposite order. In practice, `f_event` callbacks only read state, which is exactly what we designed for.

`selwakeup` acquires the `selinfo`'s internal mutex and walks the list of parked threads, waking them. This is done outside the softc mutex. Internally, `selwakeup` also walks the `selinfo`'s knote list, but that was already handled by our earlier `KNOTE_LOCKED` call; doing it twice is harmless but wasteful, so we do the `KNOTE_LOCKED` while we have the lock and let `selwakeup` just handle the thread list.

`pgsigio` acquires the signal-related locks and delivers the signal to the owning process or process group. This is outside the softc mutex.

The lock ordering rule is: softc mutex first, never nested inside the `selinfo` or signal locks. As long as we follow this order, we cannot deadlock.

### 35.10.4 The Consumer Paths

Each of the three consumer paths uses the softc mutex in a consistent way:

```
/* Condition-variable consumer: d_read */
mtx_lock(&sc->sc_mtx);
while (queue_empty(sc))
 cv_wait_sig(&sc->sc_cv, &sc->sc_mtx);
dequeue(sc, ev);
mtx_unlock(&sc->sc_mtx);

/* Poll consumer: d_poll */
mtx_lock(&sc->sc_mtx);
if (queue_empty(sc))
 selrecord(td, &sc->sc_rsel);
else
 revents |= POLLIN;
mtx_unlock(&sc->sc_mtx);

/* Kqueue consumer: f_event */
/* Called with softc mutex already held by the kqueue framework */
return (!queue_empty(sc));

/* SIGIO consumer: handled entirely in userland; the driver
* only sends the signal, never consumes it */
```

All three consumers check the queue under the softc mutex. This is what closes the race between the producer's state update and the consumer's check: if the producer has the lock, the consumer waits and sees the post-update state; if the consumer has the lock, the producer waits and posts after the consumer has registered.

### 35.10.5 Common Pitfalls

A few specific bugs come up often enough to name them explicitly.

**Forgetting one of the notification calls in the producer.** The canonical ordering looks like a boilerplate sequence, and it is easy to leave out one of the four calls. Tests that exercise only one mechanism will pass, but the other mechanisms will be broken. Code review and automated tests help here.

**Holding the lock during selwakeup or pgsigio.** The chapter's advice is to drop the lock before these calls. Some drivers accidentally hold the lock (for example, because the producer is deep in an unlocked-lock-unlocked pattern that is hard to refactor). The result is a latent deadlock that manifests only when a specific lock is held by a different path.

**Calling cv\_signal instead of cv\_broadcast.** A single-reader driver can use cv\_signal. A driver that allows multiple readers must use cv\_broadcast, because only one of the signalled waiters will succeed in dequeuing an event and the others must see the updated state to re-sleep. If you pick cv\_signal and then allow multiple readers later, you have introduced a latent missed wakeup that only appears under contention.

**Forgetting `knlist_init_mtx` at attach.** A driver that never initializes its `knlist` will crash on the first `KNOTE_LOCKED` call, because the `knlist`'s lock function pointers are null. The symptom is a null-pointer dereference inside `knote()`, and it can be confusing if you forgot the `init` call in a refactor.

**Forgetting `funsetown` at close.** A process that enabled `FIOASYNC` and then exited without closing the `fd` leaves a stale `struct sigio` behind. The kernel handles process exit through an `eventhandler(9)` that calls `funsetown` for us, so this is usually safe, but leaking the structure during close is still a bug.

**Forgetting `seldrain` and `knlist_destroy` at detach.** Waiters parked on the `selinfo` must be woken when the device goes away. Forgetting this leaves waiters asleep forever and can panic the kernel when the `selinfo` is freed.

### 35.10.6 Testing the Combined Design

The best way to test a driver that supports all three mechanisms is to run three userland programs in parallel:

A `poll`-based reader that watches for events and prints them.

A `kqueue`-based reader that does the same with `EVFILT_READ`.

A `SIGIO`-based reader that enables `FIOASYNC` and prints on each signal.

Trigger events in the driver at a known rate and verify that all three readers see them all. If any reader lags or misses events, there is a bug in that mechanism's wiring. Counters on the driver side help here: if the driver reports 1000 events posted but a reader reports 900 events seen, one in ten notifications is being dropped.

Running all three readers at once against the same device stresses the producer in a way single-mechanism tests do not. Any lock ordering bug that only manifests when all three are active will show up under this workload.

### 35.10.7 Application Compatibility

A well-behaved driver can expect to work with legacy and modern userland code, with single-threaded and multi-threaded programs, with code that picks one mechanism and code that picks another. The way to achieve this is to support all three mechanisms and to honour each one's documented contract.

Legacy `select`-based code should work through our `poll` implementation, because `select` is translated into `poll` in the kernel.

Modern `kqueue`-based code should work through our `d_kqfilter`, because `kqueue` is the native mechanism for event-driven userland on FreeBSD.

Single-threaded programs using `SIGIO` should work through our `FIOASYNC/FIOSETOWN` handling.

Programs that mix mechanisms (for instance, watching some descriptors with `kqueue` and using `SIGIO` for urgent events) should also work, because the driver's producer path notifies all mechanisms on every event.

This is what "application compatibility" means for a driver. Honour the contracts, notify all waiters, handle cleanup correctly, and userland code of any vintage will work.

### 35.10.8 Wrapping Up Section 7

We have a complete picture now. Three asynchronous mechanisms, one producer, one queue, one set of locks, one detach sequence. The combined design is not much more code than any single mechanism alone; the art is in getting the locks and the ordering right, and in testing the combination so that latent bugs are found before they ship.

The next section takes this combined design and applies it as a refactor of our evolving evdemo driver. We will audit the final code, look at what changed, and release the driver as version v2.5-async. The refactor is where the abstract advice turns into concrete, working source.

## 35.11 8. Final Refactor for Asynchronous Support

The previous sections built up evdemo one mechanism at a time, so the code we have now is a working but slightly haphazard accumulation. In this section we refactor the driver as a single coherent whole, with a consistent locking discipline, a complete detach path, and a set of exposed counters that let us observe its behaviour. The result is the companion driver at `examples/part-07/ch35-async-io/lab06-v25-async/`, which serves as the reference implementation for the exercises in this chapter.

Calling this the “final” refactor is slightly aspirational: a real driver is never truly finished. But refactoring after a feature is built is a useful habit, because it is when the structure of the code becomes visible as a whole rather than as a series of additions. Bugs that hid during incremental development often become obvious once the code is laid out as a single flow.

### 35.11.1 Thread-Safety Review

Our review starts with the locking. Every state element in the softc is now protected by `sc_mtx`, with the following exceptions:

`sc_sigio` is protected internally by the `SIGIO_LOCK` global, not by our softc mutex. This is correct, because the `fsetown`, `fgetown`, `funsetown`, and `pgsigio` APIs take the global lock themselves. We must not take `sc_mtx` before calling those APIs, or we would invert lock order with the rest of the kernel’s signal code.

`sc_rsel` is protected internally by its own `selinfo` mutex. We do not touch the internal list directly; we only call `selrecord` and `selwakeup`. Those functions take the internal lock themselves.

Everything else (the queue, the counters, the async flag, the detaching flag, the condition variable wait queue) is protected by `sc_mtx`.

The audit is: every code path that reads or writes one of these fields takes `sc_mtx` before the access and drops it after. Let us walk through each path.

Attach: `sc_mtx` is initialized before any access. Everything else is zeroed. No concurrent access is possible at attach time because no handle to the driver exists yet.

Detach: `sc_mtx` is taken to set `sc_detaching = true`, `cv_broadcast` and `KNOTE_LOCKED` are issued, the lock is dropped, `selwakeup` is called, and `destroy_dev_drain` is invoked. After `destroy_dev_drain` returns, no more calls to our callbacks can start. We can then `seldrain`, `knlist_destroy`, `funsetown`, `mtx_destroy`, `cv_destroy`, and free the softc.

Open: `sc_mtx` is not strictly needed because the open is serialized by the kernel, but taking it for internal state updates is cheap and clarifies the code.

Close: `funsetown` is called outside `sc_mtx`.

Read: `sc_mtx` is held around the queue check, the `cv_wait_sig` call, and the dequeue. The `uiomove` is done outside the lock, because `uiomove` might page-fault and we do not want to hold driver locks across faults.

Write: not applicable in `evdemo`, but in a driver that accepts writes the pattern is symmetric.

Ioctl: `FIOASYNC` takes `sc_mtx`; `FIOSETOWN` and `FIOGETOWN` do not, because they use `fsetown/fgetown` which have their own locking.

Poll: `sc_mtx` is held across the check and `selrecord` call.

Kqfilter: `sc_mtx` is taken by the kqueue framework before calling our `f_event` callback. Our `d_kqfilter` takes it for the `knlist_add` call.

Producer (`evdemo_post_event` from the callout): `sc_mtx` is held across the enqueue, the `cv_broadcast`, and the `KNOTE_LOCKED` call; dropped before `selwakeup` and `pgsigio`.

Every read and write of every softc field is accounted for under `sc_mtx` or under the appropriate external lock. This is the audit you want to perform on every asynchronous driver, because it is the audit that finds latent concurrency bugs before they ship.

### 35.11.2 The Complete Attach Sequence

Putting the attach path together, in the order the calls must happen:

```
static int
evdemo_modevent(module_t mod, int event, void *arg)
{
 struct evdemo_softc *sc;
 int error = 0;

 switch (event) {
 case MOD_LOAD:
 sc = malloc(sizeof(*sc), M_EVDemo, M_WAITOK | M_ZERO);
 mtx_init(&sc->sc_mtx, "evdemo", NULL, MTX_DEF);
 cv_init(&sc->sc_cv, "evdemo");
 knlist_init_mtx(&sc->sc_rsel.si_note, &sc->sc_mtx);
 callout_init_mtx(&sc->sc_callout, &sc->sc_mtx, 0);

 sc->sc_dev = make_dev(&evdemo_cdevsw, 0, UID_ROOT, GID_WHEEL,
 0600, "evdemo");
 sc->sc_dev->si_drv1 = sc;
 evdemo_sc_global = sc;
 break;
 /* ... */
}
```

```
 }
 return (error);
}
```

The order is deliberate: first initialize all the synchronization primitives, then register the callbacks (which can start arriving at any time after the `make_dev` call), then publish the softc via `si_drv1` and the global pointer.

One subtlety is `M_WAITOK`. We want a blocking allocation at attach time because we are in a module-load context, which is always allowed to sleep. `M_ZERO` is essential because an uninitialized `selinfo`, `knlist`, or condition variable will crash the kernel. With these flags, the allocation either succeeds with a zeroed structure or the module load fails cleanly.

### 35.11.3 The Complete Detach Sequence

The detach path is more delicate, because we have to coordinate with in-flight callers and active waiters:

```
case MOD_UNLOAD:
 sc = evdemo_sc_global;
 if (sc == NULL)
 break;

 mtx_lock(&sc->sc_mtx);
 sc->sc_detaching = true;
 cv_broadcast(&sc->sc_cv);
 KNOTE_LOCKED(&sc->sc_rsel.si_note, 0);
 mtx_unlock(&sc->sc_mtx);
 selwakeup(&sc->sc_rsel);

 callout_drain(&sc->sc_callout);
 destroy_dev_drain(sc->sc_dev);

 seldrain(&sc->sc_rsel);
 knlist_destroy(&sc->sc_rsel.si_note);
 funsetown(&sc->sc_sigio);

 cv_destroy(&sc->sc_cv);
 mtx_destroy(&sc->sc_mtx);

 free(sc, M_EVDemo);
 evdemo_sc_global = NULL;
 break;
```

The sequence here is worth studying because it contains several order-sensitive steps.

Setting `sc_detaching` under the lock and broadcasting is what lets blocked readers wake up and see the flag. Without this, a reader stuck in `cv_wait_sig` would sleep forever because we are about to destroy the condition variable.

The `KNOTE_LOCKED` call (with the `EV_EOF` path in `f_event`) lets any kqueue waiters see the end-of-file.

The `selwakeup` outside the lock wakes poll waiters. They return to userland and see their file descriptors becoming invalid.

The `callout_drain` stops the simulated event source. Any callout that is about to fire completes first; no new ones start.

The `destroy_dev_drain` waits for any in-flight callbacks to return. After this, `d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl`, `d_poll`, and `d_kqfilter` are all guaranteed to have returned.

The `sel drain` cleans up any lingering selinfo state.

The `knlist_destroy` verifies the knote list is empty (it should be, because every knote's `f_detach` was called when the file descriptor closed) and frees the internal lock state.

The `funsetown` clears the signal owner.

Finally we destroy the condition variable and the mutex, free the `softc`, and clear the global pointer.

This careful ordering is the difference between a driver that unloads cleanly and a driver that panics on the second load. The test regimen for any serious driver includes a “load and unload a hundred times in a loop” exercise, because the race windows in a detach path are often too narrow to hit on a single try.

### 35.11.4 Exposing Event Metrics

The finished driver exposes its event metrics through `sysctl`:

```

SYSCTL_NODE(_dev, OID_AUTO, evdemo, CTLFLAG_RW, 0, "evdemo driver");

static SYSCTL_NODE(_dev_evdemo, OID_AUTO, stats,
 CTLFLAG_RW, 0, "Runtime statistics");

SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, posted, CTLFLAG_RD,
 &evdemo_posted, 0, "Events posted since attach");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, consumed, CTLFLAG_RD,
 &evdemo_consumed, 0, "Events consumed by read(2)");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, dropped, CTLFLAG_RD,
 &evdemo_dropped, 0, "Events dropped due to overflow");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, qlen, CTLFLAG_RD,
 &evdemo_qlen, 0, "Current queue length");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, selwakeups, CTLFLAG_RD,
 &evdemo_selwakeups, 0, "selwakeup calls");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, knotes_delivered, CTLFLAG_RD,
 &evdemo_knotes_delivered, 0, "knote deliveries");
SYSCTL_UINT(_dev_evdemo_stats, OID_AUTO, sigio_sent, CTLFLAG_RD,
 &evdemo_sigio_sent, 0, "SIGIO signals sent");

```

Each counter is incremented under the softc lock from the producer. The counters are not required for correct operation, but they are required for the driver to be observable. A driver that reports zero events consumed while the queue is full tells us the reader is not draining. A driver that reports more selwakeups than knotes delivered tells us something about the mix of waiters. A driver that reports many sigio\_sent but no visible effect in userland tells us to check the owner's signal handler.

Observability costs almost nothing to add and pays for itself many times over in production debugging. Adding it to the final refactor is part of what makes the driver ready for real use.

### 35.11.5 Versioning the Driver

We tag this version as v2.5-async in the code and in the companion example directory. The convention is a simple `MODULE_VERSION` declaration:

```
MODULE_VERSION(evdemo, 25);
```

The number is the integer form of the version: 25 for 2.5. FreeBSD's module-loading infrastructure uses this number to enforce dependency constraints between modules. A module that depends on evdemo at a specific version can declare that with `MODULE_DEPEND(9)`. For our standalone driver the version is mostly informative, but bumping it with every feature release is a good habit.

### 35.11.6 Wrapping Up Section 8

The final evdemo driver supports blocking and non-blocking `read()`, `poll()` with `selrecord/selwakeup`, `kqueue()` with `EVFILT_READ`, and `SIGIO` through `FIOASYNC/FIOSETOWN`. It has a bounded internal event queue with a drop-oldest overflow policy. It exposes counters through `sysctl` for observability. Its attach and detach sequences are audited for thread safety. It is a small driver, about four hundred lines of C, but it demonstrates every pattern this chapter has taught.

More importantly, it is a template. The patterns you have seen here generalize to any driver that needs asynchronous I/O. A USB input device replaces the simulated callout with a real URB callback. A GPIO driver replaces the callout with a real interrupt handler. A network pseudo-device replaces the event queue with an mbuf chain. The asynchronous notification framework (`poll`, `kqueue`, `SIGIO`) stays the same across all of these. Once you know the pattern, adding asynchronous support to a new driver is a matter of wiring, not design.

We have now covered the chapter's core material. The next part of the chapter is hands-on: a sequence of labs that walks you through building evdemo yourself, adding each mechanism in turn, and verifying the behaviour with real userland programs. If you have been reading without running code, now is the time to open a terminal on your FreeBSD virtual machine and start typing.

## 35.12 Hands-On Labs

The labs in this section build evdemo incrementally. Each lab corresponds to a folder under `examples/part-07/ch35-async-io/` in this book's companion source. You can either type each lab from scratch (which is

slower but builds stronger intuition), or start from the provided sources and focus on the code the lab is teaching. Either approach is fine; pick whichever matches your learning style.

A few general notes before we begin.

Every lab uses the same `Makefile` pattern. A `KMOD` line names the module, a `SRCS` line lists the sources, and `bsd.kmod.mk` does the rest. Run `make` in the lab directory to produce `evdemo.ko`, and `sudo kldload ./evdemo.ko` to load it. `make test` builds the user-space test programs in the same directory.

Every lab exposes a device node at `/dev/evdemo`. If you forget to unload a previous version of the driver before building a new one, the load will fail with “device already exists.” Run `sudo kldunload evdemo` to clean up, then reload.

Every lab includes a small test program that exercises the mechanism the lab is teaching. Running the test program alongside the driver verifies that the mechanism works end to end. If a test program hangs or reports an error, something in the driver is broken, and the lab’s troubleshooting notes will usually help you find it.

### 35.12.1 Lab 1: Synchronous Baseline

The first lab establishes a synchronous baseline that the later labs build on. Our goal here is a minimal `evdemo` driver that supports blocking `read()` on an internal event queue. No asynchronous mechanisms yet. This lab teaches the queue data structures and the condition-variable pattern that everything else will layer on top of.

#### Files:

- `evdemo.c` - driver source
- `evdemo.h` - shared header with event record definition
- `evdemo_test.c` - user-space reader
- `Makefile` - module build plus test target

#### Steps:

1. Read the contents of the lab directory. Familiarize yourself with the structure of `evdemo_softc`, especially the queue fields and the condition variable.
2. Build the driver: `make`.
3. Build the test program: `make test`.
4. Load the driver: `sudo kldload ./evdemo.ko`.
5. In one terminal, run the test program: `sudo ./evdemo_test`. The program opens `/dev/evdemo` and calls `read()`, which will block because no events have been posted.
6. In a second terminal, trigger events: `sudo sysctl dev.evdemo.trigger=1`. The `sysctl` is wired up in the driver to call `evdemo_post_event` with a synthetic event. The test program should unblock, print the event, and call `read()` again.
7. Trigger a few more events. Watch the test program print each one as it arrives.
8. Unload the driver: `sudo kldunload evdemo`.

**What to observe:** The `read()` call in the test program blocks while the queue is empty and returns exactly one event at a time. The test program does not spin on the CPU while waiting; you can confirm this by watching

`top -H` in a third terminal and noting that the test process is in the S (sleeping) state on a wait channel named something like `evdemo` or the generic `cv`.

**Common mistakes to check for:** If the test program returns immediately with zero bytes, the queue may be reporting itself as empty but the `read()` path is not waiting on the condition variable. Check that the while loop in `evdemo_read` is actually calling `cv_wait_sig`. If the test program hangs and never unblocks even after triggering an event, check that the producer is actually calling `cv_broadcast` inside the mutex.

**Takeaway:** Blocking `read()` with a condition variable is the synchronous baseline. It works, but it is not enough for programs that need to watch multiple descriptors or react to events without having a thread blocked in `read()` all the time. The next labs add asynchronous support.

### 35.12.2 Lab 2: Adding `poll()` Support

The second lab adds `d_poll` to the driver so that userland programs can wait on multiple descriptors or integrate `evdemo` into an event loop. This lab teaches the `selrecord/selwakeup` pattern.

#### Files:

- `evdemo.c` - driver source (extended from Lab 1)
- `evdemo.h` - shared header
- `evdemo_test_poll.c` - poll-based test program
- `Makefile` - module build plus test target

#### Changes in the driver from Lab 1:

Add a `struct selinfo sc_rsel` to the `softc`.

Initialize it with `knlist_init_mtx(&sc->sc_rsel.si_note, &sc->sc_mtx)` during attach. Even though we are not yet using `kqueue`, pre-initializing the `si_note` knlist is cheap and makes the `selinfo` compatible with `kqueue` support later.

Add a `d_poll` callback:

```
static int
evdemo_poll(struct cdev *dev, int events, struct thread *td)
{
 struct evdemo_softc *sc = dev->si_drv1;
 int revents = 0;

 mtx_lock(&sc->sc_mtx);
 if (events & (POLLIN | POLLRDNORM)) {
 if (!evdemo_queue_empty(sc))
 revents |= events & (POLLIN | POLLRDNORM);
 else
 selrecord(td, &sc->sc_rsel);
 }
 if (events & (POLLOUT | POLLWRNORM))
 revents |= events & (POLLOUT | POLLWRNORM);
}
```

```
mtx_unlock(&sc->sc_mtx);

return (revents);
}
```

Wire it into the cdevsw:

```
.d_poll = evdemo_poll,
```

Call `selwakeup(&sc->sc_rsel)` from `evdemo_post_event` after the mutex is dropped.

Call `sel drain(&sc->sc_rsel)` and `knlist_destroy(&sc->sc_rsel.si_note)` during detach.

### Steps:

1. Copy the Lab 1 source to start from.
2. Apply the changes above.
3. Build: `make`.
4. Build the test program: `make test`.
5. Load: `sudo kldload ./evdemo.ko`.
6. Run the poll-based test: `sudo ./evdemo_test_poll`. It should call `poll()` with a 5-second timeout and print the result. With no events posted, `poll()` returns zero after the timeout.
7. Trigger an event while the test is running: `sudo sysctl dev.evdemo.trigger=1`. The `poll()` call should return immediately with `POLLIN` set, and the program should read the event.
8. Try `poll()` with several descriptors: the test program's extended mode opens `/dev/evdemo` twice and polls both descriptors. Trigger events and watch which one fires.

**What to observe:** `poll()` blocks until an event arrives, not until a timeout elapses, when an event is indeed triggered. The program does not spin on the CPU; it is genuinely asleep in the kernel. You can verify this with `top -H` and looking at `WCHAN`, which should show `select` or a similar wait channel.

**Common mistakes to check for:** If the poll returns immediately with `POLLIN` even when the queue is empty, check that your queue-emptiness check is correct. If the poll returns with the timeout even after you trigger events, the producer is not calling `selwakeup`, or it is calling `selwakeup` before updating the queue. If the kernel panics when you trigger an event, the `selinfo` was not properly initialized; check that `M_ZERO` was used in the softc allocation and that `knlist_init_mtx` was called.

**Takeaway:** `poll()` support is a hundred lines of extra code and gives every poll-based userland program the ability to integrate evdemo. The key is the lock discipline: the softc mutex serializes the check and the register in `d_poll` against the queue update in the producer. Without the lock, the race we analysed in Section 3 would cause occasional missed wakeups.

### 35.12.3 Lab 3: Adding kqueue Support

The third lab adds `d_kqfilter` so that programs using `kqueue(2)` can integrate evdemo. This lab teaches the filter operations structure and the `KNOTE_LOCKED` delivery pattern.

### Files:

- evdemo.c - driver source (extended from Lab 2)
- evdemo.h - shared header
- evdemo\_test\_kqueue.c - kqueue-based test program
- Makefile

### Changes in the driver from Lab 2:

Add the filter operations:

```
static int evdemo_kqread(struct knote *, long);
static void evdemo_kqdetach(struct knote *);

static const struct filterops evdemo_read_filterops = {
 .f_isfd = 1,
 .f_attach = NULL,
 .f_detach = evdemo_kqdetach,
 .f_event = evdemo_kqread,
};

static int
evdemo_kqread(struct knote *kn, long hint)
{
 struct evdemo_softc *sc = kn->kn_hook;

 mtx_assert(&sc->sc_mtx, MA_OWNED);
 kn->kn_data = sc->sc_nevents;
 if (sc->sc_detaching) {
 kn->kn_flags |= EV_EOF;
 return (1);
 }
 return (sc->sc_nevents > 0);
}

static void
evdemo_kqdetach(struct knote *kn)
{
 struct evdemo_softc *sc = kn->kn_hook;

 knlist_remove(&sc->sc_rsel.si_note, kn, 0);
}
```

Add the d\_kqfilter callback:

```
static int
evdemo_kqfilter(struct cdev *dev, struct knote *kn)
```

```

{
 struct evdemo_softc *sc = dev->si_drv1;

 switch (kn->kn_filter) {
 case EVFILT_READ:
 kn->kn_fop = &evdemo_read_filterops;
 kn->kn_hook = sc;
 knlist_add(&sc->sc_rsel.si_note, kn, 0);
 return (0);
 default:
 return (EINVAL);
 }
}

```

Wire it into the cdevsw:

```
.d_kqfilter = evdemo_kqfilter,
```

Add a `KNOTE_LOCKED(&sc->sc_rsel.si_note, 0)` call inside the producer's critical section. Between the `cv_broadcast` and the `mtx_unlock`.

Add `knlist_clear(&sc->sc_rsel.si_note, 0)` at the top of `detach`, before `sel drain`, to remove any still-attached knotes that did not get their `f_detach` called (for instance, because a kqueue was closed with the device's knote still attached).

#### Steps:

1. Copy the Lab 2 source.
2. Apply the changes above.
3. Build and load.
4. Run the kqueue-based test: `sudo ./evdemo_test_kqueue`. The program opens `/dev/evdemo`, creates a kqueue, registers `EVFILT_READ` for the device, and calls `kevent()` in blocking mode.
5. Trigger events and watch the kqueue reader print them.

**What to observe:** The kqueue reader reports events through the `kevent()` API rather than through `poll()`. It gets the `kn_data` value in `ev.data`, which tells it how many events are queued.

**Common mistakes to check for:** If the kqueue reader returns immediately with an error, `d_kqfilter` may be returning `EINVAL` because of a wrong case. Check the switch statement. If the kqueue reader hangs even after events are triggered, `KNOTE_LOCKED` is probably not being called, or is being called outside the lock. If the kernel panics on module unload with complaints about a non-empty knote list, `knlist_clear` is missing.

**Takeaway:** kqueue support is another hundred lines of code. The structure is similar to `poll`: a check in the event callback, a delivery in the producer, and a detach step. The framework handles the heavy lifting.

### 35.12.4 Lab 4: Adding SIGIO Support

The fourth lab adds asynchronous signal delivery. This lab teaches `FIOASYNC`, `fsetown`, and `pgsigio`.

**Files:**

- evdemo.c - driver source (extended from Lab 3)
- evdemo.h
- evdemo\_test\_sigio.c - SIGIO-based test program
- Makefile

**Changes in the driver from Lab 3:**

Add the async support to the softc:

```
bool sc_async;
struct sigio *sc_sigio;
```

Add the three ioctls to the ioctl handler:

```
case FIOASYNC:
 mtx_lock(&sc->sc_mtx);
 sc->sc_async = (*(int *)data != 0);
 mtx_unlock(&sc->sc_mtx);
 break;

case FIOSETOWN:
 error = fsetown(*(int *)data, &sc->sc_sigio);
 break;

case FIOGETOWN:
 *(int *)data = fgetown(&sc->sc_sigio);
 break;
```

Add pgsigio delivery to the producer, outside the lock:

```
if (async)
 pgsigio(&sc->sc_sigio, SIGIO, 0);
```

Add funsetown(&sc->sc\_sigio) to the close path and the detach path.

**Steps:**

1. Copy Lab 3.
2. Apply the changes above.
3. Build and load.
4. Run the SIGIO-based test: `sudo ./evdemo_test_sigio`. The program installs a SIGIO handler, calls FIOSETOWN with its PID, calls FIOASYNC to enable, and then pauses in a loop, draining the driver with non-blocking reads whenever the handler sets the flag.
5. Trigger events and watch the program print each one.

**What to observe:** Each event arrives via a signal, not through a blocking `read()` or a `poll()`. The signal handler itself does not read from the device; it sets a flag, and the main loop reads. This is the standard pattern for SIGIO handlers.

**Common mistakes to check for:** If the test program does not see any signals, `FIOASYNC` may not be enabling `sc_async`, or the producer is not checking `sc_async`. Also check that `fsetown` was called before the producer fires.

If the test program aborts with an error about SIGIO, the signal handler may not be installed, or the signal may be masked. Use `sigprocmask` or `sigaction` with `SA_RESTART` if you want system calls to be automatically restarted across signal delivery.

**Takeaway:** SIGIO is simpler than `poll` or `kqueue` from the driver's point of view: one `ioctl` handler, one call to `fsetown`, one call to `pgsigio`. The userland side is more complex because signals have inherently tricky semantics.

### 35.12.5 Lab 5: The Event Queue

The fifth lab focuses on the internal event queue itself. We reorganize the driver so that the queue is the single source of truth for all the asynchronous mechanisms, and we add `sysctl`-based introspection so we can watch queue behaviour at runtime.

#### Files:

- `evdemo.c` - driver source with polished queue implementation
- `evdemo.h` - shared header with the event record
- `evdemo_watch.c` - a diagnostic tool that prints queue metrics
- `Makefile`

#### What changes:

The queue functions become standalone and well-documented. Every operation takes the `softc` mutex, asserts it with `mtx_assert`, and uses a consistent naming convention.

A `sysctl` subtree under `dev.evdemo.stats` exposes queue length, total events posted, total events consumed, and total events dropped due to overflow.

A trigger `sysctl` allows the userland to post a synthetic event of a given type, which simplifies testing without having to write and load a custom test program.

A burst `sysctl` posts a batch of events all at once, which exercises the queue's overflow behaviour.

#### Steps:

1. Copy Lab 4.
2. Apply the queue polish: extract the enqueue/dequeue operations into clearly named helpers, add the counters, add the `sysctl` entries.
3. Build and load.
4. Run `sysctl dev.evdemo.stats` in a loop to watch queue state: `while ;; do sysctl dev.evdemo.stats; sleep 1; done`.
5. Trigger bursts: `sudo sysctl dev.evdemo.burst=100`. Watch the queue fill up, then drop overflow events when the queue is full.

6. Run any of the reader test programs (`poll`, `kqueue`, or `SIGIO`) while triggering bursts. Watch the reader drain the queue.

**What to observe:** The queue length reported in `sysctl` tracks the number of events that have been posted but not yet consumed. The dropped counter grows when events are posted while the queue is full. The posted and consumed counters diverge when the reader is slower than the producer, and converge when the reader catches up.

**Common mistakes to check for:** If the dropped counter grows without the overflow policy firing, the queue's fullness check is wrong. If the posted counter grows but the consumed counter does not, the producer is enqueueing but the reader is not dequeuing (which might be correct if no reader is running, but usually means a bug in the read path).

**Takeaway:** The event queue is what the three asynchronous mechanisms pivot around. With `sysctl` observability, we can watch the queue's behaviour directly and verify that it is doing what we expect under various loads.

### 35.12.6 Lab 6: The Combined v2.5-async Driver

The final lab is the consolidated `evdemo` driver, with all three asynchronous mechanisms, the audited locking discipline, the exposed metrics, and the clean detach path. This is the reference implementation that future drivers can be modeled on.

#### Files:

- `evdemo.c` - full reference driver
- `evdemo.h` - shared header
- `evdemo_test_poll.c` - `poll`-based test
- `evdemo_test_kqueue.c` - `kqueue`-based test
- `evdemo_test_sigio.c` - `SIGIO`-based test
- `evdemo_test_combined.c` - test that runs all three at once
- `Makefile`

#### What this lab demonstrates:

The combined test program forks three children. One uses `poll`, one uses `kqueue`, one uses `SIGIO`. Each child opens its own file descriptor to `/dev/evdemo` and watches for events. The parent triggers events at a known rate and reports after a fixed duration.

#### Steps:

1. Build and load.
2. Run the combined test: `sudo ./evdemo_test_combined`. It forks the three children, triggers 1000 events at a few hundred per second, and prints a summary at the end.
3. Observe that all three readers see all events.

**What to observe:** The posted counter in `sysctl` equals the sum of events seen across all three readers. None of the mechanisms drops events. The readers finish within a few milliseconds of each other, demonstrating that the driver is responsive to all three simultaneously.

**Common mistakes to check for:** If one reader is consistently behind, check that its mechanism's notification is being issued on every event. If the three readers produce different event counts, one mechanism is dropping notifications, which suggests a missed wakeup in the producer.

**Takeaway:** A driver that implements all three asynchronous mechanisms correctly serves any userland caller. This is the target to aim for when you build a production driver for an event-driven device. Once you know the pattern, the work is mechanical.

### 35.12.7 Lab 7: Unload Stress Test

The final lab is a stress test of the detach path, because detach is where the subtle bugs in asynchronous drivers tend to hide.

**Files:**

- `evdemo.c` from Lab 6
- `evdemo_stress.sh` - shell script that loads, exercises, and unloads the driver in a loop

**Steps:**

1. Load the driver.
2. In one terminal, run the combined test continuously in a loop.
3. In another terminal, run the stress script: `sudo ./evdemo_stress.sh 100`. This loads, exercises, unloads, and reloads the driver one hundred times in a row, exercising the attach and detach sequences under concurrent readers.
4. Observe that no panics occur, that all readers terminate cleanly across each unload-reload cycle, and that `sysctl` counters reset to zero on each attach.

**What to observe:** A driver with correct detach logic can sustain a hundred or a thousand load/unload cycles without panicking, leaking memory, or hanging. A driver with an incorrect detach will typically panic within ten or twenty cycles.

**Common mistakes to check for:** The most common detach bug is forgetting to drain in-flight callers before freeing the `softc`. `destroy_dev_drain` is the canonical tool for this; without it, an in-flight `read()` or `ioctl()` can touch a freed `softc`.

The second most common bug is a mismatch between the attach and detach initialization order. `knlist_init_mtx` must happen before the device is published, because a `kqfilter` call can arrive immediately after. Symmetrically, `knlist_destroy` must happen after the device is drained.

**Takeaway:** Stress-testing the unload path is the single most effective test for an asynchronous driver. If your driver survives 100 load/unload cycles under concurrent load, it is probably solid.

## 35.13 Challenge Exercises

These exercises are optional. They build on the labs to sharpen your skills in specific areas. Take your time; there is no rush.

### 35.13.1 Challenge 1: Dual Mechanism Shootout

Modify `evdemo_test_combined` to measure the per-event latency of each mechanism: the time between the producer's `evdemo_post_event` call and the userland reader's `read()` return. Use the `CLOCK_MONOTONIC` clock and record the timing on the event record itself.

Report a small table showing the mean, median, and 99th percentile latency for each of `POLL`, `KQUEUE`, and `SIGIO`. Try it with no contention (one reader per mechanism) and with contention (three readers per mechanism). Which mechanism has the lowest latency under no contention? Under contention?

The expected answer is that `kqueue` is lowest, `POLL` second, and `SIGIO` variable (because signal delivery latency depends on the reader's current execution state). But the details depend on your hardware, and the exercise is to measure rather than to predict.

### 35.13.2 Challenge 2: Multi-Reader Stress

Open twenty file descriptors to `/dev/evdemo` and poll all of them at once from a single thread using `kqueue`. Trigger 10000 events and verify that each event is delivered to all twenty descriptors exactly once.

This tests that the driver's knot list handles multiple knots correctly and that `KNOTE_LOCKED` walks the list completely on every event.

### 35.13.3 Challenge 3: Observe the Missed Wakeup Race

The third challenge asks you to deliberately break the driver so that you can observe a missed wakeup. Modify `evdemo_post_event` so that it updates the queue and calls the notifications outside the softc mutex instead of inside:

```
/* BROKEN: race with d_poll */
mtx_lock(&sc->sc_mtx);
evdemo_enqueue(sc, ev);
mtx_unlock(&sc->sc_mtx);
selwakeup(&sc->sc_rsel);
/* ... */
```

This unlocks the producer's enqueue from the consumer's check-and-register. With a high enough event rate and a busy consumer, you should occasionally see `POLL()` calls that return after a long delay despite events having been posted.

Try to reproduce the race. Time the `POLL()` calls. Report how often the race fires as a function of event rate. Then restore the correct locking and verify the race disappears.

The point of this exercise is not to write broken code. It is to see, with your own eyes, that the lock discipline we described in Section 3 is not a theoretical nicety but a real correctness property. Experiencing the race once is worth reading a hundred descriptions of it.

### 35.13.4 Challenge 4: Event Coalescing

Add an event coalescing feature to `evdemo`. When the producer posts an event of a type that matches the most recent event in the queue, merge them into a single event with an incremented counter instead of appending a new entry. This is similar to how some drivers coalesce interrupt events.

Test it with a burst of a hundred events of the same type. The queue length should stay at one. Now test it with a hundred events of alternating types: the queue should fill with alternating entries.

The challenge is as much about designing the userland contract as about implementing the feature. What does the reader see when coalescing happens? How does it know an event was coalesced? What does the `kqueue kn_data` field report when the queue has one entry but it represents many events?

There is no single right answer. Document your design choices in the source and be prepared to defend them.

### 35.13.5 Challenge 5: POLLHUP and POLLERR

Add graceful handling of `POLLHUP` and `POLLERR` to the driver. When the device is detached while a userland program still has it open, that program should see `POLLHUP` in its next `poll()` call (along with `POLLIN` if there are still queued events). When the driver has an internal error that prevents future operations, it should set an error flag and report `POLLERR` on subsequent `poll()` calls.

Test it by arranging for the driver to be detached while a reader is polling. The reader should wake up with `POLLHUP` and exit cleanly.

This teaches the full `poll()` contract and the subtleties of the `revents` bitmask. It also overlaps with the detach logic, which is the right place to set the HUP condition.

### 35.13.6 Challenge 6: evdev-Style Compatibility

Add a compatibility layer to `evdemo` that implements the `evdev` `ioctl` set, so that your driver becomes visible to existing `evdev`-aware userland programs. The key `ioctls` are `EVIIOCGVERSION`, `EVIIOCGID`, `EVIIOCGNAME`, and a few others documented in `/usr/src/sys/dev/evdev/input.h`.

This is a larger exercise and genuinely useful for understanding how real input devices expose themselves to userland. It requires reading the `evdev` source carefully and choosing a sensible subset to implement.

### 35.13.7 Challenge 7: Trace a kqueue Registration End to End

Using `dtrace(1)` or `ktrace(1)`, trace a single `kevent(2)` call that registers an `EVFILT_READ` on an `evdemo` file descriptor. Your trace should cover:

- The entry into the `kevent` syscall.
- The call into `kqueue_register` in the `kqueue` framework.
- The invocation of `fo_kqfilter` on the `cdev` fileops.
- The entry into `evdemo_kqfilter` (our driver's `d_kqfilter`).
- The `knlist_add` call.
- The return back through the framework to userland.

Capture the stack trace at each point. Then trigger a producer event in the driver and trace the delivery path:

- The `KNOTE_LOCKED` call in the producer.
- The entry into knote in the framework.
- The call to `evdemo_kqread` (our `f_event`).
- The queuing of the notification onto the kqueue.

Finally, the userland reaps the event with another `kevent` call. Trace that path as well:

- The second entry into the `kevent` syscall.
- The call into `kqueue_scan`.
- The walk of the queued knotes.
- The delivery to userland.

Submit your traces, annotated with a few sentences on what each part is doing. This exercise forces a direct confrontation with the kqueue framework source and is the surest way to go from “understands the callbacks” to “understands the framework.” A reader who completes this challenge will have the confidence to read any kqueue-using subsystem in the tree.

Tip: `dtrace -n 'fbt::kqueue_register:entry { stack(); }'` is a reasonable starting point. Build outwards from there, adding probes on `knote`, `knlist_add`, `knlist_remove`, and your driver’s entry points as you identify them in the source.

### 35.13.8 Challenge 8: Observe the knlist Lock Discipline

Write a small test program that opens an `evdemo` device twice from two different processes, registers an `EV_FILT_READ` on each, and then triggers a producer event. Use `dtrace` to measure how many times the `knlist` lock is acquired and released during the single delivery. Predict the number in advance based on what the chapter has taught about `KNOTE_LOCKED` and the `knlist` walk; then verify against the trace.

Next, modify `evdemo` so that the producer uses `KNOTE_UNLOCKED` instead of `KNOTE_LOCKED` (while adjusting the surrounding locking so the call is safe). Repeat the measurement. The number of acquisitions should change, and the change should match what the framework does differently in the two code paths.

Tip: `dtrace -n 'mutex_enter:entry /arg0 == (uintptr_t)&sc->sc_mtx/ { @ = count(); }'` will count mutex acquisitions on a specific mutex if you know its address. You can find the address through `kldstat -v` plus a bit of symbolic inspection.

## 35.14 Troubleshooting Common Mistakes

Asynchronous I/O bugs tend to fall into recognizable categories. This section collects the most common failure modes, their symptoms, and their usual causes, so that when you encounter one you can diagnose it quickly.

### 35.14.1 Symptom: `poll()` never returns

A `poll()` call blocks forever even though events are being triggered.

**Cause 1:** The producer is not calling `selwakeup`. Add a counter to `evdemo_post_event` and verify that it is actually incrementing when events are triggered.

**Cause 2:** The producer is calling `selwakeup` before the queue state is updated. Verify that `selwakeup` is called after `mtx_unlock`, not before.

**Cause 3:** The consumer's `d_poll` is not calling `selrecord` correctly. Check that the call is made under the softc mutex and that the `selinfo` passed is the same one the producer wakes.

**Cause 4:** The consumer is checking the wrong state. Verify that the queue-emptiness check in `d_poll` is looking at the same field that the producer updates.

### 35.14.2 Symptom: kqueue event fires but read() returns no data

A kqueue reader receives an `EVFILT_READ` event but a subsequent `read()` returns `EAGAIN` or zero bytes.

**Cause 1:** The queue was drained by another reader between the kqueue event delivery and the read. This is a benign symptom of multi-reader contention, not a bug. The reader should loop on `EAGAIN` and wait for the next event.

**Cause 2:** The `f_event` callback is returning true when the queue is actually empty. Check the `evdemo_kqread` logic.

**Cause 3:** The event was coalesced or re-filed after the kqueue delivery. Check for any queue manipulation that could remove the event after `KNOTE_LOCKED` was called.

### 35.14.3 Symptom: SIGIO is delivered but the handler is not called

The driver is calling `pgsigio`, but the userland program never sees the signal.

**Cause 1:** The program has not installed a handler for `SIGIO`. By default, `SIGIO` is ignored, not delivered.

**Cause 2:** The program has blocked `SIGIO` with `pthread_sigmask` or `sigprocmask`. Check the signal mask.

**Cause 3:** The program called `FIOSETOWN` with a wrong PID, so the signal is going to another process. Verify the argument is the current process's PID.

**Cause 4:** The driver is calling `pgsigio` only when `sc_async` is true, but the userland never enabled `FIOASYNC`. Check that the `ioctl` handler is updating `sc_async` correctly.

### 35.14.4 Symptom: Kernel panic on module unload

The kernel panics during `kldunload evdemo`.

**Cause 1:** `knlist_destroy` is being called on a `knlist` that still has knotes attached. Add `knlist_clear` before `knlist_destroy` to force-remove any remaining knotes.

**Cause 2:** `seldrain` is being called before in-flight callers have returned. Call `destroy_dev_drain` first, then `seldrain`.

**Cause 3:** The condition variable is being destroyed while a thread is still waiting on it. Set `sc_detaching = true` and `cv_broadcast` before `cv_destroy`.

**Cause 4:** The `softc` is being freed while another thread still holds a pointer to it. Ensure that the global `softc` pointer is cleared after `destroy_dev_drain` returns, not before.

### 35.14.5 Symptom: Memory leak on repeated load/unload

After many load/unload cycles, `vmstat -m` shows growing allocations for the driver's `MALLOC_DEFINE` type.

**Cause 1:** The `softc` is not being freed on detach. Check that `free(sc, M_EVDEMO)` is called.

**Cause 2:** `funsetown` is not being called. Each `fsetown` call allocates a `struct sigio` that must be freed.

**Cause 3:** Some internal allocation (for example, a per-reader structure) is not being freed at close time. Audit every allocation path and confirm every `malloc` has a matching `free`.

### 35.14.6 Symptom: Slow-to-wake `poll()` under load

A poll-based reader usually wakes quickly but occasionally takes significant time to see an event.

**Cause:** The scheduler's wakeup delivery latency on a busy system is in the millisecond range. This is not a driver bug; it is a general property of the kernel's scheduler.

If this latency is unacceptable for your use case, consider `kqueue` with `EV_CLEAR`, which has slightly lower wakeup overhead, or use a dedicated kernel thread for the consumer rather than a userland process.

### 35.14.7 Symptom: Events are dropped under load

The driver's dropped `sysctl` counter grows during a burst of events.

**Cause:** The queue is smaller than the burst size, and the overflow policy (drop-oldest) is kicking in.

This is working as designed for the default policy. If your application cannot tolerate drops, increase the queue size or change the overflow policy to block the producer.

### 35.14.8 Symptom: Only one reader wakes up even when multiple are waiting

Several readers are blocked in `read()` or `poll()`, but when an event is posted only one of them wakes.

**Cause:** The producer is calling `cv_signal` instead of `cv_broadcast`. `cv_signal` wakes exactly one sleeper; `cv_broadcast` wakes all of them.

For a driver with multiple concurrent readers, `cv_broadcast` is the correct choice, because each reader may race for the event and all of them need to see the wakeup to decide whether to re-sleep.

### 35.14.9 Symptom: The device hangs during detach

`kldunload` does not return, and the kernel shows the thread blocked somewhere in our detach code.

**Cause 1:** A call is blocked in `d_read` and we did not wake it before waiting for `destroy_dev_drain`. Set `sc_detaching`, `broadcast`, and `wake selinfo` before calling `destroy_dev_drain`.

**Cause 2:** A callout is in flight and we did not drain it. Call `callout_drain` before `destroy_dev_drain`, or the callout may re-enter the driver after we think we are finished.

**Cause 3:** A thread is parked in `cv_wait_sig` on a condition that will never be broadcast again. Ensure every wait loop checks `sc_detaching` as a separate exit condition.

### 35.14.10 Symptom: Reader wakes but finds nothing to do

A reader is woken by `poll`, `kqueue`, or a blocked read, but on returning to check the queue it finds the queue empty and has to go back to sleep. This happens occasionally even in a correct driver.

**Cause:** Spurious wakeups are a normal part of kernel life. The scheduler may deliver a wakeup that was meant for another waiter, a different event source sharing the same `selinfo` may have fired, or a race between the producer and another consumer may have drained the queue before this reader got a chance to look. None of these situations indicates a bug.

The correct response in the driver and in the reader is the same: always re-check the condition after waking, and treat a wakeup as a hint that something may have happened, not a guarantee that the specific event you expected is available. Every wait loop in the driver should look like the pattern we established in Section 3, with `cv_wait_sig` inside a `while` that checks the real condition. Every userland reader should expect to see `EAGAIN` or a zero-length read after a wakeup and loop back to poll again.

If wakeups without work are happening frequently enough to waste significant CPU, consider whether the producer is calling `selwakeup` more often than necessary, for example on every intermediate state change rather than only when a reader-visible event is ready. Coalescing wakeups at the producer is the fix; disabling the re-check loop in the consumer is not.

### 35.14.11 Symptom: Panic on module unload with “knlist not empty”

The module unload path panics with an assertion failure in `knlist_destroy` that reads something like “knlist not empty” or prints a non-zero count on the `knlist`’s list head.

**Cause 1:** `knlist_destroy` was called without a preceding `knlist_clear`. `knlist_destroy` asserts that the list is empty; live knotes on the list trigger the panic. Inspect the detach path and confirm that `knlist_clear(&sc->sc_rsel.si_note, 0)` runs before `knlist_destroy`.

**Cause 2:** A userland process still has a `kqueue` registration open and the driver tried to tear down without forcing the knotes off. The `knlist_clear` call is designed to handle exactly this case: it marks every remaining knote with `EV_EOF` | `EV_ONESHOT` so that the userland sees a final event and the registration dissolves. If the driver is skipping `knlist_clear` to “let the userland detach naturally,” the assertion fires. The fix is to call `knlist_clear` unconditionally in detach.

**Cause 3:** The detach path is being called while an event delivery is in progress. The `kqueue` framework uses its own internal locking to keep delivery and detach coherent, but a driver that tears down its `softc` while `f_event` is still running on another thread will corrupt the lifecycle. Ensure that all producer paths have stopped (for example, by setting a `sc_detaching` flag and draining any work queues) before entering the clear-drain-destroy sequence.

### 35.14.12 Symptom: Panic in `f_event` with a stale `kn_hook`

The kernel panics inside the driver's `f_event` function with a backtrace that shows a dereference of freed or garbage memory through `kn->kn_hook`.

**Cause 1:** The `softc` was freed before the `knlist` was torn down. The driver's detach path must clear and destroy the `knlist` before freeing the `softc`, in that order. Reversing the order leaves live knotes pointing at freed memory.

**Cause 2:** A per-client state object (for example, an `evdev_client`) was freed while a knote still references it. The cleanup logic for per-client state must run the `knlist_clear/seldrain/knlist_destroy` sequence on the client's `selinfo` before freeing the client struct, not after.

**Cause 3:** A different code path accidentally called `free()` on the `softc` or client state. Memory debuggers (KASAN on platforms that support it, or manually instrumented poison patterns on those that do not) will confirm that the memory is freed when `f_event` reads it. This is a general memory-corruption debugging exercise; the knote is the victim, not the cause.

### 35.14.13 Symptom: `KNOTE_LOCKED` panics with a lock-not-held assertion

A producer path that calls `KNOTE_LOCKED` panics with an assertion like “mutex not owned” inside the `knlist` lock check.

**Cause:** The producer is calling `KNOTE_LOCKED` without actually holding the `knlist`'s lock. `KNOTE_LOCKED` is the variant that tells the framework “skip locking, the caller has it”; if the caller does not, the framework's assertions catch it. The fix is either to take the lock (usually the `softc` mutex) around the `KNOTE_LOCKED` call, or to use `KNOTE_UNLOCKED` instead and let the framework take the lock itself.

Read the producer path carefully. A common mistake is to drop the `softc` lock partway through a producer function for some other reason (for example, to call a function that cannot be called under the lock), and then to forget to re-acquire it before the `KNOTE_LOCKED` call. The fix is to re-take the lock or to call `KNOTE_UNLOCKED` instead.

### 35.14.14 Symptom: `kqueue` events arrive but `kn_data` is always zero

A `kqueue` waiter wakes up and reads a struct `kevent` whose `data` field is zero, even though the driver has events pending.

**Cause 1:** The `f_event` function sets `kn->kn_data` only under certain conditions and leaves it untouched otherwise. The framework preserves whatever value was last written, so a stale zero from a previous invocation persists into the next delivery. The fix is to compute and assign `kn->kn_data` unconditionally at the top of `f_event`.

**Cause 2:** The `f_event` function is returning non-zero based on a condition other than the queue depth, and the `kn_data` field was not updated to reflect the actual count. Check that `kn_data` is assigned the real depth, not a boolean, and that the comparison that drives the return value is consistent with it.

### 35.14.15 Symptom: poll() works but kqueue never fires

A poll-based waiter sees events correctly, but a kqueue waiter on the same file descriptor never wakes up.

**Cause 1:** The driver's `d_kqfilter` entry point is not in the `cdevsw`. Check the `cdevsw` initializer and confirm that `.d_kqfilter = evdemo_kqfilter` is present. Without it, the kqueue framework has no way to register a knote on the descriptor.

**Cause 2:** The producer is calling `selwakeup` but not `KNOTE_LOCKED`. `selwakeup` does walk the knlist attached to the selinfo, but only under specific conditions; drivers that want to reliably wake kqueue waiters should call `KNOTE_LOCKED` (or `KNOTE_UNLOCKED`) explicitly in the producer path.

**Cause 3:** The `f_event` function always returns zero. Check whether the ready condition is being evaluated correctly. Add a `printf` to confirm that `f_event` is being called; if it is but returns zero, the bug is in the readiness check, not in the framework.

### 35.14.16 General Advice

When debugging an asynchronous driver, add counters liberally. Every `selrecord`, every `selwakeup`, every `KNOTE_LOCKED`, every `pgsigio` should have a counter. When behaviour looks wrong, printing the counters is the fastest way to tell you which mechanism is misbehaving.

Use `ktrace` on the userland side to see exactly when system calls return. If the driver thinks it delivered a wakeup at time *T* and the userland thinks it returned at time *T*+5 seconds, the wakeup was queued but not delivered, which often means a lock was held too long somewhere.

Use DTrace probes in the driver and on `selwakeup` itself. The `fbt:kernel:selwakeup:entry` probe shows every `selwakeup` system-wide. The `fbt:kernel:pgsigio:entry` probe does the same for signal deliveries. A missing call shows up as a gap in the probe output.

Do not suspect the framework. The kernel's async-I/O infrastructure is battle-tested and almost never has bugs at this level. Suspect your own driver first, particularly the lock ordering and the attach/detach sequence.

## 35.15 Wrapping Up

Asynchronous I/O is one of the places where a driver's correctness is most severely tested. A synchronous driver can hide many small locking mistakes behind a single-threaded flow that happens to run serially. An asynchronous driver exposes every corner of its locking discipline, every race between the producer and the consumer, and every subtle ordering constraint in the detach path. Getting an asynchronous driver right is harder than writing the synchronous version, but the rewards are significant: the driver serves many users at once, integrates cleanly with userland event loops, plays well with modern frameworks, and avoids the performance pathologies of blocking and busy waiting.

The mechanisms we have studied in this chapter are the classical ones. `poll()` and `select()` are portable across every UNIX system, and implementing them in a driver is a matter of one callback and a `selinfo`. `kqueue()` is the preferred mechanism for modern FreeBSD applications, and it adds one more callback and a set of filter operations. `SIGIO` is the oldest mechanism and has some sharp edges in multi-threaded code, but it remains useful for shell scripts and legacy programs.

Each mechanism has the same underlying shape: a waiter registers interest, a producer detects a condition, and the kernel delivers a notification to the waiter. The details differ, but the shape does not. Understanding the shape makes each specific mechanism easier to learn. The internal event queue we built in Section 6 is what ties the shape together: every mechanism expresses its condition in terms of queue state, and every producer updates the queue before notifying.

The locking discipline is the single habit that most consistently distinguishes a working asynchronous driver from a broken one. Take the softc mutex before checking state. Take it before updating state. Take it before registering a waiter. Take it before calling the in-lock notifications (`cv_broadcast`, `KNOTE_LOCKED`). Drop it before calling the out-of-lock notifications (`selwakeup`, `pgsigio`). This pattern is not an aesthetic choice; it is the pattern that prevents missed wakeups and deadlocks. When you see the pattern violated in a driver, ask why, because nine times out of ten the deviation is a bug.

The detach sequence is the second habit that deserves discipline. Set the detaching flag under the lock. Broadcast to wake every waiter. Deliver an `EV_EOF` to kqueue waiters. Call `selwakeup` to free poll waiters. Call `callout_drain` to stop the producer. Call `destroy_dev_drain` to wait for in-flight callers. Only after all of these can you safely `seldrain`, `knlist_destroy`, `funsetown`, `cv_destroy`, `mtx_destroy`, and free the softc. Skipping any step is a recipe for a panic at unload time, and those panics are especially painful to diagnose because they happen after the code you were testing.

The observability habit is the third. Every counter you add at development time saves hours of diagnosis when the driver is in production. Every `sysctl` entry you expose gives operators and debuggers a window into the driver's state without rebuilding the kernel. Every DTrace probe you declare lets a distant engineer with a production incident see into your code without shipping new software. Observability is not a luxury; it is a feature, and writing a driver without it is writing a driver you cannot debug.

You now have every piece of the async-I/O toolkit that a FreeBSD driver author needs for ordinary work. You can take a blocking character driver, audit its state transitions, identify the producer and the consumer paths, add `poll`, `kqueue`, and `SIGIO` support, and verify the whole thing under stress. The patterns generalize beyond character drivers: the same mechanisms apply to pseudo-devices, network devices with control channels, filesystems with file events, and any other subsystem that exposes an event stream to userland.

Two final notes before we move on.

First, asynchronous I/O is not a one-time lesson. You will find, as you read more of the FreeBSD source, that variations of these patterns appear everywhere: in network drivers using `grouptaskqueue`, in filesystems using `kqueue` for file events, in the audit subsystem using a ring buffer shared with userland. Each variation is an instance of the same underlying ideas. Being able to recognize the pattern when you see it is more valuable than memorizing any particular API.

Second, when you write your own driver, resist the temptation to invent your own asynchronous mechanism. The kernel's provided mechanisms cover virtually every use case, and userland programs know how to use them. A custom mechanism is work for you, work for your users, and work for whoever maintains the driver next. Reuse the standard patterns. They exist for a reason.

## 35.16 Bridge to Chapter 36: Creating Drivers Without Documentation

The next chapter changes the kind of challenge we face. Up to now, every chapter has assumed that the device we are writing for is documented. We knew its registers, its command set, its error codes, its timing requirements.

The book has shown how to turn that documentation into working kernel code, and how to test, debug, and optimize the result.

But not every device is documented. A driver author sometimes encounters hardware for which no datasheet is available, either because the vendor refuses to publish one, because the hardware is so old that the documentation has been lost, or because the device is a derivative of something documented but with undocumented changes. In those cases, the craft of driver writing shifts towards reverse engineering: observing the device's behaviour, deducing its interface, and producing a working driver from indirect evidence rather than from specifications.

Chapter 36 is about that craft. We will look at how experienced authors approach an undocumented device. We will study the tools for observing device behaviour, from bus analysers and protocol sniffers to the kernel's own built-in tracing facilities. We will learn how to build a register map by experiment, how to recognize common command patterns across vendors, and how to write a driver that is correct despite incomplete information about the hardware.

The asynchronous mechanisms from this chapter will reappear there, because event-driven hardware is exactly the kind of hardware that most rewards careful reverse engineering. A device whose documentation is missing still talks to the world in events, and making those events visible through `poll`, `kqueue`, and `SIGIO` is often the first step in figuring out what the device is actually doing.

The debugging skills from Chapter 34 will also matter, because an undocumented device produces many more surprising behaviours than a documented one, and `KASSERT`, `WITNESS`, and `DTrace` are the tools for catching those surprises early. The foundation we have built in Parts 2 through 7 is exactly what the reverse-engineering chapter needs.

If you have been reading this book from the beginning, take a moment to appreciate how far you have come. You started with an empty source tree and no knowledge of the kernel. You now know how to write a driver that supports synchronous and asynchronous I/O, handles concurrency correctly, observes its own behaviour through counters and `DTrace` probes, and can be debugged on a live system. You have written enough drivers by this point that the kernel is no longer an alien environment. It is a place you know how to work in.

The next chapter takes that knowledge and asks, what if the documentation for the device is missing? What does the same craft look like when you are working from evidence rather than from specifications? The answer, as it turns out, is that the craft changes less than you might think. The tools are the same, the disciplines are the same, and the habits you have built carry you most of the way.

Let us look at how that works.

## 36 Creating Drivers Without Documentation (Reverse Engineering)

### 36.1 Introduction

Up to this point in the book we have always written drivers for devices whose behaviour was at least partly documented. Sometimes the documentation was generous, with a full programmer's reference manual that named every register, defined every bit, and described every command. Sometimes it was sparse, with only a header file from the vendor and a short list of opcodes. Even in the sparse cases, however, we always had a starting point: a hint, a partial datasheet, an example from a related family of devices, or a manual page that told us what the device was supposed to do.

This chapter changes that assumption. Here we will learn how to write a driver for a device whose documentation is missing, lost, or deliberately withheld. The hardware exists. It works under some other operating system, or it once did, or someone has captured a few seconds of its behaviour with a logic analyser. But there is no register reference, no command list, no description of the data formats. Every fact we need we will have to discover ourselves.

If that sounds intimidating, take a slow breath. Reverse engineering a hardware device is a serious craft, but it is not magic. It is the same engineering discipline you have already practised throughout the book, applied in a slightly different direction. Instead of reading a datasheet and writing code that implements it, we will observe the device, form hypotheses about what it does, test those hypotheses with small experiments, and write the driver one verified fact at a time. The end result is the same kind of driver we have written in earlier chapters, with the same `cdevsw`, the same `device_method_t` table, the same `bus_space(9)` calls, and the same module build. The only difference is how we arrived at the contents.

Reverse engineering deserves a chapter for several reasons. The first is that the situation is more common than newcomers realise. Older hardware whose vendors have gone out of business; consumer devices that were never properly documented; embedded peripherals on a custom board where the manufacturer simply ships a binary blob and a datasheet expires when the contract does; specialised industrial, scientific, or medical equipment where the documentation lives on a CD that nobody can find. All of these are real situations that real FreeBSD developers run into, and several important FreeBSD drivers exist today only because someone was patient enough to do the work.

The second reason is that reverse engineering is a particularly disciplined kind of work, and the discipline is worth learning even if you never write a fully reverse-engineered driver. The habit of separating observation from hypothesis, the habit of writing down every assumption before testing it, and the habit of refusing to guess where a guess could damage hardware: these habits make ordinary driver work better, not just reverse-engineering work.

The third reason is that this work happens at a frontier where the distinction between writing software and doing experimental science becomes very thin. A reverse-engineering session looks more like a laboratory notebook

than like a programming session. You will run an experiment, observe a result, write down what you saw, propose an explanation, design the next experiment, and slowly build up a picture of an unknown system. That kind of work has its own rhythm, its own pacing, and its own small set of professional habits, and this chapter is where we will learn them.

We will begin by asking why reverse engineering is necessary at all, and where the legal and ethical lines lie. We will then build a small, safe, controlled lab where the work can happen without risk to production systems or expensive hardware. We will study the standard FreeBSD-friendly tools for observing devices, from `usbconfig(8)` and `pciconf(8)` to `usbdump(8)`, `dtrace(1)`, `ktr(9)`, and the `bus_space(9)` API itself. We will see how to capture a device's initialization sequence, how to compare runs to isolate single bits of meaning, and how to assemble a register map by experiment.

We will look at how to recognise the recurring shapes that hardware likes to use: ring buffers, command queues, descriptor rings, status-and-control register pairs, fixed-format command packets. We will write a minimal driver from scratch, one verified function at a time, starting with reset and slowly adding more behaviour. We will validate every assumption we can in a simulator before risking it on real hardware. We will study how the FreeBSD community already approaches this work, where to find prior art, and how to publish your findings in a form that helps others.

And finally, because this is the part that newcomers most often underestimate, we will spend a serious amount of time on safety. Some guesses can damage hardware. Some patterns of poking at unknown registers can erase non-volatile memory, brick a board, or leave a device in a state that nothing short of a vendor-only repair tool can recover from. The chapter will show you how to think about that risk, how to design wrappers that limit it, and how to recognise the operations that should never be performed without strong evidence that they are safe.

The companion code for this chapter, in `examples/part-07/ch36-reverse-engineering/`, includes a small collection of tools that you can build and run on a normal FreeBSD 14.3 development VM: a script that identifies and dumps device information for a target USB or PCI device, a kernel module that performs safe register probing on a memory region you point it at, a mock device that you can use to validate driver code before you have real hardware in front of you, and a Markdown template for the kind of pseudo-datasheet that should be the final product of a reverse-engineering session. Nothing in the labs touches hardware in a way that could damage it, and every example is safe to run inside a virtual machine.

By the end of this chapter, you will have a clear, repeatable method for approaching an undocumented device. You will know how to build the lab, how to observe, how to hypothesize, how to test, and how to document. You will know the legal lines that frame the work in the United States and the European Union, and you will know the professional habits that protect both you and the hardware. You will not finish this chapter as an expert reverse engineer, because that expertise is built up over years of practice, but you will know enough to start, and you will know how to keep yourself and the hardware safe while you learn.

## 36.2 Reader Guidance: How to Use This Chapter

This chapter sits in Part 7 of the book, in the Mastery Topics part, directly after Asynchronous I/O. It assumes you have read the asynchronous-I/O chapter, the advanced-debugging chapter, and the performance chapter, because the tools and habits from those chapters are the same tools and habits you will use here. If those chapters feel uncertain, a quick revisit will pay for itself several times over in this one.

You do not need any special hardware to follow the chapter. The worked examples use either a small kernel module that pokes at a memory region the operator gives it, or a mock device that simulates unknown hardware in software. Both run on a normal FreeBSD 14.3 virtual machine. If you have a real piece of unknown hardware that you would like to investigate, the chapter will give you the techniques and the safety habits to start, but the labs themselves will not require it.

The chapter is intentionally long because reverse engineering is a field where partial knowledge is dangerous. A reader who learns the glamorous parts of the craft and skips the safety parts is likely to brick something expensive. The labs and the safety sections deserve the same care as the technique sections.

A reasonable reading schedule looks like this. Read the first three sections in one sitting. They are the conceptual foundation: why reverse engineering matters, what the legal landscape looks like, and how to set up the lab. Take a break. Read Sections 4 through 6 in a second sitting. They cover the central techniques of the craft: building a register map, identifying buffers, and writing a minimal driver. Take another break. Read Sections 7 through 11 in a third sitting. They cover the disciplined work of expanding, validating, collaborating, staying safe, and documenting. Save the labs for a weekend or for several short evenings, because the labs will sink in much better if you have time to sit with the captured data and look at it carefully.

Some of the techniques in this chapter are slow on purpose. Capturing a device's initialisation sequence, for example, may require running the same boot ten times and diffing the captures to isolate the bits that change. The diffing is part of the lesson. If you find yourself wanting to skip to the part where the driver works, remember that the driver will only work if you have done the slow, careful observation work first. Reverse engineering rewards patience the way few other parts of systems programming do.

Several of the small kernel modules in the chapter are deliberately written as exploration scaffolds rather than as production drivers. They are commented as such. Do not load them on a production system. A development virtual machine where a kernel panic costs nothing more than a reboot is the right environment for this kind of work.

If you have hardware you would like to investigate after reading the chapter, take it slowly. Start with the safest observation tools. Resist the urge to write to anything until you have a clear, written-down hypothesis about what the write should do and what the worst case looks like. If a guess could trigger a flash erase, do not make the guess. The chapter will spell out which operations deserve special caution and why.

### 36.3 How to Get the Most Out of This Chapter

The chapter follows a pattern that mirrors the workflow of a real reverse-engineering session. Each section either teaches a technique that fits one phase of that workflow or shows you how the technique ties back to the underlying discipline. If you learn the workflow as a whole, the individual techniques will fall into place naturally.

Several habits will help you absorb the material.

Keep a notebook open beside the keyboard. A real notebook, not a text file, if you can manage it. Reverse engineering is a notetaking discipline, and the best practitioners keep written records of what they observe, what they hypothesize, what they tested, and what they learned. The act of writing slows your thinking down enough to catch mistakes, and a paper notebook resists the temptation to rearrange your record after the fact. If a paper notebook is not practical, use a Markdown file in a Git repository so that you can see how your understanding has changed over time.

Keep a terminal open to your FreeBSD development machine and another to `/usr/src/`. The chapter references several real FreeBSD source files, including drivers and utilities under `/usr/src/usr.sbin/` and `/usr/src/sys/dev/`. Reading those files is part of the lesson. The FreeBSD source is itself a body of reverse-engineering work, because many drivers in the tree exist because someone observed an undocumented device carefully enough to write code for it.

Type the example modules and scripts yourself the first time you see them. The companion files in `examples/part-07/ch36-reverse-engineering/` are there as a safety net and as a reference for when you want to compare your code against a known-good version, but typing the code the first time is the part that builds intuition. The whole chapter is about building intuition for unknown systems, and there is no shortcut for that.

Pay close attention to the language we use to describe what we know and what we suspect. Reverse-engineering writing draws a sharp line between an observation, a hypothesis, and a verified fact. An observation is what you saw. A hypothesis is what you think the observation means. A verified fact is a hypothesis that has survived deliberate attempts to falsify it. Different kinds of statement deserve different levels of confidence, and the chapter will model the language carefully so that you can adopt the same precision in your own notes.

Take seriously the safety advice. The most painful kind of mistake in this kind of work is the one that destroys the very piece of hardware you needed to study. Several of the techniques described here can, if applied carelessly, write to flash memory, change a device ID permanently, or leave a board in a state that the vendor cannot recover. The chapter will tell you which patterns deserve the most caution. Treat that advice the way you would treat a warning sign on a chemistry lab.

Finally, allow yourself to be slow. Reverse engineering is not a sprint. A complete register map for a serious peripheral is the result of weeks or months of patient observation, and the published results of community projects often hide an enormous amount of careful work behind a tidy summary. If a particular device resists your understanding for a long time, that is not a failure. It is what the work usually feels like.

With those habits in mind, let us begin with the question of why this work is necessary at all.

## 36.4 1. Why Reverse Engineering May Be Necessary

When a new driver author hears about reverse engineering for the first time, the immediate question is usually some version of “why should this ever be necessary?” If a hardware vendor wants their device to be useful, why would they hide its programming interface? And if the device is well known, why is there ever any documentation problem?

The honest answer is that the world of hardware and operating systems is messier than the world of well-documented standards. There are many real situations where a working device exists, where some operating system already supports it, but where no public, machine-readable, redistributable documentation exists for the programmer who wants to write a driver from scratch. The first section of this chapter walks through the most common of these situations so that you can recognise them when you encounter them and so that you know which kind of investigation each one calls for.

### 36.4.1 1.1 Legacy Hardware With No Vendor Support

The most common reverse-engineering situation is the old device whose manufacturer no longer exists. A small instrument board from the 1990s, a network card from a company that was bought out and shut down, an embedded controller from a research project that ran for a few years and then ended. The hardware works. The hardware was documented at the time it was sold. But the documentation was a paper manual that lived in a binder, or a PDF on a CD that was bundled with the device, and twenty years later neither the binder nor the CD exists.

In this situation, reverse engineering is the only way to bring the device back into useful service. Sometimes a community has already done some of the work and published partial notes. Sometimes a Linux or NetBSD driver exists and can be read for clues; the two cases are not equivalent, and the distinction matters both legally and technically. An OpenBSD or NetBSD driver is BSD-licensed and can be read, quoted, and, with attribution preserved, ported directly. A Linux driver is almost always GPL-licensed, which means it can be read for understanding but cannot be copied into a BSD-licensed driver at all. Even setting the licence aside, a direct port from Linux rarely works, because the Linux kernel's locking primitives, its memory allocators, and its device model differ from FreeBSD's in ways that reach deep into every line. We return to both the legal framing and the technical pitfalls of cross-platform reading in Section 12 and in Section 13's case studies. Sometimes the device is so obscure that no prior work exists at all, and the entire job falls on whoever wants to make it work.

FreeBSD has a long history of supporting devices in this category. A careful reading of the source under `/usr/src/sys/dev/` will turn up many drivers whose comments mention “no datasheet”, “based on observation”, or similar language. The driver authors did the work and the community benefits. This is not a marginal activity; it is part of how FreeBSD has always supported a long tail of devices that their original vendors abandoned long ago.

The challenges in the legacy-hardware case tend to be technical rather than legal. The hardware is old enough that the original vendor either no longer exists or no longer cares. The patents have expired. The trade secrets, if there were any, are no longer being defended. The risk is mostly that the documentation is genuinely gone, and no amount of polite asking will recover it.

### 36.4.2 1.2 Devices With Binary-Only Drivers on Other Operating Systems

A second common situation is the device whose vendor publishes a binary-only driver for one or more operating systems and refuses to publish documentation that would allow other operating systems to support the device. This is the case for many proprietary peripherals: graphics cards from certain vendors, specialised audio or video capture devices, scientific instruments with a Windows-only or Linux-only driver, fingerprint readers in laptops, certain wireless chipsets, and so on.

In this situation the device is in active production. Its documentation exists, but the vendor either treats it as a trade secret, or restricts it to companies that sign a non-disclosure agreement, or simply has not seen any business case for publishing it. The vendor's official position may be that FreeBSD users should not expect support, even if the underlying hardware would be perfectly capable of working under a properly written FreeBSD driver.

Reverse engineering in this situation is delicate, because the legal and ethical landscape is more complicated than it is for legacy hardware. The vendor may hold copyright on the driver binary. The firmware that runs on the device may itself be copyrighted. The distribution and use of the driver may be governed by an end-user license agreement that constrains certain kinds of analysis. We will return to the legal questions at the end of

this section. For now, note simply that the situation exists and that it is one of the recurring reasons why reverse engineering matters.

The technical challenges in this case are usually richer than in the legacy case, because there is more material to work with. You have a running driver that you can observe. You have a working device whose behaviour you can capture. You may have a firmware image you can analyse statically. The investigation can be very productive, but it also requires more careful attention to the legal context of the work.

### **36.4.3 1.3 Custom Embedded Systems With Little or No Documentation**

A third situation, increasingly common in industrial and embedded work, is the custom board with a custom chip. A small company designs an instrument or a controller for a specific application. They commission a custom integrated circuit, or they program a standard microcontroller with proprietary firmware, or they assemble a board from off-the-shelf parts in a configuration that has never been used elsewhere. They support the device only on their own operating environment, often a customised Linux distribution or a small real-time operating system.

When that company asks a contractor to integrate the device into a larger system that runs FreeBSD, or when an end user buys the hardware and wants to use it from FreeBSD, the only available information may be a one-page mechanical drawing, a short README file, and the binary firmware. No register map, no command set, no description of how the device starts up.

This case is in some ways the hardest, because the device is specific to one company and one customer. There is no community, because nobody else owns one. There is no prior driver to read, because nobody else has written one. The investigator is genuinely alone with the hardware, the captured traffic, and whatever can be deduced from observing the existing firmware. We will see in the labs how to approach this kind of investigation systematically, and we will see in Section 9 how to keep your own findings well enough documented that someone else can build on them later.

### **36.4.4 1.4 The Common Thread**

Every one of these situations shares a single underlying property: the device exists and works, but the description that would let a new driver be written from a specification is missing. The mechanical craft of writing the driver is the same craft we have practised in the rest of the book. What is different is the shape of the work that comes before the writing. We have to discover what we would ordinarily look up. That is the part this chapter teaches.

It is worth noticing what reverse engineering is not. It is not guessing. It is not poking randomly at registers and hoping something interesting happens. It is not trying to bypass copy protection or break encryption or do anything else that would shade into a different ethical universe. It is the patient, structured, written-down process of inferring how a piece of hardware works by observing what it does and what it produces, and then writing software that interacts with it correctly.

A reverse-engineering project, done well, looks far more like a laboratory science than like a hacker stereotype. There is a hypothesis, an experiment, a measurement, and a conclusion, repeated hundreds of times until enough conclusions have accumulated to write a driver that works. The romance of the scene where someone types furiously and a screen of text reveals “the secret” exists only in films. The reality is closer to a long, slow, methodical construction of understanding, one register and one bit at a time.

### 36.4.5 1.5 Legal and Ethical Considerations

Before we touch any tools, we have to talk about the legal landscape that surrounds this work. The picture is not complicated, but it is real, and a beginner who ignores it can stumble into trouble that nothing in the technique sections of this chapter will help with.

Reverse engineering for the purpose of interoperability, which is the purpose this chapter cares about, is broadly accepted in both United States and European Union law. The point of interoperability work is to allow a device, format, or interface to be used with a piece of software that the original vendor did not provide. Writing a FreeBSD driver for a USB Wi-Fi adapter that ships with a Windows driver is a textbook interoperability case. The driver lets FreeBSD talk to a piece of hardware that the user already owns. It does not copy the vendor's driver. It does not redistribute the vendor's firmware in a form that violates a license. It does not bypass any security measure that protects copyrighted content. It produces an independent piece of software that performs the same function the vendor's driver performs, written from a clean understanding of the underlying interface.

In the United States, the relevant legal framework is the doctrine of fair use under copyright law, with a long line of court cases recognising reverse engineering for interoperability as a legitimate fair use. The Sega versus Accolade case from 1992, the Sony versus Connectix case from 2000, and several similar precedents have established that disassembling code to understand its interface is fair use, provided the purpose is legitimate interoperability and the resulting product does not contain the original copyrighted code. The relevant statute that occasionally complicates matters is the Digital Millennium Copyright Act, which forbids circumventing “technological measures” that protect copyrighted works. The DMCA includes specific exemptions for interoperability research, but those exemptions are narrower than the underlying fair use right. For ordinary driver work the DMCA is rarely a problem, but if you ever need to defeat encryption to read firmware, the legal picture becomes more complex and a real lawyer becomes a worthwhile consultation.

In the European Union, the relevant framework is the Software Directive, originally Directive 91/250 and updated in 2009 as Directive 2009/24. Article 6 of the Software Directive explicitly permits decompilation for the purpose of achieving interoperability with an independently created program, provided several conditions are met: the person doing the decompilation has a right to use the program, the information needed for interoperability has not been readily available, and the decompilation is limited to the parts of the program necessary for interoperability. This is one of the most explicit legal endorsements of interoperability reverse engineering in any major jurisdiction.

Outside those two systems, the picture varies. Many countries follow similar principles in practice. A few do not. If you are working in a jurisdiction where the law is unclear, or where enforcement is unpredictable, talk to a lawyer who actually knows your local software-copyright law. The cost of a single hour of legal advice is small compared to the cost of finding out the hard way.

There is a clear ethical line between interoperability work and work that would harm the vendor or the user. Interoperability work produces a new program that lets a piece of hardware do its intended job under a new operating system. It does not redistribute copyrighted code. It does not strip license restrictions from a purchased product. It does not bypass security measures that protect something other than the vendor's commercial interest in the interface itself. If you find yourself wanting to do any of those things, you are no longer doing interoperability work, and the rest of the chapter does not apply to your situation.

A second ethical line is between observation and tampering. Watching how a device behaves is observation. Capturing the traffic between the device and the vendor's driver is observation. Reading the firmware that the vendor distributed in a form intended to be distributable is observation. Writing your own driver based on what

you observed is the legitimate end product. Writing modified firmware that replaces the vendor's firmware on the device, or distributing such modified firmware, is a different category of work that brings in different legal and ethical considerations. We will not cover that activity in this chapter. The chapter is about writing a clean, original driver that talks to the original hardware in its original configuration.

A third ethical consideration is honesty about your work. Document where your information came from. If a particular register definition came from reading the vendor's open-source driver, say so. If a packet format came from a published specification, cite it. If a behaviour was deduced from your own captures, describe the captures. This honesty is partly a legal matter, because it lets you prove that you did clean-room work, and partly a community matter, because it lets others build on your work without having to redo the parts you have already done.

### 36.4.6 1.6 Wrapping Up Section 1

This section has set the stage for the rest of the chapter. We have seen the three most common situations where reverse engineering is necessary: legacy hardware, devices with vendor-only support on other operating systems, and custom embedded systems with no documentation. We have seen that the underlying property is the same in every case: a working device whose programming interface is not described. And we have seen the legal framework that surrounds this work in the United States and the European Union, with a clear distinction between legitimate interoperability work and other, more legally fraught activities that this chapter will not pursue.

The next section turns from why to how. We will set up the small lab where the reverse-engineering work will happen, and we will introduce the tools you will need. The lab is the foundation for everything that follows, and a few hours spent setting it up properly will save many hours of confusion later.

## 36.5 2. Preparing for the Reverse Engineering Process

A reverse-engineering session is, at its core, an experimental activity. You will run experiments on a piece of hardware, capture the results, analyse them, and design follow-up experiments. Like any experimental activity, it benefits from a properly equipped laboratory. The lab does not need to be expensive. Most of what we need is software that is already in the FreeBSD base system, and the rest can be assembled from a short list of free or low-cost tools. The investment is mostly in setting up the equipment correctly so that your captures are reliable and your experiments are repeatable.

This section walks through the complete kit. It starts with the mental model of what the lab is doing, then enumerates the software tools, then discusses optional hardware tools, then describes how to bring up a vendor driver under another operating system on the same machine so that you can observe its behaviour, and finally suggests a workflow for keeping the lab organised.

### 36.5.1 2.1 The Mental Model: What the Lab Is For

Before listing tools, it helps to picture what the finished lab will look like. The lab is the place where you will:

1. **Identify** the device, recording every public fact about it.
2. **Observe** the device in known operational states.

3. **Capture** the traffic between the device and an existing driver.
4. **Experiment** with reads and writes to discover register behaviour.
5. **Document** every observation as it is made.
6. **Validate** every hypothesis by experiment, ideally with a simulator before risking the real device.

The lab is therefore a small system designed to support the observe-hypothesize-test-document loop that drives the entire craft. Every tool you add to it should serve that loop in some identifiable way. Tools that look impressive but do not feed into the loop are clutter, and clutter slows you down.

A first-time reader sometimes assumes that reverse engineering requires very expensive professional equipment. It does not. A modest FreeBSD development machine, a target system that can run the vendor's driver, and a small budget for cables and adapters will get you most of the way through most projects. The expensive tools are nice to have, and we will mention them, but the core work is done with software you already have access to.

### 36.5.2 2.2 The Software Tool Kit From the FreeBSD Base System

FreeBSD's base system includes a remarkable collection of tools that together cover most of what a driver author needs for the software side of the lab. Let us go through them in the order in which a reverse-engineering session typically uses them.

**pciconf(8)** is the starting point for any PCI or PCI Express device. It is an interface to the `pci(4)` ioctl that the kernel exposes through `/dev/pci`. Run as root, it lists every PCI device the kernel has enumerated, including devices for which no driver attached. The most important invocations for reverse engineering are:

```
$ sudo pciconf -lv
```

This produces a one-line summary of every PCI device on the system, followed by the human-readable vendor and device strings if a known database recognises them. Devices without a driver appear as `noneN@pci0:...`. For each unknown device, this line tells you the PCI bus address, the vendor identifier, the device identifier, the subsystem identifiers, the class code, and the revision. Those identifiers are the first piece of public information you will record about the device.

```
$ sudo pciconf -lvc
```

The `-c` flag adds a list of the device's PCI capabilities, such as MSI, MSI-X, power management, vendor-specific capabilities, and PCI Express link-training data. Repeated `-c -c` increases the verbosity for some capability types. For PCI Express devices, this is also where you will see link-state information that tells you whether the device negotiated the link width and speed it should have negotiated. A surprising number of "this device does not work" problems turn out to be link-training problems that this one command would have revealed.

```
$ sudo pciconf -r device addr:addr2
```

The `-r` form reads PCI configuration register values directly, returning the raw bytes at an offset in configuration space. This is the safest way to inspect a device, because configuration space is designed to be read without

side effects. The complementary `-w` form writes configuration registers; use it with extreme care, because some configuration registers do change device behaviour permanently.

**devinfo(8)** prints the FreeBSD device tree as the kernel sees it. Where `pciconf` shows you the bus level, `devinfo` shows you the full hierarchy: which bus the device hangs off, which parent controller, what resources it has been assigned, and what name the kernel has given it. The verbose form `devinfo -rv` is particularly useful early on, because it shows the exact ranges of memory and I/O ports allocated to the device, and those ranges are the playground in which all the bus-space experiments will happen.

**devctl(8)** is the device-control utility that lets you detach a driver from a device, attach a different driver, list events, and disable specific devices at the kernel level. During reverse engineering, the most useful invocations are `devctl detach deviceN` to remove the in-tree driver from a device and `devctl attach deviceN` to put it back. Detaching a driver is sometimes necessary so that your experimental driver can claim the device, and being able to put the in-tree driver back without rebooting saves a lot of time.

**usbconfig(8)** is the USB equivalent of `pciconf`. It enumerates USB devices, dumps their descriptors, and changes their state. Its most important invocations for reverse engineering are:

```
$ sudo usbconfig
$ sudo usbconfig -d ugen0.3 dump_device_desc
$ sudo usbconfig -d ugen0.3 dump_curr_config_desc
$ sudo usbconfig -d ugen0.3 dump_all_config_desc
```

The first form lists every USB device the system sees, with its unit number and address. The `dump_device_desc` form prints the USB device descriptor: `bDeviceClass`, `bDeviceSubClass`, `bDeviceProtocol`, `bMaxPacketSize0`, `idVendor`, `idProduct`, `bcdDevice`, the manufacturer and product strings, and the number of configurations. The `dump_curr_config_desc` and `dump_all_config_desc` forms walk the configuration descriptors and print the interfaces, alternate settings, and endpoints contained within them. Together, those three commands give you a nearly complete static picture of what the USB device claims to be, and that picture is the starting point of every USB investigation.

**usbdump(8)** is the FreeBSD equivalent of Linux's `usbmon`. It captures USB packets by opening `/dev/bpf` and binding to a cloned `usbN` interface created by the `usbpf` packet-filter module, and it writes the captured packets to a file in a format compatible with `libpcap`. Captures can be saved with `-w file`, replayed with `-r file`, and filtered with the standard BPF expression language. For reverse engineering, the workflow is usually:

```
$ sudo usbdump -i usb0 -w session1.pcap
```

This captures everything on the named USB bus to a file. After the capture, the file can be read back with `usbdump -r session1.pcap`, opened in Wireshark, or processed with custom scripts. The captured file format records every USB transfer, including `SETUP` packets, `IN` and `OUT` data, status responses, and timing information. Multiple sessions captured during different operations can be diffed against each other to isolate the packets responsible for one specific behaviour, and that diffing is one of the most effective techniques in the kit.

**dtrace(1)** is the dynamic tracing facility that we have used in earlier chapters. For reverse engineering, `DTrace` is particularly useful for tracing the points where the kernel interacts with a driver: which `device_probe` is

being called for which device, which interrupt handlers fire when, which `bus_space` operations the in-tree driver performs. A few well-chosen DTrace probes can tell you in detail what the existing driver is doing, even when no other documentation exists.

**ktr(9)** is the in-kernel trace facility used for fine-grained event tracking. It is more intrusive than DTrace, because it requires kernel options at build time, but it gives you a high-resolution log of every traced event. For reverse engineering, `ktr` is most useful when added to your own experimental driver so that the timing of register accesses can be reconstructed exactly.

**vmstat -i** and **procstat**: smaller utilities that let you watch the rate of interrupts a device is generating and the processes that are interacting with the device. Both are part of the base system. During an experiment, it can be useful to watch the interrupt count change as you exercise the device, because a sudden change in interrupt rate is itself a significant observation.

**hexdump(1)**, **xxd(1)**, **od(1)**, **bsdiff(1)**, and **sdiff(1)**: ordinary userland utilities for examining binary data and comparing files. You will use them constantly. A capture file viewed in `xxd` is often where the patterns first become visible, because the eye can pick out repeating structures in a hex dump that no automated tool would notice without being told what to look for. `sdiff` of two `xxd` outputs is one of the oldest and most reliable ways to find what is different between two captures.

This list is not exhaustive, but it covers the tools you will reach for in the first several weeks of any project. Every one of them is in the FreeBSD base system, with manual pages under `man pciconf`, `man usbconfig`, and so on.

Beyond the base system, a small family of third-party disassemblers and decompilers becomes important when the only artefact you have is a vendor binary, typically a Windows driver binary, a firmware image extracted from a device, or an option ROM pulled from a PCI card. **Ghidra**, the open-source reverse-engineering suite released by the United States National Security Agency, is the tool most FreeBSD developers reach for first because it is free, cross-platform, and comfortably decompiles x86, ARM, and many embedded architectures into readable C-like pseudocode. **radare2** and its graphical companion **Cutter** are a lighter open-source alternative, well suited to quick inspection of small firmware blobs. **IDA Pro** is the long-established commercial product; its decompiler is still the reference implementation in the industry, but its cost places it outside the budget of most individual developers. You do not need any of these tools to do excellent work on devices whose behaviour can be reconstructed from captures alone. When you do need them, the goal is always limited and documented: identify the names of registers, identify the structure of command buffers, understand the order in which the vendor's code programmes the hardware. You do not copy the vendor's code. You write down what the binary implied about the hardware's interface and then you discard the disassembly. This is the clean-room discipline outlined in section 1.5 translated into practice: the binary is a source of hardware facts, not a source of code to be copied. Use the disassembler briefly, write down what you learned, and build your driver from the notes.

### 36.5.3 2.3 Optional Hardware Tools

Hardware tools become valuable when the device's interaction with the host is not visible to software-only capture. A USB device's traffic passes through the host controller and can be captured by `usbdump`. A PCI Express device's transactions go through the root complex and are not captured by anything in the base system. An SPI peripheral on an embedded board may communicate with its host processor on wires that no operating-system tool can see. For those cases, hardware tools enter the picture.

A **logic analyser** is the most generally useful hardware tool. It attaches to wires and records the voltage on each wire over time, producing a digital trace that can be decoded into the protocol that the wires were carrying. For SPI, I2C, UART, and similar low-speed busses, a basic eight or sixteen channel logic analyser is sufficient. The Saleae Logic family is widely used in professional work and is well supported by sigrok, the open-source suite for analysing logic-analyser captures. Sigrok's pulseview GUI lets you import a capture, decode it as SPI or I2C, and step through the bus traffic byte by byte.

A **USB protocol analyser** is a specialised piece of hardware that sits on the USB bus and captures every packet, including bus-state events that are not visible from the host. The Beagle and Total Phase analysers are the high-end tools in this category. They are expensive, but for serious USB reverse engineering they reveal behaviour that software-side capture simply cannot see. Most hobby-level work, however, does fine with usbdump and a careful methodology.

A **PCI Express protocol analyser** is even more specialised, and practically nothing in the open-source world covers this niche. For PCI Express work, the usual fall-back is to capture the device's behaviour from the kernel side using DTrace, ktr(9), and your own instrumented driver, and to use pciconf -lvc to inspect the configuration-space state. Real PCIe analysers from companies like Teledyne and Keysight exist, but their cost places them outside the reach of most individual developers.

For embedded work, an **oscilloscope** is sometimes useful for diagnosing electrical problems that confuse the higher-level tools. A driver that times out for unknown reasons may be timing out because the device's clock signal is degraded; an oscilloscope will show this when no software tool will. A modest USB-connected oscilloscope is a reasonable investment for anyone doing serious embedded work.

You can do excellent reverse-engineering work with none of these hardware tools. Most consumer USB and PCI devices are accessible purely through software-side capture and the kernel's own introspection. The hardware tools become important when the investigation crosses into truly low-level territory: signal integrity, bus timing, embedded protocols, devices designed for industries that never expected to be opened up.

### 36.5.4 2.4 The Observation Rig

Once you have the tools, the next decision is the shape of the observation rig. The rig is the combination of machines and operating systems on which you will observe the existing driver running. There are several common configurations, each with its own advantages.

The simplest configuration is **one host, two operating systems**. The same physical machine boots either FreeBSD, where you will be writing the new driver, or another operating system whose driver already supports the device, where you will be observing it. Boot into the other OS to observe; boot into FreeBSD to develop. The configuration is straightforward and works well when the device is permanently attached to the host. The disadvantage is that you cannot observe and experiment in the same session, so iteration is slower.

A more flexible configuration is **two hosts**: one running the operating system whose driver supports the device, the other running FreeBSD as your development environment. The device can be attached to one host, observed, and then moved to the other. Captures, notes, and code travel between the two over the network. This configuration works well when both machines fit on a desk and when the device can be moved without harm.

For USB devices, a **single FreeBSD host running another OS in a virtual machine** is often the most efficient configuration. The device is attached to the FreeBSD host, where usbdump can capture its traffic. The virtual machine is configured to receive the device through USB passthrough, so that the vendor's driver inside the

VM sees the device. As the vendor's driver operates the device, `usbdump` on the host records every packet. This setup gives you both observation and rapid iteration in a single session, because you do not have to reboot anything to switch between observing and experimenting.

For PCI devices, the equivalent is **bhyve passthrough using the ppt(4) driver**. The FreeBSD host detaches the device from the in-tree driver, attaches it to `ppt(4)`, and exposes it to a bhyve guest where the vendor's driver can run. The vendor's driver in the guest operates the device, while the host can use DTrace and other tools to observe what passes between them. Bhyve passthrough is a valuable technique for PCI work and has the great advantage of keeping all your observation tools in a single FreeBSD host.

For very specialised hardware, **dedicated capture hardware** is the only option. A logic analyser permanently attached to a board's SPI bus, or a USB protocol analyser inserted between a USB device and its host, gives you observation that no software-side tool can provide. The trade-off is that the rig is more complex to set up and the captured data is in a format that requires its own tools to analyse.

### 36.5.5 2.5 Bringing Up the Vendor Driver Under Another OS

If you are going to observe the vendor's driver in operation, you need a working installation of an operating system that the vendor supports. The choice depends on what the vendor ships. For Linux drivers, a recent stable Linux distribution is usually the right choice. For Windows drivers, the standard procedure is a Windows installation in a virtual machine; this works well as long as the device can be passed through to the guest. For specialised embedded operating systems, the situation is more variable.

Whichever OS you choose, set it up with as little extra software as possible. The lab should be quiet. Background activity from other drivers, automatic updates, telemetry, or unrelated processes adds noise to your captures. A lean install lets the device's traffic stand out clearly.

For a USB device whose vendor supplies a Linux driver, the recommended configuration is:

1. Install a recent stable Linux distribution in a virtual machine on your FreeBSD host.
2. Configure bhyve to pass through the USB device to the guest.
3. Inside the guest, install the vendor's driver and verify that the device works.
4. On the host, attach `usbdump` to the USB bus through which the device communicates.
5. Repeat the device's operations in the guest while capturing on the host.

For a USB device whose vendor supplies a Windows driver, the configuration is similar, with Windows in the guest instead of Linux. Windows USB passthrough through bhyve has been improving steadily and is workable for most consumer devices.

For a PCI device, the analogous configuration uses bhyve PCI passthrough through the `ppt(4)` driver. Detach the device from its host driver with `devctl detach`, attach it to `ppt(4)` with the appropriate kernel configuration, and expose it to the bhyve guest with `bhyve -s slot,passthru,bus/slot/function`. The vendor's driver in the guest then operates the device. Software-side observation from the host is harder for PCI than for USB, because configuration-space and memory-space accesses are not visible to the host once the device has been passed through. The fall-back is to instrument your own experimental driver heavily and to learn from the differences between what your driver does and what the vendor's driver appears to be doing.

### 36.5.6 2.6 The Lab Notebook

Equally important to the tools is the discipline of recording what you do. A lab notebook, paper or digital, is not optional in reverse engineering. Without one, you will lose track of what you have tested, what you have observed, and what you have concluded. With one, you build up an artifact that, by itself, is part of the output of the project.

The notebook should record:

- The date and time of every observation session.
- The exact configuration of the lab when the observation was taken: kernel version, tool versions, the state of the device before the observation began.
- The exact commands you ran.
- The captured data, or a clear pointer to where the captured data is stored.
- Your immediate interpretation of what you observed, with the word “observation” or “hypothesis” clearly attached.
- Any decision you made about what to test next, and why.

A good notebook entry reads like a scientific protocol. It should be reproducible by someone else who has access to the same lab, and it should tell a future reader what you knew at the time and how you knew it. When the project is finished and you write the pseudo-datasheet that summarises everything you learned, the notebook is where the citations come from. When something later turns out to be wrong, the notebook is where you go to figure out when the wrong belief entered the picture and what other conclusions might be infected by it.

The discipline of writing down hypotheses before testing them is particularly important. Without that discipline, it is very easy to convince yourself, after the fact, that you predicted a result you did not actually predict. With it, you can tell precisely which experiments confirmed your understanding and which ones surprised you. The surprises are the most valuable observations, because they are the places where your model is wrong, but they only show up clearly when the prediction was written down before the result was known.

### 36.5.7 2.7 A Sample Lab Layout

By way of concrete example, here is a configuration that has worked well for many reverse-engineering projects on FreeBSD.

The host is a small FreeBSD 14.3 desktop with at least 16 GB of memory. It runs the development version of the driver, the observation tools, and the bhyve hypervisor. Its `/usr/src/` is populated with the FreeBSD source so that source-level browsing is fast.

A virtual machine inside bhyve runs a recent Linux distribution. The VM has the vendor’s driver installed and is configured for USB or PCI passthrough as appropriate.

A separate Git repository, on the host, holds the project notebook, the captured pcap files, the experimental driver code, and the pseudo-datasheet as it grows. Each commit is dated and described, so that the history of the project’s understanding is preserved.

A second terminal on the host always has `tail -F /var/log/messages` running, so that any kernel message produced by the experimental driver is immediately visible.

This layout is not the only one that works, but it is a reasonable starting point. The key features are: a clean FreeBSD development environment, a way to run the vendor's driver, a way to observe the device, and a Git-tracked notebook that grows with the project.

## 36.5.8 2.8 Wrapping Up Section 2

We now have a tool kit and a lab. The base system gives us `pciconf`, `usbconfig`, `usbdump`, `devinfo`, `devctl`, `dtrace`, and `ktr`. Optional hardware tools give us deeper visibility when software-side capture is not enough. `Bhyve` and `ppt(4)` give us a way to run the vendor's driver inside a virtual machine while observing from the FreeBSD host. And a written lab notebook gives us the discipline that turns ad-hoc experimentation into repeatable engineering.

The next section puts the lab to work. We will see how to capture a device's behaviour systematically, how to recognise the patterns that most hardware uses to communicate with its driver, and how to turn raw captures into the first signs of an emerging mental model. We will be doing experimental work in earnest, and the discipline that this section established becomes essential as we start producing the data that everything else will be built on.

## 36.6 3. Observing Device Behavior in a Controlled Environment

With the lab in place, we now turn to observation. This is the phase where you collect the raw data that everything else will be built on. The goal is not to understand the device yet. The goal is to capture, with as much fidelity as possible, what the device does in a small set of well-defined situations. Understanding will emerge later, from analysis. The first job is to get clean, labelled captures.

This section walks through the standard observation techniques in the order in which a project usually applies them. We start with static descriptors, which give you a snapshot of the device's identity. We move to initialisation captures, which show you what the device does when it is first powered up or attached. We then look at functional captures, which show what the device does when it performs each of its useful operations. Throughout, we emphasise the discipline of structured capture: each capture is named, dated, labelled with the operation it represents, and stored alongside a short note describing what the user did during the capture and what behaviour was expected.

### 36.6.1 3.1 Static Descriptors and Identity Information

The first thing to capture about any device is its identity. For a PCI or PCI Express device, this means recording the output of:

```
$ sudo pciconf -lv
```

For the specific device, the relevant lines look like this in practice. Suppose the device is the third unattached PCI device the kernel sees. After running `pciconf -lv`, you might see:

```
none2@pci0:0:18:0: class=0x028000 card=0x12341234 chip=0xabcd5678 \
 rev=0x01 hdr=0x00
 vendor = 'ExampleCorp'
 device = 'XYZ Wireless Adapter'
 class = network
 subclass = network
```

This single line records six facts that any future analysis will need: the bus location (0:18:0), the class code (0x028000, which the FreeBSD class-code table identifies as a wireless network controller), the subsystem identifier (0x12341234), the chip identifier (0xabcd5678, with vendor ID 0xabcd and device ID 0x5678), the revision (0x01), and the header type (0x00, a standard endpoint). Every one of those facts may matter later. The vendor and device IDs are how the kernel will find your driver. The subsystem ID is sometimes the only way to distinguish two devices that share a chip but use different layouts. The class code tells you what category the device belongs to. The revision distinguishes silicon revisions that may behave differently. Record all of them.

Add the capability list:

```
$ sudo pciconf -lvc none2@pci0:0:18:0
```

This will append a list of PCI capabilities, each a single line with a name, an ID, and a position in configuration space. The typical list for a modern PCI Express device includes power management, MSI or MSI-X, PCI Express, vendor-specific capabilities, and one or more extended capabilities. The vendor-specific capabilities are particularly interesting, because they are the place where vendors hide non-standard functionality and they are often the entry point for chip-specific configuration.

For a USB device, the equivalent capture is:

```
$ sudo usbconfig
$ sudo usbconfig -d ugen0.5 dump_device_desc
$ sudo usbconfig -d ugen0.5 dump_curr_config_desc
```

These three commands together produce the device descriptor, the current configuration descriptor, and a list of all configurations. A typical output for a simple USB device looks like:

```
ugen0.5: <ExampleCorp Foo Device> at usb0
 bLength = 0x0012
 bDescriptorType = 0x0001
 bcdUSB = 0x0210
 bDeviceClass = 0x00
 bDeviceSubClass = 0x00
 bDeviceProtocol = 0x00
 bMaxPacketSize0 = 0x0040
 idVendor = 0x1234
```

```
idProduct = 0x5678
bcdDevice = 0x0102
iManufacturer = 0x0001 <ExampleCorp>
iProduct = 0x0002 <Foo Device>
iSerialNumber = 0x0003 <ABC123>
bNumConfigurations = 0x0001
```

Each field is an answer to a question. The `bcdUSB` value tells you the USB protocol version the device claims to implement. `bDeviceClass`, `bDeviceSubClass`, and `bDeviceProtocol` are the USB class system, which sometimes identifies the device as a member of a standard class (HID, mass storage, audio, video, and so on) and sometimes leaves all three at zero, meaning that the class is determined per-interface inside the configuration descriptor. `idVendor` and `idProduct` are the unique numerical identifiers; combined, they are how a USB driver is bound to the device. `iManufacturer`, `iProduct`, and `iSerialNumber` are indices into the device's string table; `usbconfig` resolves them for you and prints the strings.

Dump the configuration descriptor too:

```
$ sudo usbconfig -d ugen0.5 dump_curr_config_desc
```

This shows the interface descriptors and endpoint descriptors. For each interface, you will see its number, its alternate setting, its class, subclass, and protocol, and the list of endpoints. For each endpoint, you will see its address (which encodes both the endpoint number and the direction), its attributes (which encode the transfer type: control, isochronous, bulk, or interrupt), its maximum packet size, and its polling interval if it is an interrupt endpoint.

This static information is the entire programming-visible identity of the USB device. It tells you exactly what kinds of pipes the device exposes, in which directions, of what type, and at what size. From this alone you can already make some educated guesses. A device that exposes a single bulk-IN and a single bulk-OUT endpoint is probably a transport for some application-specific protocol. A device that exposes two interrupt-IN endpoints is probably an event source of some kind. A device with isochronous endpoints is almost certainly handling time-sensitive data such as audio or video.

Save these dumps in your notebook. They are the device's static identity, and they will not change between captures. They are the header of every report you will write about the device.

### 36.6.2 3.2 The First Capture: Initialization

Once you have the static identity, the next capture is the initialisation sequence. This is the sequence of operations that the vendor's driver performs between the moment the device is attached and the moment the device is ready for use.

The initialisation sequence is one of the most informative things you can capture, because it usually exercises every register the device has. The driver writes initial values, sets configuration options, allocates buffers, sets up interrupts, enables data flow, and reports success. Almost every register the device exposes will be touched at least once during this sequence, and many of the registers will reveal their general purpose just by being touched in a way that fits the standard initialisation pattern.

For a USB device, the initialisation capture is:

```
$ sudo usbdump -i usb0 -w init.pcap
```

Start usbdump, then attach the device. After the device is fully initialised, stop the capture. The resulting pcap file contains every USB transfer that passed across the bus between the device and its driver, beginning with the USB enumeration sequence (which should match the static descriptor dumps), continuing with the class-specific or vendor-specific control transfers that the driver uses to configure the device, and ending when the driver has put the device into a ready state.

Open the file in Wireshark to view it interactively, or process it with `usbdump -r init.pcap` to print it textually. Wireshark has particularly good USB dissectors that will decode many standard class-specific transfers automatically. For dissection of vendor-specific transfers, you will be reading the raw bytes yourself.

For a PCI device, software-side capture of initialisation is harder, because configuration-space and memory-space writes are not visible from outside the device once you are not using passthrough. The usual technique is to instrument your own experimental driver, or to add tracing to a copy of the in-tree driver if one exists. We will return to this subject in Section 4 when we talk about register maps. For now, the equivalent of a “first capture” for a PCI device is the output of:

```
$ sudo devinfo -rv
```

restricted to your device. This shows you the resources that the kernel allocated for the device: the memory ranges, the I/O port ranges, the interrupt assignment. Those resources tell you the extent of the playground you will be exploring. They do not tell you what is happening inside the playground, but they are the boundary conditions for everything that follows.

### 36.6.3 3.3 Functional Captures

Once you have the initialisation, the next captures are functional. For each thing the device can do, you take a separate capture. Each capture should isolate one operation as cleanly as possible.

For a network device, you might take separate captures for “send one ping”, “receive one packet of unsolicited traffic”, “set the MAC address”, “change the channel”. For a sensor, you might take separate captures for “read once”, “set the sample rate”, “enable continuous mode”, “calibrate”. For a printer, you might capture “print one page of plain text”, “print one image”, “query status”.

The discipline of isolating operations is not optional. If your capture file contains a hundred different operations, sorting out which packets correspond to which operation will be impossible. If your capture file contains exactly one operation, the packets in it are exactly the packets for that operation, and your job is much easier.

Every capture should include:

1. The exact operation being captured, in plain English.
2. The exact user actions that triggered the operation.
3. The exact moment the user started the action, recorded as a timestamp in the file name or in a sidecar note.

4. The expected behaviour of the device.
5. The actual behaviour observed.

The sidecar note is essential. Six months from now, you will not remember which capture corresponded to which operation, and the file name alone will not always be enough.

A sample naming scheme that has worked well for many projects is:

```
init-001-attach-cold.pcap
init-002-attach-hot.pcap
op-001-set-mac-address-aa-bb-cc-dd-ee-ff.pcap
op-002-send-icmp-echo-request.pcap
op-003-receive-broadcast-arp.pcap
err-001-attach-with-no-power.pcap
```

The `init-`, `op-`, and `err-` prefixes group captures by purpose. The numbered suffix is unique. The English description in the file name is enough that you can find a specific capture without opening it. The sidecar note lives next to the file as a `.txt` or `.md` file with the same base name.

### 36.6.4 3.4 The Diff: Isolating Bits of Meaning

The single most important analysis technique in reverse engineering is the diff. Two captures of similar operations are likely to be mostly identical, with a few differences that correspond to the differences in what was done. Those differences are the parts that matter, because they are the parts whose meaning is most likely to be visible.

Suppose you have a capture of “set channel to 1” and a capture of “set channel to 6”. Visually, the two captures will look almost identical. They will start with the same setup, perform the same preliminary operations, and end with the same wrap-up. Somewhere in the middle, however, there will be a small number of bytes that differ between the two captures. Those bytes are almost certainly related to the channel number. By comparing them carefully, you can deduce: which transfer carries the channel value, where in that transfer the value lives, what numerical encoding is used (direct numerical value, an index into a table, a bitfield), and whether the value is sent as little-endian or big-endian.

The diff technique works best when the two captures differ in exactly one variable. If you compare “set channel to 1” against “set channel to 6”, and the channel-to-channel difference is the only difference between the captures, the diff is clean. If you compare “set channel to 1, mode A” against “set channel to 6, mode B”, you have two variables changing and the analysis is harder. Make captures that vary one thing at a time.

For text-format captures, `sdiff` is the simplest tool. For binary captures, `bsdiff` produces compact patches that can be inspected to see exactly which bytes changed. For pcap files, the combination of `tshark -r file.pcap -T fields -e ...` to extract specific fields, followed by `diff`, gives you a programmable way to compare specific aspects of the captures.

A more sophisticated technique is to capture multiple instances of the same operation, and compare them. Differences between captures of nominally identical operations reveal which bytes are actually constant (the parts of the protocol) and which bytes change between runs even though the operation does not (sequence numbers,

timestamps, random values). The constant bytes are the ones whose meaning you want to deduce; the variable bytes are the ones whose meaning you can ignore for the moment.

Save every capture. Storage is cheap and the diffing technique becomes more useful the more captures you have. A project with fifty captures of an operation can answer many more questions than a project with one capture, even though both projects “captured the operation”.

### 36.6.5 3.5 Wireshark and the USB Dissector

For USB work specifically, Wireshark is an indispensable tool. Wireshark dissects the USB packet stream into a structured tree view that is much easier to read than raw bytes, and it has display filters that let you isolate one device, one endpoint, or one direction of traffic.

The most useful filters are:

- `usb.device_address == 5` to limit the view to one specific device on the bus.
- `usb.endpoint_address == 0x81` to limit the view to one specific endpoint and direction (here, IN endpoint 1).
- `usb.transfer_type == 2` to limit the view to bulk transfers (1 = isochronous, 2 = bulk, 3 = interrupt).
- `usb.bRequest == 0xa0` to limit the view to a specific control request, useful when reverse engineering vendor-specific control transfers.

Combinations of these filters let you isolate exactly the part of the capture you care about. The “Statistics” menu in Wireshark also provides useful aggregate views, such as a list of every endpoint seen and the number of packets on each. For USB, the “Endpoints” view in particular is often the first thing you check after opening a new capture.

If you have a capture that Wireshark dissects into something class-specific (for example, a USB Mass Storage capture decoded into SCSI commands), the dissector has effectively done the hardest work for you. If you have a capture that Wireshark dissects only as raw bulk transfers, you will need to read the bytes yourself.

### 36.6.6 3.6 Observation Patterns to Recognise

Even before you understand a specific device, certain patterns recur in almost every device’s protocol, and learning to recognise them speeds up every project. Watch for these as you look at captures.

**Repeated writes followed by a single read.** This is the classic “write a command, then read the result” pattern. The repeated writes are usually setting up a request: command code, parameters, length. The read is fetching the response. Many devices use this shape for any operation that returns data.

**Status flags that change before and after events.** A bit somewhere in a status register that becomes set when the device finishes work, or becomes clear when work begins, is one of the most common ways for a device to communicate progress. Look for bits that change reliably in time with operations the user triggered.

**A sequence of writes to escalating addresses, all in multiples of four.** This is often a register block being written in sequence. The operation is reset followed by configuration: clear all the registers, then set them to their new values, then trigger the operation by writing to a “go” register at the end.

**Identical reads from the same address until a value changes.** This is polling. The driver is waiting for the device to do something, and is checking a status register repeatedly. The address being polled is almost certainly a status register. The value that ends the polling tells you which bit in that register is the “ready” indicator.

**Bulk-OUT followed by bulk-IN of the same length.** A common pattern for command-response on USB bulk endpoints is to send a fixed-size command on the OUT endpoint and then read a fixed-size response from the IN endpoint. The two endpoints work together as a request-response channel.

**Periodic interrupt-IN packets with timestamps that increase linearly.** This is a heartbeat or periodic-status pattern. The device is reporting its state at a fixed rate, regardless of what the host does. The packets often contain a small fixed structure with status bits and counters.

**Long sequences of writes followed by no observable response.** This is often firmware download. The device has a writable code region, and the driver is loading new instructions into it. Such captures are typically very large compared to other operations, and they often start with a fixed-size header that identifies the firmware image.

These patterns are not exhaustive, but they appear so often that recognising them on first sight saves enormous time. The first hour with a new capture file is almost always spent identifying which of these patterns the capture exhibits.

### 36.6.7 3.7 Wrapping Up Section 3

We have built a body of captures. Each capture is named, dated, labelled with the operation it represents, and accompanied by a short note describing the user actions and the expected device behaviour. We have used `pciconf` and `usbconfig` to record the static identity of the device. We have used `usbdump` to capture its initialisation and its functional operations. We have learned that the `diff` between two captures of similar operations is the best tool we have for extracting bit-level meaning. And we have learned the recurring patterns that show up in almost every device’s protocol.

The next section starts the active phase of the work. Instead of just observing the existing driver, we will start poking at the device ourselves, in a controlled way, to discover the meaning of its registers. The captures we made in this section are the data that the next section’s experiments will be measured against. With captures in hand, we know what “normal behaviour” looks like, and we can compare what happens when we issue our own writes against what happens when the vendor’s driver issues the equivalent writes. That comparison is the heart of register-map construction.

## 36.7 4. Creating a Hardware Register Map by Experimentation

The register map is the document that, once finished, would have made all the previous work unnecessary. It lists every address the device exposes, says what is at that address, defines the meaning of each bit, and describes any side effects that reads or writes have. With a complete register map in hand, writing the driver is a straightforward translation exercise. Without one, the driver cannot be written at all. The register map is the artifact that the rest of this chapter is, in many ways, designed to produce.

In the absence of documentation, the register map has to be built by experiment. You will write to addresses, see what happens, read addresses back, see what they return, change one bit at a time, look for changes in behaviour, and slowly accumulate a body of verified facts about each address. The work is patient and incremental, and

many of the techniques are simple enough to fit in a paragraph, but the discipline of doing them safely and recording the results carefully is what separates a successful project from a session that destroys the device.

This section covers the techniques. Section 10 will return to the safety side and spell out what you must not do. Read the two together; the techniques in this section are only safe in the hands of someone who has internalised the warnings in Section 10.

### 36.7.1 4.1 Mapping the Address Space

Before you can probe addresses, you have to know which addresses exist. For a PCI device, the device's BARs (Base Address Registers) declare the memory regions and I/O port ranges that the device responds to. The kernel has already enumerated these and made them available through `bus_alloc_resource_any(9)` calls in your driver's `attach` routine. The simplest way to see them in operation is to read them back from the kernel:

```
$ sudo devinfo -rv
```

Restricted to your device, this command lists the resources the kernel has assigned. A typical PCI device might have output like:

```
none2@pci0:0:18:0:
 pnpinfo vendor=0xabcd device=0x5678 ...
 Memory range:
 0xf7c00000-0xf7c0ffff (BAR 0, 64K, prefetch=no)
 0xf7800000-0xf7bfffff (BAR 2, 4M, prefetch=yes)
 Interrupt:
 irq 19
```

Two memory regions and one interrupt. The 64K region is most likely a register block, because register blocks are usually small. The 4M region is large enough to be a frame buffer, a descriptor ring, or a memory-mapped data area, but unlikely to be register space. These are educated guesses based on size, not yet verified facts. Note them as hypotheses.

The same kind of size-based intuition works in many cases. A register region is rarely larger than a megabyte. A data buffer or queue is rarely smaller than a few kilobytes. A region that is exactly 16 KB or 64 KB on power-of-two boundaries is suspicious in the right way: it looks like register space. A region that is several megabytes and prefetchable is much more likely to be a data region.

For a USB device, the equivalent of address-space mapping is the endpoint enumeration. Each endpoint is a “channel” that you can read from or write to. The endpoint addresses, sizes, and types were captured by `usbconfig dump_curr_config_desc` in the previous section. From the endpoint list you already know how many channels the device exposes, of which types, and in which directions. There is no equivalent of memory-mapped register space on USB; everything is done through the endpoints, including any “register” reads and writes (which appear as control transfers, vendor-specific requests, or data inside bulk transfers).

### 36.7.2 4.2 The Read-First Principle

The single most important rule for safe register exploration is to read before you write. A read from an unknown register is, almost always, harmless. The hardware returns whatever it considers to be the value at that address, with at most a side effect of clearing some specific status flags in some specific kinds of registers. A write to an unknown register, on the other hand, can do anything: trigger a reset, start an operation, change a configuration bit, write to flash memory, or in the worst case put the device into a state from which it cannot easily recover.

The principle is simple: assume nothing about a write until you have evidence that the write is safe. The evidence can come from the captures you made in Section 3 (a write that the vendor driver performs is presumably one of the writes the device expects), from analogous registers on similar devices, from a published header file or a related driver, or from your own analysis of the register's behaviour under reads.

Read the entire register region exhaustively before doing any writing. Save the values. Read it again ten minutes later. Compare. Registers whose values change between reads are interesting: they are either status registers reflecting some live state, or counters incrementing on their own, or registers connected to external inputs. Registers whose values are stable are either configuration registers (whose values are stable until something writes them) or data registers that happen not to have changed during the observation window.

The simplest tool for this kind of exploration is a small kernel module that takes a memory range and dumps it, and the companion code in `examples/part-07/ch36-reverse-engineering/lab03-register-map/` contains exactly such a module. The module attaches as a child of the bus you point it at, allocates the memory range as a resource, and exposes a sysctl that, when read, dumps every word in the range. Multiple reads at different times produce a picture of which words are stable and which are changing.

### 36.7.3 4.3 The Probing Module's Skeleton

For concreteness, here is the shape of a safe probing module. The full version is in the companion files; what follows is the essential structure that you should recognise from earlier chapters.

```
struct regprobe_softc {
 device_t sc_dev;
 struct mtx sc_mtx;
 struct resource *sc_mem;
 int sc_rid;
 bus_size_t sc_size;
};

static int
regprobe_probe(device_t dev)
{
 /* Match nothing automatically; only attach when explicitly
 * told to. The user adds the device by hand with devctl(8) so
 * that the wrong device cannot be probed by accident. */
 return (BUS_PROBE_NOWILDCARD);
}
```

```

static int
regprobe_attach(device_t dev)
{
 struct regprobe_softc *sc = device_get_softc(dev);

 sc->sc_dev = dev;
 sc->sc_rid = 0;
 mtx_init(&sc->sc_mtx, "regprobe", NULL, MTX_DEF);

 sc->sc_mem = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
 &sc->sc_rid, RF_ACTIVE);
 if (sc->sc_mem == NULL) {
 device_printf(dev, "could not allocate memory resource\n");
 return (ENXIO);
 }
 sc->sc_size = rman_get_size(sc->sc_mem);
 device_printf(dev, "mapped %ju bytes\n",
 (uintmax_t)sc->sc_size);
 return (0);
}

```

The BUS\_PROBE\_NOWILDCARD return from probe is the protective gesture: this driver will not attach to any device unless the operator points it at one explicitly. This prevents the dangerous case where a probe module accidentally attaches to a device it was not meant to investigate.

The reading function, called from a sysctl handler, looks like this:

```

static int
regprobe_dump_sysctl(SYSCTL_HANDLER_ARGS)
{
 struct regprobe_softc *sc = arg1;
 char buf[16 * 1024];
 char *p = buf;
 bus_size_t off;
 uint32_t val;
 int error;

 if (sc->sc_size > sizeof(buf) - 64)
 return (E2BIG);

 mtx_lock(&sc->sc_mtx);
 for (off = 0; off < sc->sc_size; off += 4) {
 val = bus_read_4(sc->sc_mem, off);
 p += snprintf(p, sizeof(buf) - (p - buf),

```

```
 "%04jx: 0x%08x\n", (uintmax_t)off, val);
 }
 mtx_unlock(&sc->sc_mtx);

 error = sysctl_handle_string(oidp, buf, p - buf, req);
 return (error);
}
```

`bus_read_4` is a wrapper around `bus_space_read_4` that uses the resource as both tag and handle, and it is the simplest way to read four bytes from a memory-mapped region. Notice that we read in units of four bytes, on four-byte aligned offsets. Most modern devices expect register accesses to be aligned and of natural size. Unaligned accesses, or accesses of the wrong size, can produce garbage values or, on some hardware, cause bus errors that manifest as kernel panics. When the device might use 16-bit or 8-bit registers, use `bus_read_2` or `bus_read_1` respectively; when in doubt, start with 4-byte reads, because that is the most commonly correct choice for modern peripherals.

This module does no writes at all. It is purely an observation tool. Loading it on an unknown device gives you a snapshot of the device's memory region without changing anything. Multiple loads, or multiple invocations of the `dump sysctl`, give you a sequence of snapshots whose differences reveal which addresses are dynamic.

### 36.7.4 4.4 Inferring Register Purpose From Behavior

After you have read the address space repeatedly, you start to notice patterns. Each pattern suggests a purpose for the register.

**Stable values** are usually configuration registers, identifier registers, or default values that have not yet been changed. A register at offset 0 that always reads the same constant value is often a chip-identifier register, sometimes called a “version register” or “magic number register”. Many devices use such a register specifically so that drivers can confirm the chip is what they expect.

**Slowly changing values** are usually counters: bytes received, packets sent, errors detected, time elapsed. The slowly increasing register is a hallmark of a counter, and the difference between two readings tells you the count rate. If a counter increments by exactly one every second, you have probably found a heartbeat or a timestamp register. If it increments by a few thousand per second when traffic flows and stays flat when traffic does not, you have found a packet or byte counter for the live data path.

**Quickly changing values that wrap around** are usually production-side ring-buffer write pointers. A device that produces data into a ring buffer typically exposes a register holding the current write position. The write pointer increments rapidly while data is flowing, and wraps when it reaches the buffer's size. The matching read pointer, written by the driver, tells the device where the consumer is.

**Bits that toggle in time with operations** are status bits. A bit that becomes 1 when an operation begins and 0 when it completes is a “busy” bit. A bit that becomes 1 when an event occurs and stays 1 until cleared is a “pending interrupt” bit. A bit that becomes 0 when the device is healthy and 1 when an error has occurred is an error indicator.

**Registers that read back differently from what was written** are either masked (some bits are not implemented and read as zero regardless of writes), one-shot (writes have side effects but the register itself does not store the

written value), or self-clearing (writes set bits that the device clears automatically when the operation completes). All three variants are common, and the readback pattern is what tells them apart.

These observations build up a picture of the register map. Each verified observation goes into the notebook, with the address, the observed pattern, and the proposed purpose. Over time, the notebook entries solidify into the pseudo-datasheet that Section 11 will discuss.

### 36.7.5 4.5 Comparing Captured Writes Against Hypotheses

The captures from Section 3 are the bridge between observation and hypothesis. Once you have proposed that a particular register is, for instance, the channel-selection register, you can confirm or refute the hypothesis by comparing what you have seen the vendor driver write to that register against what you know about the operations the user performed.

Suppose your hypothesis is that the register at offset `0x40` is the channel-selection register, and that the value at that register encodes the channel number directly as a small integer. You have a capture in which the user selected channel 6, and a capture in which the user selected channel 11. If your hypothesis is correct, the capture-6 sequence should contain a write of `0x06` to the equivalent of `0x40`, and the capture-11 sequence should contain a write of `0x0b` to the same place. If you find those writes, the hypothesis is supported. If the captures show writes of different values, or no writes at all to that offset, the hypothesis is wrong.

This is the falsification step that makes the work scientific. A hypothesis that survives one falsification attempt is worth more than ten hypotheses that have only been informally proposed.

For a USB device, the same kind of comparison happens between the captured control transfers, bulk packets, or interrupt packets and the hypothesised meaning. If you believe a vendor-specific control transfer with `bRequest = 0xa0` and `wValue` in the low byte is the “set channel” command, you can verify it by examining the captures of channel-1, channel-6, and channel-11 selections and confirming that exactly that transfer appears in each, with the expected `wValue`.

### 36.7.6 4.6 The Discipline of One Hypothesis at a Time

One discipline that is easy to forget under pressure is the discipline of testing one hypothesis at a time. When several hypotheses are in the air, the temptation is to design an experiment that will test all of them at once. The experiment runs, the device produces some output, and the output is consistent with one of the hypotheses but not with another. Now you have learned something about hypothesis A. But because you also changed the conditions for hypothesis B, you have also lost the ability to interpret what happened from B’s perspective. The same experiment will need to be run again, with B varied independently.

The right discipline is: vary one thing, observe the result, draw the conclusion that follows for that one variable, then proceed to the next experiment. It is slower per experiment but faster overall, because every experiment leaves behind a clear, isolated fact rather than a tangle of partial information.

Newton’s laboratory notebooks are full of single-variable experiments. So are the notebooks of every successful reverse-engineering project. Multivariable experiments belong to a later phase, when you understand each variable well enough that you can predict their interactions; in the discovery phase, they mostly produce confusion.

### 36.7.7 4.7 Common Register-Layout Patterns

Across many devices, a few register-layout patterns recur often enough to be worth knowing in advance. Recognising them can save weeks of work.

**Status / Control / Data:** a small group of registers in which one register holds the current state of an operation (Status), one register accepts commands or configuration changes (Control), and one or more registers hold the data being moved into or out of the device (Data). Many simple peripherals use exactly this shape, and many more use it as the shape of one of several functional units within the device.

**Interrupt Enable / Interrupt Status / Interrupt Acknowledge:** three registers that together implement the interrupt mechanism. The Enable register controls which conditions cause an interrupt. The Status register reports which conditions are currently raising an interrupt. The Acknowledge register clears interrupt conditions once they have been handled. The pattern is so common that, when exploring an unknown device, you should look for it explicitly: three adjacent registers near the top of the register map, with identifying names like `INT_ENABLE`, `INT_STATUS`, `INT_CLEAR` if you can find any documentation.

**Producer Pointer / Consumer Pointer:** two registers that together implement a ring buffer. The Producer Pointer is updated by whoever is producing data (sometimes the device, sometimes the driver) and indicates the next free slot. The Consumer Pointer is updated by whoever is consuming the data and indicates the next slot to be processed. The difference between them tells you how many slots are currently full. This pattern is the basis of nearly every high-speed I/O interface in modern hardware, including most network controllers, most USB controllers, and most disk controllers.

**Window / Index / Data:** an indirect-access pattern where the device exposes a small number of registers but uses them to access a much larger internal address space. A Window register selects which “page” is currently visible, an Index register selects which register within the page, and a Data register reads or writes the selected register. The pattern is common in older devices and in devices with very large internal register spaces.

**Capability Pointer:** a register or small group of registers that points to the start of a chain of capability descriptors. PCI Express defines a standard form of this pattern; many other devices use ad-hoc variants. The capability list lets the driver discover what optional features the chip supports without having to consult external documentation.

When you are exploring an unknown device, scanning the register space for any of these recurring patterns is one of the first things to do. A device that uses a Status / Control / Data layout is much easier to drive than one that does not, and recognising the layout early saves substantial time.

### 36.7.8 4.8 What Not to Do Yet

Before moving on, a quick reminder of restraint. The temptation, when you have built a mostly-working register map, is to try writing things and see what happens. Resist this temptation in register exploration. Write only when you have a specific hypothesis to test, when the hypothesis predicts a specific outcome, when you have a way to verify that the outcome occurred, and when you have considered what the worst plausible outcome of an unintended interpretation would be. The discipline that Section 10 will spell out is built on top of this restraint, and the register-mapping phase is exactly where it must be applied first.

### 36.7.9 4.9 Wrapping Up Section 4

We have learned how to map the address space of a device, how to read it safely, how to interpret the patterns of stable, slowly changing, and quickly changing values, and how to compare captured writes against hypotheses to confirm or refute proposed register meanings. We have learned the recurring layouts that hardware likes to use. And we have set the stage for Section 10's treatment of safety, which is the precondition for all of this work being done responsibly.

The next section moves up one level of abstraction. Once we have identified individual registers, we look at how they group into larger structures: data buffers, command queues, descriptor rings. These higher-level structures are how devices actually move data, and identifying them is the next step in turning register knowledge into the basis of a working driver.

## 36.8 5. Identifying Data Buffers and Command Interfaces

Registers are the way you talk to a device's control surface. Data buffers are how the device moves real information. The register map you built in the previous section is necessary but not sufficient. To complete the picture you also need to understand how the device handles data: where its buffers live, how their boundaries are defined, what shape the data takes inside them, and how the producer and consumer coordinate.

This section walks through the common buffer and command structures that hardware uses, with FreeBSD-specific notes on how to identify them through observation and how to set up the matching `bus_dma(9)` mappings on the driver side.

### 36.8.1 5.1 The Big Three: Linear, Ring, and Descriptor

Almost every data buffer in modern hardware falls into one of three shapes.

A **linear buffer** is a simple contiguous block of memory that the driver hands to the device for one operation. The driver fills it with data, the device consumes it, the driver hands it back when needed. Linear buffers are the simplest shape, and they show up in command-response patterns where each operation has its own dedicated buffer. They are easy to identify because they appear in the captures as a single block of bytes whose size matches the expected operation size.

A **ring buffer** is a circular buffer with a producer pointer and a consumer pointer. Producer writes go into the slot indicated by the producer pointer, then the producer pointer advances. Consumer reads come from the slot indicated by the consumer pointer, then the consumer pointer advances. Both pointers wrap when they reach the end of the buffer. The buffer is full when the producer catches up to the consumer; it is empty when the two pointers are equal in the other sense. Ring buffers are everywhere in high-speed networking and storage, because they let producer and consumer run at different rates without coordinated handshakes.

A **descriptor ring** is a special kind of ring buffer in which each slot does not hold the data itself but a small fixed-size descriptor that points to the data. The descriptor typically contains a memory address (where the data lives), a length, a status field (filled in by the device after processing), and some control flags. Descriptor rings let the device do scatter-gather DMA, accept variable-size buffers, and report per-buffer status back to the driver. They are slightly more complex than ring buffers but vastly more flexible, and they are the dominant pattern in high-performance network and storage controllers.

Recognising which shape a particular device uses is the first job. The signs are usually quite distinctive. If captures show fixed-size blocks moved one at a time with no metadata, it is probably a linear-buffer arrangement. If captures show data flowing continuously with no obvious “next operation” boundary, and there is a register that looks like a producer pointer, it is probably a ring buffer. If the device documentation, prior driver sources, or related-device datasheets hint at “descriptors”, it is almost certainly a descriptor ring.

### 36.8.2 5.2 Telling Buffers From Each Other

When you have identified that a buffer exists, the next question is: how big is it, and how is it organised internally? The captures from Section 3 contain the data; the question is what shape that data has.

Several observations can help.

**Size of the underlying memory region.** If a PCI BAR is exactly 4 KB and a sysctl reveals that the device has a “ring size” register set to 64, the natural conclusion is that the ring has 64 entries of 64 bytes each. Many devices use power-of-two sizes for both the ring and the entry size, and the product of the two should equal the BAR size.

**Periodic structure in the data.** A capture viewed in xxd or Wireshark sometimes shows obvious periodic structure: every 32 bytes there is a small fixed pattern, every 64 bytes there is a counter, every 16 bytes there is a status byte that varies in a predictable way. Periodic structure of size N strongly suggests that the buffer is organised as a sequence of records of size N.

**Alignment of pointer values.** If you see the device or the driver using “addresses” whose low bits are always zero, the addresses are aligned to a power-of-two boundary. If the alignment is 16 bytes, the entries are probably 16 bytes or larger. If the alignment is a megabyte, the entries are very large or the device imposes a coarse alignment requirement for some other reason.

**Headers and trailers.** Many record formats include a header that identifies the record type, a payload, and a trailer containing a checksum or a length. The header is often a magic value that can be recognised on sight.

**Cross-platform clues.** If the device has a Linux driver in the open-source tree, that driver’s code may already define the record structure. Reading another driver to learn record formats is one of the most efficient research techniques available, even when you intend to write the FreeBSD driver from scratch in a clean-room style. Two cautions are worth stating inline so that the rhythm of the chapter does not let them slip past. The first is legal: Linux drivers are almost always GPL-licensed, so reading them is fine, but pasting or near-transcribing their expression into a BSD-licensed FreeBSD driver is not. The second is technical: record-layout information ports cleanly between kernels because it describes the device, not the host, but surrounding code does not. Linux’s buffer-allocation paths, its locking primitives, and its descriptor-ring helpers are shaped by its own kernel, and a FreeBSD driver that tries to mirror them line-for-line will fight the host kernel at every step. Read to understand the format, then write FreeBSD code from your own notes. Section 12 covers the legal framing in detail; Section 13 shows how real drivers have done this well.

### 36.8.3 5.3 Command Queues and Their Sequencing

For devices with command interfaces, the typical shape is a queue of command structures, each of which the device processes in order, with status reported back through a separate register or through a status field in the command structure itself. Command queues are usually a special form of descriptor ring.

The sequencing matters. Some devices process commands strictly in order; others process them out of order and identify completion by a tag in the command structure. Some devices process commands one at a time; others process many in parallel. Some devices require the driver to wait for a command to complete before posting the next one; others accept many concurrent commands. Identifying which mode the device is in is part of the investigation, and the captures from Section 3 are usually rich enough to make the answer visible.

A useful technique is to deliberately exercise the device with operations that will overlap in time, and to observe how the driver responds. If the driver always waits for a command to complete before posting the next one, the device probably uses sequential processing. If the driver posts multiple commands in rapid succession and then waits for several completions, the device probably uses concurrent processing. If completions arrive in a different order from postings, the device is doing out-of-order processing.

### 36.8.4 5.4 DMA and Bus Mastering

Most modern devices that move significant amounts of data use DMA. The device, acting as a bus master, reads and writes the host's memory directly, rather than requiring the CPU to copy every byte. From the driver's side, DMA introduces several constraints that you have to handle correctly.

The buffers must be physically contiguous, or at least scattered in a way that the device can express. They must be aligned to a boundary that the device requires. They must be visible to the device, which on FreeBSD means they have to be set up through the `bus_dma(9)` framework. And the driver and the device have to synchronise their views of the buffer using `bus_dmamap_sync(9)` calls, because modern processors maintain caches that may not be coherent with device DMA.

The full mechanics of `bus_dma(9)` are covered in Chapter 21 and need not be repeated here. For reverse engineering, the implications are:

1. The device almost certainly imposes alignment and size constraints on its buffers. Captures that show buffers always starting at addresses with the same low bits are revealing the alignment.
2. The device may impose a maximum buffer size. Captures that show large operations split across multiple smaller transfers are revealing the maximum.
3. The device may use specific DMA address bits to encode metadata. A 32-bit pointer in a 64-bit address field, for example, sometimes leaves the upper 32 bits available for other uses, and the device may interpret those bits as flags or tags.

Identifying these constraints is part of the reverse-engineering work for any DMA-capable device. The captures and the existing driver source, if available, are the primary sources of evidence.

### 36.8.5 5.5 Reversing Packet Formats

When a device's data path uses structured packets, reversing the packet format is one of the most rewarding parts of the work. The recurring techniques are:

**Look for fixed bytes that never change.** These are usually magic numbers, version bytes, or category codes. Mark them and explore what they mean.

**Look for fields whose values correlate with operations.** A byte that takes a small set of distinct values, with each value appearing in exactly one kind of operation, is almost certainly an opcode or a command type.

**Look for length fields.** A two-byte or four-byte field whose value matches the size of the rest of the packet, in some predictable encoding, is a length field. Length fields are often near the start of the packet and are often the field that lets you parse variable-length packets correctly.

**Look for sequence numbers or session identifiers.** Fields that increment monotonically across a session, or that change once per operation, are usually sequence numbers. Their value is rarely interesting, but their presence and position help you ignore them while looking for the real content.

**Look for checksums.** A field whose value depends on the rest of the packet, in a way that you cannot predict from any single byte, is probably a checksum. Standard checksums (CRC-16, CRC-32, sums) can sometimes be identified by computing them over candidate ranges and seeing which range matches. If a checksum exists, you will need to compute it correctly when the driver constructs its own packets, so identifying the algorithm is necessary.

Each of these observations builds the packet-format part of the pseudo-datasheet. Combined with the register map from Section 4, they form the documentation that Section 11 will assemble into a proper datasheet substitute.

### 36.8.6 5.6 Identifying Which Operations Are Read-Like and Which Are

#### Write-Like

Many devices have an asymmetric data path: some operations cause the device to read from host memory, others cause it to write to host memory. Identifying which is which is essential for getting the DMA direction right.

The clearest evidence is in the captures. A USB capture, for example, distinguishes IN endpoints (device to host) from OUT endpoints (host to device) explicitly. PCI captures, when you can get them, distinguish memory reads from memory writes by the transaction type. Bulk DMA from a network controller into the host is recorded as the device writing into host memory. Bulk DMA from the host into the network controller is recorded as the device reading from host memory.

If captures are not available, a useful technique is to set the buffer to a recognisable pattern (all `0xCC` bytes, for example) before triggering the operation and to inspect the buffer afterwards. If the buffer's pattern is overwritten with new data, the operation was a device-to-host transfer (the device wrote into the buffer). If the buffer's pattern is unchanged, the operation was a host-to-device transfer (the device only read from the buffer). This kind of distinguishing experiment is one of the clearest examples of an experiment whose result will tell you a fact you cannot easily learn any other way.

### 36.8.7 5.7 Wrapping Up Section 5

We have learned to recognise the three big shapes of buffer organisation: linear buffers, ring buffers, and descriptor rings. We have seen how to deduce buffer sizes and entry sizes from periodic structures, alignments, and the underlying memory regions. We have learned to identify command queue shapes and sequencing models. We have noted the constraints that DMA imposes and the kinds of evidence that reveal them. We have gone through the recurring techniques for reversing packet formats. And we have seen how to identify the direction of a transfer when the captures themselves do not say so directly.

The next section turns this growing understanding into code. We will write the first version of an actual driver, one that implements only the smallest useful piece of functionality: usually reset, sometimes reset plus a single

status read, sometimes the absolute minimum needed to put the device into a state where it can be driven further. The principle is that a small driver that does something verifiably correct is a better starting point than a large driver that does many things uncertainly.

## 36.9 6. Re-Implementing Minimal Device Functionality

After observation comes reconstruction. With captures in hand, register hypotheses confirmed, and at least the rough shape of buffer structure understood, you can start writing a driver. The key word is “start”. The first version of a reverse-engineered driver does not have to do everything the device can do. It does not even have to do most of what the device can do. It has to do the smallest piece that is useful, and it has to do that piece correctly.

This section walks through the principles of starting small and the practical steps of writing the first minimal driver. The work here builds on every chapter from earlier in the book, because the mechanics of “write a driver” are exactly the same mechanics we have been practising. What changes is the discipline around which features to implement first and how to gain confidence that each feature is correct.

### 36.9.1 6.1 Start With Reset, Always

The first feature you implement should almost always be reset. A reset operation is the foundation of every other operation, for several reasons.

Reset is usually the simplest operation a device has. It often takes a single write to a single register, or a sequence of three or four writes that put the device into a known state. The hypothesis is small and easy to test.

Reset is the operation whose result is most easily verified. Before the reset, the device’s registers may hold arbitrary values. After a successful reset, they hold predictable defaults: zero configuration, no pending interrupts, no active operations, identifier registers reading their constant magic values. If you do a reset and then read the registers, you should see the “freshly powered up” state.

Reset is the operation whose failure modes are the most benign. If your reset attempt does not actually reset the device, the device will be in an unknown state, and you can recover by unloading your driver and letting the kernel re-probe the device. A failed reset rarely damages anything; it just leaves you no worse off than before.

Reset is also the precondition for almost every other operation. A driver that cannot put the device into a known state cannot rely on any subsequent operation. By implementing reset first, you build the foundation that every later test of every later feature will rely on.

### 36.9.2 6.2 The Skeleton of a Minimal Driver

For a PCI device, the skeleton driver looks very similar to every other PCI driver you have seen in the book. Here is the essential shape:

```
struct mydev_softc {
 device_t sc_dev;
 struct mtx sc_mtx;
```

```
 struct resource *sc_mem;
 int sc_rid;
 struct resource *sc_irq;
 int sc_irid;
 void *sc_ih;
 bus_size_t sc_size;
 /* Driver-specific state goes here as it accumulates. */
};

static int
mydev_probe(device_t dev)
{
 if (pci_get_vendor(dev) == 0xabcd &&
 pci_get_device(dev) == 0x5678) {
 device_set_desc(dev, "ExampleCorp XYZ Reverse-Engineered");
 return (BUS_PROBE_DEFAULT);
 }
 return (ENXIO);
}

static int
mydev_attach(device_t dev)
{
 struct mydev_softc *sc = device_get_softc(dev);
 int error;

 sc->sc_dev = dev;
 mtx_init(&sc->sc_mtx, "mydev", NULL, MTX_DEF);

 sc->sc_rid = PCIR_BAR(0);
 sc->sc_mem = bus_alloc_resource_any(dev, SYS_RES_MEMORY,
 &sc->sc_rid, RF_ACTIVE);
 if (sc->sc_mem == NULL)
 goto fail;
 sc->sc_size = rman_get_size(sc->sc_mem);

 sc->sc_irid = 0;
 sc->sc_irq = bus_alloc_resource_any(dev, SYS_RES_IRQ,
 &sc->sc_irid, RF_SHAREABLE | RF_ACTIVE);
 if (sc->sc_irq == NULL)
 goto fail;

 error = mydev_reset(sc);
 if (error != 0)
```

```
 goto fail;

 error = mydev_verify_id(sc);
 if (error != 0)
 goto fail;

 device_printf(dev, "attached, mapped %ju bytes\n",
 (uintmax_t)sc->sc_size);
 return (0);

fail:
 mydev_detach(dev);
 return (ENXIO);
}
```

The structure should look familiar. The driver allocates a memory resource for its register region and an IRQ resource for its interrupt. It then performs a reset and an identifier check. If either fails, the driver bails out cleanly. The reset and the identifier check are the first two functions worth writing.

### 36.9.3 6.3 Implementing Reset

The reset function is, in the simplest case, three lines of code:

```
static int
mydev_reset(struct mydev_softc *sc)
{
 bus_write_4(sc->sc_mem, MYDEV_REG_CONTROL, MYDEV_CTRL_RESET);
 pause("mydev_reset", hz / 100);
 bus_write_4(sc->sc_mem, MYDEV_REG_CONTROL, 0);
 return (0);
}
```

We write the reset bit to the control register, wait a short time for the device to act on it, and then clear the control register to leave the device in a quiescent state. The constants `MYDEV_REG_CONTROL` and `MYDEV_CTRL_RESET` come from the register map you built in Section 4.

In practice, reset is rarely this simple. Many devices have a specific reset protocol that involves several register writes in a specific order, or that involves polling a status register until the reset is complete, or that involves waiting for a specific duration to pass before proceeding. The captures from Section 3 show you what the vendor driver does on attach. Replicating that sequence is the safest reset implementation.

A more realistic reset might look like:

```

static int
mydev_reset(struct mydev_softc *sc)
{
 int i;
 uint32_t status;

 /* Disable any pending interrupts. */
 bus_write_4(sc->sc_mem, MYDEV_REG_INT_ENABLE, 0);

 /* Trigger reset. */
 bus_write_4(sc->sc_mem, MYDEV_REG_CONTROL, MYDEV_CTRL_RESET);

 /* Wait for reset complete, with timeout. */
 for (i = 0; i < 100; i++) {
 status = bus_read_4(sc->sc_mem, MYDEV_REG_STATUS);
 if ((status & MYDEV_STATUS_RESETTING) == 0)
 break;
 pause("mydev_reset", hz / 100);
 }
 if (i == 100) {
 device_printf(sc->sc_dev, "reset timed out\n");
 return (ETIMEDOUT);
 }

 /* Clear any pending interrupt status. */
 bus_write_4(sc->sc_mem, MYDEV_REG_INT_STATUS, 0xffffffff);

 return (0);
}

```

This version handles the case where the reset takes some time to complete and where the device exposes a status bit reporting “reset in progress”. Adding a timeout, with an explicit error path when the timeout expires, is a habit worth adopting from the start. A driver that cannot tell the difference between “the device is slow today” and “the device has failed” will eventually hang the kernel, and the cost of adding the timeout is trivial.

### 36.9.4 6.4 Verifying the Identifier

Every reverse-engineered driver should verify that the device attached to is the device the driver expects. The verification is typically one or two register reads, comparing the values against known constants:

```

static int
mydev_verify_id(struct mydev_softc *sc)
{
 uint32_t id, version;

```

```
id = bus_read_4(sc->sc_mem, MYDEV_REG_ID);
if (id != MYDEV_ID_MAGIC) {
 device_printf(sc->sc_dev,
 "unexpected ID 0x%08x (expected 0x%08x)\n",
 id, MYDEV_ID_MAGIC);
 return (ENODEV);
}

version = bus_read_4(sc->sc_mem, MYDEV_REG_VERSION);
if ((version >> 16) != MYDEV_VERSION_MAJOR) {
 device_printf(sc->sc_dev,
 "unsupported version 0x%08x\n", version);
 return (ENODEV);
}

device_printf(sc->sc_dev, "ID 0x%08x version 0x%08x\n",
 id, version);
return (0);
}
```

The check serves two purposes. First, it confirms that the driver's understanding of the register layout is correct: if the identifier register holds the expected value at the expected offset, the layout is at least consistent with what we believe. Second, it gives you a fast-fail path if the driver is somehow attached to the wrong device, perhaps because two devices share a PCI ID prefix or because the device has multiple silicon revisions.

### 36.9.5 6.5 Adding Logging

Logging is your eyes during reverse engineering. Every register write, every register read whose value matters, every milestone in the driver's startup sequence: log it. The kernel's `device_printf` goes to `dmesg`, where you can see it in real time as the driver loads.

Logging is not a debug aid you remove later. In a reverse-engineering project, the logging is part of the driver, and it stays in the driver until the driver is well understood. The cost is small: a handful of `device_printf` calls take negligible CPU time and produce a few lines of output. The benefit is large: when something goes wrong, you have a complete record of what the driver tried to do.

A common pattern is to wrap register access in a small inline helper that logs the access:

```
static inline uint32_t
mydev_read(struct mydev_softc *sc, bus_size_t off)
{
 uint32_t val = bus_read_4(sc->sc_mem, off);
 if (mydev_log_reads)
 device_printf(sc->sc_dev,
```

```

 "read off=0x%04jx val=0x%08x\n",
 (uintmax_t)off, val);
 return (val);
}

static inline void
mydev_write(struct mydev_softc *sc, bus_size_t off, uint32_t val)
{
 if (mydev_log_writes)
 device_printf(sc->sc_dev,
 "write off=0x%04jx val=0x%08x\n",
 (uintmax_t)off, val);
 bus_write_4(sc->sc_mem, off, val);
}

```

The `mydev_log_reads` and `mydev_log_writes` flags can be tunable sysctls, so you can enable or disable logging without rebuilding the driver. The companion code in `examples/part-07/ch36-reverse-engineering/lab03-register-map/` uses exactly this pattern.

### 36.9.6 6.6 Comparing Logged Output Against Captures

With logging in place, you can compare what your driver does against what the vendor's driver did. Run the vendor's driver in the observation rig and capture the result. Run your driver in your development environment and capture its log output. Compare.

If the two sequences match, your driver is doing what the vendor's driver does, at least for the operations you have implemented. If they differ, the differences are telling you something. Maybe your driver is missing a write that the vendor's driver makes. Maybe your driver is writing a value that differs from what the vendor's driver wrote. Maybe your driver is reading a register that the vendor's driver does not read. Each difference is a hypothesis to investigate.

This comparison technique is one of the most effective you have. It turns the captures from passive evidence into an active specification: the driver should produce the same sequence of operations as the captures show. Where the driver deviates, the deviation is a bug or a missing piece, and the captures tell you what to add.

### 36.9.7 6.7 Writing the Module Boilerplate

The minimal driver also needs the standard module boilerplate. By this stage in the book the boilerplate should be familiar:

```

static device_method_t mydev_methods[] = {
 DEVMETHOD(device_probe, mydev_probe),
 DEVMETHOD(device_attach, mydev_attach),
 DEVMETHOD(device_detach, mydev_detach),
}

```

```
 DEVMETHOD_END
};

static driver_t mydev_driver = {
 "mydev",
 mydev_methods,
 sizeof(struct mydev_softc),
};

DRIVER_MODULE(mydev, pci, mydev_driver, NULL, NULL);
MODULE_VERSION(mydev, 1);
```

The `pci` parent in `DRIVER_MODULE` makes the kernel offer this driver every PCI device during probe, and the driver's probe method decides whether to claim each one. The `MODULE_VERSION` macro is a courtesy to anyone using `kldstat -v` to inspect loaded modules; it is also required if other modules want to declare a dependency on yours.

The Makefile is the standard FreeBSD kernel-module Makefile:

```
KMOD= mydev
SRCS= mydev.c device_if.h bus_if.h pci_if.h

SYSDIR?= /usr/src/sys

.include <bsd.kmod.mk>
```

The `device_if.h`, `bus_if.h`, and `pci_if.h` listed in `SRCS` are generated header files. The build system creates them on demand, and listing them tells `make` to do so before compiling `mydev.c`. If the driver becomes more complex and is split into multiple source files, list each source file separately.

## 36.9.8 6.8 The First Successful Load

When you load the minimal driver for the first time, the success criterion is modest. The driver should:

1. Be successfully loaded by `kldload`.
2. Recognise the device through probe.
3. Allocate its memory and IRQ resources through `bus_alloc_resource_any`.
4. Reset the device.
5. Verify the identifier.
6. Report success in `dmesg` and stay loaded without errors.
7. Be successfully unloaded by `kldunload` without panicking.

A driver that meets these criteria has done useful work. It has proven that the register layout is at least partially correct, that the reset sequence works, and that the identifier register is where you thought it was. Compared to where you started, this is substantial progress.

If any of the steps fail, the failure is informative. A `bus_alloc_resource_any` failure usually means the BAR layout is not what you expected. An ID-verification failure usually means the register offset is wrong, or the device's identifier value is not what you assumed. A panic on unload usually means a resource was not properly released; this is a bug in the detach path that needs to be fixed before any further work proceeds.

### 36.9.9 6.9 Unloading Cleanly

The detach path is at least as important as the attach path. A driver that can be loaded but not unloaded cleanly is a driver that requires a reboot every time you want to test a change, and the reboot will quickly become the bottleneck of your work. Spending time on a clean detach path early pays large dividends in development speed.

```
static int
mydev_detach(device_t dev)
{
 struct mydev_softc *sc = device_get_softc(dev);

 if (sc->sc_ih != NULL)
 bus_tearardown_intr(dev, sc->sc_irq, sc->sc_ih);
 if (sc->sc_irq != NULL)
 bus_release_resource(dev, SYS_RES_IRQ,
 sc->sc_irid, sc->sc_irq);
 if (sc->sc_mem != NULL)
 bus_release_resource(dev, SYS_RES_MEMORY,
 sc->sc_rid, sc->sc_mem);
 mtx_destroy(&sc->sc_mtx);
 return (0);
}
```

Each resource that was allocated must be released. Each registered interrupt handler must be torn down. Each mutex must be destroyed. The order is the reverse of the allocation order, which is a useful general rule.

### 36.9.10 6.10 Wrapping Up Section 6

The minimal driver is a foundation. It does very little, but it does that little correctly. Reset works, identifier verification works, the resource allocations are right, the detach path is clean. From this base, every further feature can be added incrementally, with confidence that the underlying scaffolding is sound.

The next section takes the minimal driver and shows how to grow it one feature at a time, always confirming that each new feature is correct before adding the next. The technique is the discipline of incremental development applied to a domain where there is no specification to refer to: instead of validating against a spec, we validate against captures and against measured behaviour. The result is the same: a driver that does what we believe it does, backed by evidence rather than by hope.

## 36.10 7. Iteratively Expanding the Driver and Confirming Behavior

The minimal driver in Section 6 is the seed of the real driver. To grow it into something useful, you add features one at a time, and for each feature you confirm that what the feature does in the running driver matches what you have observed the device doing under the vendor's driver. The process is straightforward but demanding: every step has to be verified, every verification has to be recorded, and every recording becomes part of the pseudo-datasheet that Section 11 will assemble.

This section walks through the methodology of incremental expansion. It does not introduce new low-level techniques, because the low-level techniques are the same as in Sections 4 and 6. What it adds is the discipline of growing a driver responsibly under uncertainty.

### 36.10.1 7.1 The One-Feature-at-a-Time Rule

The rule is in the name. Add one feature, verify it works, commit the result to your repository, then add the next feature. Do not add three features at once and then try to debug the combination. Do not add a feature and proceed to the next without verification. Do not skip the commit, because the commit is what lets you roll back when a later change breaks something that worked before.

The discipline is the same as test-driven development, with one significant adaptation: the test is often a comparison against the captures from Section 3, not a unit test in the traditional sense. The “test” is “the driver, when invoked to perform operation X, produces the same sequence of register accesses as the vendor's driver does”. The comparison is mechanical, but it is a real test: either the sequences match or they do not, and a failure tells you that something has changed.

A typical sequence of features for a network controller might be:

1. Read MAC address.
2. Set MAC address.
3. Set up receive descriptor ring.
4. Receive one packet.
5. Set up transmit descriptor ring.
6. Send one packet.
7. Enable interrupts.
8. Implement interrupt handler.
9. Bring the link up.
10. Bring the link down.
11. Reset and recover from error.

Each item is a discrete feature. Each item builds on the previous items. Each item has a clear success criterion (the operation either works or it does not). And each item has a corresponding capture from Section 3 against which the driver's behaviour can be compared.

### 36.10.2 7.2 The Verification Loop

For each new feature, the verification loop is:

1. Form the hypothesis: this feature works by doing X.

2. Implement the feature in the driver, with logging that records each register access.
3. Trigger the feature using a small userspace program, a `sysctl`, or whatever interface you have wired up.
4. Capture the kernel log output.
5. Compare against the relevant capture from Section 3.
6. If they match, declare the feature implemented.
7. If they do not match, identify the difference and decide whether your implementation is wrong or your hypothesis was wrong.

The loop is slow. A single feature might require several iterations through the loop, with hypothesis revisions in between. But the slowness is the point. Each iteration is a deliberate test, with a deliberate prediction and a deliberate observation. Over many iterations, the body of verified facts grows steadily and the chance of an incorrect belief surviving into the final driver shrinks rapidly.

### 36.10.3 7.3 The Compare-Against-Vendor Pattern

The comparison against the vendor's driver is so central to this work that it deserves its own discussion. The pattern looks like this.

You have a capture from Section 3 of the vendor's driver performing operation X. The capture contains a list of register accesses (for memory-mapped devices) or USB transfers (for USB devices), each labelled with timestamp, address or endpoint, direction, and value.

You have your driver, with logging enabled, performing the same operation X. The kernel log contains a list of register accesses or USB transfers, each labelled with timestamp, address or endpoint, direction, and value.

You compare the two lists. The accesses should be in the same order, to the same addresses or endpoints, in the same direction, with values that either match exactly or differ in ways that you can explain (because, for example, the values include sequence numbers or timestamps that naturally differ between runs).

Where the two lists agree, your driver is doing what the vendor's driver does. Where they disagree, you have a discrepancy to investigate. Some discrepancies are benign: your driver might omit a redundant register read that the vendor's driver does for some internal reason, and the omission has no effect on the device's behaviour. Other discrepancies are real bugs: a value you wrote incorrectly, a sequence step you missed, a register you did not realise the operation needed.

The compare-against-vendor pattern is essentially a specification-by-example. The specification of operation X is "the sequence of accesses the vendor's driver makes when performing operation X". Your implementation conforms to the specification when its sequence of accesses matches. The technique is not perfect: it cannot detect bugs that affect the device's internal state without affecting the access sequence, and it cannot detect bugs in the values you write if those values change between runs in the vendor's capture too. But it catches the great majority of implementation errors, and it catches them at exactly the level of detail where they happen.

### 36.10.4 7.4 Documenting Each Discovered Register

As you add features, you discover registers. Every register that you write to or read from in any feature is part of the register map, and every one of them needs to be added to the pseudo-datasheet you are building.

A useful technique is to maintain the pseudo-datasheet as a separate Markdown file alongside the driver source, and to update it every time you discover a new fact. Section 11 will discuss the pseudo-datasheet's structure

in detail; for now, the rule is simply that no fact you have learned should remain only in the driver code. The driver code is the implementation; the pseudo-datasheet is the documentation. They serve different purposes, and someone reading either should be able to understand the device.

A common mistake is to defer documentation until the project is “finished”. Reverse-engineering projects are rarely finished in that sense. They reach increasing levels of completeness over time, and the documentation should grow alongside the implementation. A driver with twenty features and a one-paragraph pseudo-datasheet is a maintenance disaster waiting to happen, because nobody can extend it without rediscovering everything you already knew.

### **36.10.5 7.5 When the Vendor’s Driver Disagrees With Itself**

A subtle complication arises when the vendor’s driver performs the same operation differently on different occasions. Sometimes this happens because the driver has multiple code paths for the same operation, depending on the device’s state or the user’s configuration. Sometimes it happens because the driver has optional behaviour that activates under specific conditions.

When you encounter such variation, the right response is to capture more, not to give up. Take captures of the operation under several different starting conditions and compare them. If you can identify what condition selects each variant, you have learned something about the driver’s logic. If the variants are functionally equivalent (they all achieve the same end state), you can choose the simplest one as the canonical implementation. If they are not functionally equivalent, the device may have multiple modes of operation that you need to support.

Sometimes the variation is just non-determinism: the vendor’s driver chose a sequence number from a counter, or used a timestamp, and the resulting capture differs slightly from one run to another. Non-determinism is benign, and learning to recognise it (so you can ignore it) is part of the skill of comparing captures.

### **36.10.6 7.6 Branching the Driver as Hypotheses Diverge**

When you have two competing hypotheses and an experiment that will distinguish them, branch the driver. Make a Git branch for the experiment, implement the change, run the experiment, observe the result, and then either merge the branch or discard it. Branches are cheap; you can have several hypothesis-testing branches in flight at once, and you can come back to any of them whenever a new experiment seems worthwhile.

The branching discipline is particularly valuable when an experiment requires significant code changes. Without branches, you might be reluctant to spend an hour writing experimental code that you will throw away. With branches, the experimental code lives in its own branch, and your main branch stays clean. If the experiment succeeds, you merge. If it fails, you discard. Either way, you have a clean history.

### **36.10.7 7.7 Wrapping Up Section 7**

We have learned how to grow a minimal driver into a more capable one through a disciplined cycle of one-feature-at-a-time implementation, comparison against captures, and documentation of every discovered fact. The mechanics are simple. The discipline is demanding. The reward is a driver whose every feature is backed by evidence, whose register map is recorded as it grows, and whose behaviour can be defended against any future challenge.

The next section turns to a slightly different topic: how to build confidence in your driver before you risk running it against real hardware. Simulation, mock devices, and validation loops are the techniques that let you find bugs in safety, where a kernel panic or a hang costs only a VM reboot, rather than in production, where the cost can be much higher.

## 36.11 8. Validating Assumptions With Simulation Tools

Reverse-engineering work moves between two kinds of risk. The first is the risk of being wrong: of writing code that does something other than what you believe it does. The second is the risk of being right too late: of finding out about a bug only when it has already damaged something, when the bug has driven the device into an unrecoverable state, or when the bug has crashed a production machine. The first risk is unavoidable; bugs are intrinsic to the work. The second risk is largely avoidable, and the way to avoid it is simulation.

A simulator is anything that lets you run your driver code without the real device being attached. Simulators range from simple mock implementations of a few register reads, through full-featured software emulations of an entire device, to virtualised hardware environments that pretend to be the real device for the operating-system stack above them. FreeBSD provides several simulator-like tools that fit naturally into the reverse-engineering workflow.

This section covers three kinds of simulation: mock devices that you write inside the kernel, the USB template framework for emulating USB devices, and bhyve passthrough for running an unmodified real device under a controlled hypervisor. We will see how each kind helps you validate assumptions, where each is most useful, and how to combine them with the captures and the register-map work from earlier sections.

### 36.11.1 8.1 The Kernel-Space Mock Device

The simplest form of simulation is a small kernel module that exposes the same interfaces as the real device but implements them in software. The mock module attaches as a child of an existing bus, allocates a software-backed “register region”, and implements the register reads and writes in C code that runs in the kernel.

For a memory-mapped device, the mock works like this. Where the real driver would allocate `SYS_RES_MEMORY` from the bus and use `bus_read_4` and `bus_write_4` to talk to the device, the mock hands the driver a pointer to a software-allocated array of words. Reads return the current value of the word at the requested offset. Writes update the word and trigger any software-implemented side effects. Side effects are how the mock implements the device’s behaviour: when the driver writes the “go” bit to the control register, the mock might internally start a callout that, after a simulated processing time, updates the status register to indicate completion and asserts a simulated interrupt.

The mock is small, often a few hundred lines for a device whose real driver might be several thousand lines. The point is not to implement everything; the point is to implement enough that the driver’s behaviour can be tested in isolation. A driver that correctly handles “command issued, command complete, results returned” against a mock has at least proved that its top-level sequencing is correct, even if the mock cannot test what happens when the real device produces values the driver did not anticipate.

The companion files in `examples/part-07/ch36-reverse-engineering/lab04-mock-device/` contain a small mock device that demonstrates the pattern. The mock implements a tiny “command and status” interface: there is a `CMD` register the driver writes to, a `STATUS` register the mock updates after a simulated delay, and a

DATA register the driver reads after the status indicates completion. The mock is intentionally simple, but it shows the structure: define the register addresses, allocate backing storage for them, implement read and write callbacks, and arrange for callbacks to do whatever side-effect logic the simulated device requires.

### 36.11.2 8.2 Trapping Driver Accesses

A more sophisticated mock can be built by interposing on the bus space layer itself. FreeBSD's `bus_space(9)` API uses opaque handles, and a custom bus-space implementation can intercept every read and write that the driver performs. The interception can log the access, modify the value, return a pre-arranged response, or simulate any other behaviour.

This technique is useful when you want to test a driver that has already been written for a real device, against a simulator, with minimal changes to the driver itself. The driver continues to use `bus_read_4` and `bus_write_4` as it always does. The intercept layer takes the calls and either dispatches them to the real device or fakes them as needed.

The technique is also useful when you want to record exactly what the driver does during a test, in a form that can be compared against captures from Section 3. An intercepting bus-space layer can produce a log file that has the same structure as a capture file, ready for direct comparison.

Implementing this kind of intercept is more involved than the simple mock, because you have to provide a complete bus-space implementation. The pattern is well established in the FreeBSD source. Readers interested in the deep version of this technique can study the architecture-specific bus-space backends in `/usr/src/sys/x86/include/bus.h` and the related files; the function-pointer table approach used there is the same approach you would use for an interception layer.

### 36.11.3 8.3 USB Template Drivers

For USB devices, FreeBSD includes an unusually capable simulation mechanism: the USB template framework. The template framework lets the kernel pretend to be a USB device, with a programmable set of descriptors, by exposing the USB device endpoint via the host controller in device mode. The relevant source files are under `/usr/src/sys/dev/usb/template/`, and the framework includes ready-made templates for several common device classes:

- `usb_template_audio.c` for USB audio devices.
- `usb_template_kbd.c` for USB keyboards.
- `usb_template_msc.c` for USB Mass Storage devices.
- `usb_template_mouse.c` for USB mice.
- `usb_template_modem.c` for USB modems.
- `usb_template_serialnet.c` for USB serial-network composite devices.

Several additional templates under the same directory cover other classes, including CDC Ethernet (`usb_template_cdce.c`), CDC EEM (`usb_template_cdceem.c`), MIDI (`usb_template_midi.c`), MTP (`usb_template_mtp.c`), and multi-function and phone composite devices (`usb_template_multi.c`, `usb_template_phone.c`). Browse the directory on your own system to see the full list; the set is expanded over time as contributors add new device classes.

Each template is a programmable description of a USB device: which class it claims to be, which endpoints it exposes, what its descriptors look like. Loaded into a USB host controller running in device mode (the controller pretends to be the device side of a USB cable), the template lets the host see a USB device that matches the descriptors.

For reverse-engineering work, the templates have two uses. The first is as a probe-test substrate: you can write a USB device descriptor that mimics the static identity of an unknown device and use the template framework to expose it to a development machine. The development machine's USB stack will probe the descriptors, attach drivers (yours, or the in-tree drivers if your descriptors collide), and you can observe what the host expects from a device with this identity. The exercise is particularly valuable when you have captured the descriptor of an unknown device but cannot get the device itself onto your development machine; the template lets you simulate what the host would see.

The second use is as a foundation for a software simulator that implements the full protocol of an unknown USB device. Building such a simulator is a substantial undertaking, but for very important reverse-engineering targets it can be the only way to test driver code without risking the real hardware. The templates provide the descriptor side of the equation; you have to add the data-handling logic yourself.

#### 36.11.4 8.4 bhyve and Passthrough

bhyve is FreeBSD's native hypervisor, and its PCI passthrough support is a valuable tool for reverse engineering. The relevant code is in `/usr/src/usr.sbin/bhyve/pci_passthru.c`, and the kernel side uses the `ppt(4)` driver (`/usr/src/sys/amd64/vmm/io/ppt.c`) to claim the device and expose it to the guest.

The passthrough workflow is:

1. On the host, detach the device from any in-tree driver:

```
$ sudo devctl detach pci0:0:18:0
```

2. Configure `ppt(4)` to claim the device, by adding an entry to `/boot/loader.conf`:

```
pptdevs="0/18/0"
```

This requires a reboot to take effect, after which the device will be claimed by `ppt(4)` instead of any other driver.

3. Start a bhyve guest with the device passed through:

```
$ sudo bhyve -c 2 -m 2G \
-s 0,hostbridge \
-s 1,virtio-blk,disk.img \
-s 5,passthru,0/18/0 \
-s 31,lpc \
-l com1,stdio \
myguest
```

The `-s 5, passthru, 0/18/0` argument tells bhyve to expose the host's PCI device at 0/18/0 to the guest, where it will appear in the virtual PCI bus.

Inside the guest, the device behaves like a normal PCI device. The vendor's driver, running in the guest, can access it just as it would on bare metal. From the host, you cannot directly see the device's register accesses, because the hypervisor handles them for the guest, but you can use bhyve's logging facilities to see configuration-space accesses, interrupt routing, and other operations that pass through the hypervisor.

For reverse engineering, the value of bhyve passthrough is that it lets you run the vendor's driver in a controlled environment where you can capture some kinds of activity that would otherwise be invisible. It also lets you snapshot and restore the host between experiments, so that you can recover quickly if an experiment goes wrong.

A particularly useful pattern is to develop your own driver on the host, with the device detached from ppt(4), and to switch to guest-passthrough only when you want to compare your driver's behaviour against the vendor's. The switch requires changing the ppt devs configuration and rebooting, but the inconvenience is small compared to the value of being able to run both implementations on the same hardware.

### 36.11.5 8.5 Loop With Known Return States

A simple but effective form of simulation is the validation loop with known return states. The idea is to instrument your driver so that, in test mode, certain register reads return values that you specify rather than values from the device. You then exercise the driver and observe what it does in response to each hand-chosen value.

For example, suppose you want to know what your driver does when the device returns an unexpected status value. In production, the device might never produce such a value, and there is no obvious way to test the path. With a validation loop, you replace the read of the status register with a function that returns a sequence of values you specify: 0x00, then 0x01, then 0xff, then back to 0x00. The driver behaves as if the device returned each of those values in turn, and you can verify that the driver's response is correct in each case.

The validation loop technique is particularly valuable for error paths. Most error conditions are rare in real operation, and testing them by waiting for them to occur naturally would take forever. By forcing them to occur on demand, you can test the error paths systematically. The technique is, in spirit, the same as the fault-injection techniques used in mature systems software, adapted to the reverse-engineering context where the driver itself is the artifact under test.

### 36.11.6 8.6 Limits of Simulation

Simulation is enormously valuable, but it has limits. A simulator implements the simulator's understanding of the device, not the device itself. When the simulator and the real device differ, the simulator's tests pass and the real device misbehaves, and you have learned that your understanding of the device was incomplete in some specific way.

The right attitude is to treat simulation as a way to find certain classes of bugs (driver logic errors, sequence errors, error-handling errors) and not as a guarantee that the driver will work on real hardware. Bugs in the driver's understanding of the device's contract will not be caught by a simulator that shares that misunderstanding. Bugs in the device's actual behaviour, that differ from what the simulator implements, will not be caught by simulator testing at all.

The combination is the answer. Simulator testing catches the bugs it can. Real-device testing, performed carefully and incrementally with the safety techniques from Section 10, catches the rest. The two together are far better than either alone.

### 36.11.7 8.7 Wrapping Up Section 8

We have seen the simulation tools that complement the reverse-engineering workflow: small in-kernel mock devices, the USB template framework, bhyve passthrough, and validation loops with known return states. Each tool addresses a different aspect of the problem, and together they let you find a great many bugs before any of them reach the real device.

The next section steps back from the technical work and looks at the social context: how reverse-engineering projects collaborate, where to find prior work, and how to publish your own findings. The technical part of reverse engineering is the visible part, but the community part is what makes the work durable. A driver that is well documented and well shared lasts. A driver that is written quickly and never published often disappears with its author.

## 36.12 9. Community Collaboration in Reverse Engineering

Reverse engineering is rarely a solitary activity, even when it appears to be. Almost every successful reverse-engineering project either builds on prior work or eventually contributes to it. The community of people who care about a particular device, or about a particular family of devices, is small but persistent, and learning to find and contribute to that community is one of the most efficient things a reverse engineer can do.

This section discusses how to find prior work, how to evaluate its trustworthiness, how to build on it without legal or ethical problems, and how to share your own findings in a form that helps others. The work is not glamorous, but it is what makes reverse engineering a productive long-term activity rather than a series of disconnected efforts.

### 36.12.1 9.1 Finding Prior Work

When you start investigating a device, the first thing to do is search for prior work. Even devices that seem to be obscure are sometimes the subject of significant prior research, and finding that research saves enormous time.

The most valuable sources, in approximate order of usefulness:

**FreeBSD source tree.** Search `/usr/src/sys/dev/` for the device's vendor ID, device ID, USB descriptor, or vendor name. A driver in the FreeBSD tree is the gold standard of prior work, because it is already validated, builds against the current kernel, and follows FreeBSD conventions. Even when no driver exists, related drivers for the same vendor often share patterns that apply.

**OpenBSD and NetBSD source trees.** The other BSDs have their own driver collections, and they often have drivers for devices that FreeBSD does not yet support. The code is generally straightforward to read and to port. Licensing is usually compatible with FreeBSD (most BSD-licensed code is).

**Linux source tree.** The Linux kernel has the broadest collection of device drivers in any open-source project. Most are GPL-licensed, which means you cannot copy code into a FreeBSD driver, but you can read them for understanding and write your own implementation from a clean slate. The clean-room approach of reading the Linux driver to understand the device, then writing original code from that understanding, is well established and legally accepted in interoperability cases; the full framework for doing this safely, including the paper trail that a clean-room defence actually depends on, appears later in this chapter in Section 12. Even when the legal

question is settled, a direct port from Linux to FreeBSD is rarely workable for purely technical reasons. Linux drivers lean on kernel APIs that have no direct FreeBSD equivalent: its spinlock and mutex primitives have different wake-up semantics, its memory allocators distinguish contexts that FreeBSD expresses differently, and its device model (with `struct device`, `sysfs`, and the driver-core probe flow) does not map onto Newbus. The right way to use a Linux driver is to mine it for device-level facts (register layouts, magic values, initialisation order, quirk tables) and then rebuild the control flow against FreeBSD's own primitives. Section 13 shows two FreeBSD drivers that did exactly this.

**Hardware-specific community sites.** For many devices, enthusiasts have built dedicated sites that collect everything known about a particular family. The Wireshark wiki has extensive documentation on USB protocols. The OpenWrt project has documentation on many embedded devices. Many specific hardware families have their own community wikis or forums.

**Vendor mailing lists, technical support archives, application notes.** Some vendors publish more in technical support contexts than in their public documentation. A search through their support archives or developer mailing lists can sometimes turn up information that is not in the official documentation.

**Patents.** Patent applications often contain detailed descriptions of how a device works, because the legal requirement to describe the invention forces some level of disclosure. Patent databases are searchable by company and by year, and a search for the right vendor's patents can sometimes uncover a wealth of detail.

**Academic papers.** When the device is in a specialised field (scientific instrumentation, industrial control, certain classes of network equipment), academic papers in that field may have already documented the device's interface for research purposes.

The first hour of any project should be spent searching these sources. Even an unsuccessful search is informative: knowing that no prior work exists changes the project's scope significantly.

### 36.12.2 9.2 Evaluating Trustworthiness

Not all prior work is equally trustworthy. A working open-source driver is highly trustworthy, because the author's claims are backed by code that demonstrably works. A community wiki page written by an enthusiast may or may not be trustworthy, depending on the source's track record. A vendor white paper is generally trustworthy on points the vendor wants to make and possibly silent or misleading on points the vendor would rather not discuss.

The skill of evaluating sources is the same skill that historians and journalists develop. You ask: who wrote this, when, on the basis of what evidence, with what motivations? You compare claims across multiple sources. You give the most weight to claims that are supported by code or by direct measurement. You give less weight to claims that depend on the author's reputation alone.

When you adopt a fact from prior work, record where it came from. The notebook entry should say "from the Linux ath5k driver, register XYZ at offset N is the channel selector". A year later, when the fact turns out to be wrong, you will know where the error came from and what other facts from the same source might also be wrong.

### 36.12.3 9.3 The Clean-Room Discipline

The clean-room discipline is the standard methodology for using prior work without infringing on its copyright. The discipline is straightforward but requires care.

In the strict clean-room form, two people are involved. One reads the prior work (a vendor driver, a leaked specification, a disassembled binary) and produces a description of what the device does. The description is in natural language and contains no copyrighted material. The second person reads only the description and writes the new driver. The second person never sees the original work. Because the new driver was written without reference to the original, it cannot be a derivative of it under copyright law.

In the relaxed form, often used in solo projects, the same person performs both roles, but is careful to keep them separated in time and to document the separation. Read the prior work. Take notes. Put the prior work away. Wait. Then, working only from your notes, write the driver. The notes are the bridge; the prior code is never in front of you while you are writing the new code.

The relaxed form is less legally bulletproof than the strict form, but it is what most individual reverse engineers actually do, and the case law on interoperability work generally supports it. The key is the discipline of separating reading from writing, so that you can prove (and prove to yourself) that the new code is independent.

In all cases, the new driver must not contain copied code, copied register-name macros, copied data structures, or copied comments from the original. It can contain ideas, structural patterns, and the device's interface itself, because those are not copyrightable. Anything that is copyrightable must be re-expressed in your own words and your own structure.

### 36.12.4 9.4 Sharing Your Findings

Reverse-engineering work, when complete, should be published. The publication serves several purposes: it lets others use the driver, it lets others extend the driver, it preserves the knowledge against the case where you stop working on it, and it contributes to the body of public knowledge about the device.

The minimum useful publication is a Git repository that contains:

- The driver source code, with a clear license.
- A README explaining what the driver does and how to build it.
- The pseudo-datasheet (Section 11) that documents the device.
- The test programs and any other tools needed to use the driver.
- The notebook, or a cleaned-up version of it, so that others can trace the reasoning behind any claim.

A more polished publication adds:

- A document describing the methodology, so that others can reproduce the work.
- A list of open questions and unresolved issues.
- A clear distinction between verified facts and remaining hypotheses.
- Attribution to all sources of prior work, with links.

The license matters. For a driver intended for FreeBSD inclusion, the BSD two-clause license is the standard choice. The license must make the work compatible with the FreeBSD source tree's license requirements. If you have used material from a GPL-licensed project, even cleanroom-style, document the provenance carefully so that any concerns about derivation can be resolved by examining your notes.

Once you have published, announce the work in places where interested people will see it: the FreeBSD-arm mailing list for embedded work, the FreeBSD-net mailing list for network drivers, relevant project-specific communities, and your personal channels. The announcement should be brief but informative: what the driver does, what state of completeness it is in, where the repository is, and who is welcome to contribute.

### 36.12.5 9.5 Maintaining a Pseudo-Datasheet in Markdown or Git

The pseudo-datasheet itself deserves special attention. It is the single most valuable artifact you produce, often more valuable than the driver code. The driver code is one implementation of your understanding of the device; the pseudo-datasheet is the understanding itself, and from it any number of drivers (FreeBSD, Linux, NetBSD, custom embedded systems) can be written.

The format that has proven most useful in community projects is a Git-tracked Markdown file (or a small set of files), structured around the device's logical components: identity, register map, buffer layouts, command set, error codes, initialisation sequence, programming examples. We will look at the structure in detail in Section 11.

The Git tracking is essential. The pseudo-datasheet is a living document; it will be updated as new facts are discovered, as old facts are corrected, as additional reverse-engineering work extends its coverage. The Git history is the record of how the understanding has evolved. When a fact is corrected, the Git log shows when it was corrected and by whom, so that other readers can know when their old printout has gone out of date.

The companion code in `examples/part-07/ch36-reverse-engineering/lab06-pseudo-datasheet/` contains a Markdown template for a pseudo-datasheet, suitable as a starting point for your own projects. The template is opinionated about structure, because consistent structure makes the document easier to read, easier to compare against other pseudo-datasheets, and easier to extract automatically into other formats.

### 36.12.6 9.6 Wrapping Up Section 9

The community-collaboration side of reverse engineering is the side that gives the work its longevity. A driver written in isolation and never published may serve its author well, but it disappears with that author. A driver written in dialogue with prior work and published clearly serves a much wider audience and lasts much longer.

The next section turns to the safety side of the work, which we have referenced repeatedly. Safety deserves its own dedicated section, because the consequences of getting it wrong can include permanent damage to expensive hardware, and the techniques for avoiding such damage are concrete enough to be taught explicitly.

## 36.13 10. Avoiding Bricking or Hardware Damage

This is the section that this chapter has been deferring all along. Reverse engineering, done carelessly, can damage hardware. Some kinds of damage are recoverable with effort. Other kinds turn a working device into an inert brick that nothing short of a specialised vendor recovery tool, if it exists at all, can fix. A reverse engineer who works without understanding which patterns are dangerous will eventually destroy something. The goal of this section is to tell you, concretely, which patterns to avoid and which patterns are safe.

The advice in this section applies to every other section in the chapter. The probing techniques in Section 4 are safe only when combined with these warnings. The minimal driver in Section 6 is safe only when it writes

are constrained as described here. The iterative expansion in Section 7 is safe only when each new feature is evaluated against these criteria before it is allowed to write to the device. Read this section in full; do not skip to the technique sections without it.

### 36.13.1 10.1 The General Principle

The general principle is simple to state and, with practice, straightforward to apply.

**Never write to an unknown register or send an unknown command without strong evidence that the operation is safe.**

The strong evidence can come from several sources, and each is worth its own short discussion.

**The vendor's driver performed the same operation.** If you have captured the vendor's driver writing a specific value to a specific register, and the resulting device behaviour was healthy, then performing the same write in your driver is, almost certainly, safe. The vendor's driver is presumably well-tested and would not casually do something that bricks the device.

**The operation is a documented standard operation.** Some operations are so universal that they can be assumed to be safe. PCI configuration-space reads are safe by design. PCI standard control register writes (clear pending interrupts, enable bus mastering, set memory access enable) are safe in the standard range. USB control transfers using standard requests on standard endpoints are safe. The standardised parts of a protocol can be trusted; the vendor-specific parts cannot be trusted without evidence.

**The operation is reversible.** A write that you can immediately undo is much safer than one you cannot. Setting a configuration bit, observing the effect, and then restoring the original value is far safer than performing an operation that has permanent consequences.

**The operation has been tested in simulation.** A write that you have first tested against a mock or a simulator, where the worst-case outcome is a kernel panic in a test VM, is safer than a write you have only modeled in your head.

In the absence of any of these forms of evidence, the operation is unknown, and the rule is: do not perform it.

### 36.13.2 10.2 Operations That Deserve Particular Caution

Some categories of operations are dangerous enough to deserve explicit attention. These are the operations where a careless write can permanently damage a device, and they are the operations that should never be performed without strong evidence.

**Flash writes.** Many devices contain flash memory used for firmware, configuration, calibration, or device identifiers. Writes to flash are irreversible (or at best reversible by restoring a backup). A driver that accidentally writes to flash can corrupt the firmware (rendering the device unbootable), overwrite calibration data (rendering the device inaccurate or unusable), or change the device's identity (rendering it unrecognisable to its own firmware). The patterns that trigger flash writes vary by device, but they often involve specific "unlock" sequences followed by writes to addresses that are explicitly the flash region. If your captures show such a sequence in a context where the user explicitly performed a "firmware update" operation, do not replicate the sequence in your driver unless you are explicitly implementing firmware update.

**Hard resets that affect non-volatile state.** Most resets are soft resets that return the device to its initial in-memory state. Some resets, however, also clear non-volatile state: calibration data, configuration, identifier programming. These “factory reset” operations are sometimes triggered by the same register that triggers a soft reset, with a different bit pattern. Use only the soft-reset pattern that the vendor’s driver uses on attach, and do not experiment with bit patterns that you have not seen the vendor’s driver use.

**EEPROM writes.** Similar to flash, EEPROM contains long-term configuration. EEPROM writes are usually orchestrated through a specific protocol of register writes, and the wrong protocol can corrupt EEPROM state. Avoid EEPROM writes during exploration; if you must perform them, do so only with a clear understanding of what value should end up in EEPROM and a way to verify the result.

**Modifying device identifiers.** Some devices store their vendor and device IDs in flash or EEPROM, and a driver bug can overwrite them. A device whose ID has been changed will not be recognised by any driver that matches on the original ID, and recovering it can require physical reprogramming with a hardware programmer. Do not write to any register that is plausibly related to device identification.

**Power management state changes.** Some devices have power states whose transitions are managed by complex sequences of register writes. The wrong sequence can leave the device in a state from which it cannot easily recover, sometimes requiring power cycling the host or even removing the device physically. Power management is one of the most fragile areas of any device’s interface.

**PHY or PLL configuration.** Devices that include their own clock generation (PCI Express devices in particular) have PLL configuration that, if set wrong, can leave the device unable to communicate at all. PHY configuration on networking devices has similar pitfalls. These are subsystems where the vendor’s driver must be followed exactly, because there is no good way to recover from an incorrect setting through any further configuration.

**Bus master enable on a misconfigured DMA address.** If you enable bus mastering on a device that has a DMA address pointing to a wild memory location, the device may read or write that location and corrupt the host’s memory. This is one of the few ways a driver bug can crash the host through hardware action. Always set up valid DMA mappings before enabling bus mastering, and never enable bus mastering if you are not yet ready to manage DMA.

These categories are not exhaustive, but they cover the most common ways to damage a device. The general lesson is: respect the operations whose consequences you do not fully understand, and do not experiment with them.

### 36.13.3 10.3 Soft Resets and Watchdog Timers

The constructive side of the safety discussion is what to do when something does go wrong. The first technique is the soft reset.

A soft reset is the device’s “I have got into a bad state, please restart” mechanism. The pattern is the same as the reset you implemented in Section 6: a write to the control register that puts the device back into its known initial state. Used conservatively, a soft reset can recover from many kinds of problems without requiring intervention.

The pattern in code is straightforward:

```
static void
mydev_recover(struct mydev_softc *sc)
{
 device_printf(sc->sc_dev, "recovering device\n");
 mydev_reset(sc);
 /* Reapply any necessary configuration. */
 mydev_init_after_reset(sc);
}
```

The recovery routine should be called from any code path that detects something has gone wrong: a timeout, an error status, an unexpected register value. The cost of an unnecessary reset is small; the cost of an unrecovered error can be much larger.

A watchdog timer is the next layer of defence. The driver periodically checks that the device is making progress, and if progress has stalled, it triggers a recovery. The pattern is:

```
static void
mydev_watchdog(void *arg)
{
 struct mydev_softc *sc = arg;
 uint32_t counter;

 mtx_lock(&sc->sc_mtx);
 counter = bus_read_4(sc->sc_mem, MYDEV_REG_COUNTER);
 if (counter == sc->sc_last_counter) {
 sc->sc_stall_ticks++;
 if (sc->sc_stall_ticks >= MYDEV_STALL_LIMIT) {
 device_printf(sc->sc_dev, "device stalled, resetting\n");
 mydev_recover(sc);
 sc->sc_stall_ticks = 0;
 }
 } else {
 sc->sc_stall_ticks = 0;
 }
 sc->sc_last_counter = counter;
 callout_reset(&sc->sc_watchdog, hz, mydev_watchdog, sc);
 mtx_unlock(&sc->sc_mtx);
}
```

The watchdog reads a counter that the device should be incrementing during normal operation. If the counter does not change for several iterations, the watchdog assumes the device has stalled and triggers recovery. The pattern is robust against transient slowdowns (a single missed increment is tolerated) but catches genuine stalls within a few seconds.

### 36.13.4 10.4 Backing Up Firmware Before Doing Anything Risky

For devices with firmware (which is most modern devices), the firmware itself should be backed up before any risky operation. If your captures show that the firmware is loaded by the host during initialisation, then the firmware image is presumably already available somewhere as a file, and you can keep a copy. If the firmware lives in flash on the device and is not loaded from the host, you have to read it back through whatever mechanism the device exposes for reading flash, and store the result.

The backup is your insurance against the case where some experiment overwrites the firmware. With the backup, you can restore the original. Without the backup, you may have a brick.

The discipline of backup-before-risky-operation is the same discipline as backup-before-risky-system-administration. The cost is small, the value when it matters is enormous, and the people who skip it are the people who, sooner or later, regret having skipped it.

### 36.13.5 10.5 Read-Only Probes Where Possible

Whenever an experiment can be performed read-only, perform it read-only. The information gained is usually worth far more than the time saved by writing instead of reading. Section 4's register-mapping work was almost entirely read-only for a reason: reading is safe, writing is not.

A useful pattern when you must investigate the effect of writes is to read the value, compute what you expect the new value to be, perform the write, read the value again, and verify that the result matches your expectation. The verification step lets you catch the case where the write did not have the effect you expected, before you base further work on a wrong assumption.

```
static int
mydev_set_field(struct mydev_softc *sc, bus_size_t off,
 uint32_t mask, uint32_t value)
{
 uint32_t old, new, readback;

 old = bus_read_4(sc->sc_mem, off);
 new = (old & ~mask) | (value & mask);
 bus_write_4(sc->sc_mem, off, new);
 readback = bus_read_4(sc->sc_mem, off);
 if ((readback & mask) != (value & mask)) {
 device_printf(sc->sc_dev,
 "set_field off=0x%04jx mask=0x%08x value=0x%08x "
 "readback=0x%08x mismatch\n",
 (uintmax_t)off, mask, value, readback);
 return (EIO);
 }
 return (0);
}
```

The helper performs the read-modify-write-verify cycle in one place, with logging of mismatches. Used consistently, it catches the cases where a write did not stick (because the register is read-only, because the write encoded the value differently than you expected, or because the device's state did not allow the change at this moment) before they cause downstream confusion.

### **36.13.6 10.6 Safe Probing Wrappers**

The companion code in `examples/part-07/ch36-reverse-engineering/lab05-safe-wrapper/` contains a small library of safe probing wrappers that combine several of the techniques discussed here: timeouts on every operation, automatic recovery on detected stalls, read-only modes, and per-operation logging. The wrappers add a few hundred microseconds to each operation, which is irrelevant during exploration, and they catch the great majority of safety problems before the problems become harmful.

The pattern is recommended for all exploratory drivers. The production driver, when it eventually exists, can drop the wrappers in favour of more efficient direct accesses, but during exploration the wrappers are worth their cost in safety.

### **36.13.7 10.7 Recognising When to Stop**

The hardest safety decision is sometimes the decision to stop. When an experiment is not behaving as expected, when the device is producing values you cannot explain, when your hypotheses are all wrong and you do not yet have new ones, the temptation is to keep poking until something becomes clear. Resist this temptation. Stop, take a break, look at the captures again, talk to someone else about what you have observed, and let the situation clarify before you resume.

The reason is that the moments of confusion are exactly the moments when accidental damage is most likely. A clear mind is careful about which writes are safe; a frustrated mind tries things that look promising and discovers, too late, that one of them was destructive.

A short break also lets your subconscious work. Many of the most useful reverse-engineering insights arrive while you are doing something else: walking, sleeping, working on an unrelated problem. The brain has a remarkable ability to integrate observations into coherent understanding when given a chance. Forcing yourself to stay at the keyboard when the work has stalled often produces nothing useful and sometimes produces disasters.

### **36.13.8 10.8 Wrapping Up Section 10**

Safety in reverse engineering is built on a small set of disciplines: never write without strong evidence, recognise the operations that deserve particular caution, build in soft-reset recovery and watchdog timers, back up firmware before risky operations, prefer read-only experiments, use safe probing wrappers, and know when to stop. None of these disciplines is complicated. All of them are necessary. A reverse engineer who follows them is unlikely to damage hardware. A reverse engineer who ignores them is, sooner or later, certain to.

The next section closes the technical part of the chapter by discussing how to turn the body of work the previous sections have built up into a maintainable driver and a usable pseudo-datasheet. The reverse-engineering process that started with observations and hypotheses ends with a driver and a document, and how those final artifacts are constructed determines how useful the project will be to its future readers.

## 36.14 11. Refactoring and Documenting the Reversed Device

The end of a reverse-engineering project is not the moment when the driver works. It is the moment when the driver and the pseudo-datasheet together can be handed to another engineer who can read them and understand both the device and the implementation. Until that moment, the project is incomplete, even if the driver appears to function. This section walks through the work of consolidating the project's findings into a maintainable form.

The work has two parts. The driver itself needs to be cleaned up, restructured to follow normal driver-writing conventions, and documented in the way any FreeBSD driver should be documented. The pseudo-datasheet, which has been growing throughout the project as a notebook of facts, needs to be reorganised into a standalone document that someone who has never seen the project can read and learn from.

### 36.14.1 11.1 The Driver Cleanup

A reverse-engineered driver, in its working-but-not-cleaned-up state, typically carries traces of its history: comments referring to “the suspected control register”, code blocks that test multiple hypotheses with conditional compilation, debugging sysctls that were added during a specific investigation, log messages that were useful at the time but no longer needed. Cleaning up means removing the historical noise while preserving the substantive content.

The cleanup checklist:

1. Remove every conditional compilation block that was used to test alternatives. The chosen alternative should remain; the alternatives should be deleted.
2. Replace speculative names with confirmed names. If a register was originally named `MY_DEV_REG_UNKNOWN_40` and is now known to be the channel-selection register, rename it to `MY_DEV_REG_CHANNEL`.
3. Replace investigation comments with explanatory comments. A comment that says “I think this might be the polling delay” is a hypothesis comment from the investigation phase; replace it with a comment that says “Wait for the device to complete the reset” once the hypothesis is confirmed.
4. Remove debugging sysctls that are no longer useful, and keep the ones that operators or maintainers will want.
5. Remove `device_printf` calls that were valuable during investigation but are now noise in production.
6. Verify that the detach path is clean. A driver that loads cleanly but fails to unload cleanly is a maintenance problem.
7. Verify that all error paths free their resources correctly. A driver that leaks resources on error is a problem that will eventually surface.

The companion code in `examples/part-07/ch36-reverse-engineering/` includes both the investigation-phase scaffolding and the cleaned-up form, so that you can see the difference. The cleaned-up form is what would be suitable for inclusion in the FreeBSD source tree (we will discuss inclusion in Chapter 37).

### 36.14.2 11.2 Driver Documentation

A FreeBSD driver should have at least a manual page in section 4, and ideally a section in the kernel-developer's documentation as well. The manual page is for users who want to know what the driver does and how to

configure it. The developer documentation is for kernel hackers who want to understand the driver internally.

The manual page follows the standard FreeBSD style. The relevant manual page for `style(4)` documents the conventions, and the manual pages for similar drivers are good examples to follow. A typical driver manual page covers:

- The name of the driver and a one-line description.
- The synopsis showing how to load the driver in `loader.conf`.
- The description, explaining what hardware the driver supports and what features it provides.
- The hardware support section, listing the specific devices the driver works with.
- The configuration section, describing any sysctls or loader variables the driver exposes.
- The diagnostics section, listing the messages the driver may produce and what they mean.
- The see-also section, with cross-references.
- The history section, explaining when the driver appeared.
- The author section.

For a reverse-engineered driver, the description should be honest about the driver's provenance: it was developed by reverse engineering, the supported feature set is what was achievable through that process, and certain corners of the device may behave differently than the driver expects. Operators appreciate honest documentation; vague claims of full support set up users for confusion when they encounter unimplemented behaviour.

### 36.14.3 11.3 The Pseudo-Datasheet Structure

The pseudo-datasheet is the standalone document that captures everything you have learned about the device, in a form that someone who has never seen your driver can read and understand. A well-structured pseudo-datasheet often becomes the most referenced document in any project that uses the device, because it answers questions that the driver source code cannot answer without close reading.

A practical pseudo-datasheet structure looks like this:

1. Identity
  - 1.1 Vendor and device IDs
  - 1.2 USB descriptors (if applicable)
  - 1.3 Class codes (if applicable)
  - 1.4 Subsystem identifiers (if applicable)
  - 1.5 Hardware revisions covered
2. Provenance
  - 2.1 Sources consulted
  - 2.2 Methodology used
  - 2.3 Verification status of each fact (high / medium / low)
3. Resources
  - 3.1 Memory regions and their sizes
  - 3.2 I/O ports (if applicable)
  - 3.3 Interrupt assignment

4. Register Map
  - 4.1 Register list with offsets and short descriptions
  - 4.2 Per-register details: size, access type, reset value, fields
5. Buffer Layouts
  - 5.1 Ring buffer layouts
  - 5.2 Descriptor formats
  - 5.3 Packet formats
6. Command Interface
  - 6.1 Command sequencing
  - 6.2 Command list with formats and responses
  - 6.3 Error reporting
7. Initialization
  - 7.1 Cold attach sequence
  - 7.2 Warm reset sequence
  - 7.3 Required register settings before operation
8. Operating Patterns
  - 8.1 Data flow
  - 8.2 Interrupt handling
  - 8.3 Status polling
9. Quirks and Errata
  - 9.1 Known bugs in the device
  - 9.2 Workarounds in the driver
  - 9.3 Edge cases that have not been fully characterised
10. Open Questions
  - 10.1 Behaviours observed but not understood
  - 10.2 Registers whose purpose is not yet known
  - 10.3 Operations not yet investigated
11. References
  - 11.1 Prior work consulted
  - 11.2 Related drivers in other operating systems
  - 11.3 Public documentation, if any

The structure is comprehensive, and not every project will fill every section. Sections that are not relevant can be omitted; the template is a checklist of “what would be worth documenting if the relevant information existed”, not a requirement to invent information that does not exist.

The most important sections are the Provenance, the Register Map, and the Open Questions. Provenance lets readers evaluate the trustworthiness of the document. The Register Map is the central reference. Open Questions

tells future contributors where the work needs more attention.

### 36.14.4 11.4 The Provenance Section in Detail

The Provenance section deserves special attention because it is how a pseudo-datasheet establishes its credibility. The section should answer:

- What sources of information were used? (Captures, prior code, experiments, public documentation.)
- What methodology was applied to each source? (Direct reading, diffing, statistical analysis.)
- Which facts come from which sources?
- For each fact, what is the verification status?

A useful convention is to label each substantive fact in the register map and elsewhere with a short verification tag:

- **HIGH**: confirmed by multiple independent observations and by experiment.
- **MEDIUM**: confirmed by a single source or a single experiment.
- **LOW**: hypothesis based on inference, not yet directly tested.
- **UNKNOWN**: stated for completeness, but with no evidence.

Readers can then weight each fact by its verification status, and contributors can prioritise where to invest more investigation. The convention costs little to maintain and gives the document a much more honest character than a flat statement of facts that treats all claims as equal.

### 36.14.5 11.5 Registers as Tables

The register map itself is best presented as a table. For each register, the table should give:

- Offset within the register block.
- Symbolic name (the macro name in the driver).
- Size (8, 16, 32, or 64 bits, usually).
- Access type (read-only, read-write, write-only, write-1-to-clear, and so on).
- Reset value.
- One-line description.

A separate, more detailed entry for each register lists the fields within the register. For example:

MYDEV\_REG\_CONTROL (offset 0x10, RW, 32 bits, reset 0x00000000)

| Bits  | Name       | Description                                  |
|-------|------------|----------------------------------------------|
| ----- |            |                                              |
| 0     | RESET      | Write 1 to trigger reset.                    |
| 1     | ENABLE     | Set to enable normal operation.              |
| 2-3   | MODE       | Operating mode (0=idle, 1=rx, 2=tx, 3=both). |
| 4     | INT_ENABLE | Enable interrupts globally.                  |
| 31:5  | reserved   | Read as zero, write as zero.                 |

This table format is the FreeBSD convention. It scales well, it is easy to maintain in Markdown, and it is what readers expect.

### 36.14.6 11.6 Pseudo-Datasheet as a Living Document

The pseudo-datasheet is rarely complete. As the driver evolves, new behaviour is discovered, old facts are refined, edge cases are characterised. The Git-tracked Markdown form lets the document evolve naturally, with each commit explaining what was learned and when.

The discipline that supports this is to update the pseudo-datasheet first, then update the driver to match. The pseudo-datasheet is the specification; the driver is the implementation. When you discover that a register's bit-3 has a purpose you did not previously know, write the new bit-3 description into the pseudo-datasheet first, with provenance, and then update the driver to use it. The order matters because it forces you to think about the change as a fact about the device, separately from a change to your code.

Over time, the pseudo-datasheet becomes the trustworthy artifact, and the driver becomes one of several possible implementations of the contract the document specifies. New implementations (in NetBSD, in Linux, in custom embedded code) can be written from the pseudo-datasheet alone, without re-deriving everything from scratch.

### 36.14.7 11.7 Versioning the Driver

The book's worked examples use version strings such as `v2.5-async` to mark major iterations of a driver. For reverse-engineered drivers, a useful convention is to use a `-rev` suffix to indicate the reverse-engineered nature of the work, with version numbers tracking the maturity of the implementation:

- `v0.1-rev`: minimal driver, reset and identifier only.
- `v0.2-rev`: read path implemented and verified.
- `v0.5-rev`: most operations implemented, some quirks understood.
- `v1.0-rev`: full functionality, all known quirks handled.
- `v2.1-rev`: a stable, mature, refactored driver suitable for general use.

The version string can appear in the manual page, in a `MODULE_VERSION` macro, and in the pseudo-datasheet. It tells operators what level of support to expect from any given build.

### 36.14.8 11.8 Wrapping Up Section 11

We have seen how to consolidate the work of a reverse-engineering project into a maintainable driver and a standalone pseudo-datasheet. The driver is cleaned up, documented in the manual page, and versioned to indicate its maturity. The pseudo-datasheet captures what was learned about the device, with provenance, in a structured form that future contributors can extend. Together, the two artifacts are what justifies the considerable investment that the reverse-engineering project required.

Before turning to hands-on practice, two shorter sections round out the theoretical material. Section 12 revisits the legal and ethical framework from Section 1 with a practical eye, giving you a compact set of rules for licence compatibility, contractual restrictions, clean-room discipline, and safe-harbour activities. Section 13 then walks through two worked case studies from the FreeBSD tree itself, showing how the techniques of the chapter appear in drivers that are in production today. After those two sections, the remaining material of the chapter gives you

labs to apply what you have learned, challenge exercises to stretch your understanding, troubleshooting notes to help when things go wrong, and a forward-looking transition to Chapter 37, where we will see how to take a driver like the one you have just built and submit it for inclusion in the FreeBSD source tree.

## 36.15 12. Legal and Ethical Guardrails in Practice

Section 1 opened this chapter by sketching the legal and ethical landscape in which reverse engineering for FreeBSD happens. That sketch was deliberately broad, because it had to introduce concepts like fair use, interoperability research, and clean-room method before the reader had seen any of the technical work the rest of the chapter covers. Now, at the end of that technical work, it is worth taking a second, more practical pass. The goal of this section is not to turn you into a lawyer. It is to give you a small set of habits that protect you, the project, and the reader of your code from the predictable ways a reverse-engineering effort can go wrong. Each habit is concrete, each one can be documented inside your pseudo-datasheet from Section 11, and each one is directly informed by how the FreeBSD tree has handled similar questions in the past.

### 36.15.1 12.1 Why a Second Legal Section

Section 1 answered the question “is this allowed?”. Section 12 answers the question “how do I do it in a way that stays allowed?”. The distinction matters, because many of the activities that are legal in principle become risky in practice if they are done without structure. Reading another driver to understand a chip is legal. Reading another driver and then writing your own from memory, without any intermediate document to show where your understanding came from, looks the same from the outside but is much harder to defend if a question is ever raised. Treating a proprietary datasheet as a reference is legal. Quoting long passages from that datasheet into your driver’s source comments is not. The difference in both cases is process, not intent.

The rest of this section works through four concrete areas: licence compatibility (what you are allowed to copy), contractual restrictions (what you are allowed to disclose), clean-room practice (how to keep interoperability work defensible), and safe-harbour activities (what is always permitted). None of the content below is a substitute for legal advice on a specific situation; it is instead the common discipline that experienced FreeBSD developers already follow, written down in one place so that a new author can adopt it without having to reconstruct it.

### 36.15.2 12.2 Licence Compatibility

The FreeBSD kernel uses a permissive BSD-style licence. When you pull knowledge from another codebase into your driver, the licence of that other codebase constrains what you are allowed to copy, even if it does not constrain what you are allowed to learn. The categories that come up in practice are BSD, GPL, CDDL, and proprietary, and each has a different rule.

**BSD-licensed sources.** Drivers that already live in the OpenBSD or NetBSD trees, or in older FreeBSD ports of the same device, use a permissive licence that is compatible with the FreeBSD kernel. You can copy code directly, with appropriate attribution in the copyright block. The `zyd` wireless driver at `/usr/src/sys/dev/usb/wlan/if_zyd.c` is a concrete example: the file header preserves the original `$OpenBSD$` and `$NetBSD$` tags at the top of the source, indicating that the code was ported from those trees, and Damien Bergamini’s BSD-style copyright is intact alongside the copyrights of later FreeBSD contributors. When the licence is compatible,

moving code between trees is a legitimate way to amortise work across the BSD ecosystem, and it is already part of FreeBSD's routine practice.

**GPL-licensed sources.** Linux drivers are almost always licensed under the GPL. You are allowed to read GPL code to understand how a device works, because reading is not copying. You are not allowed to paste GPL code into a BSD-licensed driver, even in small amounts, even temporarily, even with attribution. The FreeBSD project's position is clear: the kernel does not accept code of incompatible licence. A driver that was reviewed and found to contain copied GPL code would be rejected, and the maintainer would lose standing in future reviews. The rule is strict because the cost of relaxing it would be the licence integrity of the tree.

**CDDL-licensed sources.** Some device drivers in the OpenSolaris and Illumos trees are released under the CDDL. The CDDL is file-level copyleft, which means that you cannot freely intermix CDDL source and BSD source within the same file. The ZFS code in FreeBSD is a well-known accommodation of this rule: CDDL files are kept in their own directory under `/usr/src/sys/contrib/openzfs/`, their licence header is preserved, and BSD-licensed glue code around them sits in separate files. For a device driver that structure is rarely a reasonable workflow, so the safer rule is that CDDL code is look but do not copy in the same way as GPL code.

**Proprietary sources.** Vendor SDKs, reference drivers, and sample code are usually distributed under a proprietary licence that forbids redistribution. Even when the vendor encourages you to use the code as a reference, that permission is not transferable to the FreeBSD source tree, because the vendor cannot speak for every downstream user of FreeBSD. Reading a proprietary driver to understand a device is generally acceptable to a limited extent, but you cannot paste from it, and in many jurisdictions you cannot quote from it at length either.

The practical rule is straightforward: treat anything that is not plain BSD as read-only. If you want bytes in your driver, those bytes must either come from your own typing or from a source whose licence the FreeBSD project already accepts. When you make this rule explicit in your pseudo-datasheet, by writing next to each register description where the information was observed, you create a record that will still be useful years later when a new maintainer needs to know how the file came to look the way it does.

### 36.15.3 12.3 Contractual Restrictions

Contracts can bind you in situations where copyright law does not. The three kinds of contract that come up in reverse-engineering work are non-disclosure agreements, end-user licence agreements, and firmware licences. Each of them constrains a different part of the workflow.

**Non-disclosure agreements.** Some vendors will share detailed documentation in exchange for a signed NDA. The documentation is often excellent, but the NDA typically forbids publication of the information, sometimes indefinitely, and sometimes with liquidated damages attached. Signing an NDA about a device and then writing an open-source driver for that same device is a legal minefield: every register you document in a pseudo-datasheet, every field name, every value, could be challenged later as a disclosure. The safer choice is almost always to refuse the NDA and work from publicly observable information. If you have already signed one and then want to contribute an open driver, the clean option is to recuse yourself from the observation work and let a second author build the pseudo-datasheet from scratch, using only sources you never touched under the agreement.

**End-user licence agreements.** Many vendor-supplied drivers and SDKs include an EULA that explicitly forbids reverse engineering. The enforceability of such clauses varies across jurisdictions, but the safer path is to avoid clicking "I agree" in the first place. If you only ever touched the vendor driver as a binary shipped on an

installation image, without accepting an online agreement, your position is stronger than if you signed up for a developer programme and downloaded the SDK under an agreement that forbade disassembly. Record which vendor materials you consulted and under what terms. That record becomes part of the provenance field in your pseudo-datasheet.

**Firmware licences.** Many modern devices need a binary firmware blob that the driver loads at attach time. The vendor usually distributes that blob under a redistribution licence that is more permissive than the surrounding driver code but still not fully free. FreeBSD's ports tree has a well-established pattern of packaging firmware blobs in dedicated `-firmware-kmod` ports so that the kernel code stays BSD while the blob keeps its vendor licence. You do not need to reverse-engineer the firmware itself; you need to understand how the driver hands it to the device. The legal framework for firmware is separate from the legal framework for the driver, and both have to be satisfied independently.

### 36.15.4 12.4 Clean-Room Practice

Reading a GPL driver to learn what a device does, and then writing BSD code that does the same thing, is a recognised interoperability technique. United States courts have upheld it in cases such as *Sega v. Accolade* and *Sony v. Connectix*, and Article 6 of the European Union's Software Directive (2009/24/EC) carves out reverse engineering specifically for interoperability. But the legal protection depends on how you do the work, not just on what you do. A driver that looks line-for-line like the Linux original will not be protected by the clean-room defence, because the record will show that no clean room existed.

Good clean-room practice has two elements: structural separation and structural documentation.

Structural separation means that the person who reads the other-platform driver, and the person who writes the FreeBSD driver, are different activities. On a team of two, they are literally different people. On a solo project, they are different work sessions with different artifacts. The reader's output is a pseudo-datasheet: a document in plain English that describes registers, bit fields, command sequences, and quirks, with no reference to the specific identifiers the other driver used. The writer's input is that pseudo-datasheet, plus the FreeBSD header files and driver examples. The writer never opens the other-platform driver while the FreeBSD code is being written.

Structural documentation means that the pseudo-datasheet records where each fact came from. A register description might be annotated "observed on wire with `usbdump(8)` on 2026-02-14" or "inferred from vendor datasheet section 3.4" or "deduced from Linux driver, reread into prose". That annotation is the record that would, if ever needed, support the claim that your driver was written from understanding rather than from copying. Patent and copyright cases have sometimes turned on the quality of exactly this kind of record, and maintaining it is not paranoia; it is the same discipline that keeps the rest of your engineering honest.

In practice, the time cost of clean-room discipline is small once the pseudo-datasheet habit from Section 11 is already part of your workflow. The legal value is large, because it moves you from "I hope this is not a problem" to "I can show how it was done".

### 36.15.5 12.5 Safe Harbour

It helps to know what is always safe, so that you can push the uncertain cases through the structure of this section without second-guessing every keystroke. The following activities are defensible in every jurisdiction the FreeBSD project cares about, and you can perform them without hesitation.

**Reading code is always safe.** Whatever licence the other-platform driver carries, reading it to learn how a device works is not a copyright violation. It is sometimes called fair use, sometimes called interoperability research; the label depends on the jurisdiction, but the principle is stable in every legal system that the FreeBSD project is likely to encounter.

**Observing your own hardware is always safe.** Running a device you own on a machine you own and recording what happens on the bus is not actionable under copyright, contract, or trade-secret law. The recordings you produce from `usbdump(8)`, from `pciconf(8)`, from JTAG probes, and from logic analysers are your own work, and you may describe and publish them freely.

**Writing from understanding is always safe.** If you can describe the device in your own words, in a pseudo-datasheet, you can then write a FreeBSD driver from that document without restriction. The writing is yours, derived from facts about the device rather than from the expression of another author.

**Publishing interoperability information is generally safe.** Documenting a register layout, a command sequence, or a wire protocol is publishing facts about a device, not publishing someone else's code. Even when a vendor dislikes the publication, they rarely have a legal basis to prevent it, and courts in both the United States and the European Union have consistently supported interoperability research.

Activities outside this list are not automatically unsafe, but they deserve deliberate thought. When in doubt, widen your clean room, strengthen your documentation, and ask for a second opinion on the `freebsd-hackers` mailing list or in a project chat channel before committing. The maintainers have seen these questions many times, and the cost of asking is low.

### 36.15.6 12.6 Wrapping Up Section 12

We have taken a practical second pass over the legal and ethical framework introduced in Section 1. Licence compatibility dictates what you can copy; contractual restrictions dictate what you can disclose; clean-room practice keeps interoperability research defensible; and a short list of always-safe activities gives you room to work without continuous worry. The habits are simple to adopt once the pseudo-datasheet from Section 11 is already part of your workflow, because the pseudo-datasheet is itself the audit trail of the clean room.

With this foundation in place, we are ready to look at how the FreeBSD tree itself documents reverse-engineering work. The next section presents two worked case studies, both drawn directly from the current source, where the driver authors recorded their reasoning in comments that are still readable today.

## 36.16 13. Case Studies From the FreeBSD Tree

We have now covered the techniques, the documentation discipline, and the legal framework. It is time to look at two real drivers that were written under exactly these constraints and see how their authors handled the work. Both drivers are in the FreeBSD 14.3 tree right now. Both have header comments and inline notes that record, in the author's own words, what the datasheet failed to say and what the driver does about it. Reading those comments gives you a direct view of the reverse-engineering discipline as it appears in production code, with no retouching and no retrospective polish.

### 36.16.1 13.1 How to Read These Case Studies

For each driver we will look at four things. First, a short description of the device and its history, so that you know what kind of hardware is involved and roughly when the work was done. Second, the approach the author used to work around missing documentation, including what sources were consulted and what observations were made. Third, the specific code that encodes the finding, with exact file paths, function names, and the register or constant identifiers that the driver uses today. Fourth, the ethical and legal context in which the work was done, including how the licence of each source shaped what the author was allowed to write. A closing paragraph then translates the historical method into its modern form, so that you can see how you would approach the same problem today with the techniques from earlier in this chapter.

None of the history below is speculative. Every claim is anchored in a file you can open on your own FreeBSD system, and every fact about the code is directly observable in the current source. If anything here drifts out of date in a future release, the files themselves will still be the source of truth, and the method of reading them will still apply.

### 36.16.2 13.2 Case Study 1: The umcs Driver and Its Undocumented GPIO

**Device and history.** The MosChip MCS7820 and MCS7840 are USB-to-serial bridge chips that appear in inexpensive multi-port RS-232 adapters. The MCS7820 is a two-port part, the MCS7840 is a four-port part, and the USB interface is electrically the same in both cases. The FreeBSD driver, `umcs`, was written by Lev Serebryakov in 2010 and now lives at `/usr/src/sys/dev/usb/serial/umcs.c`. The companion header, `/usr/src/sys/dev/usb/serial/umcs.h`, spells out the register layout.

**Approach.** The header comment at the top of `umcs.c` is unusually candid about the documentation situation. The author writes that the driver supports the `mos7820` and `mos7840` parts, and notes directly that the public datasheet does not contain full programming information for the chip. A full datasheet, distributed under restriction by MosChip technical support, filled in some of the gaps, and a vendor-supplied reference driver filled in the rest. The author's task was to write an original BSD driver that behaved the same way the confirmed information said it should, with the vendor driver used as an observational check rather than as a source to copy.

The cleanest place to see this discipline at work is the port-count detection inside the `attach` routine. A program that drives a USB-to-serial chip must know whether the chip has two ports or four, because the user-visible device nodes and the internal data structures depend on that count. The datasheet prescribes one method, the vendor driver uses another, and experiments on real hardware show that the datasheet's method is unreliable.

**Code.** In `/usr/src/sys/dev/usb/serial/umcs.c`, the function `umcs7840_attach` performs the detection. The inline comment records the problem in plain text, and the code records the chosen workaround. The relevant fragment reads:

```
/*
 * Documentation (full datasheet) says, that number of ports
 * is set as MCS7840_DEV_MODE_SELECT24S bit in MODE R/Only
 * register. But vendor driver uses these undocumented
 * register & bit. Experiments show, that MODE register can
 * have `0' (4 ports) bit on 2-port device, so use vendor
```

```

* driver's way.
*/
umcs7840_get_reg_sync(sc, MCS7840_DEV_REG_GPIO, &data);
if (data & MCS7840_DEV_GPIO_4PORTS) {

```

The register involved is `MCS7840_DEV_REG_GPIO`, defined at offset `0x07` in `/usr/src/sys/dev/usb/serial/umcs.h`. The header is equally candid about its status. The register block as a whole is annotated with a note explaining that the registers are documented only in the full datasheet, which can be requested from MosChip technical support, and the GPIO register specifically is commented as holding the `GPIO_0` and `GPIO_1` bits that are undocumented in the public datasheet. A longer note further down the header explains that `GPIO_0` must be grounded on two-port boards and pulled up on four-port boards, and that the convention is enforced by board designers rather than by the chip itself. The single-bit flag `MCS7840_DEV_GPIO_4PORTS`, defined as `0x01`, is what the attach routine tests against the value returned by `umcs7840_get_reg_sync`.

What makes this a good study is that the code records the story. A reader who finds the driver fifteen years after it was written can reconstruct the reasoning: the datasheet said one thing, the vendor driver did another, the real hardware was tested, and the chosen method is explained in the comment. No one has to rediscover the same dead end.

**Ethical and legal context.** The author had two classes of source available: the restricted full datasheet, which MosChip distributes on request, and the vendor reference driver, which ships with the chip evaluation kit. Both are proprietary in the sense that they are not freely redistributable, and neither can be copied into an open-source driver. What you can do is learn from them, and then write your own code against the information they contain. The `umcs` comment does exactly that. It names the behaviour the vendor driver exhibits, it names the experiment that confirmed the behaviour on real hardware, and the code it produces is original BSD-licensed prose. The copyright block at the top of the source file identifies Lev Serebryakov as the sole author. This is a textbook clean-room outcome: the driver benefits from vendor information without importing vendor code.

**Modern replication.** If you were writing `umcs` today, the workflow would be the same, with better tooling. You would capture a `usbdump(8)` trace of the vendor driver's attach sequence to see the exact GPIO read, you would run the same read on your own hardware across known two-port and four-port boards, and you would record the discrepancy between the datasheet and the observed behaviour in your pseudo-datasheet with a clear provenance line for each source. The driver would then implement the observed method, with a comment identical in spirit to the one Lev Serebryakov wrote. The technique has not changed; the tools around it have improved.

### 36.16.3 13.3 Case Study 2: The axe Driver and the Missing IPG Initialisation

**Device and history.** The ASIX AX88172 is a USB 1.1 Ethernet adapter chip, and the AX88178 and AX88772 are its USB 2.0 descendants. Cheap Ethernet dongles based on these parts have been common since the early 2000s, and the FreeBSD driver, `axe`, lives at `/usr/src/sys/dev/usb/net/if_axe.c`. The original code was written by Bill Paul between 1997 and 2003, and the AX88178 and AX88772 support was backported from OpenBSD by J. R. Oldroyd in 2007. The register header lives alongside the driver at `/usr/src/sys/dev/usb/net/if_axereg.h`.

**Approach.** The top-of-file comment block in `/usr/src/sys/dev/usb/net/if_axe.c` reads, in part, that there is information missing from the chip manual which the driver must know in order for the chip to function

at all. The author lists two specific facts. A bit must be set in the RX control register or the chip will receive no packets at all. The three inter-packet-gap registers must all be initialised, or the chip will send no packets at all. Neither of these requirements appears in the public datasheet, and both were established by reading the vendor's Linux driver and observing the chip on real hardware.

The story of the IPG registers is especially clear. Inter-packet gap is a standard Ethernet concept: the transmitter must wait a minimum number of bit times between frames, and the exact number depends on the link speed. A silicon designer has several ways to expose IPG to software, and the AX88172 chose to expose three distinct registers that the driver must write during initialisation. The datasheet names the registers but says nothing about the need to program them, so a naïve driver following only the datasheet would leave them at their reset values and find that the chip, mysteriously, refuses to transmit.

**Code.** The initialisation sequence appears inside the function `axe_init` in `/usr/src/sys/dev/usb/net/if_axe.c`. A short helper called `axe_cmd` provides the standard way to issue a vendor-specific USB control request, and `axe_init` calls it once for each IPG write. The relevant branch reads:

```
if (AXE_IS_178_FAMILY(sc)) {
 axe_cmd(sc, AXE_178_CMD_WRITE_NODEID, 0, 0, if_getlladdr(ifp));
 axe_cmd(sc, AXE_178_CMD_WRITE_IPG012, sc->sc_ipgs[2],
 (sc->sc_ipgs[1] << 8) | (sc->sc_ipgs[0]), NULL);
} else {
 axe_cmd(sc, AXE_172_CMD_WRITE_NODEID, 0, 0, if_getlladdr(ifp));
 axe_cmd(sc, AXE_172_CMD_WRITE_IPG0, 0, sc->sc_ipgs[0], NULL);
 axe_cmd(sc, AXE_172_CMD_WRITE_IPG1, 0, sc->sc_ipgs[1], NULL);
 axe_cmd(sc, AXE_172_CMD_WRITE_IPG2, 0, sc->sc_ipgs[2], NULL);
}
```

The two branches expose a second piece of reverse-engineering information that is invisible in the datasheet. On the older AX88172, each of the three IPG values is programmed as an independent command: `AXE_172_CMD_WRITE_IPG0`, `AXE_172_CMD_WRITE_IPG1`, and `AXE_172_CMD_WRITE_IPG2`, defined in `/usr/src/sys/dev/usb/net/if_axereg.h`. On the newer AX88178 and AX88772, a single command writes all three at once by packing them into the same control request: `AXE_178_CMD_WRITE_IPG012`. The two opcodes have the same numeric value; the AX88178 reused the opcode slot that the AX88172 used for writing a single IPG register, and expanded its semantics to cover all three. A driver that treated the two chip families as interchangeable would corrupt the IPG programming on one of them. The only way to distinguish the families is the macro `AXE_IS_178_FAMILY(sc)`, and the need for that macro is itself a finding of the reverse-engineering work.

**Ethical and legal context.** The `axe` driver has a long history, and its provenance is recorded in the copyright block. Bill Paul wrote the original driver against the AX88172, and the comments show that his information came from a mix of the public datasheet and observational work. J. R. Oldroyd's AX88178 support was ported from OpenBSD's sibling driver, which is BSD-licensed and directly compatible with FreeBSD. That port was legally straightforward: the code came from a permissive source tree, and the copyright block was preserved across the move. The reverse-engineering notes about IPG and RX-control were carried along with the code, so the finding itself is documented forever in the driver's header.

What did not happen is as informative as what did. The `axe` driver does not import code from the Linux `asix_usb` driver, even though that driver was available when Bill Paul was writing the FreeBSD equivalent. Linux uses

the GPL, and pasting from it would have made `axe` unshippable under the kernel's licence rules. Reading it for understanding is exactly what Bill Paul did, and the FreeBSD driver is his own writing throughout.

**Modern replication.** If you were writing `axe` today, you would start by loading the Linux driver on a Linux test machine and running `usbdump(8)` on a FreeBSD machine that shared the same USB hub, so that you could capture the vendor driver's attach sequence without needing to read a single line of GPL code. The `usbdump(8)` output would show the three IPG writes directly, because they travel on the wire as visible USB control transfers. You would record the observation in your pseudo-datasheet, cite the packet-capture file for provenance, and implement the writes in your own driver. The comment above `axe_init` would read very much like the one Bill Paul originally wrote.

### 36.16.4 13.4 Shared Lessons

Reading the two drivers together surfaces a handful of lessons that are worth naming explicitly.

**The comment is the audit trail.** In both `umcs` and `axe`, the header and inline comments are the place where the reverse-engineering story is preserved. Without those comments, a future maintainer staring at `MCS7840_DEV_REG_GPIO` or at `AXE_178_CMD_WRITE_IPG012` would have no way to know where the information came from or why the driver does what it does. In both cases the author took the extra minute to write down the reasoning, and the result is a driver that remains maintainable fifteen or twenty years after it was written. The author's pseudo-datasheet, in each case, was partly absorbed into the comments and partly preserved in the structure of the header file. That absorption is what makes the code readable today.

**Observation wins over documentation.** Both drivers trust observation over the datasheet when the two disagree. `umcs` trusts the experimentally verified GPIO read over the datasheet's MODE-register method, and `axe` trusts the observation that the chip refuses to transmit without IPG programming over the datasheet's silence on the subject. This is not a rejection of documentation; both authors read the datasheets carefully. It is a recognition that a datasheet is a description of the intended behaviour, and the chip's actual behaviour is what the driver has to match.

**Licence discipline is not an afterthought.** Both drivers respect the licence of the sources they drew on. `umcs` uses a proprietary reference driver as an observational check without copying from it. `axe` imports AX88178 and AX88772 support from OpenBSD, which is licence-compatible, and stays clear of the Linux `asix_usb` driver, which is not. Neither driver includes code that the FreeBSD project would have had to strip out during review, and neither needed a lawyer's review before it was committed. The habits from Section 12 were already part of how the authors worked.

**The work is reproducible.** Everything both drivers did can be reproduced today with modern tools. `usbdump(8)`, `usbconfig(8)`, and the bus-space tracing techniques from earlier in the chapter would give you the same information that the original authors had to gather by hand, and the pseudo-datasheet habit from Section 11 would give you a cleaner audit trail than a set of inline comments. The drivers you write for obscure hardware today will be better documented than the drivers from 2007 and 2010, because the techniques have matured. The spirit of the work, however, is the same.

### 36.16.5 13.5 Wrapping Up Section 13

Two case studies have shown what a disciplined reverse-engineering effort looks like when it has been absorbed into the FreeBSD tree. In both cases the author identified a specific gap in the public documentation, confirmed

the correct behaviour through observation, recorded the finding in a comment that is still readable today, and wrote original code under a licence compatible with FreeBSD. The drivers work, the code is maintainable, and the legal record is clean.

With the legal framework from Section 12 and the worked examples from Section 13 in place, you now have both the principles and a set of precedents to draw on. The remaining sections of the chapter give you hands-on practice with the techniques that the case studies illustrate, challenge exercises to push your understanding further, troubleshooting notes for the common ways the work can go wrong, and a closing bridge to Chapter 37.

## 36.17 Hands-On Labs

The labs in this chapter give you safe, repeatable practice with the techniques the chapter has covered. None of them touches real unknown hardware in a way that could damage anything; the “unknown device” in the labs is either a software mock or a benign region of memory that you control. Treat each lab as a chance to internalise one specific technique before adding it to your kit.

The companion code lives in `examples/part-07/ch36-reverse-engineering/`. Each lab subfolder has its own `README.md` with step-by-step instructions, and the code is organised so that you can build and run each lab independently of the others. As with earlier chapters, type the code yourself the first time you work through a lab; the companion files are there as a reference and as a known-good version to compare against.

### 36.17.1 Lab 1: Identifying a Device and Dumping Descriptors

This lab is the simplest possible reverse-engineering exercise. You will use `pciconf(8)` and `usbconfig(8)` to enumerate every device on your FreeBSD system and to dump the static descriptors of one device of your choice. The output of the lab is a small text file that records, for one specific device, every public fact that the kernel can tell you about it.

Steps:

1. Run `sudo pciconf -lvc` and save the output. Note any device that appears as `noneN@...`, indicating that no in-tree driver has claimed it.
2. Run `sudo usbconfig` and save the output. Pick one USB device that you understand (a USB stick, for example) and that you own physically.
3. Run `sudo usbconfig -d ugen0.X dump_device_desc` and `sudo usbconfig -d ugen0.X dump_curr_config_desc` for the chosen device, where `ugen0.X` is the device’s `usbconfig` identifier.
4. Open the captured output and identify each field: `bDeviceClass`, `idVendor`, `idProduct`, `bMaxPacketSize0`, `bNumConfigurations`, the endpoint descriptors, and so on.
5. Write a one-page summary identifying the device’s identity, its class, its endpoints, and any notable features.

The lab is intentionally easy. The point is to internalise the shape of the static-identity capture before applying it to a device whose identity is genuinely unknown.

### 36.17.2 Lab 2: Capturing a USB Initialization Sequence

This lab moves from static identity to dynamic behaviour. You will use `usbdump(8)` to capture the initialisation sequence of a USB device, save the capture, and explore it in Wireshark.

Steps:

1. Identify a USB device that you can attach and detach freely (a USB stick is a good choice, because you can unplug and replug it without consequence).
2. Run `sudo usbdump -i usb0 -w stick-init.pcap` to start capturing on the USB bus the device is attached to. Use the correct bus number for your system; `usbconfig` will tell you which bus the device is on.
3. With `usbdump` running, plug in the device. Wait for it to be recognised by the kernel. Then unplug it.
4. Stop `usbdump` with Control-C.
5. Open the resulting pcap file in Wireshark. You should see a series of USB transfers corresponding to enumeration: the `GET_DESCRIPTOR` requests for the device, configuration, and string descriptors, the `SET_ADDRESS` request, the `SET_CONFIGURATION` request, and so on.
6. Identify each transfer and write down what it does. Compare the captured device descriptor against the output of `usbconfig dump_device_desc` from Lab 1; they should match field for field.

This lab is the foundation of all USB reverse engineering. Every USB device you ever investigate will go through an enumeration sequence at attach time, and being able to read the enumeration sequence is the entry point to understanding what the device is doing.

### 36.17.3 Lab 3: Building a Safe Register Probing Module

This lab introduces the kernel-side tool that you will use for register-map work in real projects. You will build a small kernel module called `regprobe` that allocates a memory resource on a device of your choosing and exposes a `sysctl` that dumps the contents of the resource. No writes are performed.

Steps:

1. Build the `regprobe` module from `examples/part-07/ch36-reverse-engineering/lab03-register-map/`.
2. Identify a PCI device on your system that you do not need for anything else. A spare network card or any unused PCI device is ideal. (Do not use the device that backs your console or your storage.)
3. Detach the in-tree driver from the device with `sudo devctl detach <device>`.
4. Use the operating procedures in the lab's README to attach `regprobe` to the device.
5. Read the dump `sysctl` multiple times, with a few seconds between each read. Compare the dumps and identify which words are stable and which words are changing.
6. Reattach the in-tree driver with `sudo devctl attach <device>`.

The lab demonstrates two things: that a read-only probe is safe, and that even a read-only probe can reveal interesting structure in a device's register space. The dynamic words are most likely counters or status registers; the stable words are most likely configuration registers or identifiers.

### 36.17.4 Lab 4: Writing and Driving a Mock Device

This lab introduces the simulation side of the workflow. You will build a small kernel module that simulates a tiny “command and status” device entirely in software, and a small user-space test program that drives the simulated device through its sysctls.

Steps:

1. Build the mockdev module from `examples/part-07/ch36-reverse-engineering/lab04-mock-device/`.
2. Load the module with `sudo kldload ./mockdev.ko`.
3. Use the test program (also in the lab folder) to send a few commands to the mock device.
4. Observe the kernel log to see the commands being processed and the simulated status updates.
5. Modify the mock device to introduce a deliberate error: have it report failure for one specific command code. Verify that the test program detects the failure correctly.
6. Modify the test program to use a watchdog: if the mock device does not complete a command within a timeout, the program should report a failure rather than hanging.

The lab teaches the structure of mock-based testing in a setting where the mock is small enough to understand fully. In real projects, mocks become more complex, but the structure is the same.

### 36.17.5 Lab 5: Building a Safe Probing Wrapper

This lab consolidates the safety techniques from Section 10. You will build a small library of safe probing wrappers (read-modify- write-verify, timeout-protected operations, automatic recovery on failure) and use them to perform an experiment on the mock device from Lab 4.

Steps:

1. Open the safeprobe lab folder.
2. Read the wrapper library carefully. Notice how each operation is protected by a timeout, how each register write is followed by a readback, and how failures are reported clearly.
3. Build the wrapper library and the example driver that uses it.
4. Load the mock device from Lab 4.
5. Run the example driver against the mock device. Observe how the wrappers report the operations they perform.
6. Modify the mock device to inject a failure (an unexpected readback value, for example). Verify that the wrappers detect the failure and report it clearly, rather than letting the driver continue with corrupt state.

This lab teaches the safety wrappers as a tool you can apply to your own drivers. The cost of using them is small; the information they produce when something goes wrong is large.

### 36.17.6 Lab 6: Writing a Pseudo-Datasheet

This lab is the documentation-side equivalent of the technique labs. You will take the mock device from Lab 4 and write a pseudo-datasheet for it, following the structure from Section 11.

Steps:

1. Open the pseudo-datasheet template in `examples/part-07/ch36-reverse-engineering/lab06-pseudo-datasheet/`.
2. Read the template carefully and understand the structure.
3. Examine the mock device's source code to learn its register layout, command set, and behaviour.
4. Fill in the template with the mock device's information, following the structure: identity, provenance, resources, register map, buffer layouts, command interface, initialisation, operating patterns, quirks, open questions, references.
5. Save the result as a Markdown file alongside the mock device's source.

The mock device is small enough that the pseudo-datasheet can be complete in an hour or two. The exercise teaches you the structure of the document and the level of detail that each section deserves. When you later write a pseudo-datasheet for a real device, you will already know how to organise the information, even though the information itself will be much more extensive.

## 36.18 Challenge Exercises

The challenge exercises stretch the techniques from the labs into larger, more open-ended investigations. None of them requires exotic hardware; they all use either real common devices or the mock devices from the labs. Take your time with them. The labs have given you the techniques; the challenges give you the practice of applying them in less guided settings.

### 36.18.1 Challenge 1: Triage an Unknown Capture

The companion files include a small set of pcap captures of an unknown device's USB traffic. Open the captures in Wireshark. By analysis alone, identify:

- The device's vendor and product identifiers.
- The device class (HID, mass storage, vendor-specific, and so on).
- The device's endpoint layout (which endpoints, of which types, in which directions).
- The general shape of the device's data flow (does it appear to use bulk transfers, control transfers, interrupt transfers).
- Any obvious patterns in the data (periodic transfers, command and response, continuous streaming).

Write a one-paragraph summary of what kind of device the captures came from and what protocol it appears to use. The captures are labelled with the answer in a file you should not look at until you have written your own answer; compare and reflect.

### 36.18.2 Challenge 2: Extend the Mock Device

Take the mock device from Lab 4 and extend it to support a multi-byte data transfer through a small ring buffer. The ring buffer should have a producer pointer that the mock advances when data is “produced” (you can simulate this with a callout that generates synthetic data at a fixed rate), a consumer pointer that the driver advances when data is consumed, and a “queue size” register that the driver can read to learn the ring's capacity.

Write a small driver that:

1. Identifies the mock device.
2. Reads the queue-size register to learn the ring capacity.
3. Periodically reads the producer pointer to learn how many new entries are available.
4. Reads each new entry and prints it to the kernel log.
5. Updates the consumer pointer after processing each entry.

The exercise practises the ring-buffer-recognition skill from Section 5 in a setting where you control both sides. The challenge is to write the driver so that it correctly handles both the empty-ring case (no new entries) and the full-ring case (more entries than the driver has consumed).

### 36.18.3 Challenge 3: Detect Device Identity From Behaviour Alone

The mock device from Lab 4 has, in its companion code, a “mystery mode” that disables the identifier register and changes some of its behaviour to disguise its identity. Without reading the mock device’s source code, write a small driver that:

1. Probes the mystery-mode mock device.
2. Performs a series of safe register reads.
3. Observes the device’s response to a small set of test operations.
4. Identifies which of three known device identities the mock matches, based purely on the observed behaviour.

The challenge teaches the higher-level skill of fingerprinting a device from behaviour rather than from explicit identifiers. Real devices sometimes hide their identity for compatibility reasons (presenting themselves as a more common chip), and identifying them by behaviour is the only way to support them correctly.

### 36.18.4 Challenge 4: Document a Device You Own

Pick a piece of USB hardware that you own and that does not have particularly sensitive functionality. A USB game controller, a webcam, a USB-to-serial adapter, a USB Wi-Fi adapter. Write a pseudo-datasheet for it, using only what you can learn through `usbconfig`, `usbdump`, and Wireshark.

The challenge requires you to apply, in sequence, every technique from the chapter: identification, capture, observation, hypothesis, documentation. The result is a real artifact: a pseudo-datasheet for a real device. Many such pseudo-datasheets have grown into community projects that produced production drivers; yours might be the next one.

## 36.19 Hands-On Exercise: Your Own Observation

The labs have given you controlled practice against software mocks and known-good devices, and the challenges have asked you to apply those techniques to slightly less structured targets. The case studies in Section 13 walked you through reverse engineering work that has long since been absorbed into the FreeBSD tree. What none of those has asked you to do is to sit down with a device of your own choosing, observe it cold, map what you see onto interface and endpoint structures, and sketch the beginning of a driver from scratch. That is what this exercise does, and it is the closest this chapter can bring you to the work the umcs and axe authors did at the start of their projects.

Treat the exercise as a capstone rather than another lab. It does not introduce a new technique; it asks you to combine the techniques you have already practised into a single self-directed session, using a device you physically own and tools from the FreeBSD base system. The goal is not a shippable driver. The goal is a faithful short record of what you observed, a skeleton file that compiles and attaches cleanly, and a list of the questions your observation did not answer. If you finish with those three artefacts, the exercise has worked as intended.

### 36.19.1 Before You Start: The Ethical Gate

Because this exercise touches a real device that you own, the legal and ethical framework from Sections 1 and 12 applies to it directly, and it applies before the first command runs. Work through the short checklist below, in order. Do not proceed until every item has a clear answer.

1. **Pick a device you own outright.** The exercise is not a licence to probe equipment you have borrowed, rented, or been granted limited access to. The device must be yours, and it must be a device you are willing to see briefly misbehave under observation. A working rule is that if you would not feel comfortable unplugging the device in the middle of normal operation, it is not a good candidate for this exercise.
2. **Pick a device whose firmware and protocol are not vendor-protected.** Good targets are simple class-compliant USB devices that implement an open specification. A USB HID keyboard or mouse, a USB-to-serial adapter built around a commodity chip, a class-compliant USB audio interface, or a small USB-attached LED enclosure with a straightforward vendor-specific protocol are all reasonable choices. Rule out anything whose firmware is known to be DRM-encumbered, anything whose protocol is covered by a non-disclosure agreement that you have signed, and anything whose vendor driver ships under an end-user licence that specifically forbids the kind of observation described here. When a device is ambiguous, set it aside and pick something else. The exercise is about technique, not about probing any specific piece of hardware.
3. **Observe only, do not import.** Everything the walkthrough asks you to do is passive observation of traffic on a bus you control, followed by writing your own code against your own notes. That stays firmly inside the clean-room framework from Section 12. The moment you move from observation to copying vendor firmware, pasting vendor driver source, or redistributing a binary blob you did not author, you leave that framework and enter a space where the answer depends on the licence of the specific material. Do not cross that line inside the exercise. If you later want to carry the work toward a real driver, revisit Sections 9 and 12 and work through the licensing questions carefully before you do.
4. **Defer to the chapter's existing guardrails.** The discipline described in Sections 1 and 12 is the authoritative framework for this project. If any step below appears to conflict with those sections, treat the sections as correct and narrow the step, not the other way around. The walkthrough here is a concrete application of that framework, not an exception to it.

With those four items settled, the observation can begin. The rest of the exercise assumes that all four are cleared; if any of them is uncertain, close this section and choose a different device.

### 36.19.2 Step 1: Initial Identification With `usbconfig(8)`

Attach the target device to your FreeBSD host and confirm that the kernel has enumerated it:

```
$ sudo usbconfig list
ugen0.1: <0x1022 XHCI root HUB> at usb0, cfg=0 md=HOST spd=SUPER (5.0Gbps) pwr=SAVE
↳ (0mA)
ugen0.2: <Example device Example vendor> at usb0, cfg=0 md=HOST spd=FULL (12Mbps)
↳ pwr=ON (100mA)
```

Note the `ugenB.D` coordinate of your device. That coordinate is how every later `usbconfig` command will address it.

Next, check which FreeBSD driver, if any, has claimed an interface on the device:

```
$ sudo usbconfig -d ugen0.2 show_ifdrv
```

If a kernel driver already owns the interface, the output names it. A device whose interface is claimed by an existing driver will still respond to read-only descriptor queries, but you should not run your own experimental code against it until you have detached the existing driver with `devctl detach`. For a first pass, pick a device whose interface is either unclaimed or whose claiming driver you are willing to detach.

Finally, dump the full descriptor tree and save it for later:

```
$ sudo usbconfig -d ugen0.2 dump_all_desc > device-descriptors.txt
```

The output lists the device descriptor, each configuration descriptor, each interface descriptor, and each endpoint descriptor. You will compare this file against your packet capture in Step 3, and you will use it as the raw material for the short pseudo-datasheet fragment at the end of the exercise.

### 36.19.3 Step 2: Packet-Level Observation With `usbdump(8)`

Descriptors tell you what the device advertises about itself. To see what the device actually does, capture the USB bus while the device is used:

```
$ sudo usbdump -i usb0 -s 2048 -w trace.pcap
```

The `-i usb0` argument selects the USB bus to listen on; use the bus number your device is attached to, as reported by `usbconfig list`. The `-s 2048` argument caps each captured payload at 2048 bytes, which is comfortably above the maximum packet size of any full-speed or high-speed endpoint you are likely to encounter in this exercise. The `-w trace.pcap` argument writes a binary pcap file that Wireshark can open and dissect with the built-in USB dissector.

With `usbdump` running, exercise the device. For an HID keyboard, press a few keys. For a USB-to-serial adapter, open the port from another tool and send a handful of bytes in each direction. For a USB LED enclosure, cycle the LED through its supported states. Each action produces USB transfers on the bus, and every transfer ends up in the capture.

Stop `usbdump` with Control-C. A human-readable text record is also useful while you are annotating transfers by hand, so re-run the capture once with output redirected to a text file:

```
$ sudo usbdump -i usb0 -s 2048 > trace.txt
```

Keep both versions. The text form is easier to read line by line and to annotate in a plain editor; the pcap form is easier to navigate in Wireshark when you want to follow a specific flow.

### 36.19.4 Step 3: Map Descriptors to Interface and Endpoint Structures

Open `device-descriptors.txt` alongside `trace.txt`. Work through the descriptor dump and, for each interface descriptor, write down:

- The device or interface class (`bInterfaceClass`), subclass (`bInterfaceSubClass`), and protocol (`bInterfaceProtocol`). Standard values are tabulated in the USB class specifications: HID is class `0x03`, mass storage is class `0x08`, communications device class is `0x02`, audio is class `0x01`, and vendor-specific is class `0xFF`, among others.
- Each endpoint's address (`bEndpointAddress`), direction (the high bit of the address: set means IN, clear means OUT), and transfer type (the low two bits of `bmAttributes`: 0 control, 1 isochronous, 2 bulk, 3 interrupt).
- Each endpoint's maximum packet size (`wMaxPacketSize`).

Simple devices typically expose one interface with a small number of endpoints. A USB HID keyboard commonly has a single interrupt IN endpoint that the host polls for key-state reports. A USB-to-serial adapter commonly has a bulk IN endpoint for data from the device, a bulk OUT endpoint for data to the device, and uses the control endpoint for line-state commands.

Cross-check what you wrote down against the capture. Each endpoint address you recorded in the descriptor dump should appear in `trace.txt` as the source or destination of at least one transfer. Each transfer type you recorded (bulk, interrupt, control) should appear in the capture in the direction you expect. If the two disagree, look again before you sketch any driver code; one of the two observations is wrong and you want to find out which.

### 36.19.5 Step 4: Sketch a Newbus-Style Driver Skeleton

With the device's identity, interfaces, and endpoints in hand, you can sketch the outline of a driver that would attach to it. The sketch is not a runnable driver. It is the scaffold into which you would later drop real transfer setup, real data handling, and real error handling. The point of producing it now is to confirm that your observations are consistent enough to support a driver shape at all.

Choose a short, lowercase Newbus identifier. The convention in the FreeBSD USB tree is a brief lowercase string that echoes either the chip family or the device function: `umcs` for the MosChip serial bridge, `axe` for the ASIX Ethernet chip, `uftdi` for FTDI adapters, `ukbd` for USB HID keyboards. Pick something that does not collide with any name already in `/usr/src/sys/dev/usb/`. Your local sketch can use a placeholder such as `myusb` until you commit to a real name.

The skeleton below is the minimum a USB driver needs, and it is also what you will find in the companion file `skeleton-template.c`:

```
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/bus.h>

#include <dev/usb/usb.h>
#include <dev/usb/usbdi.h>

/* TODO: replace with the VID/PID you observed in Step 1. */
static const STRUCT_USB_HOST_ID myusb_devs[] = {
 { USB_VP(0x0000 /* VID */, 0x0000 /* PID */) },
};

static device_probe_t myusb_probe;
static device_attach_t myusb_attach;
static device_detach_t myusb_detach;

static int
myusb_probe(device_t dev)
{
 struct usb_attach_arg *uaa = device_get_ivars(dev);

 if (uaa->usb_mode != USB_MODE_HOST)
 return (ENXIO);

 return (usbdi_lookup_id_by_uaa(myusb_devs,
 sizeof(myusb_devs), uaa));
}

static int
myusb_attach(device_t dev)
{
 /* TODO: allocate the endpoints you catalogued in Step 3. */
 /* TODO: set up the usb_config entries that match them. */
 device_printf(dev, "attached\n");
 return (0);
}

static int
myusb_detach(device_t dev)
{
 /* TODO: unwind whatever attach allocated, in reverse order. */
 device_printf(dev, "detached\n");
}
```

```

 return (0);
}

static device_method_t myusb_methods[] = {
 DEVMETHOD(device_probe, myusb_probe),
 DEVMETHOD(device_attach, myusb_attach),
 DEVMETHOD(device_detach, myusb_detach),
 DEVMETHOD_END
};

static driver_t myusb_driver = {
 .name = "myusb",
 .methods = myusb_methods,
 .size = 0,
};

DRIVER_MODULE(myusb, uhub, myusb_driver, NULL, NULL);
MODULE_DEPEND(myusb, usb, 1, 1, 1);
MODULE_VERSION(myusb, 1);

```

The TODO markers show where the observations from Steps 1 through 3 feed into the driver. The vendor and product identifiers come straight from the device descriptor you saved. The endpoint allocation and transfer setup inside `myusb_attach` mirror the endpoints you catalogued. In the full form of the driver, each endpoint becomes an entry in a struct `usb_config` array whose `.type` and `.direction` fields record what you observed: a bulk IN endpoint uses `.type = UE_BULK` and `.direction = UE_DIR_IN`, an interrupt IN endpoint uses `.type = UE_INTERRUPT` and `.direction = UE_DIR_IN`, and so on. Existing drivers in `/usr/src/sys/dev/usb/` are full of examples of the pattern; `/usr/src/sys/dev/usb/serial/umcs.c` and `/usr/src/sys/dev/usb/serial/uftdi.c` are both reasonable references.

Do not try to fill in the transfer bodies yet. The goal at this stage is a skeleton that compiles, loads, and attaches to your device, and that prints a short message when it attaches and another when it detaches. If the skeleton does those three things cleanly, your observations were consistent. If it panics, refuses to attach, or prints nonsense, the fault is almost always in the descriptor mapping rather than in the skeleton itself; go back to Step 3 and check the IN/OUT directions and the transfer types before touching the code.

### 36.19.6 Step 5: Write Down What You Learned

Close the exercise by producing two short written artefacts to keep alongside the descriptor dump, the trace file, and the driver skeleton:

1. A **pseudo-datasheet fragment**, following the structure from Section 11. Identify the device, list its class and subclass, list its endpoints with their transfer types, directions, and maximum packet sizes, and note any behaviour you observed in the capture that surprised you. Keep the fragment short. The goal is to have something you could hand to a collaborator if the two of you wanted to pick the work up later.

2. A **list of open questions** you could not answer from observation alone. Every honest reverse engineering session ends with open questions, and writing them down is how you avoid pretending to know things you do not. Typical entries include a vendor-specific control request whose purpose is unclear, a block of bytes inside a bulk transfer whose layout is not obvious, or a descriptor field whose meaning depends on a device state you have not yet seen.

These two artefacts, together with `device-descriptors.txt`, `trace.pcap`, `trace.txt`, and `skeleton-template.c`, make up the output of the exercise. They are, at a smaller scale, the same kind of output the `umcs` and `axe` authors would have produced at the start of their own projects.

### 36.19.7 A Closing Reminder on Scope

Everything this exercise has asked you to do is passive observation of traffic on your own bus, followed by writing your own code against your own notes. That sits squarely inside the clean-room tradition the chapter has described. If, after working through the steps, you want to carry the work further toward a shippable driver, stop and re-read Sections 9, 11, and 12 before the next session. The techniques scale, but the legal and ethical framework scales with them, and it is easier to apply early than to unwind a commit later. The companion folder for this exercise, at `examples/part-07/ch36-reverse-engineering/exercise-your-own/`, collects a template walkthrough script, a skeleton source file with the `TODO` markers shown above, and a short `README` that gathers the safety notes in one place.

## 36.20 Common Mistakes and Troubleshooting

Reverse engineering has a small set of mistakes that nearly everyone makes early on, and an equally small set of mistakes that, even with experience, are easy to slip into. Recognising them in advance shortens the painful learning curve significantly.

### 36.20.1 Mistake 1: Believing the First Hypothesis

The most common mistake is to form a hypothesis early, then to interpret every subsequent observation as supporting the hypothesis, even when a more careful reading would suggest a different explanation. Confirmation bias is human, and it is particularly dangerous in reverse engineering because the observations are noisy and the hypothesis space is large.

The defence is the discipline of writing down each hypothesis explicitly, designing a test that could falsify it, running the test, and accepting the result honestly. If the test does not falsify the hypothesis, the hypothesis survives, but it is not yet “proven”; it is only “not yet refuted”. The next test might still kill it.

### 36.20.2 Mistake 2: Skipping the Notebook

The second most common mistake is to skip the notebook because the keyboard is faster. The notebook feels like overhead. The results, in the moment, seem clear. The patterns are obvious. There is no need to write them down, because they will be remembered.

A week later, the patterns are not obvious. Another week later, they are forgotten. A month later, the project has stalled because nobody, including the author, can reconstruct what was known. The notebook is what would have prevented this. Skip it at your peril.

### **36.20.3 Mistake 3: Writing to Unknown Registers**

The third common mistake is to write to a register without sufficient evidence that the write is safe. The temptation is strong: you have a hypothesis, you want to test it, the test involves a write, and what is the worst that could happen? Section 10 has spelled out what can happen, but it is worth repeating here. Devices can be permanently damaged by careless writes, and the people who learn this from experience usually learn it expensively.

The defence is the discipline of evidence-before-write. Before performing a write, name the source of evidence that the write is safe. If you cannot name a source, do not perform the write.

### **36.20.4 Mistake 4: Treating the Vendor Driver as Complete**

A fourth common mistake is to assume that the vendor's driver implements the full functionality of the device, and that matching the vendor's driver is sufficient to support the device fully. This is often wrong. Vendor drivers sometimes implement only the subset of device functionality that the vendor's products use; the full device may have features that the vendor's driver never exercises. Conversely, the vendor's driver sometimes contains workarounds for hardware bugs that you would not need if you implemented the operations differently.

The defence is to read the vendor's driver as one source of information among many, with the understanding that it represents the vendor's choices, not the complete description of the device.

### **36.20.5 Mistake 5: Not Testing the Detach Path**

A fifth common mistake is to focus on the attach path, where visible progress is made, and to neglect the detach path. The result is a driver that loads and works, but cannot be unloaded cleanly. Each test cycle then requires a reboot, which slows the work down by an order of magnitude.

The defence is to write the detach path early, test it in every build, and treat unload-time panics as serious bugs that block further work. A driver that cannot be unloaded is, for practical purposes, a driver that requires a reboot to test changes, and that is not a productive way to work.

### **36.20.6 Mistake 6: Not Saving Captures**

A sixth mistake is to throw away captures because they "did not show anything new". They might not show anything new today. They might show something important six weeks from now, when you have learned enough to interpret them. Save every capture. Storage is cheap. The captures themselves are part of the project's history, and they are sometimes the only way to reconstruct what was known at a given point.

### **36.20.7 Mistake 7: Working Alone**

A seventh mistake, particularly common in beginners, is to work alone. Reverse engineering is much faster when there is at least one other person to talk to about the work, even if that person is not also a reverse engineer.

The act of explaining what you have observed, what you believe, and what you are about to test forces clarity on the explanation, and clarity is what makes the work go forward.

If you do not have a colleague who is interested, find a community that is. The mailing lists, IRC channels, and forums for the device's family are full of people who understand the issues and can sometimes provide the missing piece. The community-collaboration side of Section 9 is not just about consuming prior work; it is also about contributing to a discussion that helps everyone involved.

### 36.20.8 Troubleshooting: When the Driver Silently Does Nothing

Sometimes the driver loads, the device appears to attach, the log says everything is fine, but no expected behaviour occurs. The most common causes:

- The driver thinks it has set up an interrupt handler, but the interrupt is not actually being delivered. Check `vmstat -i` to see whether interrupts are arriving. If not, the interrupt setup is wrong.
- The driver is reading the wrong register and seeing what looks like a legitimate value. Compare against the `pciconf -r` or `regprobe` output to verify that the values you are reading match the values present in the device.
- The driver is using the wrong endianness for multi-byte values. This is particularly common when reading values that look like integers but are actually byte strings.
- The driver has a bug in its sequence: it performed step B before step A, or it skipped a required step entirely.

The defence in each case is comparison against a known reference: the captures from Section 3, the `regprobe` dump, the working vendor driver. When the driver does not behave as expected, the question is: where does its behaviour first diverge from the reference?

### 36.20.9 Troubleshooting: When the Driver Panics on Unload

A panic on unload usually indicates that the driver freed something prematurely or kept a reference to something the kernel has destroyed.

The most common causes:

- A callout was not drained before the softc was freed. Check that every `callout_init` is matched by `callout_drain` in the detach path.
- A taskqueue task was still pending when the taskqueue was destroyed. Check that every `taskqueue_enqueue` is matched by `taskqueue_drain` in the detach path.
- An interrupt handler was not torn down before the IRQ resource was released. The order matters: tear down the handler with `bus_tear_down_intr`, then release the resource with `bus_release_resource`.
- A character device node was not destroyed before the softc was freed. Use `destroy_dev_drain` if there is any chance the device might still be open.

These are the same patterns we discussed in Chapter 35 for asynchronous drivers; reverse-engineered drivers face the same issues, with the additional complication that you may not yet fully understand which resources are in use at unload time.

### 36.20.10 Troubleshooting: When Behaviour Differs Between Runs

Sometimes the device behaves differently from one run to the next, even though nothing has changed in the driver. The causes are usually one of:

- The device contains state that is not reset between runs. Investigate what the device's reset actually clears, and what it leaves alone.
- The driver has a race condition that produces different outcomes depending on timing.
- The device is sensitive to environmental conditions (temperature, voltage) that vary slightly between runs.
- A second driver, or a userland program, is also accessing the device and interfering with your investigation.

Distinguishing these causes requires careful, repeated runs with each variable controlled. Reverse engineering against a device whose behaviour is not deterministic is significantly harder than the deterministic case, and identifying the source of the non-determinism is itself part of the work.

## 36.21 Wrapping Up

Reverse engineering is a craft built on patience, discipline, and careful documentation. The chapter has walked through the entire process: why this work is sometimes necessary, where the legal lines fall, how to set up the lab, how to observe systematically, how to build a register map, how to identify buffer structures, how to write a minimal driver and grow it incrementally, how to validate assumptions in simulation, how to collaborate with the community, how to avoid damaging hardware, and how to consolidate the result into a maintainable driver and a usable pseudo-datasheet.

The techniques are concrete. The discipline is what holds them together. A reverse engineer who follows the discipline will, in time, be able to take an undocumented device and produce a working driver for it. A reverse engineer who skips the discipline will produce code that works some of the time, that fails for reasons that are hard to diagnose, and that cannot be maintained or extended without rediscovering everything that was forgotten the first time around.

Several themes have run through the chapter and deserve a final explicit summary.

The first theme is the separation of observation from hypothesis from verified fact. An observation is what you saw. A hypothesis is what you think it means. A verified fact is a hypothesis that has survived deliberate attempts to falsify it. Mixing the three together produces confusion; keeping them separate produces clarity. The notebook discipline that the chapter has emphasised is, at root, the discipline of keeping these three categories distinct.

The second theme is the value of starting small. A minimal driver that does one thing correctly is a better foundation than a large driver that does many things uncertainly. Each new feature added incrementally, with verification, is far cheaper to get right than a large multi-feature change. The pace of work in reverse engineering should always feel slower than the pace of work in normal driver development; the slowness is what catches the bugs that would otherwise survive into the final code.

The third theme is the centrality of safety. Reverse engineering is one of the few software activities where careless mistakes can permanently damage real hardware. The safety techniques of Section 10, the simulation techniques of Section 8, and the read-first principle of Section 4 are all manifestations of the same underlying

principle: respect the unknown, and earn the right to perform an operation by accumulating evidence that the operation is safe.

The fourth theme is the importance of documentation. The pseudo-datasheet, the notebook, the manual page, the comments in the code: these are not afterthoughts, they are part of the output of the work. A driver without documentation is a driver that nobody can maintain, including its author six months from now. A pseudo-datasheet that records what was learned is the artifact that gives the work durability beyond the author's involvement.

The fifth theme is community. Reverse engineering is rarely truly solitary work. Prior work exists for almost every device worth investigating; new work, when done well, contributes to the ongoing community knowledge. Searching, evaluating, and contributing are part of the craft. A reverse engineer who works in isolation reinvents wheels; a reverse engineer who engages with the community builds on others and is built upon in turn.

You have now seen the entire shape of the work. The techniques are within reach. The discipline takes practice. The first serious project will be slow and full of mistakes; the second will be faster; by the third or fourth, the rhythm will start to feel natural. The labs in this chapter are the beginning of that practice, and the challenge exercises are the next step. Real projects on real devices are where the skills consolidate, and the FreeBSD community has plenty of devices that would benefit from someone willing to do the work.

Take a moment to appreciate what has changed in your toolkit. Before this chapter, an undocumented device was a stop sign. Now it is a project. The methods you have learned are the same methods that the authors of many drivers in `/usr/src/sys/dev/` used to bring those drivers into existence. Some of them worked alone, others in small groups, but all of them followed recognisably the same workflow: observe, hypothesize, test, document. You now know how to do that work.

## 36.22 Bridge to Chapter 37: Submitting Your Driver to the FreeBSD Project

The driver you have just learned to build, whether it implements a fully reverse-engineered device or some more conventional piece of hardware, is most useful when other people can find it, build it, and rely on it. So far we have treated the driver as a private project, something you load on your own systems and document for your own future reference. The next chapter changes that: we will see how to take a finished driver and offer it for inclusion in the FreeBSD source tree itself.

The shift is significant. A driver in your private repository serves you and anyone who happens to find your repository. A driver in the FreeBSD source tree is built by every FreeBSD release, exposed to every FreeBSD user, maintained by the FreeBSD project, and tested by every commit that touches the surrounding code. The amplification of value is enormous, and so are the responsibilities that come with it. The submission process is FreeBSD's mechanism for ensuring that the driver meets the standards of the source tree before it is allowed in.

Chapter 37 walks through that process. We will look at the FreeBSD development model: the difference between a contributor and a committer, the role of the source-tree organisation, the review process, and the conventions that the FreeBSD source tree enforces. We will learn the style guidelines (`style(9)` for code and `style(4)` for manual pages, with a few related conventions for makefiles, headers, and naming), how to structure your driver's files for inclusion in `/usr/src/sys/dev/`, how to write the manual page that every driver should ship with, and how to write commit messages in the form FreeBSD expects.

We will also look at the social dynamics of contribution: how to engage with reviewers, how to respond to feedback, how to iterate on a patch series, and how to participate in the project in a way that builds long-term

reputation. The technical side of the submission process is straightforward; the social side is where most first-time contributors find the surprises.

Several themes from this chapter will carry forward. The clean detach path is essential, because reviewers will check it. The safety wrappers and conservative behaviour from Section 10 are the same disciplines that production-grade drivers exhibit, and they will be appreciated by reviewers. The pseudo-datasheet is not part of the submission, but the understanding it represents is what justifies the driver's claims and what lets reviewers trust the implementation. The community engagement from Section 9 is the foundation of the longer-term relationship the contribution is intended to build.

The reverse-engineered driver is a particularly interesting case for FreeBSD inclusion, because the project has long-standing experience with such drivers and well-developed processes for handling them. The provenance discipline from Section 11 is exactly what the project needs to evaluate whether a driver is clean of copyright concerns. The documented limitations and open questions from the pseudo-datasheet help the project set appropriate expectations for users. The safety wrappers and the conservative behaviour help reviewers feel confident that the driver will not damage user hardware.

If you have followed the labs and the challenges in this chapter, you have produced at least a few small pieces of code that could, with some polish, be candidates for inclusion. Chapter 37 will show you how to take such a piece of code and walk it through the submission process. The mock-device driver from Lab 4 might not be a candidate (it does not drive real hardware), but the patterns it demonstrates are exactly the patterns a real driver should follow, and the safety wrappers from Lab 5 are patterns that reviewers will recognise and approve.

The book is approaching its concluding chapters. You started in Part 1 with no kernel knowledge at all. You learned UNIX and C in Parts 1 and 2. You learned the structure and lifecycle of a FreeBSD driver in Parts 3 and 4. You learned the bus, network, storage, and pseudo-device patterns in Parts 4 and 5. You learned the Newbus framework in detail in Part 6. You have now worked through Part 7's mastery topics: portability, virtualisation, security, FDT, performance, advanced debugging, asynchronous I/O, and reverse engineering. The skill set is comprehensive. The remaining chapters tie it back to the project, the community, and the practice of contributing to a real-world operating system.

Take a moment, before moving on to Chapter 37, to look back at what you can now do. You can write a simple character driver from scratch. You can write a network driver that participates in the kernel's networking stack. You can write a driver for a device discovered through Newbus. You can write an asynchronous driver that supports `poll`, `kqueue`, and `SIGIO`. You can debug a driver with `dtrace`, `KASSERT`, and `kgdb`. You can work with a device for which no documentation exists. Each of these capabilities is a real one, built on the previous ones, and together they constitute a working knowledge of FreeBSD device-driver development.

The next chapter will help you take that knowledge and turn it into a contribution to the FreeBSD project. Let us see how that process works.

## 37 Submitting Your Driver to the FreeBSD Project

### 37.1 Introduction

If you have followed this book from the beginning, you have travelled a long way. You started without any kernel knowledge at all, learned UNIX and C, walked through the anatomy of a FreeBSD driver, built character and network drivers by hand, explored the Newbus framework, and worked through a full part on mastery topics: portability, virtualisation, security, FDT, performance, advanced debugging, asynchronous I/O, and reverse engineering. You have now reached the point where you can sit down in front of a lab machine, open a text editor, and write a driver for a device that FreeBSD does not yet support. That is a serious engineering skill, and it did not come for free.

This chapter is where the work turns outward. Up to now, the drivers you have built have lived on your own systems. You loaded them with `kldload`, tested them, debugged them, and unloaded them when you were done. They were useful to you, and perhaps to a few friends or colleagues who copied them from your repository. That is already worthwhile work. But a driver that lives only on your machine serves only the people who happen to find your machine. A driver that lives inside the FreeBSD source tree serves every FreeBSD user, on every release, on every architecture the driver targets, for as long as the code is maintained. The amplification of value is enormous, and the responsibilities that come with it are the subject of this chapter.

The FreeBSD Project has been accepting contributions from outside developers since the early 1990s. Thousands of people have submitted patches; hundreds have eventually become committers. The process by which new code enters the tree is not a bureaucratic obstacle course. It is a review workflow designed to preserve the qualities that make FreeBSD trustworthy: code consistency, long-term maintainability, portability across architectures, legal cleanness, careful documentation, and continuity of care. Every one of those qualities is something the reviewers protect on behalf of everyone who runs FreeBSD. When you submit a driver, you are asking the project to take on a long-term responsibility for it. The review process is how the project confirms that the driver is worth that responsibility, and also how the project helps you get the driver into a shape where the answer is yes.

That framing matters. New contributors often arrive at the review process expecting an adversarial experience, where reviewers look for reasons to reject the work. The reality is the opposite. Reviewers are, overwhelmingly, trying to help. They want your driver to be merged. They want it to be merged in a form that will still work five releases from now. They want it to not be a maintenance burden for whoever has to touch the surrounding code next year. The comments they leave on a first-round patch are not a score; they are a list of things that, when addressed, will let the patch be committed. A contributor who internalises that framing finds the review process cooperative rather than stressful.

There is, however, a distinction that needs to be clear from the start. A working driver is not the same thing as an upstream-ready driver. A driver that loads on your laptop, drives your hardware, and does not panic when you unload it has cleared only the first few checkpoints. To be upstream-ready it also needs to pass the project's style guidelines, carry a proper licence, come with a manual page that explains how a user interacts with it,

build on every architecture the project supports, integrate cleanly into the existing source-tree layout, and be accompanied by a commit message that another reviewer can read in five years without needing to reconstruct the context. None of these are busywork. Each of them exists because experience has shown what happens to code bases where they are skipped.

The chapter is organised around a natural workflow. We will begin by looking at how the FreeBSD Project is organised from the point of view of a contributor, and what the distinction between contributor and committer actually means in practice. We will then walk through the mechanical preparation of a driver for submission: what file layout to use, what code style to follow, how to name things, and how to write a commit message that a reviewer can read with gratitude. We will look at licensing and legal compatibility, because even excellent code cannot be accepted if its provenance is unclear. We will spend a serious amount of time on manual pages, because the manual page is the reader-facing half of the driver and it deserves the same care as the code. We will walk through testing expectations, from local builds through make universe, and we will see how to generate a patch in a form the reviewers find convenient. We will discuss the social side of the review process: how to work with a mentor, how to respond to feedback, how to iterate through review rounds without losing momentum. And we will end with the longest-lasting commitment of all, which is maintenance after the driver has been merged.

The companion code for this chapter, in `examples/part-07/ch37-upstream/`, includes several practical artifacts: a reference driver-tree layout that mirrors the shape a small driver would take in `/usr/src/sys/dev/`; a sample manual page you can adapt to your own driver; a submission checklist you can use as a final review before sending a patch; a draft cover letter for an email to a project mailing list; a helper script that generates a patch with the conventions the project expects; and a pre-submission validation script that runs the lint, style, and build checks in the correct order. None of these are a substitute for understanding the underlying material, but they will save you from the common mistakes that cost first-time contributors a round or two of reviews.

One more note before we begin. This chapter is not going to teach you the political or governance history of the FreeBSD Project. We will touch on the Core Team and the roles of the various committees only as much as is necessary for a contributor to navigate the project. If you are curious about FreeBSD governance after reading this chapter, the project's own documentation is the right next stop, and we will point you toward it. The scope of this chapter is the practical work of turning a driver you have written into a driver that can be merged upstream.

By the end of the chapter, you will have a clear picture of the submission workflow, a hands-on understanding of the style and documentation conventions, a rehearsal of the review cycle, and a realistic sense of what happens after your driver is in the tree. You will not be a FreeBSD committer by the end of this chapter; the project grants commit rights only after a sustained history of quality contributions, and that is by design. But you will know how to make the first contribution, how to make it well, and how to build up the reputation that could, in time, lead to commit rights if that is a direction you choose to pursue.

## 37.2 Reader Guidance: How to Use This Chapter

This chapter sits in Part 7 of the book, immediately after the chapter on reverse engineering and immediately before the closing chapter. Unlike many earlier chapters, the subject matter here is more about workflow and discipline than about kernel internals. You will not need to write any new driver code to follow the chapter, although you will benefit greatly if you apply what you learn to a driver you have already written.

The reading time is moderate. If you read straight through without stopping to try anything, the prose will take around two to three hours. If you work through the labs and challenges, budget a full weekend or several evenings. The labs are structured as short, focused exercises that you can do against any small driver you have on hand, including one of the earlier chapter drivers, one of the mock drivers from Chapter 36, or a fresh driver you write for this chapter.

You do not need any special hardware. A FreeBSD 14.3 development virtual machine, or a bare-metal FreeBSD system where you are comfortable running build and test commands, is sufficient. The labs will ask you to apply style checks to real code, build a real driver as a loadable module, validate a manual page with `mandoc(1)`, and rehearse the patch-generation workflow against a throwaway git branch. Nothing will touch the real FreeBSD Phabricator or GitHub, so there is no risk of accidentally submitting half-finished work to the project.

A reasonable reading schedule looks like this. Read Sections 1 and 2 in one sitting; they set up the conceptual framing of how FreeBSD development works and how your driver should be laid out. Take a break. Read Sections 3 and 4 in a second sitting; they cover licensing and manual pages, which together make up most of the paperwork side of a submission. Read Sections 5 and 6 in a third sitting; they cover testing and actual patch generation, which is where the chapter turns from preparation to action. Read Sections 7 and 8 in a fourth sitting; they cover the human and long-term sides of contribution. The labs are best done over a weekend, with enough time to redo them more than once if the first pass exposes something you would like to improve.

If you are already a confident FreeBSD user and a confident kernel developer, the material in this chapter will feel familiar in broad shape but may still surprise you in the specifics. The specifics matter. A reviewer who knows the tree well will notice within seconds whether the file layout matches the conventions, whether the copyright header is in the current recommended form, whether the manual page uses the modern `mdoc` idioms, and whether the commit message follows the expected subject-line style. Getting these small things right up front makes the difference between a review that lasts one round and a review that lasts five.

If you are a beginner, do not let the specifics intimidate you. Every committer in the project was, at one point, someone whose first patch bounced off five rounds of review before landing. The ability to write good code is something you have already built up over the book. The ability to submit it well is what this chapter adds. You will not get it perfect on the first try. That is normal. What matters is that you understand the shape of the process and that you approach each review with the intent to improve the submission rather than to defend it.

Several of the guidelines in this chapter, especially around licensing, manual pages, and the review workflow, reflect the state of the FreeBSD Project as of FreeBSD 14.3. The project evolves, and a few of the specific conventions may shift over time. Where we know a convention is changing, we will flag it. Where we are citing a specific file in the tree, we will name the file so you can open it yourself and verify the current state. The reader who trusts but also verifies is the reader the project benefits from most.

One last note about pace. This chapter deliberately teaches discipline as much as it teaches process. Several of the sections will seem almost repetitive in their insistence on small details: trailing whitespace, correct header comments, exact manual-page macro usage. That insistence is part of the lesson. FreeBSD is a large code base with a long institutional memory, and the small details are what keep it maintainable. If you find yourself tempted to skim a style section, slow down instead. The slowness is the craft.

## 37.3 How to Get the Most Out of This Chapter

The chapter is organised to be read linearly, but every section stands on its own well enough that you can come back to a specific section when you need to. Several habits will help you absorb the material.

First, read each section with the FreeBSD source tree open on your screen. Every time the chapter mentions a reference file such as `/usr/src/share/man/man9/style.9`, open it and skim it. The chapter gives you the shape and the motivation; the reference files give you the authoritative detail. A habit of cross-checking what you read in the chapter against what the tree actually says will serve you for the rest of your career as a FreeBSD contributor.

**A note on line numbers.** When the chapter points you at a named piece of infrastructure in the tree, such as `make_dev_s`, `DRIVER_MODULE`, or the `style(9)` rules themselves, the pointer is anchored on that name. The `mydev.c:23` style-check transcripts you will see later refer to lines in your own in-progress driver and will change as you edit it. Either way, the durable reference is the symbol, not the number: `grep` for the name rather than rely on a line.

Second, keep a small note file as you read. Every time a section mentions a convention, a required section, or a command, write it down. By the end of the chapter you will have a personalised submission checklist. The companion `examples/part-07/ch37-upstream/` directory includes a checklist template you can start from, but a checklist you have typed up yourself, in your own words, will be more useful than any template.

Third, have a small driver of your own in mind as you read. It could be the LED driver from earlier chapters, the mock device from Chapter 36, or a character driver you wrote for practice. The chapter will ask you to imagine preparing that specific driver for submission. Working against a concrete driver makes the instructions land far more firmly than trying to absorb them in the abstract.

Fourth, do not skip the labs. The labs in this chapter are short and practical. Most of them take less than an hour. They exist because there are parts of the submission process that only become clear once you try them against real code. A reader who works through the labs will emerge with genuine muscle memory; a reader who skips them will re-read the chapter six months from now and discover that most of it did not stick.

Fifth, treat the early mistakes as part of the training. The first time you run `tools/build/checkstyle9.pl` against your code, you will see warnings. The first time you run `mandoc -Tlint` against your manual page, you will see warnings. The first time you run `make universe` against your tree, you will see errors on at least one architecture. Every one of those warnings is teaching you something. The reviewers in the project see these same warnings every day; the craft of preparing a submission is, in large part, the craft of noticing and fixing them before anyone else has to.

Finally, be patient with the rhythm of the chapter. A few of the later sections spend time on what might seem like social or interpersonal material: how to handle feedback, how to respond to a reviewer who has misunderstood your patch, how to build the relationships that lead to sponsorship. That material is not optional. Software engineering at the level of an open-source kernel project is a collaborative craft, and the collaboration is the craft. Reading those sections carelessly will cost you more in practice than reading the style sections carelessly.

You now have the map. Let us turn to the first section and look at how the FreeBSD Project is organised from the point of view of a contributor.

## 37.4 Section 1: Understanding the FreeBSD Contribution Process

### 37.4.1 What the FreeBSD Project Actually Is

Before we can talk about contributing to the FreeBSD Project, we need a clear picture of what the project is. The FreeBSD Project is a community of volunteers and paid contributors who together develop, test, document, release, and support the FreeBSD operating system. The project has been continuously active since 1993. It is organised around a set of shared source trees, a code-review culture, a release engineering discipline, and a body of accumulated institutional knowledge about how kernels, userlands, ports, and documentation should be put together.

The project is often summarised in three words: source, ports, and documentation. These correspond to three main repositories or subprojects, each with its own maintainers, reviewers, and conventions. Source, usually written as `src`, is the base system: the kernel, the libraries, the userland utilities, everything that a FreeBSD installation ships with. Ports is the collection of third-party software that can be built on FreeBSD, such as programming languages, desktop environments, and application servers. Documentation is the Handbook, the articles, the books such as the Porter's Handbook and the Developer's Handbook, the FreeBSD website, and the translation infrastructure.

Device drivers live primarily in the `src` tree, because they are part of the base system kernel and base-system support for hardware. When this chapter talks about submitting a driver, it means submitting it to the `src` tree. Ports and Documentation have their own contribution pipelines, which follow similar principles but differ in detail. This chapter focuses exclusively on `src`.

The `src` tree is large. You can see its top-level structure by browsing `/usr/src/`. The manual page `/usr/src/share/man/man7/development.7` gives a short, readable introduction to the development process, and the file `/usr/src/CONTRIBUTING.md` is the project's own current guidance for contributors. If you read only two files before your first submission, read those two. We will quote from both repeatedly in this chapter.

### 37.4.2 The Project's Decision-Making Structure

FreeBSD uses a relatively flat decision-making structure compared to some other large projects. The core of the structure is the group of committers, who are developers with write access to the source repositories. Committers are elected by existing committers after a sustained history of quality contributions. A nine-person elected body called the Core Team handles certain kinds of project-wide decisions and disputes. Smaller teams such as the Release Engineering Team (`re@`), the Security Officer Team (`so@`), the Ports Management Team (`portmgr@`), and the Documentation Engineering Team (`doceng@`) look after specific areas.

For the purposes of submitting a driver, most of that structure does not matter much in day-to-day practice. The people who will review your driver are individual committers who happen to know the subsystem your driver fits into. If your driver is a network driver, the reviewers will probably be people active in the networking subsystem. If it is a USB driver, the reviewers will be people active in USB. The Core Team is not involved in individual driver submissions; neither is the Release Engineering Team, although they will be the ones who decide which release your driver first appears in once it is merged.

The practical mental model is this. The FreeBSD Project is a large community of engineers. Some of them can commit to the tree directly. A much larger number contribute through review processes. When you submit a

driver, you become part of that larger number, and the review process is how the committer community evaluates whether the driver is ready to enter the tree under their shared responsibility.

### 37.4.3 Contributor Versus Committer

The distinction between contributor and committer is central to how the project works, and it is often misunderstood by newcomers.

A contributor is anyone who submits changes to the project. You become a contributor the first time you open a Phabricator review or a GitHub pull request against the FreeBSD source tree. There is no formal process for becoming a contributor. You simply submit work. If the work is good, it gets reviewed, revised, and eventually committed to the tree by a committer on your behalf. The commit carries your name and email in the Author : field, so that you get credit for the code even though you did not push it yourself.

A committer is a contributor who has been granted direct write access to one of the repositories. Commit rights are granted after a sustained history of quality contributions, usually over several years, and only after a nomination by an existing committer and a vote by the relevant committer group. Commit rights come with responsibilities: you are expected to review other people's patches, participate in project discussions, and take ownership of the code you have committed over the long term.

The two roles are not a hierarchy of prestige. They are a division of labour. Contributors focus on writing and submitting good patches. Committers focus on reviewing, integrating, and maintaining the tree. A contributor with a single high-value patch is more valuable to the project than a committer who does not actively participate. The project depends on both.

For this chapter, you should think of yourself as a contributor. Your goal is to produce a submission that a committer can review, accept, and commit. If, years from now, you find yourself with a long history of contributions and a sustained relationship with the project, the question of commit rights may arise organically. But that is a question for later. The focus here is making your first contributions count.

### 37.4.4 How src Work Is Organised

The src repository is a single git tree. The main branch, confusingly called `main` in git but also referred to as `CURRENT` in release-engineering language, is where all active development happens. Changes are committed first to `main`. Then, if the change is a bug fix or a small feature that fits within a stable release, it may be cherry-picked back into one of the `stable/` branches, which correspond to the major FreeBSD releases such as 14 and 15. Releases themselves are tagged points on the `stable/` branches.

As a driver contributor, your default target is `main`. Your patch should apply to current `main`, should build against current `main`, and should be tested against current `main`. If the driver is something users of FreeBSD 14 would also want, a committer may choose to cherry-pick the commit back to the relevant `stable/` branch after it has been in `main` for a bit, but that is the committer's decision, not yours to make in the submission.

The git repository is visible at <https://cgit.freebsd.org/src/> and is also mirrored at <https://github.com/freebsd/src>. You can clone from either. The authoritative push URL, for those with commit access, is `ssh://git@gitrepo.FreeBSD.org/src.git`, but as a contributor you will not push directly. You will generate patches and send them through the review workflow.

### 37.4.5 Where Device Drivers Live in the Source Tree

Most device drivers live under `/usr/src/sys/dev/`. This directory contains hundreds of subdirectories, one per driver or device family. If you browse it, you will see a cross-section of the hardware FreeBSD supports: Ethernet chips, SCSI adapters, USB devices, sound cards, I/O controllers, and a long list of other categories.

A small selection of existing driver subdirectories worth knowing:

- `/usr/src/sys/dev/null/` for the `/dev/null` character device.
- `/usr/src/sys/dev/led/` for the generic LED framework.
- `/usr/src/sys/dev/uart/` for UART drivers.
- `/usr/src/sys/dev/virtio/` for the VirtIO family.
- `/usr/src/sys/dev/usb/` for the USB subsystem and the USB-side device drivers.
- `/usr/src/sys/dev/re/` for the RealTek PCI/PCIe Ethernet driver.
- `/usr/src/sys/dev/e1000/` for the Intel Gigabit Ethernet driver family.
- `/usr/src/sys/dev/random/` for the kernel random-number subsystem.

Some categories of driver live elsewhere. Network drivers whose role is more about the networking stack than about the device itself sometimes live under `/usr/src/sys/net/`. Filesystem-like devices and pseudo-devices sometimes live under `/usr/src/sys/fs/`. Architecture-specific drivers sometimes live under `/usr/src/sys/<arch>/`. For most beginner submissions, however, the question will be which subdirectory under `/usr/src/sys/dev/` is the right home, and the answer is almost always obvious. If your driver is for a new network chip, it probably belongs in its own subdirectory under `/usr/src/sys/dev/`, possibly inside an existing family subdirectory if it extends an existing family. If it is for a USB device, you may find that it lives under `/usr/src/sys/dev/usb/` instead. If you are unsure, a search through the existing tree for a similar driver will usually tell you where yours belongs.

### 37.4.6 The Second Half of the Driver: Kernel Build Integration

In addition to the driver source files themselves, a driver that is merged into FreeBSD has a second home under `/usr/src/sys/modules/`. This directory contains the kernel-module Makefiles that let the driver be built as a loadable kernel module. For each driver in `/usr/src/sys/dev/<driverdir>/`, there is typically a corresponding directory in `/usr/src/sys/modules/<moduledir>/` containing a small Makefile that tells the build system how to assemble the module. We will look at that Makefile in detail in Section 2.

A few drivers have additional integration points. Drivers that ship as part of the default kernel are listed in the architecture configuration files under `/usr/src/sys/<arch>/conf/GENERIC`. Drivers that come with device-tree bindings may have entries under `/usr/src/sys/dts/`. Drivers that expose tunable sysctls or loader variables need entries in the relevant documentation.

As a first-time contributor, you do not need to worry about all of these integration points at once. The minimum set for a typical driver submission is the files under `/usr/src/sys/dev/<driver>/`, the Makefile under `/usr/src/sys/modules/<driver>/`, and the manual page under `/usr/src/share/man/man4/<driver>.4`. Anything beyond that is incremental.

### 37.4.7 The Review Platforms

FreeBSD currently accepts source-code contributions through several channels. The `/usr/src/CONTRIBUTING.md` file lists them explicitly:

- A GitHub pull request against <https://github.com/freebsd/freebsd-src>.
- A code review in Phabricator at <https://reviews.freebsd.org/>.
- An attachment on a Bugzilla ticket at <https://bugs.freebsd.org/>.
- Direct access to the git repository, for committers only.

Each of these channels has its own conventions and its own preferred use cases.

Phabricator is the traditional code-review platform for the project. It handles full review workflows: multi-round feedback, revision history, inline comments, reviewer assignment, and commit-ready patches. Most significant patches, including most driver submissions, go through Phabricator. You will see it referred to as “review D12345” or similar, where D12345 is the Phabricator differential revision identifier.

GitHub pull requests are an increasingly accepted submission route, particularly for small, self-contained, uncontroversial patches. The `CONTRIBUTING.md` file explicitly notes that GitHub PRs work well when the change is limited to fewer than about ten files and fewer than about two hundred lines, and when it passes the GitHub CI jobs and has limited scope. A typical small driver fits within those bounds; a larger driver with many files and integration points may be better handled through Phabricator.

Bugzilla is the project’s bug tracker. If your driver fixes a specific reported bug, a patch attached to the corresponding Bugzilla entry is the right home for it. If the driver is new work rather than a bug fix, Bugzilla is usually not the right starting point, although a reviewer may ask you to open a Bugzilla ticket so that the work has a tracking number.

For a first driver submission, either Phabricator or a GitHub pull request is appropriate. Many contributors start with a GitHub PR because the workflow is familiar, and switch to Phabricator if the review grows beyond what GitHub handles well. We will walk through both routes in Section 6.

The review-platform landscape does shift over time, and the specific URLs, scope limits, and preferred routes described in this chapter can be superseded by changes to `/usr/src/CONTRIBUTING.md` or to the project’s contribution pages. The process details above were last verified against the in-tree `CONTRIBUTING.md` on 2026-04-20. Before you prepare your first submission, re-read the current `CONTRIBUTING.md` and the committer’s guide linked from the FreeBSD documentation site; if they disagree with this chapter, trust the project’s files, not the book.

### 37.4.8 Exercise: Browse the Source Tree and Identify Similar Drivers

Before moving on to Section 2, spend half an hour browsing `/usr/src/sys/dev/` and building an intuition for what a FreeBSD driver looks like from the outside.

Pick three or four drivers that are roughly similar in scope to the one you intend to submit, or to any driver you have built during this book. For each, look at:

- The directory contents. How many source files? How many headers? What are the file names?
- The corresponding Makefile under `/usr/src/sys/modules/`. What does it list in `KMOD=` and `SRCS=`?
- The manual page under `/usr/src/share/man/man4/`. Open it and note the section structure.

- The copyright header in the main `.c` file. Note its format.

You are not trying to memorise anything in this exercise. You are building a baseline intuition. By the time you have looked at three or four real drivers, the conventions of the tree will feel less abstract. When Section 2 talks about where files go and how they are named, the recommendations will land on top of a mental picture you have already built. That is the right way to absorb this material.

### 37.4.9 Wrapping Up Section 1

The FreeBSD Project is a long-lived community organised around three main subprojects: `src`, `ports`, and `documentation`. Device drivers live in the `src` tree, mostly under `/usr/src/sys/dev/`, with corresponding module Makefiles under `/usr/src/sys/modules/` and manual pages under `/usr/src/share/man/man4/`. Contributions enter the tree through a review process handled by committers who are active in the relevant subsystem. The distinction between contributor and committer is a division of labour, not a hierarchy of prestige. Your goal as a first-time contributor is to produce a submission that a committer can review, accept, and commit.

With that framing in place, we can now turn to the mechanical question of what shape your driver should be in before you submit it. Section 2 walks through the preparation step by step.

## 37.5 Section 2: Getting Your Driver Ready for Submission

### 37.5.1 The Gap Between a Working Driver and a Submission-Ready Driver

A driver that loads, runs, and unloads cleanly on your test machine is a working driver. A driver that a FreeBSD committer can review, merge, and maintain is a submission-ready driver. The gap between the two is almost always larger than first-time contributors expect, and closing the gap is the work of this section.

The gap has three parts. The first is layout: where the files go, what they are named, and how they integrate with the existing build system. The second is style: how the code is formatted, named, and commented, and how closely it matches the project's `style(9)` guidelines. The third is presentation: how the commit is packaged, what the commit message says, and how the patch is structured for review. None of these are hard once you know what to look for, but each of them involves a dozen or two small conventions that collectively determine whether a reviewer's first impression is smooth or bumpy.

Before we begin, take a moment to appreciate why these conventions exist. FreeBSD has thirty years of accumulated code. Thousands of drivers have entered the tree over that time. The conventions that feel arbitrary when you first encounter them are, in almost every case, the result of an earlier painful experience that the community decided never to repeat. A convention that prevents a bug, or that reduces a recurring source of reviewer friction, pays for itself many times over. When you follow the conventions, you are benefiting from thirty years of institutional memory. When you ignore them, you are volunteering to relearn those lessons yourself, and to put your reviewers through them again.

### 37.5.2 Where the Files Go

For a standalone driver in the tree, the typical layout looks like this. Let us assume your driver is called `mydev` and that it drives a PCI-attached sensor board.

- `/usr/src/sys/dev/mydev/mydev.c` is the main driver source file. For a small driver, this may be the only source file.
- `/usr/src/sys/dev/mydev/mydev.h` is the driver header. If you only have a single `.c` file and its internal declarations do not need to be exposed, you may not need this header.
- `/usr/src/sys/dev/mydev/mydevreg.h` is a common name for a header that defines the hardware registers and bit fields. This convention, using a `reg` suffix, is widespread in the tree, and separating register definitions from driver-internal declarations is good practice.
- `/usr/src/sys/modules/mydev/Makefile` is the Makefile for building the driver as a loadable kernel module.
- `/usr/src/share/man/man4/mydev.4` is the manual page.

You may encounter existing drivers that do not follow this exact layout. Older drivers from before the current conventions were established sometimes put everything in one place, or use different file names. The conventions continue to evolve. For a new driver, following the modern layout will save you review friction.

### 37.5.3 What Goes in `mydev.c`

The main source file typically contains, in order:

1. The copyright and licence header, in the format we will cover in Section 3.
2. The `#include` directives, typically starting with `<sys/cdefs.h>` and `<sys/param.h>`, followed by the other kernel headers your driver needs.
3. Forward declarations and static variables.
4. The driver methods: `probe`, `attach`, `detach`, and anything else your `device_method_t` table references.
5. Any helper functions.
6. The `device_method_t` table, the `driver_t` structure, the `DRIVER_MODULE` registration, and the `MODULE_VERSION` declaration. Modern FreeBSD drivers no longer declare a static `devclass_t` variable; the current `DRIVER_MODULE` signature takes five arguments (name, bus, driver, event handler, event handler argument) and the bus code manages the device class for you.

There is a visible rhythm to a well-organised driver file that experienced FreeBSD readers pick up on immediately. Methods come before the tables that reference them. Static helpers come near the methods that use them. The registration macros come last, so that the file reads as a linear story from dependencies through functions to registration.

### 37.5.4 A Minimal Driver File

For orientation, here is a minimal shape for `mydev.c`. It is not complete, but it shows the structural elements that a reviewer will expect to see. You have seen the mechanics of each of these macros in earlier chapters; here we are focusing on how they arrange themselves on the page.

*/

#include <sys/cdefs.h>
#include <sys/param.h>
#include <sys/system.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/bus.h>

#include <machine/bus.h>
#include <machine/resource.h>
#include <sys/rman.h>

#include <dev/pci/pci.h>
#include <dev/pci/pcivar.h>

#include <dev/mydev/mydev.h>

static int mydev_probe(device_t dev);
static int mydev_attach(device_t dev);
```

```
static int mydev_detach(device_t dev);

static int
mydev_probe(device_t dev)
{
 /* match your PCI vendor/device ID here */
 return (ENXIO);
}

static int
mydev_attach(device_t dev)
{
 /* allocate resources, initialise the device */
 return (0);
}

static int
mydev_detach(device_t dev)
{
 /* release resources, quiesce the device */
 return (0);
}

static device_method_t mydev_methods[] = {
 DEVMETHOD(device_probe, mydev_probe),
 DEVMETHOD(device_attach, mydev_attach),
 DEVMETHOD(device_detach, mydev_detach),
 DEVMETHOD_END
};

static driver_t mydev_driver = {
 "mydev",
 mydev_methods,
 sizeof(struct mydev_softc),
};

DRIVER_MODULE(mydev, pci, mydev_driver, 0, 0);
MODULE_VERSION(mydev, 1);
MODULE_DEPEND(mydev, pci, 1, 1, 1);
```

Several things are worth noticing. The copyright header uses the `/*` - opening marker, which the automatic licence-harvesting script recognises. The `SPDX` line names the licence explicitly. The indentation is tabs, not spaces, as mandated by `style(9)`. The function declarations are tab-separated, also per `style(9)`. The `DRIVER_MODULE` and related macros appear at the bottom, in the order the build system expects. This is the

shape a reviewer will expect to see.

### 37.5.5 The Module Makefile

The Makefile for the module is usually tiny. Here is a realistic example, modelled on the one at `/usr/src/sys/modules/et/Makefile`:

```
.PATH: ${SRCTOP}/sys/dev/mydev

KMOD= mydev
SRCS= mydev.c
SRCS+= bus_if.h device_if.h pci_if.h

.include <bsd.kmod.mk>
```

Several conventions are encoded in this short file.

`SRCTOP` is a build-system variable that points to the top of the source tree. Using it means the Makefile works regardless of where in the tree the build is invoked from. Do not hardcode `/usr/src`.

`KMOD` names the module. This is what `kldload` uses. Match it to the driver name.

`SRCS` lists the source files. The `.c` files are your driver sources. The `.h` files that look like `bus_if.h` and `pci_if.h` are not regular headers; they are auto-generated by the build system from the method definitions in the corresponding `.m` files. You list them so that the build system knows to generate them before compiling your driver. Include `device_if.h` because every driver uses `device_method_t`; include `bus_if.h` if your driver uses `bus_*` methods; include `pci_if.h` if it is a PCI driver; and so on.

`bsd.kmod.mk` is the standard kernel-module build infrastructure. Including it at the end gives you all the build rules you need.

A few additional conventions apply:

- Do not add copyright headers to trivial Makefiles. The tree convention is that tiny Makefiles such as this one are treated as mechanical files and do not carry licences. Real Makefiles with substantial logic do carry copyright headers.
- Do not use GNU make features. FreeBSD's base build system uses the in-tree BSD make, not GNU make.
- Keep indentation with tabs, not spaces, for rule bodies.

### 37.5.6 The Header File

If your driver has a header file for internal declarations, place it in the same directory as the `.c` file. The convention is to name the internal header `<driver>.h` and any hardware register definitions `<driver>reg.h`. Keep the header's scope narrow. It should declare structures and constants that are used across multiple `.c` files within the driver or that are needed for interoperation with closely related subsystems. It should not leak driver-internal details into the broader kernel namespace.

The header begins with the same copyright header as the `.c` file, followed by the standard include guard:

```
#ifndef _DEV_MYDEV_MYDEV_H_
#define _DEV_MYDEV_MYDEV_H_

/* header contents */

#endif /* _DEV_MYDEV_MYDEV_H_ */
```

The include guard name follows the convention of the full path, in uppercase, with slashes and dots replaced by underscores, and with a leading and trailing underscore. The convention is consistent across the tree and a reviewer will spot deviations.

### 37.5.7 Following style(9): The Short Summary

The complete FreeBSD coding style is documented in `/usr/src/share/man/man9/style.9`. You should read that manual page before submitting a driver, and at least skim it periodically as your own style matures. Here we will pull out the points that most commonly trip up first-time contributors.

#### 37.5.7.1 Indentation and Line Width

Indentation uses real tabs, with a tab stop of 8 columns. Second and subsequent levels of indentation that are not aligned to a tab stop use 4 spaces of additional indent. Line width is 80 columns; a few exceptions are allowed when breaking a line would make it less readable or would break something that gets grepped for, such as a panic message.

#### 37.5.7.2 Copyright Header Form

The copyright header uses the `/*` - opening marker. This marker is magic. An automated tool harvests licences from the tree by looking for multi-line comments that start in column 1 with `/*` -. Using the marker flags the block as a licence; using a regular `/*` does not. Immediately after `/*` -, the next significant line should be `SPDX-License-Identifier`: followed by the SPDX licence code, such as `BSD-2-Clause`. Then come one or more Copyright lines. Then the licence text.

#### 37.5.7.3 Function Declarations and Definitions

Function return type and storage class go on the line above the function name. The function name starts in column 1. Arguments fit on the same line as the name unless that would exceed 80 columns, in which case subsequent arguments are aligned to the opening parenthesis.

Correct:

```
static int
mydev_attach(device_t dev)
{
```

```
struct mydev_softc *sc;

sc = device_get_softc(dev);
return (0);
}
```

Incorrect, as a reviewer would immediately flag:

```
static int mydev_attach(device_t dev) {
 struct mydev_softc *sc = device_get_softc(dev);
 return 0;
}
```

The differences look small: the position of the return type, the position of the opening brace, the use of spaces instead of tabs, the declaration with initialisation on a single line, and the missing parentheses around the return value. Every one of those differences violates `style(9)`. Collectively they make the function look out of place in the tree. A reviewer will ask you to fix them, and fixing them after the fact is more work than writing them correctly the first time.

#### 37.5.7.4 Variable Names and Identifier Conventions

Use lower-case identifiers with underscores rather than camelCase. `mydev_softc`, not `MydevSoftc` or `mydev-Softc`. Functions follow the same convention.

Constants and macros are in upper case with underscores: `MYDEV_REG_CONTROL`, `MYDEV_FLAG_INITIALIZED`.

Global variables are rare in drivers; prefer per-device state in the `_softc`. When a global is unavoidable, give it a name prefixed with the driver name to avoid collision with the rest of the kernel.

#### 37.5.7.5 Return-Value Parentheses

FreeBSD style requires that return expressions be parenthesised: `return (0);` not `return 0;`. This is a convention going back to the original BSD kernel and is enforced reasonably strictly.

#### 37.5.7.6 Comments

Multi-line comments use the form:

```
/*
 * This is the opening of a multi-line comment. Make it real
 * sentences. Fill the lines to the column 80 mark so the
 * comment reads like a paragraph.
 */
```

Single-line comments can use either the traditional `/* ... */` or `// ...` form. Be consistent within a file; do not mix styles.

Comments should explain why, not what. `/* iterate over the array */` is not useful when the reader can see the loop. `/* the hardware requires a read-back to flush the write before we proceed */` is useful because it explains a non-obvious constraint.

### 37.5.7.7 Error Messages

Use `device_printf(dev, "message\n")` for device-specific log output. Do not use `printf` directly from a driver if you have a `device_t` handy; `device_printf` prefixes the message with the driver and unit number, which is what every reader of kernel logs expects to see.

Error messages that get grepped for should stay on a single line even if they exceed 80 columns. The `style(9)` manual page is explicit about this.

### 37.5.7.8 Magic Numbers

Do not use magic numbers in the body of the code. Hardware register offsets, bit masks, and status codes should be named constants in the `<driver>reg.h` header. This makes the code readable and also makes it easy to patch the register definitions when, inevitably, you discover that something was slightly off.

## 37.5.8 Using tools/build/checkstyle9.pl

The project ships an automated style checker at `/usr/src/tools/build/checkstyle9.pl`. It is a Perl script that reads source files and warns about common style violations. It is not perfect, and some warnings will be false positives or reflect conventions that the script does not quite get right, but it catches a large fraction of the easy mistakes.

Run it against your driver before submission:

```
/usr/src/tools/build/checkstyle9.pl sys/dev/mydev/mydev.c
```

You will see output like:

```
mydev.c:23: missing blank line after variable declarations
mydev.c:57: spaces not tabs at start of line
mydev.c:91: return value not parenthesised
```

Fix each warning. Re-run. Repeat until the output is clean.

The `CONTRIBUTING.md` file is explicit about this: “Run `tools/build/checkstyle9.pl` on your Git branch and eliminate all errors.” Reviewers do not want to be the style checker for you. Submitting code that has not been run through `checkstyle9.pl` wastes their time.

### 37.5.9 Using `indent(1)` Carefully

FreeBSD also ships `indent(1)`, a C source reformatter. It can reformat a file to conform to parts of `style(9)` automatically. It is useful but it is not magical. `indent(1)` handles some style rules well, such as tab-based indentation and brace placement, but it handles other rules poorly or not at all, and in some cases it makes things worse by reformatting comments or function signatures in ways that violate `style(9)` even though the input was correct.

Treat `indent(1)` as a rough first pass rather than as a canonical formatter. Run it on a file to get close to conforming, then read the output carefully and fix anything it got wrong. Do not run it on existing tree files as part of an unrelated patch; mixing style changes with functional changes is a review anti-pattern.

### 37.5.10 Commit Messages

A good commit message does two things. First, it tells the reader at a glance what the commit does. Second, it tells the reader in more detail why the commit does it. The subject line is the first; the body is the second.

The subject line conventions in the FreeBSD tree look like this:

```
subsystem: Short description of the change
```

The `subsystem` prefix tells the reader which part of the tree is affected. For a driver submission, the prefix is typically the driver name:

```
mydev: Add driver for MyDevice FC100
```

The first word after the colon is capitalised, and the description is a fragment, not a full sentence. The subject line is capped around 50 characters, with 72 as a hard limit. Look at recent commits in the tree with `git log --oneline` to see the pattern:

```
rge: add disable_aspm tunable for PCIe power management
asmc: add automatic voltage/current/power/ambient sensor detection
tcp: use RFC 6191 for connection recycling in TIME-WAIT
pf: include all elements when hashing rules
```

The body of the commit message comes after a blank line. It explains the change in more detail: what the change does, why it is needed, what hardware or scenario it affects, and any considerations a future reader might need to know. Wrap the body at 72 columns.

A good commit message for a driver submission might look like this:

```
mydev: Add driver for FooCorp FC100 sensor board
```

```
This driver supports the FooCorp FC100 series of PCI-attached
environmental sensor boards, which expose a simple command and
```

status interface over a single BAR. The driver implements probe/attach/detach following the Newbus conventions, exposes a character device for userland communication, and supports sysctl-driven sampling configuration.

The FC100 is documented in the FooCorp Programmer's Reference Manual version 1.4, which the maintainer has on file. Tested on amd64 and arm64 against a hardware sample; no errata were observed during the test period.

Reviewed by:     someone@FreeBSD.org  
MFC after:    2 weeks

Several pieces of that message are standard. Reviewed by: names the committer who signed off on the review. MFC after: suggests a period before the commit can be merged from CURRENT back to STABLE (MFC stands for Merge From Current). You do not fill in these lines yourself as a contributor; the committer who commits your patch will add them.

What you do write is the body: the descriptive paragraphs that explain the change. Write them as if you are writing them for a future reader who will see the commit in `git log` five years from now and wonder what it was about. That reader is you, possibly, or it is someone maintaining your driver after you have moved on. Make the commit message kind to them.

### 37.5.11 Signed-off-by and the Developer Certificate of Origin

For GitHub pull requests in particular, the CONTRIBUTING.md file asks that commits include a Signed-off-by: line. This line certifies the Developer Certificate of Origin at <https://developercertificate.org/>, which in plain terms is a statement that you have the right to contribute the code under the project's licence.

Adding a Signed-off-by: is easy:

```
git commit -s
```

The -s flag adds a line of the form:

```
Signed-off-by: Your Name <you@example.com>
```

to the commit message. Use the same name and email you use for the commit author line.

### 37.5.12 What a Complete Submission-Ready Tree Looks Like

After all of this, your driver's tree within the FreeBSD source tree should look roughly like this:

```
/usr/src/sys/dev/mydev/
 mydev.c
 mydev.h (optional)
 mydevreg.h (optional but recommended)

/usr/src/sys/modules/mydev/
 Makefile

/usr/src/share/man/man4/
 mydev.4
```

And you should be able to build the module with:

```
cd /usr/src/sys/modules/mydev
make obj
make depend
make
```

And validate the manual page with:

```
mandoc -Tlint /usr/src/share/man/man4/mydev.4
```

And run the style checker with:

```
/usr/src/tools/build/checkstyle9.pl /usr/src/sys/dev/mydev/mydev.c
```

If all three of these complete without errors, your driver is mechanically ready for submission. There is still the licensing, the manual page content, the testing, and the patch generation to cover, which we will do in the next sections. But the basic layout is now in place, and a reviewer opening the patch will find that the file names, the file layouts, the style, and the build integration match what they expect to see in the tree.

### 37.5.13 Common Mistakes in Section-2 Preparation

Before we close this section, let us collect the most common preparation mistakes that first-time contributors make. Treat this as a quick self-check before moving on to Section 3.

- Files in the wrong location. The driver lives under `/usr/src/sys/dev/<driver>/`, not at the top of `/usr/src/sys/`. The module Makefile lives under `/usr/src/sys/modules/<driver>/`. The manual page lives under `/usr/src/share/man/man4/`.
- File names that do not match the driver. If the driver is `mydev`, the main source file is `mydev.c`, not `main.c` or `driver.c`.
- Missing or incorrect copyright header. The header uses `/* -` as the opening marker, the SPDX identifier comes first, and the licence text matches one of the project's accepted licences.

- Spaces instead of tabs. `style(9)` is explicit about tabs, and the style checker will flag space indentation immediately.
- Missing parentheses on return expressions. A recurring small mistake that the style checker will catch.
- Missing blank line between variable declarations and code. Another small convention that the style checker catches.
- Commit message that does not follow the subsystem: Short description form. The reviewer will ask you to rewrite it.
- Trailing whitespace. The `CONTRIBUTING.md` file explicitly flags trailing whitespace as something reviewers dislike.
- Makefile that hardcodes `/usr/src` instead of using `${SRCTOP}`.

Every one of these is an easy fix when you know to look for it. Every one of them adds one round of back-and-forth to a review when you do not. The goal of this section was to give you the knowledge to catch all of them before you submit.

### 37.5.14 Wrapping Up Section 2

Getting a driver ready for submission is less about cleverness than about attention to detail. The file layout, the style, the copyright header, the Makefile, the commit message: each of them has a conventional form, and a driver whose files match those conventions is a driver whose reviewer's first impression is "this looks right." That first impression is worth more than any other single factor in determining how many rounds of review the patch will need.

We have not yet talked about the licence itself in detail, nor about the manual page, nor about testing. Those are the subjects of the next three sections. But the mechanical preparation of the source tree, which is where first-time contributors most often stumble, is now covered.

Let us turn next to licensing and the legal considerations that frame every FreeBSD contribution.

## 37.6 Section 3: Licensing and Legal Considerations

### 37.6.1 Why Licensing Matters Up Front

The easiest way to get your driver rejected is to get the licence wrong. Licensing is not a procedural preference in FreeBSD; it is a foundation of how the project works. The FreeBSD operating system ships under a combination of permissive licences that users can rely on without surprise. A contribution that carries an incompatible licence, or an unclear licence, or no licence at all, cannot be accepted into the tree, no matter how excellent the code is in every other respect.

This is not legal formalism for its own sake. It is a practical necessity. FreeBSD is used in many environments, including commercial products that are shipped to millions of users. Those users rely on the project's licence to understand their obligations. A single file in the tree that carries a surprise licence could expose the entire project's downstream users to obligations they did not sign up for. The project cannot accept that risk.

For you as a contributor, the practical takeaway is this: get the licence right up front. It is easier, by a wide margin, than trying to fix it after the review process has flagged it. This section walks through what the project

accepts, what it does not accept, and how to structure the copyright header so that your submission sails through the licensing check.

### 37.6.2 What Licences FreeBSD Accepts

The FreeBSD Project prefers, as a default, the two-clause BSD licence, often written as BSD-2-Clause. This is the permissive licence that most of FreeBSD itself ships under, and it is the default recommendation for new code. BSD-2-Clause allows redistribution in source and binary form, with or without modification, as long as the copyright notice and the licence text are preserved. It imposes no requirement on downstream users to distribute their source, no requirement for compatibility notices, and no patent grant clause that might complicate commercial use.

The three-clause BSD licence, BSD-3-Clause, is also accepted. It adds one clause prohibiting the use of the author's name in endorsements. Some older FreeBSD code uses this form, and it is equivalent for most practical purposes.

A few other permissive licences appear in the tree for specific files contributed under them historically. The MIT-style licences and the ISC licence both appear in places. The Beerware licence, a whimsical permissive licence introduced by Poul-Henning Kamp, also appears in a few files such as `/usr/src/sys/dev/led/led.c`. These licences are compatible with FreeBSD's overall licensing scheme and are accepted when they accompany specific code contributed under them.

For a new driver that you are writing yourself, the right default is BSD-2-Clause. Unless you have a specific reason to use a different licence, use BSD-2-Clause. It is the licence your reviewers will expect, and any deviation from it will trigger a conversation you probably do not want to have on a first submission.

### 37.6.3 What Licences FreeBSD Does Not Accept

Several licences are not compatible with the FreeBSD source tree and code under them cannot be merged. The most common ones that first-time contributors sometimes try to use are:

- The GNU General Public Licence (GPL), in any version. GPL code is not compatible with FreeBSD's licensing model because it imposes source-distribution obligations on downstream users that the rest of the tree does not carry. FreeBSD does include some GPL-licensed components in userland, such as the GNU Compiler Collection, but these are specific historical cases and are not a template for new contributions. Driver code, in particular, is not accepted under GPL.
- The Lesser GPL (LGPL). Same reasoning as GPL.
- The Apache Licence, version 2 or otherwise, unless there is specific discussion and approval. The Apache Licence includes a patent grant clause that interacts in complicated ways with the permissive BSD licences. Some Apache-licensed code is accepted in specific contexts but it is not the default for new code.
- The MIT licence in its various forms, while technically permissive, is not a default choice for FreeBSD. If you have a specific reason to use MIT, discuss it with a reviewer before submission.
- Anything proprietary. The tree cannot accept code whose licence restricts redistribution or modification.
- Code with unclear licensing, including code copied from other projects whose licence is not known, code generated by tools whose licensing terms are unclear, and code contributed without a clear licence declaration.

If you are porting or adapting code from another open-source project, check the licence of the source project carefully before you start. Bringing in code from a GPL-licensed project into your driver, even a small function, contaminates the driver and makes it unable to enter the FreeBSD tree.

### 37.6.4 The Copyright Header in Detail

The copyright header at the top of every source file in the tree has a specific structure, documented in `style(9)`. Let us walk through a complete header and examine every part.

```
/*-
 * SPDX-License-Identifier: BSD-2-Clause
 *
 * Copyright (c) 2026 Your Name <you@example.com>
 *
 * Redistribution and use in source and binary forms, with or
 * without modification, are permitted provided that the
 * following conditions are met:
 * 1. Redistributions of source code must retain the above
 * copyright notice, this list of conditions and the following
 * disclaimer.
 * 2. Redistributions in binary form must reproduce the above
 * copyright notice, this list of conditions and the following
 * disclaimer in the documentation and/or other materials
 * provided with the distribution.
 *
 * THIS SOFTWARE IS PROVIDED BY THE AUTHORS ``AS IS'' AND ANY
 * EXPRESS OR IMPLIED WARRANTIES, INCLUDING, BUT NOT LIMITED TO,
 * THE IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A
 * PARTICULAR PURPOSE ARE DISCLAIMED. IN NO EVENT SHALL THE
 * AUTHORS BE LIABLE FOR ANY DIRECT, INDIRECT, INCIDENTAL,
 * SPECIAL, EXEMPLARY, OR CONSEQUENTIAL DAMAGES (INCLUDING, BUT
 * NOT LIMITED TO, PROCUREMENT OF SUBSTITUTE GOODS OR SERVICES;
 * LOSS OF USE, DATA, OR PROFITS; OR BUSINESS INTERRUPTION)
 * HOWEVER CAUSED AND ON ANY THEORY OF LIABILITY, WHETHER IN
 * CONTRACT, STRICT LIABILITY, OR TORT (INCLUDING NEGLIGENCE OR
 * OTHERWISE) ARISING IN ANY WAY OUT OF THE USE OF THIS SOFTWARE,
 * EVEN IF ADVISED OF THE POSSIBILITY OF SUCH DAMAGE.
 */
```

The opening `/* -` is not a typo. The dash after the star is significant. An automated script in the tree harvests licence information from files by looking for multi-line comments that start in column 1 with the sequence `/* -`. Using `/*` flags the block as a licence; using plain `/*` does not. `style(9)` is explicit: if you want the tree's licence harvester to pick up your licence correctly, use `/* -` for the opening line.

Immediately after the opening is the `SPDX-License-Identifier` line. `SPDX` is a standardised vocabulary for

describing licences in machine-readable form. The line tells the harvester which licence the file is under, and it does so in a form that cannot be misinterpreted. Use `BSD-2-Clause` for a two-clause BSD licence, `BSD-3-Clause` for a three-clause BSD licence. For other licences, consult the SPDX identifier list at <https://spdx.org/licenses/>. Do not invent identifiers.

The copyright line names the year and the copyright holder. Use your full legal name, or the name of your employer if you are contributing work done under employment, followed by an email address that is stable enough to contact you years from now. If you are contributing as an individual, use your personal email rather than a throwaway address.

Multiple copyright lines may be present if the file has had multiple authors. When you add a copyright line, add it at the bottom of the existing list, not at the top. Do not delete anyone else's copyright line. The existing attributions are legally significant.

The licence text itself follows. The text reproduced above is the standard `BSD-2-Clause` text. Do not modify it. The wording is legally specific, and changing it, even in a way that seems clearer, may make the licence legally distinct from what the project accepts.

Finally, there is a blank line after the closing `*/`, before the code begins. This blank line is a convention in the tree and is called out in `style(9)`. Its purpose is visual.

### 37.6.5 Reading Existing Headers to Build Intuition

The best way to internalise the licence header conventions is to look at real headers in the tree. Open `/usr/src/sys/dev/null/null.c` and read its header. Open `/usr/src/sys/dev/led/led.c` and read its header (which is under the Beerware licence, an unusual but accepted case). Open a couple of network drivers under `/usr/src/sys/dev/re/` or `/usr/src/sys/dev/e1000/` and read theirs. Within fifteen minutes you will have absorbed the pattern.

A few things you will notice:

- Some older files in the tree do not have SPDX identifiers. These predate the SPDX convention. For new contributions, use SPDX.
- Some older files still have a `$FreeBSD$` tag near the top. This was a CVS-era marker that is no longer active since the project moved to git. New contributions do not include `$FreeBSD$` tags.
- Some files have multiple copyright lines spanning multiple contributors across years. This is normal and correct. When you add a copyright line to an existing file, append it.
- A few files have non-standard licences (Beerware, MIT-style, ISC). These are historical and are accepted on a case-by-case basis. Do not use them as templates for new contributions.

### 37.6.6 Derivative Works and External Code

If your driver is entirely your own work, the header is straightforward. If it includes code derived from another project, the picture is more complicated.

Any code you copy or adapt from another project carries that project's licence along with it. If the project's licence is BSD-compatible, you can use the code, but you must preserve the original copyright notice and make the adaptation visible. If the licence is not BSD-compatible, such as GPL, you cannot use the code at all.

The convention in the tree for derivative works is to preserve the original copyright line and add your own as a separate line:

```
/*-
 * SPDX-License-Identifier: BSD-2-Clause
 *
 * Copyright (c) 1998 Original Author <original@example.com>
 * Copyright (c) 2026 Your Name <you@example.com>
 *
 * [licence text]
 */
```

If the original licence is BSD-3-Clause and you are contributing additions under BSD-2-Clause, the file is effectively BSD-3-Clause overall, because the three-clause requirement flows through derivative works. Use the more restrictive of the two licences in the SPDX identifier, or keep separate licensing at a per-section level if the code is clearly separable. When in doubt, ask a reviewer.

If the code is taken from a specific external source whose origin is relevant, mention it in a comment near the relevant function:

```
/*
 * Adapted from the NetBSD driver at
 * src/sys/dev/foo/foo.c, revision 1.23.
 */
```

This helps reviewers and future maintainers understand the provenance. It also helps anyone tracking bugs back to their upstream fix.

### 37.6.7 Adapted Code from Vendor Sources

A common scenario for hardware drivers is that the vendor provides sample code or a reference driver under some licence. If the vendor's code is under a BSD-compatible licence, you may be able to use it directly, possibly with adaptation, preserving the vendor's copyright. Read the vendor's licence carefully. If the licence is not BSD-compatible, you cannot use the vendor's code in a driver destined for the tree. You may be able to use the vendor's documentation as a reference for independently implementing the driver, but you cannot lift code.

If the vendor provides documentation under a non-disclosure agreement (NDA), the situation is more delicate still. An NDA typically prohibits you from disclosing the documentation. It may not prohibit you from using the documentation to write code, but the resulting code must be your own work, not a copy of any code the vendor provided. Be scrupulous about keeping this line clear. If there is any doubt, do not proceed without legal advice.

### 37.6.8 Code You Did Not Write but Are Submitting

If you are submitting code that someone else wrote, such as a colleague's contribution, you need their explicit permission and their copyright line in the header. You cannot contribute code on someone else's behalf without

their knowledge. The Signed-off-by: line that the project asks for is, in part, a mechanism for tracking this; the Developer Certificate of Origin that the line certifies includes a statement that you have the right to contribute the code.

If you are a company employee contributing work done under employment, your employer typically holds the copyright, not you. The copyright line should name the employer. Many companies have internal processes for approving open-source contributions; follow those before submitting. Some companies prefer to have their employees sign a contributor licence agreement (CLA) with the FreeBSD Foundation for clarity; if yours does, coordinate with your company before submitting.

### 37.6.9 Adding Licence Headers to an Existing Driver

If you are retrofitting a driver you have already written but never prepared for submission, you will need to add the proper header to each file. The steps are:

1. Decide on the licence. For a new driver, use BSD-2-Clause.
2. Write the SPDX identifier line.
3. Write the copyright line with your name, email, and the year of first creation.
4. Paste in the standard BSD-2-Clause licence text.
5. Verify that the opening is `/* -` and the file starts in column 1.
6. Verify that there is a single blank line after the closing `*/`.
7. Repeat for each file: the `.c` files, the `.h` files, the manual page (where the licence appears as `.\"` - style comments rather than `/* -` style), and any other files that contain substantial content.

For the Makefile, as noted earlier, a licence header is conventionally omitted for trivial files. The module Makefile shown in Section 2 is trivial enough that no header is required.

### 37.6.10 Validating the Header

There is no single automated tool that validates every aspect of a FreeBSD copyright header. The `check-style9.pl` script catches some kinds of formatting errors near the header. The licence harvester in the tree works on the `/* -` marker and the SPDX line. The most reliable validation, however, is to compare your header directly against a known-good header from a recent commit in the tree, such as the header in `/usr/src/sys/dev/null/null.c` or any recently added driver.

Build a small habit: when you open a new source file, paste in a known-good header as the first action. This prevents the easy mistake of forgetting the header entirely and also ensures that the shape is right from the start.

### 37.6.11 Wrapping Up Section 3

Licensing is one of the places where getting it right up front saves enormous amounts of time. The FreeBSD Project accepts BSD-2-Clause, BSD-3-Clause, and a few other permissive licences for historical files. New contributions should default to BSD-2-Clause. The copyright header uses a specific form, opening with `/* -`, followed by an SPDX identifier, followed by one or more copyright lines, followed by the standard licence text. Code derived from other projects carries its original licence obligations forward, and derivative work

must preserve the original attributions. Code you did not write yourself requires the author's permission and attribution.

With the legal side handled, we can turn to the manual page. Every driver in the tree ships with a manual page, and writing a good one is one of the places where first-time contributors most often underestimate the effort involved. Section 4 walks through the conventions and provides a template you can adapt.

## 37.7 Section 4: Writing a Manual Page for Your Driver

### 37.7.1 Why the Manual Page Matters

The manual page is the user-facing half of your driver. When someone finds your driver in the tree and wants to know what it does, they will not read the source code. They will run `man 4 mydev`. What they see will be, for most of them, the only documentation they ever have of your driver. If the manual page is clear, complete, and well-organised, users will understand what the driver supports, how to use it, and what its limitations are. If the manual page is missing, sparse, or poorly organised, users will be confused, they will file bug reports that are really documentation problems, and they will, reasonably, form a negative impression of the driver.

From the project's point of view, the manual page is a first-class artifact of the contribution. A driver without a manual page cannot be merged. A driver with a poor manual page will be delayed at review until the manual page is brought up to standard. You should think of the manual page as part of the driver, not as an afterthought.

From a practical point of view, writing the manual page is often a useful discipline in its own right. The act of explaining to a user what the driver does, what hardware it supports, what tunables it exposes, and what its known limitations are, forces you to articulate those things clearly. It is not uncommon for a well-written manual page to surface questions that the driver's design had not yet resolved. Writing the manual page is therefore part of the work of finishing the driver, not a step after the driver is done.

### 37.7.2 Manual Page Sections: A Quick Orientation

The manual pages in FreeBSD are organised into numbered sections. The sections are:

- Section 1: General user commands.
- Section 2: System calls.
- Section 3: Library calls.
- Section 4: Kernel interfaces (devices, device drivers).
- Section 5: File formats.
- Section 6: Games.
- Section 7: Miscellaneous and conventions.
- Section 8: System administration and privileged commands.
- Section 9: Kernel internals (APIs and subsystems).

Your driver belongs in Section 4. The manual-page file goes under `/usr/src/share/man/man4/` and is conventionally named `<driver>.4`, for example `mydev.4`. The `.4` suffix is the manual-page convention; it marks the file as a section-4 page.

The file itself is written in the mdoc macro language, not in plain text. Mdoc is a structured macro set that produces formatted manual pages from a source file that is more or less human-readable. The project's style for

mdoc is documented in `/usr/src/share/man/man5/style.mdoc.5`; you should read that file before writing your first manual page, though much of what it says will make more sense after you have tried to write one.

### 37.7.3 The Structure of a Section-4 Manual Page

A section-4 manual page has a well-established structure. The following sections appear in roughly this order:

1. **NAME:** The driver name and a one-line description.
2. **SYNOPSIS:** How to include the driver in the kernel or load it as a module.
3. **DESCRIPTION:** What the driver does, in prose.
4. **HARDWARE:** The list of hardware the driver supports. This section is required for section-4 pages and is drawn verbatim into the Release Hardware Notes.
5. **LOADER TUNABLES, SYSCTL VARIABLES:** If the driver exposes tunables, document them here.
6. **FILES:** The device nodes and any configuration files.
7. **EXAMPLES:** Usage examples, when relevant.
8. **DIAGNOSTICS:** Explanations of the driver's log messages.
9. **SEE ALSO:** Cross-references to related manual pages and documents.
10. **HISTORY:** When the driver first appeared.
11. **AUTHORS:** The primary author(s) of the driver.
12. **BUGS:** Known issues and limitations.

Not every section is required for every driver. For a simple driver, **NAME**, **DESCRIPTION**, **HARDWARE**, **SEE ALSO**, and **HISTORY** are the minimum. For a more complex driver, add the others as relevant.

### 37.7.4 A Minimum Working Manual Page

Here is a complete, working section-4 manual page for a hypothetical `mydev` driver. Save it as `mydev.4`, run `mandoc -T` lint on it, and you will see it pass clean. This is the kind of manual page you can adapt to your own driver.

.Dt MYDEV 4
.Os
.Sh NAME
.Nm mydev
.Nd driver for FooCorp FC100 sensor boards
.Sh SYNOPSIS
To compile this driver into the kernel,
place the following line in your
kernel configuration file:
.Bd -ragged -offset indent
.Cd "device mydev"
.Ed
.Pp
Alternatively, to load the driver as a
module at boot time, place the following line in
.Xr loader.conf 5 :
.Bd -literal -offset indent
mydev_load="YES"
.Ed
.Sh DESCRIPTION
The
.Nm
driver provides support for FooCorp FC100 series PCI-attached
environmental sensor boards.
It exposes a character device at
.Pa /dev/mydev0
that userland programs can open, read, and write using standard
system calls.
.Pp
```

Each attached board is enumerated with an integer unit number beginning at 0.

The driver supports probe, attach, and detach through the standard Newbus framework.

.Sh HARDWARE

The

.Nm

driver supports the following hardware:

.Pp

.Bl -bullet -compact

.It

FooCorp FC100 rev 1.0

.It

FooCorp FC100 rev 1.1

.It

FooCorp FC200 (compatibility mode)

.El

.Sh FILES

.Bl -tag -width ".Pa /dev/mydev0"

.It Pa /dev/mydev0

First unit of the driver.

.El

.Sh SEE ALSO

.Xr pci 4

.Sh HISTORY

The

.Nm

driver first appeared in

.Fx 15.0 .

.Sh AUTHORS

.An -nosplit

The

.Nm

driver and this manual page were written by

.An Your Name Aq Mt you@example.com .

That manual page is a complete, valid section-4 page. It is short because the hypothetical driver is simple. A more complex driver would have larger DESCRIPTION, HARDWARE, and possibly LOADER TUNABLES, SYSCTL VARIABLES, DIAGNOSTICS, and BUGS sections. But the skeleton is the same.

Let us walk through the parts that are most frequently misunderstood.

### 37.7.5 The Header Block

The header block at the top is a set of comment lines that begin with `.\`. These are mdoc comments. They are not rendered in the manual page output. They exist to carry the copyright header and any notes to future editors.

The opening marker is `.\` - with a dash, equivalent to the `/*` - in C files. The licence harvester recognises it.

The `.Dd` macro sets the document date. It is formatted as month, day, year with full month name. The project's mdoc style is to update `.Dd` whenever the content of the manual page changes meaningfully. Do not bump the date for trivial changes such as whitespace fixes, but do bump it for anything semantic.

The `.Dt` macro sets the document title. The convention is the driver name in uppercase, followed by the section number: `MYDEV 4`.

The `.Os` macro emits the operating system identifier in the footer. Use it bare; mdoc will fill in the right thing from build-time macros.

### 37.7.6 The NAME Section

The `.Sh NAME` macro opens the NAME section. The content is a pair of macros:

```
.Nm mydev
.Nd driver for FooCorp FC100 sensor boards
```

`.Nm` sets the name of the thing being documented. Once set, `.Nm` with no arguments elsewhere in the page expands to the name, which is how we avoid repeating the driver name over and over.

`.Nd` is the short description, a sentence-fragment of the form “driver for ...” or “API for ...” or “device for ...”. Do not capitalise the first word or add a period at the end.

### 37.7.7 The SYNOPSIS Section

For a driver, the SYNOPSIS typically shows two things: how to compile the driver into the kernel as a built-in, and how to load it as a module. The built-in form uses `.Cd` for a kernel configuration line. The loadable form shows the `_load="YES"` entry for `loader.conf`.

If the driver exposes a header file that userland programs must include, or if it exposes a library-like API, the SYNOPSIS can also include `.In` for the include directive and `.Ft/.Fn` for function prototypes. See `/usr/src/share/man/man4/led.4` for an example of a driver manual page whose SYNOPSIS shows function prototypes.

### 37.7.8 The DESCRIPTION Section

The DESCRIPTION section is where you explain, in prose, what the driver does. Write it for a user who has installed FreeBSD, has the hardware in front of them, and wants to know what the driver offers.

Keep the paragraphs focused. Use `.Pp` to separate paragraphs. Use `.Nm` to refer to the driver, not the driver name typed out. Use `.Pa` for path names, `.Xr` for cross-references to other manual pages, `.Ar` for argument names, and `.Va` for variable names.

Describe the driver's behaviour, its lifecycle (probe, attach, detach), its device-node structure, and any concepts a user needs to understand before interacting with it. Do not document internal implementation details here; the source code is the right place for those.

### 37.7.9 The HARDWARE Section

The HARDWARE section is required for section-4 pages. This is the section that gets drawn verbatim into the Release Hardware Notes, which is the document users consult to see whether their hardware is supported.

Several specific rules apply to this section. These rules are documented in `/usr/src/share/man/-man5/style.mdoc.5`:

- The introductory sentence should be in the form: “The `.Nm` driver supports the following :” followed by the list.
- The list should be a `.Bl -bullet -compact` list with one hardware model per `.It` entry.
- Each model should be named with its official commercial name, not an internal code name or chip revision.
- The list should include all hardware that is known to work, including revisions.
- The list should not include hardware that is known not to work; those belong in BUGS.

For a brand-new driver, the list may be short. That is fine. For a driver that has been in the tree for a while and has accumulated support for many hardware variants, the list grows over time as each new variant is tested.

### 37.7.10 The FILES Section

The FILES section lists the device nodes and configuration files that the driver uses. Use a `.Bl -tag` list with `.Pa` entries for the file names. For example:

```
.Sh FILES
.Bl -tag -width ".Pa /dev/mydev0"
.It Pa /dev/mydev0
First unit of the driver.
.It Pa /dev/mydev1
Second unit of the driver.
.El
```

Keep the `.Bl -tag -width` value wide enough to accommodate the longest path in the list. If the widths do not match, the list will render badly.

### 37.7.11 The SEE ALSO Section

The SEE ALSO section cross-references related manual pages. It is written as a list of `.Xr` cross-references, comma-separated, with the list sorted first by section number and then alphabetically within a section:

```
.Sh SEE ALSO
.Xr pci 4 ,
.Xr sysctl 8 ,
.Xr style 9
```

A driver's SEE ALSO typically includes the bus it attaches to (such as `pci(4)`, `usb(4)`, or `iicbus(4)`), any userland tool that interacts with it, and any section-9 APIs that are central to the driver's implementation.

### 37.7.12 The HISTORY Section

The HISTORY section says when the driver first appeared. For a brand-new driver that will first appear in the next release, write the release version as a placeholder:

```
.Sh HISTORY
The
.Nm
driver first appeared in
.Fx 15.0 .
```

The committer who commits your patch will verify the version number against the release schedule and may adjust it. That is fine.

### 37.7.13 The AUTHORS Section

The AUTHORS section names the primary authors of the driver. Use `.An -nosplit` at the top to tell mdoc not to split the author list across lines at name boundaries. Then use `.An` for each author with `.Aq Mt` for the email address.

```
.Sh AUTHORS
.An -nosplit
The
.Nm
driver was written by
.An Your Name Aq Mt you@example.com .
```

For a driver with multiple authors, list them in order of contribution, with the primary author first.

### 37.7.14 Validating the Manual Page

Once the manual page is written, validate it with `mandoc(1)`:

```
mandoc -Tlint /usr/src/share/man/man4/mydev.4
```

`mandoc -Tlint` runs the page through the mandoc parser in strict mode and reports any structural or semantic problems. Fix every warning. A clean `mandoc -Tlint` run is a prerequisite for submission.

You can also render the page to see what it looks like:

```
mandoc /usr/src/share/man/man4/mydev.4 | less -R
```

Read the rendered output as a user would. If something reads awkwardly, fix the source. If a cross-reference renders in a way you did not expect, check the macro usage. Read the output at least twice.

The project additionally recommends the `igor(1)` tool, available from the ports tree as `textproc/igor`. `igor` catches prose-level issues that `mandoc` does not, such as double spaces, unmatched quotes, and common prose mistakes. Install it with `pkg install igor` and run it on your page:

```
igor /usr/src/share/man/man4/mydev.4
```

Fix any warnings it produces.

### 37.7.15 The One-Sentence-Per-Line Rule

An important convention in FreeBSD mdoc pages is the one-sentence-per-line rule. Each sentence in the manual page source starts on a new line, regardless of line width. This is not about display formatting; mdoc will reflow the text for display. It is about source readability and about how `diff` shows changes. When changes are line-oriented, a diff of a manual page change shows which sentences changed; when sentences span lines, the diff is harder to read.

The `CONTRIBUTING.md` file is explicit about this:

Please be sure to observe the one-sentence-per-line rule so manual pages properly render. Any semantic changes to the manual pages should bump the date.

In practice this means you write:

```
The driver supports the FC100 family.
It attaches through the standard PCI bus framework.
Each unit exposes a character device under /dev/mydev.
```

Not:

```
The driver supports the FC100 family. It attaches through the
standard PCI bus framework. Each unit exposes a character device
under /dev/mydev.
```

The first form is conventional, the second is not.

### 37.7.16 Common Manual-Page Mistakes

Several mistakes recur in first-time submissions:

- Missing `HARDWARE` section. Section-4 pages are required to have one. If your driver supports no hardware yet (because it is a pseudo-device), document that explicitly.
- Period at the end of the `NAME` description. The `.Nd` description should be a fragment without a trailing period.
- Capitalised section headings spelled wrongly. The headings are canonical. Use `DESCRIPTION`, not `DESCRIPTIIONS`. Use `SEE ALSO`, not `See Also`. Use `HISTORY`, not `History`.
- Multi-sentence paragraphs without `.Pp` separation. Use `.Pp` between paragraphs in prose.
- Forgetting to bump `.Dd` when making semantic changes. If you change the content of the manual page, update the date.
- Using `.Cm` or `.Nm` where `.Ql` (literal quotation) or plain text is appropriate.
- Missing or malformed `.Bl/.El` pairs. Every list must be properly opened and closed.

Running `mandoc -Tlint` catches most of these. Running `igor` catches a few more. Reading the rendered output catches the remainder.

### 37.7.17 Looking at Real Manual Pages

Before you finalise your own manual page, spend time reading real ones. Three useful models:

- `/usr/src/share/man/man4/null.4` is a minimal page. Good for the basic shape.
- `/usr/src/share/man/man4/led.4` is a slightly more complex page that shows `SYNOPSIS` with function prototypes.
- `/usr/src/share/man/man4/re.4` is a full-featured network driver page. Good for seeing `HARDWARE`, `LOADER TUNABLES`, `SYSCTL VARIABLES`, `DIAGNOSTICS`, and `BUGS` in action.

Read each of them. Open them in `less`, read the rendered version, then open the source in an editor. Compare the rendered output to the source. You will see how the macros produce the formatted text, and you will absorb the conventions by osmosis.

### 37.7.18 Wrapping Up Section 4

The manual page is not an afterthought. It is a first-class artifact that ships with your driver and is the primary user-facing documentation. A good manual page has a specific structure (`NAME`, `SYNOPSIS`, `DESCRIPTION`, `HARDWARE`, and so on), is written in `mdoc`, follows the one-sentence-per-line rule, and passes `mandoc -Tlint` clean. The page deserves the same care as the code. A driver with a poor manual page will be held at review until the page is brought up to standard; a driver with a good one will clear that part of the review easily.

With the licence and the manual page in hand, you have all the paperwork of a driver submission covered. The next section turns to the technical side of testing, because a driver that compiles cleanly and passes style checks still needs to build on every supported architecture and behave correctly in a variety of situations. Section 5 walks through those tests.

## 37.8 Section 5: Testing Your Driver Before Submission

### 37.8.1 The Tests That Matter

Testing a driver before submission is not a single action. It is a sequence of verifications, each of which checks a different property. A driver that passes all of them is a driver the reviewers can focus on in terms of design and intent, rather than in terms of preventable mechanical problems. A driver that skips some of them is a driver that will have avoidable problems surfaced during review, each of which adds a round to the review cycle.

The tests fall into several categories:

1. Code-style tests, which verify that the source conforms to `style(9)`.
2. Manual-page tests, which verify that the `mdoc` source is syntactically valid and renders cleanly.
3. Local build tests, which verify that the driver builds as a loadable kernel module against the current FreeBSD source tree.
4. Runtime tests, which verify that the driver loads, attaches to its device, handles a basic workload, and detaches cleanly.
5. Cross-architecture build tests, which verify that the driver compiles on every architecture the project supports.
6. Lint and static-analysis tests, which catch bugs that the compiler does not flag but that are visible to more aggressive tooling.

Each category has its own tools and its own workflow. This section walks through them in order.

### 37.8.2 Code-Style Tests

We have already seen `tools/build/checkstyle9.pl` in Section 2. Here we will elaborate on its use.

The script lives at `/usr/src/tools/build/checkstyle9.pl`. It is a Perl program, so you invoke it as a script with Perl:

```
perl /usr/src/tools/build/checkstyle9.pl /usr/src/sys/dev/mydev/mydev.c
```

Or, if the script is executable and Perl is in its shebang line, simply:

```
/usr/src/tools/build/checkstyle9.pl /usr/src/sys/dev/mydev/mydev.c
```

The output is a list of warnings with line numbers. Typical warnings include:

- “space(s) before tab”
- “missing blank line after variable declarations”
- “unused variable”
- “return statement without parentheses”
- “function name is not followed by a newline”

Each warning maps to a specific rule in `style(9)`. Fix each one. Re-run. Repeat until the output is clean.

If you find yourself disagreeing with a warning, check `style(9)` first. It is possible for the script to produce false positives, but those are rare. Most of the time, a disagreement with the style checker is a misunderstanding of `style(9)`. Read the manual page before arguing.

Run `checkstyle9.pl` on every `.c` and `.h` file in your driver. The Makefile does not need to pass it since it is not C code.

### 37.8.3 Manual-Page Tests

For the manual page, the canonical test is `mandoc -Tlint`:

```
mandoc -Tlint /usr/src/share/man/man4/mydev.4
```

Fix every warning. Re-run. Repeat until the output is clean.

In addition, run `igor` if you have it installed:

```
igor /usr/src/share/man/man4/mydev.4
```

And render the page to read it as a user would:

```
mandoc /usr/src/share/man/man4/mydev.4 | less -R
```

You can also install your page into the system for a realistic test:

```
cp /usr/src/share/man/man4/mydev.4 /usr/share/man/man4/
makewhatis /usr/share/man
man 4 mydev
```

This last check is useful because it verifies that `man` can find the page, that `apropos` can find it via `whatis`, and that the page renders correctly in the standard pager.

### 37.8.4 Local Build Tests

Before doing anything else with the driver, verify that it builds. From the module directory:

```
cd /usr/src/sys/modules/mydev
make clean
make obj
make depend
make
```

The output should be a single `mydev.ko` file in the module's object directory. No warnings, no errors. If you see warnings, fix them. `style(9)` calls out that warnings should not be ignored; submissions that introduce warnings are held for review.

If you are running on the same machine where you will load the module, install it:

```
sudo make install
```

This copies `mydev.ko` to `/boot/modules/` so that `kldload` can find it.

### 37.8.5 Runtime Tests

Once the module is built and installed, test it:

```
sudo kldload mydev
dmesg | tail
```

The `dmesg` output should show your driver probing, attaching to any available hardware, and completing attach without error. If there is no matching hardware, the driver should simply not attach, which is fine for the loading test.

Exercise the driver as a user would. Open its device nodes, read and write to them, run the operations your driver supports, and watch for any diagnostic messages. Run it under load. Run it with multiple simultaneous openers. Run it with edge-case inputs. These are the kinds of tests that catch bugs the compiler cannot see.

Then unload:

```
sudo kldunload mydev
dmesg | tail
```

The unload should complete silently, with no “device busy” errors and no panics. If the unload produces a warning about busy resources, the driver's detach path has a leak; fix it before submission.

Repeat the load/unload cycle several times. A driver that loads and unloads once is not the same as a driver that loads and unloads repeatedly. Bugs in the detach path often show up only on the second or third unload, when the state left over from the first unload interferes with the second load.

### 37.8.6 Cross-Architecture Build Tests

FreeBSD supports several architectures. The active ones as of FreeBSD 14.3 include:

- amd64 (64-bit x86).
- arm64 (64-bit ARM, also called aarch64).
- i386 (32-bit x86).
- powerpc64 and powerpc64le (POWER).
- riscv64 (64-bit RISC-V).

- armv7 (32-bit ARM).

A driver that builds on amd64 may or may not build on all of the others. Common cross-architecture problems include:

- Integer-size assumptions. A long is 64 bits on amd64 and arm64 but 32 bits on i386 and armv7. If your code assumes `sizeof(long) == 8`, it will break on 32-bit architectures. Use `int64_t`, `uint64_t`, or similar fixed-size types when the size matters.
- Pointer-size assumptions. Similarly, pointers are 64 bits on amd64 and 32 bits on i386. Casting between pointers and integers requires `intptr_t/uintptr_t`.
- Endianness. Some architectures are little-endian, some are big-endian, some are configurable. If your driver reads or writes network-byte-order data, use the explicit byte-swap macros (`htonl`, `htons`, `bswap_32`, and friends), not hand-rolled conversions.
- Alignment. Some architectures enforce strict alignment on multi-byte loads. Use `memcpy` or the `bus_space(9)` API rather than direct casts when accessing hardware registers.
- Bus abstractions. The `bus_space(9)` API abstracts hardware access correctly across architectures; using `inline volatile *` casts does not.

The best way to catch cross-architecture problems is to build the driver for each architecture. Fortunately, FreeBSD has a build target that does exactly that:

```
cd /usr/src
make universe
```

`make universe` builds the world and the kernel for every supported architecture. The full build can take an hour or more depending on the machine, so it is not something you run on every change, but it is the canonical pre-submission test. The Makefile in `/usr/src/` describes it:

```
universe - Really build everything (buildworld and all kernels on all architectures).
```

If you do not want to build everything, you can build just a single architecture:

```
cd /usr/src
make TARGET=arm64 buildkernel KERNCONF=GENERIC
```

This is faster and is often enough to catch the typical cross-architecture issues.

For just your module, you can sometimes cross-build with:

```
cd /usr/src
make buildenv TARGET_ARCH=aarch64
cd sys/modules/mydev
make
```

But `make universe` and `make buildkernel TARGET=...` are the canonical tests, and any serious submission should pass them.

### 37.8.7 tinderbox: The Failure-Tracking Variant of universe

A variant of `make universe` is `make tinderbox`:

```
cd /usr/src
make tinderbox
```

Tinderbox is the same as `universe`, but at the end it reports the list of architectures that failed and exits with an error if any did. For a submission workflow, this is often more useful than plain `universe`, because the failure list is a clear action item.

### 37.8.8 Running Kernel Lint Tools

FreeBSD's kernel build optionally runs additional checks. The `LINT` kernel configuration is a kernel built with every driver and option turned on, which surfaces cross-cutting problems that single-feature kernels miss. Building the `LINT` kernel is not usually required for a driver submission, but it is a useful sanity check if you are touching anything widely used.

`clang` itself, as FreeBSD's default compiler, performs sophisticated static analysis during normal compilation. Build with `WARNS=6` to see the most aggressive warning set:

```
cd /usr/src/sys/modules/mydev
make WARNS=6
```

And fix any warnings that appear. Clang also has a `scan-build` tool that runs static analysis as a separate pass:

```
scan-build make
```

Install it from the ports tree (`devel/llvm`) if it is not available.

### 37.8.9 Testing in a Virtual Machine

Much of this chapter assumes you are testing on a real machine or a virtual machine. Virtual machines are particularly useful for driver testing because a panic costs nothing more than a reboot. Two common approaches:

- `bhyve`, FreeBSD's native hypervisor. A FreeBSD guest under `bhyve` can be a good testing environment, particularly for network drivers using `virtio`.
- `QEMU`. `QEMU` can emulate architectures other than the host, which makes it useful for testing cross-architecture builds at runtime without needing physical hardware in each architecture.

For cross-architecture runtime testing, `QEMU` with a FreeBSD image in the target architecture is a good workflow. Build the module for the target architecture, copy it into the `QEMU` VM, and run `kld load` there. Crashes inside the VM do not affect your host.

### 37.8.10 Testing Against HEAD

The FreeBSD source tree's main branch is sometimes called HEAD, in the release-engineering sense. Your driver should build and run against HEAD, because that is where your patch will first land. If you have been developing against an older branch, update to HEAD before final testing:

```
cd /usr/src
git pull
```

Then rebuild and retest. Kernel APIs change; a driver that built against a six-month-old tree may need small adjustments to build against current HEAD.

### 37.8.11 A Shell Script for the Whole Pipeline

For a serious submission, consider putting the test sequence into a shell script. The companion examples include one, but the skeleton is straightforward:

```
#!/bin/sh
pre-submission-test.sh
set -e

SRC=/usr/src/sys/dev/mydev
MOD=/usr/src/sys/modules/mydev
MAN=/usr/src/share/man/man4/mydev.4

echo "--- style check ---"
perl /usr/src/tools/build/checkstyle9.pl "$SRC"/*.c "$SRC"/*.h

echo "--- mandoc lint ---"
mandoc -Tlint "$MAN"

echo "--- local build ---"
(cd "$MOD" && make clean && make obj && make depend && make)

echo "--- load/unload cycle ---"
sudo kldload "$MOD"/mydev.ko
sudo kldunload mydev

echo "--- cross-architecture build (arm64) ---"
(cd /usr/src && make TARGET=arm64 buildkernel KERNCONF=GENERIC)

echo "all tests passed"
```

Run this script before every submission. If it exits clean, your driver has cleared all the mechanical tests. Reviewers can then focus on the design.

### 37.8.12 What Testing Does Not Catch

Testing tells you that your driver compiles and that it works in the situations you tested. It does not tell you that it works in all situations. A driver that passes every test may still have bugs that surface only under rare workloads, on rare hardware, or in rare interleavings of kernel state.

This is normal. Software is never fully tested. The role of pre-submission testing is not to prove the driver correct, but to catch the mistakes that are easy to catch. Design-level bugs, rare race conditions, and subtle protocol violations will still find their way into the tree and will be caught, sometimes much later, by users who encounter them. That is what post-merge maintenance is for, and we will cover it in Section 8.

### 37.8.13 Wrapping Up Section 5

Testing is a multi-stage verification process. Style checks, manual-page lints, local builds, runtime load/unload cycles, cross-architecture builds, and static analysis each test a different property. A driver that passes all of them is a driver in shape for review. The tools are standard: `checkstyle9.pl`, `mandoc -Tlint`, `make`, `make universe`, `make tinderbox`, and `clang`'s built-in analysis. The discipline is to run them in order, fix every warning they produce, and not submit until they all pass clean.

With the driver tested, we can now turn to the mechanics of actually submitting it for review. Section 6 walks through patch generation and the submission workflow.

## 37.9 Section 6: Submitting a Patch for Review

### 37.9.1 What a Patch Is, in the FreeBSD Sense

A patch, in the FreeBSD sense, is a reviewable unit of change. It can be a single commit or a series of commits. It represents one logical change to the tree. For a new driver submission, the patch is typically one or two commits that introduce the new driver files, the new module Makefile, and the new manual page.

The mechanical form of a patch is a text representation of the changes, usually in unified-diff format. There are several ways to generate such a representation:

- `git diff` produces a diff between two commits or between a commit and the working tree.
- `git format-patch` produces a patch file per commit, with the full commit metadata included, in a form suitable for email or for attachment to a review.
- `arc diff`, from the Phabricator command-line tools, posts the current working state as a Phabricator revision.
- `gh pr create`, from the GitHub command-line tools, opens a GitHub pull request.

The right tool depends on where you are sending the patch. For Phabricator, `arc diff` is standard. For GitHub, `gh pr create` or the GitHub web UI is standard. For mailing lists, `git format-patch` with `git send-email` is standard.

All of them rely on the same underlying git commit. Before you worry about the submission tool, make sure the commit itself is clean.

### 37.9.2 Preparing the Commit

Start from a clean, up-to-date clone of the FreeBSD source tree:

```
git clone https://git.FreeBSD.org/src.git /usr/src
```

Or, if you already have a clone, update it:

```
cd /usr/src
git fetch origin
git checkout main
git pull
```

Create a topic branch for your work:

```
git checkout -b mydev-driver
```

Make your changes: add the driver files, the module Makefile, and the manual page. Run all the tests from Section 5. Fix any issues.

Commit your changes. The commit should be a single logical unit of change. If you are introducing a brand-new driver, one commit is usually appropriate: “mydev: Add driver for FooCorp FC100 sensor boards.” The commit message should follow the conventions from Section 2.

```
git add sys/dev/mydev/ sys/modules/mydev/ share/man/man4/mydev.4
git commit -s
```

The `-s` adds a Signed-off-by: line. The editor opens for the commit message; fill in the subject line and body following the conventions from Section 2.

Review the commit:

```
git show HEAD
```

Read every line. Check that no unrelated files are included. Check that no trailing whitespace is present. Check that the commit message reads well. If anything is off, amend:

```
git commit --amend
```

Repeat until the commit is exactly as you want it.

### 37.9.3 Generating a Patch for Review

Once the commit is clean, generate the patch. For a Phabricator review, `arc diff`:

```
cd /usr/src
arc diff main
```

arc will detect that you are on a topic branch, generate the diff, and open a Phabricator review in your browser. Fill in the summary, tag reviewers if you know any, and submit.

For a GitHub pull request, push your branch and use gh:

```
git push origin mydev-driver
gh pr create --base main --head mydev-driver
```

Or open the pull request through the GitHub web UI. The pull request form asks for a title (use the commit subject line) and a body (use the commit body). The title and body form the description of the pull request; they should match what the committed change will eventually carry.

For a mailing-list submission or an email to a maintainer:

```
git format-patch -1 HEAD
```

This produces a file like 0001-mydev-Add-driver-for-FooCorp-FC100-sensor-boards.patch containing the commit. You can attach it to an email or send it inline with `git send-email`. Mailing-list submissions are less common today than Phabricator or GitHub but are still accepted.

### 37.9.4 Which Route to Take

The `CONTRIBUTING.md` file gives specific guidance on which route to use when. The short version:

- GitHub pull requests are preferred when the change is small (fewer than about 10 files and 200 lines), self-contained, passes CI cleanly, and needs little developer time to land.
- Phabricator is preferred for larger changes, for work that needs extended review, and for subsystems where the maintainers prefer Phabricator.
- Bugzilla is appropriate when the patch fixes a specific reported bug.
- Direct email to a committer is appropriate when you know the maintainer of the subsystem and the change is small enough to handle informally.

A new driver is usually somewhere between the GitHub size limit and the Phabricator fit. If your driver has fewer than 10 files and fewer than 200 lines, a GitHub PR will work. If it is larger, try Phabricator first.

Whichever you choose, make sure the driver has been through all the pre-submission tests. The CI that runs on GitHub and the review process on Phabricator will both catch problems, but it saves everyone time if you have caught them first.

### 37.9.5 Writing a Good Review Description

The patch itself is only half of what you submit. The other half is the description: the text that accompanies the patch and explains what it does, why it is needed, and how it was tested.

On Phabricator, the description is the Summary field. On GitHub, it is the PR body. On a mailing list, it is the body of the email.

A good description has three parts:

1. A one-paragraph summary of what the patch does.
2. A discussion of the design and any interesting decisions.
3. A list of what was tested.

For a driver submission, a typical description might read:

This patch adds a driver for FooCorp FC100 environmental sensor boards. The boards are PCI-attached and expose a simple command-and-status interface over a single BAR. The driver implements probe/attach/detach following Newbus conventions, exposes a character device for userland interaction, and documents tunable sampling intervals via sysctl.

The FC100 is documented in FooCorp's Programmer's Reference Manual version 1.4. The driver supports revisions 1.0 and 1.1 of the board, and operates the FC200 in its FC100-compatibility mode.

Tested on amd64 and arm64 with a physical FC100 rev 1.1 board. Passes `make universe`, `mandoc -Tlint`, and `checkstyle9.pl`. Load/unload cycle verified 50 times without leaks.

Reviewer suggestions welcome on the sysctl structure.

This description does several things right. It explains the driver in a way a reviewer who has never seen it can understand. It establishes what has been tested. It explicitly invites feedback on a specific design question. It reads as a collaborative request for review, not as a “here is my code, merge it” demand.

### 37.9.6 The Draft Email for the Mailing List

Even if you plan to submit via Phabricator or GitHub, a draft email to one of the FreeBSD mailing lists can be a useful introduction. The general-purpose list for development questions is `freebsd-hackers@FreeBSD.org`; there are also subsystem lists such as `freebsd-net@` for network drivers and `freebsd-scsi@` for storage. Pick the list that most closely matches the subsystem your driver lives in, and if in doubt, start with `freebsd-hackers@`.

A draft email might look like this:

To: `freebsd-hackers@FreeBSD.org`  
Subject: New driver: FooCorp FC100 sensor boards

Hello,

I am working on a driver for FooCorp FC100 PCI-attached environmental sensor boards. The boards are documented, I have two hardware samples to test against, and the driver is in a state that passes `mandoc -Tlint`, `checkstyle9.pl`, and `make universe` clean.

Before I open a review, I wanted to ask the list if anyone has:

- \* Experience with similar sensor boards that might inform the `sysctl` structure.
- \* Strong preferences about whether the driver should expose a character device or a `sysctl` tree as the primary interface.
- \* Comments on the draft manual page (attached).

The code is available at <https://github.com/<me>/<branch>> for anyone who wants to take an early look.

Thanks,

Your Name <you@example.com>

This is the kind of email that tends to generate helpful responses. It shows that the work is serious, it asks specific questions, and it offers a way to see the code. Many successful FreeBSD submissions start with an email like this.

For this book, you do not need to actually send such an email. The companion examples include a draft you can use as a template. The exercise in Section 4 of this chapter includes writing your own draft.

### 37.9.7 What Happens After You Submit

Once you submit, the review process begins. The exact flow depends on the submission route, but the general pattern is similar across routes.

For a Phabricator review:

- The revision appears in Phabricator's queue. It is automatically subscribed to any mailing lists relevant to the subsystem.
- Reviewers may pick up the review from the queue, or you may tag specific reviewers you think are relevant.
- Reviewers leave comments on specific lines, general comments, and requested changes.
- You address the comments by updating the commit and running `arc diff --update` to refresh the revision.
- The review cycle repeats until the reviewers are satisfied.
- A committer eventually lands the patch, credited to your name as the author.

For a GitHub pull request:

- The PR appears in the GitHub queue for `freebsd/freebsd-src`.
- CI jobs run automatically; they must pass.
- Reviewers comment on the PR, leave line comments, or request changes.
- You address the comments by committing fixups to your branch. Eventually, you squash the fixups into the original commit.
- When a reviewer is ready, they will either merge the PR themselves (if they are a committer) or shepherd it to Phabricator for a deeper review.

- The merged commit retains your authorship.

For a mailing-list submission:

- Mailing list readers respond with feedback.
- You iterate based on the feedback and send updated versions as replies to the original thread.
- When a committer is ready, they will commit the patch, credited to you.

In all cases, the iteration is part of the process. A patch that enters the tree in exactly the form it was first submitted is rare. Expect at least one round of feedback, often several. Each round is the reviewers helping you polish the submission.

### 37.9.8 Response Time and Patience

Reviewers are volunteers, even those who are paid by employers to work on FreeBSD. Their time is finite. Response time for a review can range from hours (for a small, well-prepared patch that matches the reviewer's current interests) to weeks (for a large, complex patch that needs careful reading).

If your patch has not received a response within a reasonable time, it is acceptable to send a polite ping. The usual conventions:

- Wait at least a week before pinging.
- Keep the ping short: "Just a friendly ping on this review, in case it slipped off anyone's radar." Nothing more.
- Do not ping more than once per week. If a patch is not getting attention after multiple pings, the issue is probably not that the reviewers have forgotten; it may be that the patch needs more work, or that the reviewers who know the subsystem are busy with other things.
- Consider asking on the relevant mailing list for review attention. A public ask is sometimes more effective than private pings.

Do not respond to review silence with anger or pressure. The project is run by volunteers. A review that takes longer than you hoped is not a personal insult.

### 37.9.9 Iteration and Patch Updates

Every round of review will have comments you need to address. Some will be small (rename a variable, add a comment, fix a typo in the manual page). Some will be larger (rework a function, change an interface, add a test).

Address each comment. If you disagree with a comment, reply explaining your reasoning; do not just ignore it. Reviewers are open to being convinced, but only if you make a case.

When you update the patch, keep the commit history clean. If you pushed a "fixup" commit earlier, squash it into the original commit before the final submission. The tree commits should each be logically complete; they should not contain messy incremental steps.

The workflow for a GitHub PR update typically looks like:

```
make the fixes
git add -p
git commit --amend
git push --force-with-lease
```

For a Phabricator update:

```
make the fixes
git add -p
git commit --amend
arc diff --update
```

Always use `--force-with-lease` rather than `--force` when force-pushing. `--force-with-lease` refuses to push if the remote has moved in a way you did not know about, which prevents accidentally overwriting a reviewer's changes.

### 37.9.10 Common Mistakes in Submission

A few common submission-time mistakes:

- Submitting a draft. Polish the patch first. Submitting a patch you know is not ready wastes the reviewers' time.
- Submitting against an outdated tree. Rebase against current HEAD before submission.
- Including unrelated changes. Each submission should be one logical change. Style cleanups, unrelated bug fixes, and random improvements should be separate submissions.
- Not responding to feedback. A patch that stalls in review because the author never replied is a patch that will die.
- Pushing back defensively. Reviewers are trying to help. Responding defensively to feedback is a quick way to sour the relationship.
- Submitting the same patch to multiple routes simultaneously. Pick one route. If you submit to Phabricator, do not also open a GitHub PR with the same content.

### 37.9.11 Wrapping Up Section 6

Submitting a patch for review is a mechanical process once the patch is in shape. The patch is a commit (or series of commits) with a proper message, against a current tree. The submission route depends on the size and nature of the change: small self-contained changes go to GitHub PRs, larger or deeper changes go to Phabricator, specific bug fixes can attach to Bugzilla entries. The accompanying description explains the patch and invites review. What follows is an iterative review cycle that ends with a committer landing the patch.

The next section looks at the human side of that iteration: how to work with a mentor or committer, how to handle feedback, and how to turn a first submission into the beginning of a longer-term relationship with the project.

## 37.10 Section 7: Working With a Mentor or Committer

### 37.10.1 Why the Human Side Matters

The submission process is ultimately a collaboration with people, not with a platform. The patch you submit is reviewed by engineers who have their own contexts, their own workloads, and their own experiences with what makes a driver easy or hard to review. The success or failure of your submission depends as much on how you engage with these people as on the technical quality of the code.

That framing bothers some first-time contributors, who would prefer that the technical work stand alone. The preference is understandable, but it does not match reality. FreeBSD is a community project, not a code-submission service. Reviewers offer their time because they care about the project and because they enjoy helping other contributors succeed. When that care is reciprocated, the experience is good for everyone. When it is not, the experience can be frustrating even for patches that are technically good.

This section walks through the human side of the contribution process. Some of it will feel obvious. Much of it is rarely discussed explicitly, which is why first-time contributors sometimes stumble even when their code is solid.

### 37.10.2 The Role of a Mentor

A mentor, in the FreeBSD context, is a committer who has agreed to guide a specific new contributor through their first submissions. Not every contribution involves a mentor; many first submissions land through ordinary review without a formal mentorship. But when a mentor is involved, the relationship has a specific shape.

A mentor typically does these things:

- Reviews your patches in detail, often before they go to wider review.
- Helps you understand the project's conventions and the specific subsystem you are working in.
- Sponsors commits on your behalf, meaning they commit the patch to the tree crediting you as the author.
- Answers questions about project process, style, and social norms.
- Vouches for you in nomination discussions if, later, commit rights become appropriate.

A mentor is not doing your work. They are accelerating your integration into the project. A good mentor is patient, willing to explain, and willing to push back when you are going in a wrong direction. A good mentee is diligent, willing to listen, and willing to do the work of iterating.

Finding a mentor is often organic. It happens because you engaged productively with a specific committer over several rounds of review, and they offered to take on a more structured mentorship role. It is rarely because you asked cold. If you are interested in mentorship, the right move is to start contributing visibly and productively, and to let the relationship develop.

The FreeBSD Project also has more formal mentorship programmes at various times, including for specific demographic groups or specific subsystems. These programmes are the right place to look for a mentor if you want a structured starting point.

### 37.10.3 Sponsorship: The Commit Pathway

A sponsor is a committer who commits a patch on behalf of a contributor. Every contribution from a non-committer goes through a sponsor at commit time. The sponsor is not necessarily the same person as the primary reviewer, and not necessarily a mentor, though they can be both.

Finding a sponsor for a patch is usually straightforward. If the patch has been through review and at least one committer has approved it, that committer is usually willing to sponsor the commit. You do not need to ask formally; the commit will happen when the reviewer is ready.

If the patch has been reviewed but no one has moved to commit it, a polite question is appropriate: “Is anyone in a position to sponsor the commit of this patch?” Asking in the review thread or on the relevant mailing list will usually find someone.

Do not confuse sponsorship with support in the abstract. A sponsor is specifically the person who runs the `git push` that lands your patch. They take on a small amount of responsibility: their name appears in the commit metadata, and they are implicitly certifying that the patch was ready to land.

### 37.10.4 Receiving Feedback Gracefully

Feedback on your patch can be hard to read, especially the first time. Reviewers write in the mode of reviewing code, which means they name specific things that need to change. That mode reads as negative even when the underlying assessment of the patch is overwhelmingly positive. A review that says “this is a great start, but here are twenty things to fix” is normal for a first submission.

The right response to feedback is to address it. For each comment:

- Read it carefully. Make sure you understand what the reviewer is asking.
- If the comment is clear and actionable, make the change. Do not argue just because the suggestion was not your first choice.
- If the comment is unclear, ask for clarification. “Can you say more about what you mean by X?” is a perfectly fine response.
- If you disagree with the comment, reply explaining your reasoning. Be specific: “I thought about using X but went with Y because Z.” Reviewers are open to being persuaded.
- If the comment is outside the scope of the patch, say so and propose handling it separately. “Good catch, but this is really a separate change; I will send it as a follow-up.”

Never respond with hostility. Even if you believe the reviewer is wrong, respond calmly and with reasoning. A review thread that descends into anger is one that the reviewer will disengage from, and your patch will stall.

Several specific responses to avoid:

- “The code already works.” The code working is not the question. The question is whether it matches the conventions and design expectations of the tree.
- “This is just style; the code is fine.” Style is part of engineering quality. Reviewers are not wasting your time when they ask about style.
- “Other drivers in the tree do it this way.” They may well, and the tree has plenty of older drivers that do not match modern conventions. The goal for new contributions is to match modern conventions, not to reproduce historical drift.

- “I will do that later.” If you say you will do it later, the reviewer has no way to verify that you will. Do it now, or discuss why a later fix is appropriate.

The review process is cooperative. The reviewer is not your adversary. Every comment, even one you disagree with, is the reviewer investing time in your patch. Respond to that investment with your own.

### 37.10.5 Iteration and Patience

Patch review is iterative by design. A typical first driver submission goes through three to five rounds of review before it lands. Each round takes days to weeks, depending on reviewer availability and the size of the changes requested.

The total elapsed time from first submission to merge, for a new driver, is often several weeks. Sometimes it is months. That is normal. FreeBSD is a careful project; careful review takes time.

Several habits that help with iteration:

- Respond quickly. The faster you respond to feedback, the faster the review proceeds. Delays on your side are as damaging to the timeline as delays on the reviewer’s side.
- Batch small fixes. If the reviewer leaves ten comments, make all ten fixes in a single update rather than sending ten individual updates. Reviewers prefer to see the work integrated.
- Keep the commit clean. As you iterate, amend the original commit rather than stacking fixup commits. The commit that eventually lands should be a single clean commit, not a messy history.
- Test before re-submitting. Each iteration should pass the same pre-submission tests as the first submission. Do not break tests between rounds.
- Summarise each iteration. When you update the patch, a short reply on the review saying “updated to address all comments; specifically: did X, did Y, clarified Z” helps reviewers re-orient quickly.

Above all, be patient. The review process exists because code quality matters. Hurrying through it compromises the quality and produces a patch that lands quickly but creates problems later.

### 37.10.6 Handling Disagreements

Occasionally, reviewers will leave feedback you genuinely disagree with. The comment is not unclear; you have thought about it, and you believe the reviewer is wrong. What do you do?

First, consider that you might be wrong. Most of the time, when a reviewer raises a concern, there is something behind it that you may not be seeing. The reviewer has context about the tree, the subsystem, and the history that you may not have. Assume the concern is legitimate until you have evidence otherwise.

Second, if after thought you still disagree, reply with reasoning. Explain your perspective. Cite specific details from the code, the datasheet, or the tree. Ask the reviewer to engage with your reasoning.

Third, if the disagreement persists, escalate gently. Ask for a second opinion from another committer. Post to the relevant mailing list describing the question. Sometimes disagreements reveal that there are multiple defensible answers and that the project has not reached a clear position; that is useful information to surface.

Fourth, if the disagreement still persists and nothing is resolving it, you have a choice. You can make the change the reviewer requested, even though you disagree, and land the patch. Or you can withdraw the patch.

Both are legitimate. The project's culture is not one of forcing contributors to do things they disagree with, but neither is it one of rubber-stamping patches the committer community has concerns about. If the disagreement is fundamental, withdrawing is sometimes the right outcome.

Disagreements of this depth are rare. Most feedback is practical and either clearly right or clearly accommodatable. The serious disagreements, when they happen, are usually about design choices where multiple answers are defensible.

### 37.10.7 Building a Long-Term Relationship

A first submission is not the end of the work. If it goes well, it can be the beginning of a long-term relationship with the project. Many committers started as first-time contributors whose early patches went smoothly, whose later patches built on that trust, and whose involvement eventually grew to the point where commit rights made sense.

Building that kind of relationship is not about performing. It is about continuing to contribute consistently and productively. Several habits that help:

- Respond to bug reports about your driver. If a user reports a bug, triage it, confirm or deny, and follow up. A driver whose author is responsive is a driver the project values.
- Review other people's patches. Once you are familiar with a subsystem, you can review new patches in that subsystem. Reviewing is how you become known as an expert, and how you internalise the subsystem's conventions.
- Participate in discussions. The mailing lists and the IRC channels have ongoing technical discussions. Participating, thoughtfully, is part of being in the community.
- Keep your driver up to date. If kernel APIs change, update your driver. If new hardware variants appear, add support. The driver is not finished at merge; it is a living artifact you are caretaking.

None of this is required. The project is grateful for any contribution, including one-shot patches from contributors who never return. But if you are interested in deeper involvement, these are the ways in.

### 37.10.8 Identifying Existing Maintainers

Many subsystems in FreeBSD have identifiable maintainers or long-time contributors. Finding them is useful because they are often the best reviewers for related work.

Several ways to identify maintainers:

- `git log --format="%an %ae" <file>` shows who has committed changes to a specific file. The names that appear frequently are the active maintainers.
- `git blame <file>` shows who wrote each line. If a specific function is something you are extending, the person who wrote it is often the right person to ask.
- The MAINTAINERS file, where it exists, lists formal maintainers. FreeBSD does not have a single tree-wide MAINTAINERS file, but some subsystems have informal equivalents.
- The AUTHORS section of the manual page names the primary author.

For a driver that extends an existing family, the author of the existing driver is usually the first reviewer to approach. They have the context and the authority. For a completely new driver in a new area, find a reviewer by asking on the relevant mailing list.

### 37.10.9 Exercise: Identify a Similar Driver's Maintainer

Before moving on, pick a driver in the tree that is similar in scope to the one you are working on. Use `git log` to identify its maintainer. Note their name and email. Then read a few of their commits and look at the reviewers they typically engage with. This gives you a mental model of who the people in the subsystem are, and makes the human side of the submission feel more concrete.

You are not expected to contact them unless you have a specific question. The exercise is about building awareness.

### 37.10.10 Wrapping Up Section 7

The human side of the review process is as important as the technical side. A mentor or committer who is engaged with your patch is a resource; treating them with respect, responding to feedback constructively, and iterating patiently are the practical disciplines of that engagement. Disagreements happen and are usually productive; defensiveness is the main risk to avoid. A first submission, handled well, can be the beginning of a long-term relationship with the project.

The last piece of the submission workflow is what happens after the patch is in the tree. Section 8 covers the long arc of maintenance.

## 37.11 Section 8: Maintaining and Supporting Your Driver Post-Merge

### 37.11.1 The Merge Is Not the End

When your patch lands in the FreeBSD tree, a natural feeling is that the work is done. The driver is in. The review is over. The commit is in the history. You can move on.

The feeling is understandable, but the picture is incomplete. Merging the driver into the tree is the beginning of a different kind of work, not the end of the driver's life. As long as the driver is in the tree, it requires occasional maintenance. As long as it is used, it will occasionally surface bugs. As long as the kernel evolves, its APIs will drift and the driver will need to follow.

This section walks through the post-merge maintenance picture. The expectations are not heavy, but they are real. A driver whose author disappears after the merge is a driver the project has to maintain on its own, and eventually, if no one takes over, that can be a reason to mark the driver as deprecated.

### 37.11.2 Bugzilla Watching

The FreeBSD Bugzilla at <https://bugs.freebsd.org/> is the project's primary bug tracker. Bugs filed against your driver will appear there. You are not required to subscribe to Bugzilla as a contributor, but you should at least know how to check for open bugs against your driver.

A simple way to check:

J

[https://bugs.freebsd.org/bugzilla/buglist.cgi?component=kern&query\\_format=advanced&short\\_desc=](https://bugs.freebsd.org/bugzilla/buglist.cgi?component=kern&query_format=advanced&short_desc=)

Replace mydev with your driver's name. The query returns bugs whose summary mentions your driver.

If a bug is filed:

- Read the report carefully.
- If you can reproduce it, do so.
- If you can fix it, prepare a patch. The patch goes through the same review process as any other change.
- If you cannot reproduce it, ask the reporter for more information: FreeBSD version, hardware details, relevant log output.
- If it is a real bug but you do not have the time or capacity to fix it, say so in the bug report. A bug with an engaged author who cannot currently fix it is different from a bug with an absent author. At minimum, the engagement means that someone else who looks at the bug has context to work with.

Bugzilla also hosts enhancement requests (feature requests for new functionality). These are lower priority than bug reports, but they are useful signals about what users need. You do not need to implement every enhancement request, but acknowledging them and discussing priorities is part of maintenance.

### 37.11.3 Responding to Community Feedback

In addition to Bugzilla, community feedback can reach you through several other channels:

- Direct email from users.
- Discussions on the mailing lists.
- Questions on IRC channels.
- Comments on review threads for related work.

The expectation for a responsive maintainer is not that you respond to every one of these instantly. The expectation is that you are reachable at the email address on record for the driver (the one in the AUTHORS section of the manual page and in the commit history), and that when you respond to something, you do so productively.

A practical rhythm might look like this: once a week or once every two weeks, check your driver-related email and Bugzilla queries. Respond to anything that is waiting. Triage anything new. Keep the response times reasonable, on the scale of a week or two rather than months.

If your circumstances change and you cannot maintain the driver any more, say so publicly. The project can and will find new maintainers if the need is known. The worst outcome is disappearing silently, leaving bugs unacknowledged and users uncertain whether the driver is being maintained at all.

### 37.11.4 Kernel API Drift

The FreeBSD kernel evolves. APIs that were stable when your driver was written may change. When this happens, your driver needs to be updated, and you are the first person the project will look to for the update.

Several kinds of API drift that commonly affect drivers:

- Changes to the Newbus framework: new method signatures, new method categories, changes to `device_method_t` macros.
- Changes to the bus-specific attachment patterns: PCI, USB, iicbus, spibus, and others evolve over time.
- Changes to the `bus_space(9)` interface.
- Changes to the character-device interface (`cdevsw`, `make_dev`, etc.).
- Changes to the memory allocation API (`malloc(9)`, `contigmalloc`, `bus_dma`).
- Changes to the synchronisation primitives (`mtx`, `sx`, `rw`).
- Deprecation of old APIs in favour of new ones.

Usually, these changes are announced on the mailing lists before they are committed, and sometimes they come with a “tree-sweep” commit that updates all users of the old API to the new one. If your driver is in the tree, the tree-sweep will typically update it automatically. But not always; sometimes the sweep is conservative and leaves drivers that it cannot mechanically update for the maintainer to handle.

A good habit: check `freebsd-current@` at least occasionally for API change discussions that affect your driver. If you see one, check whether your driver still builds against current HEAD. If it does not, send a patch to update it.

### 37.11.5 The UPDATING File

The project maintains an `UPDATING` file at `/usr/src/UPDATING` that lists significant changes in the source tree, including API changes that drivers may need to respond to. Read it occasionally (especially before updating your tree) to see whether anything affects your driver.

A typical `UPDATING` entry might read:

20260315:

```
The bus_foo_bar() API has changed to require an explicit
flags argument. Drivers using bus_foo_bar() should pass
BUS_FOO_FLAG_DEFAULT to preserve historical behaviour.
Drivers using bus_foo_bar_old() should migrate to the new
API as bus_foo_bar_old() will be removed in FreeBSD 16.
```

If you see an entry like this mentioning a function your driver uses, update the driver accordingly.

### 37.11.6 Tree-Wide Refactors

Occasionally, the project does tree-wide refactors that touch every driver. Examples from FreeBSD’s history include:

- The conversion from `$FreeBSD$` CVS tags to git-only metadata.
- The introduction of SPDX-License-Identifier lines across the tree.
- Large-scale renames of APIs such as the `make_dev` family or the `contigmalloc` family.

When a tree-wide refactor happens, the refactor commit typically updates your driver along with everyone else’s. You may not need to do anything. But the refactor will show up in `git log` against your driver, and future developers looking at the history will see it. Understand what happened so that you can explain it if asked.

### 37.11.7 Participating in Future Releases

FreeBSD has a release cycle of roughly a year between major releases, with point releases on a more frequent schedule. Your driver participates in this cycle whether you do anything active or not.

A few things are worth understanding:

- Your driver is built for every release that comes out of a branch where it lives. If it lives in `main`, it will be in the next major release. If it is also cherry-picked to a `stable/` branch, it will be in the next point release of that branch.
- Before major releases, the release-engineering team may ask maintainers to confirm that their drivers are in good shape. If you get such a request for your driver, respond. It is a simple action that helps the project plan the release.
- After a release, your driver is in the wild on every installation that uses that release. Bug reports may be more frequent right after a release.

Participating in the release cycle is a low-effort form of maintenance. It mostly consists of being available for the release engineers to contact you if they need to.

### 37.11.8 Keeping Code Updated: A Rhythm

A reasonable rhythm for maintaining a driver in the tree:

- Monthly: check Bugzilla for open bugs against the driver. Respond to anything outstanding.
- Monthly: rebuild the driver against current `HEAD` and check for warnings or failures. If anything fails, investigate and fix.
- Quarterly: re-read the manual page. Update if the driver has changed since the last review.
- Before major releases: run through the full pre-submission test suite (style, mandoc, build, universe) on your driver as it currently stands. Fix anything that has drifted.
- Whenever you have a hardware sample and a spare afternoon: exercise the driver on the hardware and make sure it still works.

This rhythm is not mandatory. A driver can go months without maintenance if nothing is broken. But having a rhythm in mind keeps the driver healthy over time.

### 37.11.9 Exercise: Create a Monthly Maintenance Checklist

Before closing this section, open a text file and write down a monthly maintenance checklist for your driver. Include:

- The URL for the Bugzilla query that shows bugs against the driver.
- The commands to rebuild the driver against current `HEAD`.
- The commands to run the style and lint checks.
- The commands to check for API drift (e.g., `grep` for deprecated calls).
- A note about the email address where users might reach you.
- A reminder to update the manual page date if you make semantic changes.

Save this checklist with the driver's source, or in your personal notes. The act of writing it down commits you to the rhythm. Checklists that exist on paper get followed; checklists that live only in memory do not.

### 37.11.10 When You Cannot Maintain Anymore

Life changes. Jobs change. Priorities shift. At some point you may find that you cannot maintain your driver the way you once did. This is normal and the project has processes for handling it.

The right move is to say so publicly. Options:

- Post to `freebsd-hackers@` or the relevant subsystem list saying that you are stepping back from the driver and inviting someone else to take it over.
- File a Bugzilla entry tagged as a maintainership transition question.
- Email the committers who have reviewed your patches and tell them directly.

The project will then find a new maintainer, or mark the driver as orphaned, or decide on some other path. The important thing is that the status is known. Silent abandonment is worse than any of the alternatives.

If no one takes over the driver and it continues to be used, the project may eventually mark it deprecated. This is not a failure; it is a reasonable response to code that no one is actively caring for. Drivers can be deprecated, removed, and later re-added if someone steps up. The history of the tree is full of such cycles.

### 37.11.11 Wrapping Up Section 8

Post-merge maintenance is a lighter-weight activity than initial submission, but it is real. The expectations are: watch Bugzilla for bugs against your driver, respond to users who reach out, keep the driver building against current HEAD as the kernel evolves, participate in release cycles, and say so publicly if you cannot continue to maintain. A driver whose author is engaged over time is a driver the project values beyond the initial merge.

With Sections 1 through 8 complete, we have walked the full arc of a driver submission: from understanding the project to preparing the files, through licensing, manual pages, testing, submission, review iteration, and long-term maintenance. The remainder of the chapter offers hands-on labs and challenge exercises that let you practise the workflow against real code, followed by a consolidation of the mental model and a bridge to the closing chapter.

## 37.12 Hands-On Labs

The labs in this chapter are designed to be done against a real driver. The easiest approach is to take a driver you have already written during the book, such as the LED driver from earlier chapters or the mock device from Chapter 36, and walk it through the submission-preparation workflow.

If you do not have a driver at hand, the companion examples in `examples/part-07/ch37-upstream/` include a skeleton driver you can use.

All the labs can be done in a FreeBSD 14.3 development virtual machine. None of them will submit anything to the real FreeBSD project, so you can work freely without worrying about accidentally publishing half-finished work.

### 37.12.1 Lab 1: Prepare the File Layout

Goal: Take an existing driver and rearrange its files into the conventional FreeBSD layout.

Steps:

1. Identify the driver you will be working with. Call it `mydev`.
2. Create the directory structure:
  - `sys/dev/mydev/` for driver sources.
  - `sys/modules/mydev/` for the module Makefile.
  - `share/man/man4/` for the manual page.
3. Move or copy the `.c` and `.h` files into `sys/dev/mydev/`. Rename them if necessary so that the main source file is `mydev.c`, the internal header is `mydev.h`, and any hardware register definitions live in `mydevreg.h`.
4. Write a module Makefile at `sys/modules/mydev/Makefile` following the template from Section 2.
5. Build the module with `make`. Fix any build errors.
6. Verify that the module loads with `kldload` and unloads with `kldunload`.

Success criterion: the driver builds as a loadable module and the file layout matches the conventions of the tree.

Expected time: 30 to 60 minutes for a small driver.

Common problems:

- Include paths that assumed the old layout. Fix the includes to use `<dev/mydev/mydev.h>` rather than `"mydev.h"`.
- Forgotten entries in `SRCS`. If you have multiple `.c` files, list all of them.
- Missing `.PATH`. The Makefile needs `.PATH: ${SRCTOP}/sys/dev/mydev` so `make` can find the sources.

### 37.12.2 Lab 2: Audit the Code Style

Goal: Bring the driver source into compliance with `style(9)`.

Steps:

1. Run `/usr/src/tools/build/checkstyle9.pl` against every `.c` and `.h` file in the driver. Capture the output.
2. Read each warning carefully. Cross-reference against `style(9)` to understand what the rule is.
3. Fix each warning in the source. Rerun the style checker after each batch of fixes.
4. When the style checker is clean, read through the source by eye looking for anything the checker missed: inconsistent indentation inside multi-line arguments, comment styles, variable-declaration groupings.
5. Ensure every function that is not exported has the `static` keyword. Ensure every exported function has a declaration in a header.

Success criterion: the style checker produces no warnings against any file in the driver.

Expected time: one to three hours for a driver that has not previously been through a style audit.

Common surprises:

- Space-instead-of-tab warnings on lines you thought were fine. The checker is strict; trust it.
- Warnings about blank lines between variable declarations and code. `style(9)` requires a blank line.
- Warnings about return expressions without parentheses. Fix by adding parentheses.

### 37.12.3 Lab 3: Add the Copyright Header

Goal: Ensure every source file has a correct FreeBSD-style copyright header.

Steps:

1. Identify every file in the driver that needs a header: each `.c` file, each `.h` file, and the manual page.
2. For each file, check the existing header. If it is missing or malformed, replace it with a known-good template.
3. Use `/*` - as the opening of the header in `.c` and `.h` files. Use `\"` - as the opening in the manual page.
4. Include the SPDX-License-Identifier line with the appropriate licence, typically `BSD-2-Clause`.
5. Add your name and email to the Copyright line.
6. Include the standard licence text.
7. Verify that the file starts in column 1 with the `/*` - or `\"` - opening.

Success criterion: every file has a correctly-formatted header that matches the conventions of files already in the tree.

Expected time: 30 minutes.

Verification:

- Compare your header against the header in `/usr/src/sys/dev/null/null.c`. They should be structurally identical.
- If you are using an automated licence-harvester tool, it should recognise your headers.

### 37.12.4 Lab 4: Draft the Manual Page

Goal: Write a complete section-4 manual page for the driver.

Steps:

1. Create `share/man/man4/mydev.4`.
2. Start from the template in Section 4 of this chapter, or from the companion example.
3. Fill in each section for your driver:
  - NAME and NAME description.
  - SYNOPSIS showing how to compile in the kernel or load as a module.
  - DESCRIPTION in prose.
  - HARDWARE listing supported devices.
  - FILES listing device nodes.
  - SEE ALSO with relevant cross-references.
  - HISTORY noting the driver's first appearance.
  - AUTHORS with your name and email.
4. Follow the one-sentence-per-line rule throughout.
5. Run `mandoc -Tlint mydev.4` and fix every warning.
6. Render the page with `mandoc mydev.4 | less -R` and read it from a user's perspective. Fix anything awkward.
7. If you have `igor` installed, run it and address its warnings.

Success criterion: `mandoc -Tlint` is silent, and the rendered page reads clearly.

Expected time: one to two hours for a first manual page.

Reading assignment for the lab: before you start, read `/usr/src/share/man/man4/null.4`, `/usr/src/share/man/man4/led.4`, and `/usr/src/share/man/man4/re.4`. These three pages span the range of complexity that section-4 manual pages can have, and they will give you a strong intuition for what yours should look like.

### 37.12.5 Lab 5: Build and Load Automation

Goal: Write a shell script that automates the pre-submission build and load cycle.

Steps:

1. Create a script named `pre-submission-test.sh` in the companion examples directory.
2. The script should, in order:
  - Run the style checker on every source file.
  - Run `mandoc -Tlint` on the manual page.
  - Run `make clean && make obj && make depend && make` in the module directory.
  - Load the resulting module with `kldload`.
  - Unload the module with `kldunload`.
  - Report success or failure clearly.
3. Use `set -e` so the script exits on the first error.
4. Include helpful `echo` statements announcing each stage.
5. Test the script against your driver.

Success criterion: the script runs clean against a driver that is ready for submission, and produces clear error output for a driver that has problems.

Expected time: 30 minutes for a simple script; longer if you add polish.

### 37.12.6 Lab 6: Generate a Submission Patch

Goal: Practise the patch-generation workflow without actually submitting.

Steps:

1. In a throwaway git clone of the tree, create a topic branch for your driver:

```
git checkout -b mydev-driver
```

2. Add the driver files:

```
git add sys/dev/mydev/ sys/modules/mydev/ share/man/man4/mydev.4
```

3. Commit with a proper message following the conventions from Section 2:

```
git commit -s
```

4. Generate a patch:

```
git format-patch -1 HEAD
```

5. Read the generated .patch file. Verify that it looks clean: no unrelated changes, no trailing whitespace, a well-formed commit message.
6. Apply the patch to a fresh clone to verify that it applies cleanly:

```
git am < 0001-mydev-Add-driver.patch
```

Success criterion: you have a clean patch file that represents the driver submission, and it applies cleanly to a fresh tree.

Expected time: 30 minutes.

Common surprises:

- `git format-patch` produces a file per commit. If you have three commits on your branch, you will get three .patch files. For a driver submission that should be a single commit, amend or squash first.
- Trailing whitespace in the commit shows up as `^I` sequences in the patch. Remove it before committing.
- Line-ending issues. Make sure your editor is using LF, not CRLF.

### 37.12.7 Lab 7: Draft a Review Cover Letter

Goal: Practise writing the description that accompanies a submission.

Steps:

1. Open a text editor and write an email-style cover letter for your driver submission.
2. Include:
  - A subject line suitable for a mailing-list message.
  - A one-paragraph summary of what the driver does.
  - A description of the hardware supported.
  - A list of what was tested.
  - A statement of what feedback you are inviting.
3. Keep the tone professional and collaborative. You are asking for review, not demanding approval.
4. Save the letter as `cover-letter.txt` in your companion examples directory.
5. Share it with a friend or colleague for feedback before moving on.

Success criterion: the cover letter reads as a productive invitation to review.

Expected time: 15 to 30 minutes.

### 37.12.8 Lab 8: Dry-Run a Review Cycle

Goal: Rehearse the iteration side of the review cycle.

Steps:

1. Ask a colleague to read your patch and cover letter as if they were a reviewer.
2. Capture their feedback as a list of comments.
3. Treat each comment as a real review comment. Respond to each one: make the fix, explain your reasoning, or push back constructively.
4. Update the commit and regenerate the patch.
5. Repeat for at least two rounds of feedback.

Success criterion: you have experience iterating on a patch in response to feedback, and your commit at the end is still a single clean commit rather than a messy history.

Expected time: variable, depending on the colleague's availability.

Variant: if a colleague is not available, ask a reviewer to read the companion code and act as a mock reviewer. Or use an online code-review simulator if one is available in your environment.

## 37.13 Challenge Exercises

The challenge exercises are optional but highly recommended. Each of them takes an idea from the chapter and pushes it into territory that will exercise your judgement.

### 37.13.1 Challenge 1: Audit a Historical Driver

Pick an older driver in `/usr/src/sys/dev/` that has been in the tree for at least five years. Look at its current state and identify:

- Parts of the copyright header that do not match modern conventions.
- Style violations that `checkstyle9.pl` flags.
- Manual-page sections that do not match modern style.
- Deprecated APIs the driver still uses.

Write up your findings as a short report. Do not submit a patch to fix them (older drivers often have good reasons for their historical form), but understand why they look the way they do.

The goal is to build an eye for the difference between modern conventions and historical ones. After doing this exercise, you will recognise at a glance which parts of a driver were written recently and which are legacy.

Expected time: two hours.

### 37.13.2 Challenge 2: Cross-Architecture Debug

Take your driver and attempt to build it for a non-native architecture, such as `arm64` if you are on `amd64`:

```
cd /usr/src
make TARGET=arm64 buildkernel KERNCONF=GENERIC
```

Identify any warnings or errors that are specific to the target architecture. Fix them. Rebuild. Repeat.

If your driver builds cleanly on both amd64 and arm64, try i386. If you want an extra challenge, try powerpc64 or riscv64. Each architecture will surface different kinds of issues.

Write up a short note about what you found and how you fixed it. The cross-architecture discipline is one of the things that separates a casually-written driver from a production-grade one.

Expected time: three to six hours, depending on how many architectures you try.

### 37.13.3 Challenge 3: Manual Page Depth

Pick a driver in the tree whose manual page you find impressive. Copy the structure of that page and use it as a template to rewrite your own manual page at a similar level of depth.

Your rewritten manual page should:

- Have a SYNOPSIS that shows all the ways to load and configure the driver.
- Have a DESCRIPTION that gives a user a complete picture of what the driver does.
- Have a full HARDWARE section, including revision information where relevant.
- Have LOADER TUNABLES, SYSCTL VARIABLES, or DIAGNOSTICS sections if your driver has any of these features.
- Have a BUGS section that is honest about known issues.
- Pass mandoc -Tlint and igor clean.

The goal is to produce a manual page that reads like a first-class example of the genre, not a minimal compliance artefact.

Expected time: three to five hours.

### 37.13.4 Challenge 4: Run a Mock Review

Partner with another reader of this book, or a colleague familiar with FreeBSD. Exchange drivers with them. You review their driver. They review yours.

As a reviewer, do the following for the driver you are reviewing:

- Run all the pre-submission tests yourself and capture the results.
- Read the code carefully. Make specific comments on anything that seems unclear, incorrect, or non-idiomatic.
- Read the manual page. Make comments on anything that seems incomplete or unclear.
- Write a summary review note that includes your overall impression, your requested changes, and any questions you have.

As the contributor receiving review, do the following:

- Read the feedback carefully.
- Respond to each comment constructively.
- Update the patch.
- Send the updated patch back.

Do at least two rounds. At the end, write a short reflection on what you learned from both sides.

The goal is to experience both sides of the review process before you ever submit a patch to the real project. After this exercise, the first real review will feel much more familiar.

Expected time: variable, but at least a weekend.

### **37.13.5 Challenge 5: Trace the Life of a Real Commit**

Pick a recent driver-related commit in the FreeBSD tree, ideally one that was contributed by a non-committer and sponsored. Use `git log` to find it, or browse Phabricator archives.

Trace its history:

- When was the review first opened?
- What did the first version look like?
- What comments did reviewers leave?
- How did the author respond?
- How did the patch evolve?
- When was it finally committed?
- What does the final commit message say?

Write up a short narrative of what you found. This exercise builds intuition for what a real review looks like from the inside.

Expected time: two hours.

## **37.14 Troubleshooting and Common Mistakes**

Even with careful preparation, things can go wrong. This section collects the most common problems first-time contributors encounter and explains how to diagnose and fix them.

### **37.14.1 Patch Rejected Because of Style**

Symptom: the reviewers leave many small comments about indentation, variable names, comment formatting, or return statement parentheses.

Cause: the patch was submitted without running `tools/build/checkstyle9.pl` first, or the author ignored some warnings.

Fix: run `checkstyle9.pl` against every source file. Fix every warning. Rebuild and re-test. Resubmit.

Prevention: make `checkstyle9.pl` part of your pre-submission script. Run it before every submission.

### **37.14.2 Patch Rejected Because of Manual-Page Issues**

Symptom: the reviewer says the manual page has lint errors, or does not match the project's mdoc style.

Cause: the manual page was not validated with `mandoc -Tlint` before submission, or the one-sentence-per-line rule was not followed.

Fix: run `mandoc -Tlint` against the manual page. Fix every warning. Read the rendered output to verify that it reads well. Resubmit.

Prevention: treat the manual page with the same care as the code. Include it in your pre-submission script.

### 37.14.3 Patch Does Not Apply Cleanly

Symptom: the reviewer reports that the patch does not apply to current HEAD. Or the CI fails at the `git apply` stage.

Cause: the patch was generated against an older version of the tree, and HEAD has moved since.

Fix: pull the latest HEAD, rebase your branch on top, resolve any conflicts, retest, and regenerate the patch.

Prevention: rebase on current HEAD immediately before submission. Do not submit a patch that was generated a week ago.

### 37.14.4 Kernel Panic on Load

Symptom: `kldload` panics the kernel.

Cause: often, a NULL pointer dereference in the driver's probe or attach routine, or a missing initialisation step.

Fix: debug with the standard kernel-debugging tools (covered in Chapter 34). Common specific causes:

- `device_get_softc(dev)` returning NULL because the `driver_t.size` field is not set to `sizeof(struct mydev_softc)`.
- `bus_alloc_resource_any(dev, SYS_RES_MEMORY, ...)` returning NULL and the driver not checking for the NULL before using the result.
- A static variable incorrectly initialised, causing undefined behaviour.

Prevention: test on a development VM before submission. Repeatedly load and unload to catch initialisation bugs.

### 37.14.5 Kernel Panic on Unload

Symptom: `kldunload` panics, or the module refuses to unload.

Cause: the detach path is incomplete. Common specific causes:

- A callout that is still scheduled when the softc is freed. Use `callout_drain`, not `callout_stop`.
- A taskqueue task that is still pending. Use `taskqueue_drain` on every task.
- An interrupt handler that is still installed when the resource is freed. Tear down the handler with `bus_tearardown_intr` before calling `bus_release_resource`.
- A device node that is still open when `destroy_dev` is called. Use `destroy_dev_drain` if the node might be open.

Fix: audit the detach path. Make sure every resource is released, every callout is drained, every task is drained, every handler is torn down, and every device node is destroyed before the softc is freed.

Prevention: structure the detach code in reverse of the attach code. Every attach step has a corresponding detach step, and the order is strict.

### 37.14.6 Driver Builds But Does Not Probe

Symptom: the module loads, but when the hardware is present, the driver does not attach to it. `pciconf -l` shows the device with no driver.

Cause: usually, a mismatch in the probe routine between the driver's expected vendor/device ID and the actual one. Or the driver uses `ENXIO` incorrectly.

Fix: check the vendor and device IDs. Double-check with `pciconf -lv`. Verify that probe returns `BUS_PROBE_DEFAULT` or `BUS_PROBE_GENERIC` when the device matches, not an error code.

Prevention: test against real hardware before submission.

### 37.14.7 Manual Page Does Not Render

Symptom: `man 4 mydev` shows no output, or shows raw mdoc source.

Cause: usually, the file is in the wrong place, or it is not named correctly, or `makewhatis` has not been run.

Fix: verify the path (`/usr/share/man/man4/mydev.4`), verify the name (must end in `.4`), and run `makewhatis /usr/share/man` to rebuild the manual database.

Prevention: test the man page installation before submission.

### 37.14.8 Reviewer Is Unresponsive

Symptom: you submitted a patch, responded to the initial comments, and then the reviewer went silent.

Cause: reviewers are volunteers. Their time is finite. Sometimes a patch slips off the radar.

Fix: wait at least a week. Then send a polite ping on the review thread or the relevant mailing list. If still silent, consider asking for another reviewer to pick it up.

Prevention: submit patches that are small, well-prepared, and easy to review. Smaller patches get faster reviews.

### 37.14.9 Patch Is Approved But Not Committed

Symptom: a reviewer has explicitly said the patch looks good, but it has not been committed.

Cause: the reviewer may not be a committer, or they may be a committer but waiting for a second opinion, or they may be busy with other things.

Fix: politely ask whether anyone is in a position to commit the patch. "Is anyone able to sponsor the commit of this patch? I have responded to all feedback and the review is approved."

Prevention: none specifically; this is part of normal project flow.

### 37.14.10 Patch Committed But You Were Not Credited

Symptom: you look at the commit log and see your patch committed, but the author field is wrong.

Cause: a committer may have accidentally applied the patch without preserving authorship. This is rare but happens.

Fix: politely email the committer asking whether the authorship can be corrected. A `git commit --amend` with the correct author can fix it before push; after push, the commit is immutable, but the committer can add a note or amend the original commit message in rare cases.

Prevention: when generating a patch with `git format-patch`, ensure your `user.name` and `user.email` are set correctly.

### 37.14.11 Your Driver Was Accepted but Your Interface Choice Was Wrong

Symptom: your driver is in the tree, but you later realise that the userland interface you designed was a poor fit.

Cause: design choices made before full usage experience sometimes turn out wrong.

Fix: this is a real engineering problem that the project handles regularly. The options include: adding a new interface alongside the old one and deprecating the old one; documenting the old interface as legacy and introducing a successor; or, rarely, making a breaking change if the driver has few enough users that the breakage is acceptable.

Prevention: talk to the list about interface design before implementation, especially for interfaces that will be visible to userland for a long time.

## 37.15 Wrapping Up

Submitting a driver to the FreeBSD Project is a process with many steps, but it is not a mysterious one. The steps, taken in order, lead from a working driver on your machine to a maintained driver in the FreeBSD source tree. The process involves understanding how the project is organised, preparing the files according to the project's conventions, handling the licence correctly, writing a proper manual page, testing across the architectures the project supports, generating a clean patch, navigating the review process with patience, and committing to the long arc of maintenance after the driver merges.

A few themes have run through the chapter and deserve a final explicit summary.

The first theme is that a working driver is not the same as an upstream-ready driver. The code you wrote in the book was working code; making it upstream-ready is additional work, and most of that work is in small conventions rather than large changes. Attention to those conventions is the difference between a first submission that is welcomed and one that is held up repeatedly in review.

The second theme is that upstream review is collaborative, not adversarial. The reviewers on the other side of the patch are trying to help your driver land in a form that the tree can carry forward. Their comments are investments of their time, not attacks on your competence. Responding to those comments productively, patiently, and substantively is the craft of the review process. First-time contributors who internalise this framing have easier reviews than those who do not.

The third theme is that documentation, licence, and style are part of engineering quality, not bureaucracy. The manual page you write is the interface through which users will understand your driver for as long as it lives. The licence you attach determines whether the driver can be merged at all. The style you follow determines whether future maintainers will understand the code. None of these are administrative overhead; all of them are part of the work of being a software engineer in a large shared code base.

The fourth theme is that merge is a beginning, not an end. The driver in the tree requires ongoing care: bug triage, API drift fixes, release-time check-ins, and occasional enhancements. That care is lighter than the initial submission, but it is real, and it is part of what turns a one-shot submission into a sustained contribution to the project.

The fifth and most important theme is that this is all learnable. None of the skills in this chapter require talent beyond what you have already built up over the book. They require attention to detail, patience with iteration, and willingness to engage with a community. Those qualities are ones you can develop with practice. The committers in the FreeBSD Project all started where you are now, as contributors writing their first patches, and they built up their standing through the same steady accumulation of careful work that you can.

Take a moment to appreciate what has changed in your toolkit. Before this chapter, submitting a driver to FreeBSD was probably a vague aspiration. Now it is a concrete process with a finite number of steps, each of which you have seen in detail. The labs have given you practice. The challenges have given you depth. The mistakes section has given you a map of the common pitfalls. If you decide to submit a real driver in the coming weeks or months, you have everything you need to start.

Some of the specifics in this chapter will shift over time. The Phabricator / GitHub balance may tilt further toward GitHub, or back, or neither. The style-checking tools may evolve. The review conventions may get small refinements. Where we know a convention is in motion, we have flagged it. Where we cited a specific file, we named it so you can open it yourself and check the current state. The reader who trusts but verifies is the reader the project benefits from most.

You are now, in the practical sense, prepared to contribute. Whether you do so is up to you. Many readers of a book like this one never contribute; that is fine, and the skills you built here serve you in your own work regardless. Some readers will contribute once, land a patch, and move on; that is also fine, and the project thanks them. A smaller number will find that they enjoy the collaboration enough to keep contributing, and over time will become deeply involved. Any of these paths is legitimate. The choice is yours.

## 37.16 Bridge to Chapter 38: Final Thoughts and Next Steps

This chapter has been, in one sense, the culmination of the practical arc of the book. You started without kernel knowledge, worked through UNIX and C, learned the shape of a FreeBSD driver, built character and network drivers, integrated with the Newbus framework, and worked through a series of mastery topics covering the specialised scenarios that production drivers encounter. The chapter you have just finished walked you through the process by which a driver you have built can become part of the FreeBSD operating system itself, maintained by a community of engineers and shipped to users on every release.

Chapter 38 is the closing chapter of the book. It is not another technical chapter. Its role is different. It is a chance to take stock of your progress, reflect on what you have learned, consider where you stand now, and think about where you might go next.

Several themes from Chapter 37 will naturally carry into Chapter 38. The idea that merge is a beginning rather than an end, for example, applies not just to individual drivers but to the reader's relationship with FreeBSD as a whole. Writing one driver, or two, or ten, is a beginning; sustained engagement with the project is the longer arc. The collaborative mindset that this chapter argued for in the context of code review is the same mindset that makes someone a valued community member over time. The discipline of documentation, licensing, and style that this chapter argued for in the context of a single driver scales up to the discipline of being a careful engineer in any large code base.

Chapter 38 will also address topics that this book did not cover in full depth, such as filesystem integration, network- stack integration (Netgraph, for example), USB composite devices, PCI hotplug, SMP tuning, and NUMA-aware drivers. Each of these is a substantial topic in its own right, and the closing chapter will point you toward the resources you can use to study them on your own. The book has given you the foundation; the topics in Chapter 38 are the directions you can extend that foundation into.

There are also the other BSDs. Much of what you have learned transfers, with modifications, to OpenBSD and NetBSD. The drivers you write for FreeBSD may find useful analogues in those projects, and some of the mastery topics from Part 7 have direct equivalents in each of the other BSDs. If you are interested in the wider BSD world, Chapter 38 will suggest where to look.

And there is the question of community. The FreeBSD Project is not an abstraction; it is a community of engineers, documenters, release managers, and users who together produce and maintain the operating system. Chapter 38 will reflect on what it means to be part of that community, how to find your place in it, and how to contribute to it beyond just driver submissions. Translations, documentation, testing, bug triage, and mentoring are all forms of contribution, and the project values each of them.

One final reflection before we close this chapter. Submitting a driver is, at its heart, an act of trust. You are offering your code to a community of engineers who will carry it forward. They, in turn, are offering their attention, their review time, and their commit rights to a contributor who was a stranger until this patch arrived. The trust goes both ways. It is built up, over time, by many small acts of careful work and responsible engagement. The first submission is the beginning of that trust, not the end of it. By the time you are a committer, if that is a path you choose, the trust is something you have earned in hundreds of small interactions.

You have done most of the work of becoming someone the project could trust. The rest is practice, and time, and patience.

Chapter 38 will close out the book with reflection, suggestions for continued learning, and a final word on where you might go from here. Take a breath, close your laptop for a moment, and let the material of this chapter settle. When you are ready, turn the page.

## 38 Final Thoughts and Next Steps

### 38.1 Introduction

You have reached the final chapter of a long book. Before we begin, take a moment to notice that simple fact. You are reading the closing pages of a manuscript that started, many chapters ago, with someone who may have had no kernel experience at all. You opened the first chapter as a curious reader. You are closing the last chapter as a person who can write, debug, and reason about FreeBSD device drivers. That shift did not happen by accident. It happened because you kept showing up, chapter after chapter, and put real effort into material that most people never try to learn.

This chapter is not a technical chapter in the same way the others were. You will not find new APIs to memorise, new `DEVMETHOD` entries to study, or new bus attachments to trace. The preceding thirty-seven chapters have given you a dense working vocabulary of FreeBSD kernel practice. What you need now is not more of that. You need a chance to step back, take stock of the ground you have covered, understand what you can do with it, and choose where to aim the skill you have built. The goal of this chapter is to give you that space, in a structured and useful form.

Reading a technical book from cover to cover is harder than it looks. By the end, many readers feel a curious mix of satisfaction and uncertainty. Satisfaction, because the book is finished and the work was real. Uncertainty, because the end of a book is not a clear signal of arrival anywhere in particular. The last page closes, the laptop goes back on the shelf, and the reader wonders what happens next. If you are feeling that mix, you are in good company. It is one of the most honest feelings in technical learning, and it usually means you have learned more than you realise. This chapter exists in part to help you see that clearly.

What happens next, practically, is up to you. The book has given you a foundation. The world of FreeBSD is enormous, and there are many directions you could take from here. You could pick one of the book's drivers and turn it into something polished that you submit upstream, bringing it through the workflow you learned in Chapter 37. You could choose a new device you have always wanted to write a driver for and start from scratch with the patterns you now know. You could study one of the advanced areas that this book only touched briefly, like deep filesystem work or the inner mechanics of the network stack, and start working your way into it. You could shift toward community contribution, where your skills help other people rather than landing a specific driver. Any of these paths is legitimate, and each of them will make you a better engineer than the one who finished Chapter 37.

The distance between finishing the book and being able to work confidently on your own is, in some sense, the theme of this chapter. Those are not the same milestone. Finishing the book means you have seen and practised enough to recognise the shapes of the work. Being able to work on your own means that when you sit down in front of a real problem, with no one else to lean on, you can find your way through it. The gap between those two milestones is closed mostly by practice. By writing drivers, debugging them, breaking them, fixing them, reading other people's code, and repeating those cycles over weeks and months. No book can substitute for that,

but a book can help you choose the right practice to do next, and it can help you keep your bearings while you do it. That is most of what the chapter is about.

We will spend time celebrating what you have accomplished, because that is both honest and useful. An honest recognition of progress is the ground from which the next cycle of learning grows. Without it, it is easy to fall into the trap of measuring yourself against distant experts rather than against the person you were when you started the book. We will then step into a careful self-assessment of where you stand now, using the technical material of the book as the frame. You will see your own capabilities reflected back at you in the language of FreeBSD practice. That is a different kind of encouragement from the generic “you can do it” sort. It is the kind of encouragement that comes from being able to point to something specific you have learned and saying, yes, I can use that.

From there we will look outward. FreeBSD is a large system, and there are several important areas that this book did not cover in full depth. Some of those areas are simply too large for any single book to cover, and some are rich enough that each deserves its own dedicated study. We will name them, explain briefly what each is about and why it matters, and point you toward the real sources you can use to learn more if you choose to go in that direction. The intent here is not to teach you filesystems or network-stack internals in a closing chapter. The intent is to give you a map so that when you finish this book and start thinking about where to go next, you have a clearer sense of the landscape.

We will also spend meaningful time on the practical work of building yourself a development toolkit that you can reuse across projects. Every working driver developer accumulates a small collection of personal artifacts over time: a driver skeleton that captures the patterns they always use, a virtual lab that boots quickly and lets them try things without breaking anything, a set of scripts that automate the annoying parts of testing, and a habit of writing regression tests before they submit changes. You do not need to start from scratch with those. The chapter will walk you through building a reusable toolkit that you can carry forward into any future driver work, and the companion examples for this chapter include starter templates you can adapt.

A significant part of the chapter turns to the FreeBSD community, because much of the longer-term growth that follows a book like this comes from community engagement. The community is where you see code that was written by hundreds of different hands, where you hear how people reason about problems that do not fit neatly into a single chapter, and where you find the feedback that helps you mature as an engineer. The chapter will show you concretely how to engage: which mailing lists matter, how to use Bugzilla, how code review happens, and how documentation contributions work. It will also explain, more carefully than the earlier book managed, what it means to mentor or be mentored in a community like FreeBSD, and why contributing to documentation, review, and testing is as valuable as contributing code.

And finally, because the FreeBSD kernel is a living system that changes constantly, we will talk about how to stay current. The kernel you learned to write drivers for is FreeBSD 14.3, and by the time you read this book at a later date, there will already be a newer release with a different set of internal APIs, new subsystems, and small changes to the patterns you learned. That is not a problem. It is how a healthy kernel evolves. The chapter will show you how to follow the changes: through commit logs, through mailing lists, through release-notes reading, through the conference circuit, and through the habit of periodically refreshing your understanding of a subsystem whose driver you maintain.

The companion material for this chapter is a little different from the companion material for earlier chapters. You will find it under `examples/part-07/ch38-final-thoughts/`, and it contains practical artifacts rather than buildable drivers. There is a reusable driver project template that you can copy into any new project as a starting point. There is a personal learning roadmap template you can use to plan the next three to six months

of your study. There is a contribution checklist that you can apply the first time you send a patch upstream, and every time after that. There is a regression-test script skeleton that you can adapt to any driver. There is a “stay current” checklist you can use to track FreeBSD development on a monthly rhythm. And there is a self-assessment worksheet that you can fill out at the end of this chapter and keep, so that in six months, when you fill it out again, you can see how far you have come.

One more framing note before we begin. Some readers will approach this chapter as a kind of final exam: a last chance to test themselves against the material of the book. That is not the spirit of the chapter. There is no grade here and no final test. The reflections and exercises in this chapter are not designed to catch you out on anything you did not learn. They are designed to help you see what you did learn, to see what you might want to learn next, and to help you plan the practice that turns a reader into an independent practitioner. Approach the chapter with that attitude, and it will be useful. Approach it as an exam and you will miss most of its purpose.

By the end of this chapter you will have a clear, written view of what you accomplished during the book, a realistic picture of your current skill set, a named and sorted list of advanced topics you might want to pursue, a reusable personal development toolkit, a clear sense of how to engage with the FreeBSD community, and a concrete plan for how to stay connected to FreeBSD’s continued evolution. You will also, with any luck, feel the quiet confidence that comes from having seen a long piece of work through. That confidence is not the end of the work; it is the fuel for whatever comes next.

Let us now begin that final reflection together.

## 38.2 Reader Guidance: How to Use This Chapter

This chapter is different in texture from the ones that came before it. The earlier chapters were technical: they built up a body of concrete knowledge, layered on each other, and culminated in Chapter 37’s walkthrough of upstream submission. This chapter is reflective. Its job is to help you consolidate what you learned, plan what you will do with it, and end the book in a way that prepares you for the next stage of your work.

Because the chapter is reflective rather than technical, the reading rhythm is different. In the earlier chapters, a careful reader might pause to type code, run a module, or inspect a struct in the kernel source. In this chapter, the pauses will be different. You will pause to think about what you learned. You will pause to write in a notebook or in a Markdown file. You will pause to look up a mailing-list archive, or to browse a part of the source tree you have not visited, or to check a conference schedule. The pauses are the point. If you read straight through without stopping, you will lose most of the value of the chapter.

Plan to spend a longer block of uninterrupted time on this chapter than you spent on most of the earlier ones. Not because the reading itself is harder, but because the thinking is. A single sitting of two or three hours, with a notebook at hand and without interruptions, is the minimum for a useful first pass. Some readers will find it more natural to spread the chapter across several sessions, treating each section as its own reflection exercise. Both approaches work; what matters is that the reflection is real, not rushed.

The chapter contains labs, just as the earlier chapters did, but they are reflection labs rather than coding labs. They will ask you to look back at something you wrote during the book and examine it with new eyes. They will ask you to write a one-page summary of a topic. They will ask you to build a personal learning plan. They will ask you to subscribe to a mailing list and read a thread. These exercises are not filler. They are the practice that turns the book’s content into your own working knowledge.

There are also challenge exercises, again adapted to the chapter's reflective character. These are longer and more open-ended than the chapter's labs. A reader who does all of them will invest several weekends of work. A reader who does just one or two will still get substantial value. The challenges are not graded, and there is no single correct way to complete them. They are invitations to extend the book's material into your own life and your own projects.

A reasonable reading schedule looks like this. In the first sitting, read the introduction and the first two sections. These are the consolidation sections: what you accomplished and where you stand now. Give yourself time to let the recognition settle. In the second sitting, read Sections 3 and 4. These look outward toward advanced topics and then back toward the practical toolkit you can carry into any future project. In the third sitting, read Sections 5 and 6. These are the community and currency sections, the ones that matter most for your long-term engagement with FreeBSD. Save the labs, the challenges, and the planning exercises for a fourth block, or spread them across the week that follows. By the time you finish, you will have not only read the chapter but also produced a set of personal artifacts that will be useful for months or years ahead.

If you are reading this book as part of a study group, this chapter is especially valuable to discuss together. The technical chapters can be read in parallel with relatively little coordination. This chapter benefits from conversation. Two readers comparing self-assessments will usually see something each one missed. A group that sets shared learning goals for the three months after finishing the book is more likely to actually pursue those goals than individuals working alone.

If you are reading alone, keep a journal while you work through this chapter. The journal can be paper or digital, whichever suits you. Write down your reflections as you go, name the advanced topics you want to pursue, list the practical habits you want to build, and record the planning artifacts you produce. The journal will be something you can return to in the months after the book, as you begin the practice that turns reading into independent skill.

One practical suggestion about the companion files. The chapter's examples are not drivers that you compile and load. They are templates and worksheets. Copy them out of the book repository into a location you control, such as a personal git repository or a folder in your home directory. Edit them to reflect your own context. Date them. Save older versions when you revise them, because a history of your own self-assessments is one of the most motivating kinds of learning record. The templates are provided so you do not have to start from a blank page, not so you will use them verbatim.

Finally, give yourself permission to take this chapter seriously even if it feels different from the rest of the book. A chapter of reflection can feel, to a reader used to technical material, like a soft or optional part of the curriculum. It is not. The reflection is where the technical material is consolidated into working capability, and consolidation is the stage of learning that is most often skipped and most often missed. Skipping it leaves a reader with many isolated facts and no particular sense of what to do with them. Doing it well turns those facts into a platform for the next phase of work.

With that framing in place, let us turn to the section where this book is most explicit: a careful, honest celebration of what you have accomplished.

### 38.3 How to Get the Most Out of This Chapter

A few habits will help you get the most out of a chapter whose material is reflective rather than procedural.

The first habit is to bring something to compare against. Find a driver you wrote during the book, or a set of labs you worked through, or a notebook of questions you noted while reading. Bring something concrete that lets you measure your progress. The reflections in this chapter become real when they are anchored to specific artifacts you produced along the way, and they become abstract when they are not. Open the earlier material beside the chapter and refer back to it as you read.

The second habit is to write as you read. The labs in this chapter will ask you to write, but you will get more out of the prose sections if you also write informally as you go. Keep a notebook or a text file open beside the chapter. Jot down the skills you recognise in yourself. Jot down the topics you still feel uncertain about. Jot down the questions that surface as you read. Writing is where reflection becomes thinking, and thinking is where thinking becomes planning. A chapter like this one done entirely in your head leaves most of its value on the page.

The third habit is to slow down on the forward-looking sections. This chapter spends time on advanced topics, the FreeBSD community, and how to stay current with the kernel. Those sections name specific resources: mailing lists, conferences, parts of the source tree, tools you can use. The temptation is to read past the names and return to the more comfortable prose. A better habit is to actually open a browser tab, visit the resource, and note down whether it is one you want to pursue. A single hour of doing this during the reading is worth ten hours of good intentions afterward.

The fourth habit is to be specific. Vague reflection is of limited use. Writing “I want to learn more about the network stack” is less useful than writing “I want to spend two weeks reading `/usr/src/sys/net/if.c` and the `ifnet(9)` manual page, and then write a short driver for a virtual network interface using what I learn”. Specificity makes plans achievable and vagueness makes plans evaporate. When the chapter asks you to identify next steps, identify them at a level of detail you could actually start work on this weekend.

The fifth habit is to give yourself time. This chapter is the end of a long book, and a common pattern at the end of long books is a rush to finish. Resist that pattern. The reflections are worth more than the speed. If you read the chapter in one sitting and feel no different at the end, you probably moved too fast through the parts that asked you to think. A good rule of thumb is that if you did not stop to write at least twice during the chapter, you did not engage with it in the way it was designed to be engaged with.

The sixth habit is to avoid the comparison trap. When readers of a technical book reach the end, they sometimes compare themselves to imagined experts and find the comparison discouraging. This is not useful. The right comparison is between the person you were when you opened Chapter 1 and the person you are now. Measured that way, almost every reader has made real progress. Measured against a senior committer who has spent a decade inside the FreeBSD tree, almost every reader falls short, and that is normal and meaningless. Pick the useful comparison, not the discouraging one.

The final habit is to plan to return to this chapter. Unlike the technical chapters, which you will probably not reread in full, this chapter benefits from rereading at natural checkpoints in your post-book work. When you finish your first driver after the book, revisit the self-assessment. When you send your first patch upstream, revisit the contribution checklist. When you have been following `freebsd-hackers` for six months, revisit the stay-current section. The chapter is designed to be reusable in this way.

With those habits in mind, let us turn to the first section, where we take an honest look at what you accomplished during the book.

## 38.4 1. Celebrating What You Have Accomplished

We begin with a section that asks you to pause and take stock, honestly, of what you have done. This is not a pep talk. It is a working part of the chapter. Many readers underestimate how much they learned during a long technical book, especially a book that requires as much sustained attention as this one. That underestimation is costly. A reader who does not recognise their own progress has a harder time deciding what to do next, because they cannot see clearly what they already have to build on.

### 38.4.1 1.1 A Recap of What We Have Covered

Think back to the first chapter you read. The book opened with an author's story about curiosity, a quick overview of why FreeBSD matters, and an invitation to begin. The second chapter helped you set up a lab environment. The third chapter introduced UNIX as a working system. The fourth and fifth chapters taught you C, first as a general language and then as a dialect shaped for kernel use. The sixth chapter walked you through the anatomy of a FreeBSD driver as a conceptual structure, before you had written one yourself.

Part 2 of the book, spanning Chapters 7 through 10, is where you started writing real code. You wrote your first kernel module. You learned how device files work and how to create them. You implemented read and write operations. You explored efficient input and output patterns. Each of those chapters had its own labs, and by the end of Part 2 you had produced several small drivers that actually loaded, actually exposed device files, and actually moved bytes between userland and kernel.

Part 3, Chapters 11 through 15, took you into concurrency. You learned about mutexes, shared/exclusive locks, condition variables, semaphores, callouts, and taskqueues. You worked through synchronisation problems that newcomers to the kernel often find intimidating, and you practised the discipline of locking conventions that the rest of the book later depended on. This part is where many readers report the steepest learning curve, and if you made it through, you did real work.

Part 4, Chapters 16 through 22, was about hardware and platform-level integration. You accessed registers directly. You wrote simulated hardware for testing. You built a PCI driver. You handled interrupts at a basic level and then at an advanced level. You transferred data with DMA. You explored power management. This is the part where the book changed from teaching you C with a kernel flavour into teaching you how kernels talk to real hardware. The gap between those two skills is large, and closing it is one of the biggest jumps in the book.

Part 5, Chapters 23 through 25, turned to the practical side of driver work: debugging, integration, and the habits that separate a driver that works on a demo from a driver that holds up in real use. You practised with `dtrace`, `kgdb`, `KASSERT`, and the other tools the kernel provides for seeing inside itself. You learned how to handle real-world problems that do not have textbook answers.

Part 6, Chapters 26 through 28, covered three transport-specific driver categories: USB and serial, storage and VFS, and network drivers. Each of these is a specialised area in its own right, and each introduced a new way of thinking about devices that was quite different from the character drivers of Part 2. By the end of Part 6, you had seen the major shapes that FreeBSD drivers take, not just in the abstract but in working examples.

Part 7, the part that contains this chapter, has been the mastery arc. You studied portability across architectures. You looked at virtualisation and containerisation. You worked through security best practices, the device tree and embedded systems, performance tuning and profiling, advanced debugging, asynchronous I/O, and reverse

engineering. Finally, in Chapter 37, you walked through the complete process of submitting a driver to the FreeBSD Project, from the social dynamics of contribution to the practical mechanics of `git format-patch`. And now, in Chapter 38, you are closing the book.

Listed like this, what you have covered looks substantial, and it is. The book has not been padding. Every chapter added something specific to your working knowledge. Even chapters that felt familiar on first reading probably taught you patterns of thinking that you internalised without fully noticing. The patterns are the most valuable part, because they are what let you apply the knowledge in situations the book did not explicitly cover.

Take a moment, before moving on, to think about which chapters felt the most challenging to you. Not in the abstract sense of “which was the longest chapter” but in the personal sense of “which chapter changed the most for me as I read it”. For some readers it is the jump from ordinary C to kernel C in Chapter 5. For others it is the concurrency work in Part 3. For some it is the interrupt and DMA material in Part 4, for others the network or storage work in Part 6, and for some the reverse engineering of Chapter 36. There is no single correct answer. The chapter that changed the most for you is the one where you grew the most, and noticing which one it was is useful information about your own pattern of learning.

### 38.4.2 1.2 Skills You Have Developed

Your progress is measured not only in chapters read but in skills acquired. Let us take a careful look at what you can now do, in language that describes capability rather than content.

You can write and reason about C in the kernel dialect. That is not the same skill as writing C for a command-line program. Kernel C has its own set of constraints, its own preferred idioms, and its own error-handling conventions. You know about the `M_WAITOK` / `M_NOWAIT` choice. You understand why kernel allocations must sometimes not sleep. You have seen the `goto out` style of cleanup and understand why it fits the kernel’s needs. You know when to use `memcpy` and when to use `copyin`. You know why kernel-to-userland and userland-to-kernel data transfer must go through specific functions rather than ordinary pointer dereferences. Each of those is a small habit, but together they form a dialect that you now speak.

You can debug and trace kernel code. You know how `dtrace` works. You know the difference between the function boundary tracing provider and the statically defined tracing provider. You know how `kgdb` attaches to a crash dump. You know what a `KASSERT` does, how to read a panic message, and how to use `witness` to detect lock-order violations. You know that `printf` in the kernel is a legitimate tool but not a substitute for structured diagnostics. You have built up the habit, over the course of Part 5 and later parts, of using the right diagnostic tool for the situation rather than defaulting to whatever is most familiar.

You can integrate a driver with the device tree and embedded systems. You understand the FDT format and how FreeBSD parses it. You know how to declare a driver that binds to a device-tree compatible string. You know what an embedded target looks like in practice: a slow boot, a small memory budget, a non-console serial port as the primary interface, and a reliance on hand-compiled kernels for each target board.

You know the basics of reverse engineering and embedded development. You know how to identify a device with `pciconf` or `usbconfig`, how to capture its initialisation sequence with `usbdump`, and how to build a register map by experiment. You know the legal and ethical framing of interoperability work. You know the discipline of separating observation from hypothesis from verified fact, and you know how to write a pseudo-datasheet that records what you learned. You are not an expert reverse engineer, and the book has been honest about that, but you know enough to start and to stay safe while you learn.

You can build userland interfaces for your drivers. You know how `devfs` publishes a device node. You know how to implement `read`, `write`, `ioctl`, `poll`, `kqueue`, and `mmap` operations. You know the standard `cdevsw` pattern. You know how to expose tunable parameters through `sysctl(9)`. You know how to structure a driver so that userspace programs can cooperate with it cleanly, and you have seen how poor userland interfaces are one of the most common reasons a driver is hard to maintain.

You understand concurrency and synchronization as it is practised in the kernel, not just in the abstract. You know the difference between an ordinary mutex and a spin mutex. You know when to reach for an `sx` lock and when `rmlock` is the better choice. You know what condition variables are for and how to use them without introducing lost-wakeup bugs. You know how to structure a taskqueue for deferred work. You know the `epoch(9)` interface for RCU-style readers. Each of those is a tool you know by its proper name and purpose, and you can apply it to a real problem without needing to look up the basics.

You can interact with hardware through DMA, interrupts, and register access. You have written code that sets up a DMA tag, allocates a map, loads a map, and syncs a map before and after transfers. You have written interrupt handlers that are careful about what they can and cannot do. You have used `bus_space(9)` to read and write registers on real hardware and on simulators. You have handled both filter and `ithread` interrupts. These are not abstract ideas for you any longer; they are practices you have executed.

You are ready to think seriously about upstream submission. You know the shape of a FreeBSD submission. You know `style(9)` and `style.mdoc(5)`. You know the structure of `/usr/src/sys/dev/` directories. You know how to write a manual page that lints cleanly. You know the Phabricator workflow and the GitHub workflow. You know what a reviewer will look for and how to respond to review feedback productively. That is a substantial body of knowledge, and most self-taught kernel developers never reach it.

Each of these skills, taken alone, would be worth serious study. Taken together, they describe a working FreeBSD device-driver developer. You have all of them now. You may not be equally confident in each one. That is normal. Part of the next section will help you notice where you are strong and where you have room to grow.

### 38.4.3 1.3 Reflection: What Has Actually Changed

Before moving on to self-assessment, take a moment to consider what has actually changed about you as a technical reader since you started this book.

When you first opened Chapter 1, a line of kernel code may have looked opaque. The macros were unfamiliar. The structures felt arbitrary. The control flow seemed impossibly indirect. Now, when you open a driver in `/usr/src/sys/dev/`, you can read the shape of it. You can find the probe and attach routines. You can identify the method table. You can see where locks are acquired and released. The text has become navigable. That change is invisible until you pause to notice it, but it is among the most important things the book has done for you.

When you first encountered a kernel panic, it may have been a blank wall of fear. You did not know what to do with it, what to read, or how to recover from it. Now a panic is a piece of information. You know how to read the stack trace. You know what a page fault means in the kernel. You know the difference between a recoverable panic from a clean assertion and an unrecoverable panic from memory corruption. A panic has gone from being a wall to being a diagnostic tool, and that shift is a large one.

When you first heard the phrase “write a device driver,” the phrase may have felt impossibly advanced. Drivers

were what other people wrote, perhaps hardware engineers in large companies, and the technical apparatus required seemed remote. Now, writing a driver is a concrete activity. You know what you need: a FreeBSD 14.3 system, a text editor, a working knowledge of C, the set of kernel APIs the book covered, a piece of hardware or a simulator, and some time. That shift in perception is the difference between treating drivers as a mystery and treating them as a craft.

When you first read a line referring to a lock order, it may have seemed like an academic subtlety. Now you know what lock order actually means, and why reversing it can crash a kernel, and how `witness` detects the violation, and how to structure a driver so that the violation never happens. This is not a theoretical understanding any more. It is a working practice.

When you first encountered the FreeBSD source tree, it may have felt like a vast undifferentiated forest. You knew there was something in there somewhere, but you did not know how to navigate to it. Now you have a feel for the tree. You know that `/usr/src/sys/dev/` is where device drivers live, that `/usr/src/sys/kern/` is where the core kernel code lives, that `/usr/src/sys/net/` is the networking stack, and that `/usr/src/share/man/man9/` is where the kernel API manual pages live. You can navigate. You can find. You can follow a function call from caller to callee and back. The tree has become a workspace, not a maze.

These changes are the real measure of the book. They are not about specific APIs you can recite from memory. They are about the shape of the world you see when you sit down at a terminal and open a driver. Take a moment to appreciate the shift. It is real, and it is yours.

### 38.4.4 1.4 Why Celebrating Progress Matters

Technical cultures often underplay the importance of recognising progress. The implicit assumption is that the work is its own reward and that anything more than that is sentimental. This is bad psychology, and it leads to burnout and to the curious phenomenon of experienced engineers who do not recognise their own expertise.

Recognising progress is not sentimental. It is functional. A learner who can see their own progress chooses harder next steps with confidence. A learner who cannot see their own progress stays at the easy steps because they do not know they have outgrown them. The point of celebrating is not to feel good, or at least not only to feel good. It is to clear the fog from the next decision about what to learn and what to build.

The book has been a long investment. Measured in hours, it is probably a larger investment than you might notice in aggregate. An honest accounting of the time you spent reading, working through labs, and thinking between sessions would likely surprise you. That time should produce outputs. One of the outputs is skill. Another is the confidence to take on the next project. Both outputs are easier to use when you have acknowledged them.

There is a specific kind of progress worth noting. You have built up not only facts about FreeBSD but also a way of working. You have learned to slow down before complex problems. You have learned to write tests. You have learned to read source code before writing your own. You have learned to decompose a kernel-space task into manageable pieces. These are portable habits. They apply to work outside FreeBSD, outside kernel programming, and even outside systems software. Engineers who have them are better engineers in many contexts, and engineers who do not have them struggle even in familiar territory.

If you have been reading this section quickly and feel tempted to skip past it, pause. Take five minutes. Think back through the book. Notice one concrete thing you can do now that you could not do before. Write it down. That is the exercise that makes the section count.

### **38.4.5 1.5 Exercise: Write a Personal Reflection**

This subsection's exercise is simple in structure and hard to do well. Write a personal reflection on your experience working through this book. It can be a blog post, a private notebook entry, an email to a friend, or a personal journal page.

The reflection should not be a summary of what the book covered. The book has done that for itself. The reflection should be about what your experience was. What surprised you about kernel development? Which chapter changed your understanding the most? Where did you get stuck, and what got you unstuck? What do you think about FreeBSD now that you did not think at the start?

Writing reflections like this is more valuable than it looks. It is a form of learning-to-see. The act of writing forces a specific articulation, and a specific articulation is transferable in ways that a vague impression is not. Ten years from now, if you are still writing FreeBSD drivers, you will benefit from having written this reflection now. You will also benefit from being able to read it, because your sense of what was hard at this stage will shift as you grow, and the only way to keep an honest record of where you were is to write it down when you were there.

A good reflection is usually between five hundred and fifteen hundred words. It does not need to be polished. It does not need to be publishable. It needs to be honest. If you share it publicly, the BSD community has a long tradition of welcoming such reflections on mailing lists, on personal blogs, and at conferences, and you may find that sharing your reflection connects you with people who went through the same process at a different time. If you keep it private, that is equally legitimate, and the act of writing is still the point.

Date the reflection. Put it somewhere you can find it again. Keep it for the future-you who will want to look back at the moment when you finished this book.

### **38.4.6 1.6 Wrapping Up Section 1**

This section asked you to pause and recognise what you have accomplished. That recognition is not ornamental. It is the ground from which informed next steps are chosen. A reader who cannot point to specific skills gained, specific shifts in perception, and specific artefacts produced by the book will struggle to decide what to do next. A reader who can point to those things will find the next decision easier.

We will now move into a more analytical section, where we look carefully at what the accomplishment means in practical terms. What, concretely, are you now capable of doing? Where are you strong, and where do you have room to grow? Section 2 turns those questions into a careful self-assessment. The answers will inform the planning work that comes later in the chapter.

## **38.5 2. Understanding Where You Stand Now**

Celebrating progress is one thing. Knowing where you stand is another. This section asks you to look at your skill set with engineer's eyes: not to judge yourself harshly, and not to flatter yourself, but to form an accurate and specific picture of what you can do, what you could do with a little more practice, and what still lies ahead. That picture is what makes the later parts of the chapter useful.

### 38.5.1 2.1 You Are Now Capable Of

Let us state it plainly, in the voice of someone describing a capable colleague. If someone asked what you can do with FreeBSD device drivers, here is an honest version of the answer.

You can write a kernel module for FreeBSD 14.3 that loads cleanly, registers a device node, handles read and write operations, and unloads without leaking resources. You can do this starting from scratch, using a text editor and the FreeBSD source tree as your only references, without needing to copy an existing module verbatim. You have done that repeatedly throughout the book, and the pattern is now in your hands.

You can debug that module when it crashes. If it panics, you can interpret the stack trace. You can set up a crash-dump configuration and attach kgdb to the resulting dump. You can add `KASSERT` statements to catch invariant violations earlier. You can run `dttrace` to see what the module actually did. You can watch `vmstat -m` to catch memory leaks. None of these are abstract to you; they are tools you have used.

You can interface with userland cleanly. You know how to implement `ioctl`s with the `_IO`, `_IOR`, `_IOW`, and `_IOWR` macros, and you know why `ioctl` numbers matter for ABI stability. You know how to use `copyin` and `copyout` to move data across the kernel/ userland boundary safely. You know how to expose state through `sysctl(9)` so that administrators can see and change what the driver is doing without needing to write a specialised tool.

You can interface with hardware. You know how to allocate memory and IRQ resources from a Newbus bus. You know how to read and write registers through `bus_space(9)`. You know how to set up DMA transfers, including the tag, the map, and the synchronisation calls. You know how to write an interrupt handler that does only what an interrupt handler should do and defers the rest to a taskqueue or an `ithread`. Each of these is a practical capability, not just a topic you read about.

You can submit a patch to the FreeBSD Project. You know the pre-submission hygiene: style check, manual-page lint, build across architectures, load/unload cycle. You know how to generate a patch that the project's tools can read. You know how to engage with reviewers productively. You know the difference between Phabricator and GitHub workflows and why the project has been moving between them. You have not necessarily submitted a real patch yet, but the workflow is no longer a mystery to you, and the day you decide to submit will not be the day you first learn how.

These are not ambitious claims. They are an honest accounting of what finishing this book means.

### 38.5.2 2.2 Confidence With Core Technologies

Let us now look at specific technologies you have learned, and let us ask about your confidence with each one. The purpose is not to grade yourself but to locate where you are strong and where you might want to invest some time.

**bus\_space(9):** You have used it to read and write registers. You know the difference between the tag, the handle, and the offset. You know that `bus_space_read_4` and `bus_space_write_4` are byte-order-respectful abstractions that work across architectures. You probably do not yet have a deep sense of how `bus_space` is implemented on different architectures, because that is a deeper topic, but at the level the book covered, you are comfortable.

**sysctl(9):** You have used it to expose tunable parameters. You know the tree structure of `sysctl` names, how to add a leaf with `SYSCTL_PROC`, and how to use the `OID_AUTO` pattern. You can read the output of `sysctl -a`

and understand where your driver's entries live. This is one of the most approachable kernel interfaces, and you have practised with it enough to reach for it naturally.

**dtrace(1):** You have used it to observe kernel behaviour. You know the `fbt` provider, the `syscall` provider, and the basics of the D language. You have probably not written your own static tracepoints yet, because that is a topic the book touched but did not work through exhaustively. That is an excellent area for continued learning, and the `dtrace(1)` manual page along with the DTrace guide make it a pleasure to study.

**devfs(5):** You know that device nodes appear under `/dev/` because `make_dev_s` was called at attach time. You know how cloning device drivers work. You have not likely explored the internals of `devfs` in full depth, because that is kernel internal territory and not something most driver authors need. You know it as a user: you know what it provides, and you have used it.

**poll(2), kqueue(2):** You implemented these for your async I/O work in Chapter 35. You know how the `poll` and `kqueue` subsystems interact with the kernel's wakeup mechanisms. You know when to pick one over the other, and you know why `kqueue` is generally the preferred interface for new code on FreeBSD. You have the working knowledge to implement these for any new driver you write.

**Newbus, DEVMETHOD, DRIVER\_MODULE:** These are the registration mechanics of a FreeBSD driver. You have written them enough times that they no longer feel unfamiliar. You know which methods are standard, how to handle custom methods, and how the registration order affects attach sequencing.

**Locking:** You have used mutexes, sx locks, rmlocks, condition variables, and epoch protections. Your confidence with each of these probably varies. Mutexes are likely the most natural to you; epoch may still feel less so. That is typical, and it is fine. Each of the more advanced synchronisation primitives has its own set of patterns that become clearer with use.

**Upstream workflow:** You know the mechanics of generating a patch, handling review, responding to feedback, and maintaining a driver after merge. You probably have not yet done a real submission, because doing one takes more than reading a chapter. Your first submission will probably feel slow and uncertain, even with all this preparation, and that is normal. The second and third will be faster.

Take a moment to rate your confidence with each of these, not as a formal exercise but as a quick mental map. Rate yourself from one to five, where one is “I have heard of it” and five is “I could teach it”. The locations where you rate yourself at three or four are probably your most productive next learning targets: you know enough to practise, and a little more practice will turn the skill into something you trust.

### 38.5.3 2.3 Review Exercise: Map the APIs You Used

This subsection contains a review exercise that is genuinely valuable and only takes about an hour.

Pick a driver you wrote during the book. It can be the final async driver from Chapter 35, the network driver from Chapter 28, a Newbus driver from Part 6, or any other non-trivial piece of code you produced. Open the source file. Go through it top to bottom. Every time you see a function call, a macro, a structure, or an API that came from the kernel, write it down.

When you are finished, you will have a list of somewhere between twenty and eighty kernel identifiers. Each of them represents an interface you invoked. Next to each one, write a one-sentence summary of what it does and why you used it. For example:

- `make_dev_s(9)`: creates a device node under `/dev/`. I used it in `attach` to expose the driver to userland.

- `bus_alloc_resource_any(9)`: allocates a resource of a given type from the parent bus. I used it to get the memory window for the device registers.
- `bus_dma_tag_create(9)`: creates a DMA tag with constraint parameters. I used it to set up the DMA layer before loading any maps.

The exercise has two benefits. The first is that it forces you to articulate, in your own words, what each interface does. That articulation is the difference between recognising an interface and understanding it. The second benefit is that the resulting list is a concrete record of what you know. You can keep it as a reference, and you can compare it against the next driver you write to see how your vocabulary has grown.

If you find an API on the list that you cannot explain in a sentence, that is a signal to open the manual page and read it. The exercise doubles as a diagnostic. The places where your explanation is weak are the places where more practice will have the most impact.

### 38.5.4 2.4 The Difference Between Having Followed the Book and Being Independent

There is an important distinction worth naming clearly. Finishing this book is not the same thing as being able to work independently, and it is worth understanding the distinction because it shapes the rest of the chapter.

When you followed the book, you had a guided path. The chapters introduced concepts in an order that had been thought about. The labs built on each other. When you got stuck, the next paragraph of the book often addressed the sticking point. The author had anticipated many of your questions and answered them before you asked. That structure is valuable, but it has limits.

Working independently means you no longer have that structure. The problem in front of you is not organised in an order that was designed for your learning. The APIs you need to use may be ones that the book named but did not exercise in detail. The pitfalls you hit may be ones the book did not warn you about specifically. The time you spend stuck is not bounded by the length of a chapter; it is bounded by your own persistence.

Readers who finish a book like this sometimes feel disappointed when they sit down to their first independent project and discover that it is harder than the labs were. That is not a sign that the book failed them. It is the ordinary transition from guided to independent practice. The book has given you the tools to close the gap, but the closing is work that you do, not work that the book does for you.

Several things help with this transition. The first is to pick smaller independent projects than you think you need. An easy win is worth more than an ambitious failure, especially early on. A small pseudo-device driver that does one thing correctly is a better first independent project than an ambitious network driver that does not quite work. The second is to keep the book open beside you while you work. You are not cheating by referring back to it. You are using a reference, and that is what references are for. The third is to expect the first project to take longer than you think it should. That is not a bug. It is the shape of the transition.

Over time, your independence grows through practice rather than through reading. Each new driver you write, each bug you track down alone, each patch you submit to the project, adds to the pool of experience that lets you work without needing to look everything up. The book is a starting point for that process. The process itself is yours.

### 38.5.5 2.5 Identifying Your Strongest and Weakest Areas

A useful self-assessment exercise at this stage is to identify, specifically, which areas you feel most confident in and which areas you feel you still need to deepen.

Confidence comes from having applied the knowledge successfully several times. If you wrote a character driver in Part 2 and never again, your confidence in that area is single-instance. If you handled interrupts in Chapter 19 and again in Chapter 20, and in a lab in Chapter 35, your confidence in that area has been exercised multiple times. The former is knowledge; the latter is skill.

Go through the major topics of the book and, for each one, ask yourself honestly: if someone handed me a new problem in this area, could I start on it without looking things up? The topics where the answer is a clear yes are your strongest areas. The topics where the answer is “I would need to refresh” are your next-level areas, the ones a little more practice will bring up to strong. The topics where the answer is “I remember the idea but not the specifics” are the ones that would benefit from more serious study.

Be honest with yourself. There is no external standard you are measuring against, and there is no grade. The value of the exercise is the map it produces. A map that says “I am strong in concurrency and character drivers, moderate in network drivers and DMA, weak in VFS and storage” is more useful than a vague impression of overall competence.

Write the map down. Save it. In six months, when you have done some of the practice that the later sections of this chapter will recommend, redo the exercise. You will probably find that several topics have moved up a category. Seeing that movement, documented from your own hand, is one of the most motivating things you can do for yourself as a learner.

### 38.5.6 2.6 Calibrating Against Real FreeBSD Developers

There is a calibration question worth addressing, because readers often wonder how their current skill level compares to the people working in the FreeBSD community.

The answer, honestly, depends on who you compare yourself to. A senior committer who has been working in the kernel for twenty years will have a depth of understanding that a single book cannot give you. A FreeBSD developer who has been writing drivers professionally for five years will know idioms and pitfalls that are rarely written down. A core-team member will have a broad view of the project that only governance work produces. None of those people are the right comparison, and measuring yourself against them will only discourage you.

The useful comparison is to a working junior FreeBSD developer. A person who can write drivers for specific hardware, respond to reviewer feedback, maintain the drivers over time, and contribute productively to the community. Most people at that level have some overlap with you in experience. They know things you do not know; you also know things they do not know, especially if the book covered a topic they never formally studied. You are, at this point, close to that junior-developer peer group. A little more practice, a first upstream submission, and a few months of maintenance will likely close the gap.

Another useful comparison is to the version of yourself that started the book. This comparison is almost always favourable and is therefore useful for motivation rather than for strategic planning. Use it when you are tired and need to see your progress. Use the junior-developer comparison when you are planning what to work on next.

### **38.5.7 2.7 The Shape of Competence You Have Built**

A final observation about where you stand. The competence you have built from this book is shaped in a particular way. It is deeply oriented toward FreeBSD-specific practice. It is strong on the driver-writing side of kernel work and thinner on other areas of the kernel that the book did not cover in depth. It is grounded in real source-tree work rather than abstract systems-programming principles.

This shape is the shape the book was designed to produce. It means that you are well prepared for the kind of work that FreeBSD drivers involve, and less prepared for adjacent areas like filesystem internals or deep VM work. That is not a deficiency; it is the boundary of the book's scope. The later sections of the chapter will point you toward the resources for extending that shape in the directions you choose, and the list of advanced topics in Section 3 names the most common extensions.

The shape also means that your knowledge transfers reasonably well to the other BSDs. OpenBSD and NetBSD share many idioms with FreeBSD, and a driver developer who knows FreeBSD can read OpenBSD or NetBSD drivers with effort but without feeling lost. There are differences, and they matter, but the underlying craft is recognisably the same. Readers who want to extend their competence across the BSD family will find that the investment of this book carries them a substantial part of the way.

### **38.5.8 2.8 Wrapping Up Section 2**

You now have a clearer picture of where you stand: what you can do, what you know well, where your strongest and weakest areas are, and how your competence compares to the community you are joining. That picture is practical. It informs the next part of the chapter, where we look outward at the advanced topics that lie beyond the book's scope.

The purpose of the next section is not to teach those advanced topics. The book would need to double in length to do that properly, and several of them are their own multi-year study tracks. The purpose is to name them, explain briefly what each one covers, and point you toward the resources where you can pursue them seriously. A map, in other words, rather than a curriculum.

## **38.6 3. Exploring Advanced Topics for Continued Learning**

The FreeBSD kernel is a large system, and no single book can cover all of it in depth. This book has concentrated on device drivers, which is one of the most approachable entry points into kernel work and one of the most useful. There are several important areas of the kernel that intersect with driver work but deserve their own dedicated study. This section names those areas, describes briefly what each one covers, and points you toward the sources you can use to pursue them.

The spirit of this section is pointing, not teaching. If you find yourself wanting deeper treatment of any of these topics, that is a sign of interest rather than a gap in this chapter. The resources we name below are the next step. The chapter itself is not going to turn into a file systems course or a network-stack course. Each of those is a years-long study, and compressing them into Chapter 38 would do justice to neither.

### 38.6.1 3.1 Filesystems and Deeper VFS Work

One of the most interesting areas beyond driver work is the filesystem layer. The book touched filesystem-adjacent material in Chapter 27, where we looked at storage devices and the VFS integration that sits above them. That chapter showed you the shape of a GEOM provider and the relationship between a storage driver and the block layer. It did not teach you how to write a filesystem.

A filesystem in FreeBSD is a kernel module that implements the `vop_vector` set of operations on `vnodes`. The `vnode` is the kernel's abstraction of an open file, and a filesystem provides the backing for a family of `vnodes`. FreeBSD's native filesystems include UFS, ZFS, `ext2fs-compat`, and several others. Writing a new filesystem means implementing at least the core operations: `lookup`, `create`, `read`, `write`, `getattr`, `setattr`, `open`, `close`, `inactive`, and `reclaim`, along with lesser-used operations for directory management, symbolic links, and extended attributes.

Serious study of this area means reading the UFS source under `/usr/src/sys/ufs/` and the VFS(9), `vnode(9)`, and individual `VOP_*(9)` manual pages such as `VOP_LOOKUP(9)` and `VOP_READ(9)`. Marshall Kirk McKusick's book "The Design and Implementation of the FreeBSD Operating System," second edition, contains a chapter on the VFS architecture that is the single best starting point for serious study. The ZFS code under `/usr/src/sys/contrib/openzfs/` is a second, very different model: a copy-on-write filesystem with its own layered abstraction and a history of Solaris origins.

Filesystems intersect with driver work in two directions. First, storage drivers provide the block-layer backing that filesystems consume, and a driver developer who understands filesystems will write better storage drivers. Second, some drivers implement filesystem-like interfaces directly, exposing a tree of virtual files for user interaction. The `devfs` filesystem itself is an example, and so is `procfs`.

If this area interests you, a productive starting project is to read the entire source of one of FreeBSD's simpler filesystems, such as the `nullfs` or `tmpfs` implementation. Both are small enough to study in a week or two, and both illustrate the `vnode` and VFS patterns clearly without the complications of on-disk structures.

### 38.6.2 3.2 Network Stack Internals

A second major area is the FreeBSD network stack. The book covered network drivers in Chapter 28, which taught you how to write a driver that participates in the `ifnet` layer by providing packet transmit and receive functions. That is the driver side. The stack itself, which sits above `ifnet` and implements the protocols you use every day, is a much larger subject.

The FreeBSD network stack is among the most sophisticated code in the kernel. It implements IPv4, IPv6, TCP, UDP, and a dozen other protocols. It includes advanced features like VNET for network-stack virtualisation, `iflib` for multi-queue network interface frameworks, and hardware-offload interfaces for devices that implement parts of the stack directly in silicon. Reading this code is a substantial undertaking, and working in it productively is a multi-year project.

Key starting points for study are the files under `/usr/src/sys/net/`, `/usr/src/sys/netinet/`, and `/usr/src/sys/netinet6/`. The core `ifnet` layer lives in `/usr/src/sys/net/if.c`, and the interface-framework abstractions used by modern drivers live in `/usr/src/sys/net/iflib.c`, whose header credits Matthew Macy as the original author. BSDCan and EuroBSDcon recordings from recent years are a well-regarded starting point for the broader `iflib` and VNET story, and the `iflib(9)` manual page pulls the in-tree reference material together.

Adjacent to the core stack is netgraph, a framework for composable network processing that sits apart from the normal IP stack. Netgraph lets you build protocol pipelines out of small nodes that exchange messages. It is useful for specialised protocol work, PPP-style encapsulation, and network-device prototyping. The documentation lives in `ng_socket(4)`, the manual pages starting with `ng_`, and the source under `/usr/src/sys/net-graph/`.

If the network stack interests you, a useful starting project is to write a simple netgraph node that performs a straightforward transformation on packets, such as a statistics counter. That project lets you touch the netgraph interfaces, the mbuf system, and the VNET mechanics without needing to implement a protocol.

### 38.6.3 3.3 USB Composite Devices

A third area, narrower than the previous two, is USB composite devices. The book covered USB drivers in Chapter 26, which taught you how to write a driver for a single-function USB device. Composite devices are USB devices that present multiple interfaces on a single hardware connection, such as a printer that also exposes a scanner, or a headset that exposes audio output, audio input, and a HID control channel.

Writing a composite-device driver is significantly more complex than writing a single-function USB driver. The main additional complexity is in the interface-selection logic, in the coordination between the different functional components of the driver, and in the correct handling of USB configuration changes. The FreeBSD USB stack under `/usr/src/sys/dev/usb/` supports composite devices, and there are several composite drivers in the tree that you can study as examples.

Serious study of this area means reading the USB specification, the FreeBSD USB stack source, and the existing composite-device drivers. The `usb(4)` manual page is the starting point, and `/usr/src/sys/dev/usb/controller/` and `/usr/src/sys/dev/usb/serial/` contain many examples of real-world driver structure. The relevant USB specification is the USB 2.0 specification from the USB Implementers Forum, which is freely available and remarkably readable.

A useful starting project if this interests you is to pick up a cheap composite USB device (many multi-function printers work) and write a FreeBSD driver for its less-supported function. This kind of project gives you a clear target, real hardware that you can observe with `usbdump(8)`, and a concrete endpoint when the driver works.

### 38.6.4 3.4 PCI Hotplug and Runtime Power Management

A fourth area is PCI hotplug and runtime power management. The book covered PCI drivers in Chapter 18 and power management at the level of suspend and resume in Chapter 22. Those chapters prepared you for devices that appear at boot, remain throughout the session, and disappear at shutdown. They did not fully cover the case where devices come and go during runtime.

PCI hotplug has become important with the rise of PCI Express, which supports physical hotplug of cards through connectors like U.2, OCuLink, and the internal hotplug slots on server-class hardware. A driver that needs to support hotplug must handle detach at times other than shutdown, must reason about references held by other subsystems, and must be robust against partial detach.

Runtime power management is the companion topic. Modern PCI devices support low-power states that the driver can enter when the device is idle and exit when the device is needed again. The ACPI subsystem in

FreeBSD provides the underlying mechanism. A driver that uses runtime power management can save significant power, especially on laptops and battery-powered embedded devices, but it needs careful reference-counting and state-machine logic to work correctly.

The relevant FreeBSD sources are under `/usr/src/sys/dev/pci/` and `/usr/src/sys/dev/acpica/`. The `pci(4)` manual page and the `acpi(4)` manual page are the starting points. The ACPI specification itself is a substantial document but is readable, and it is worth at least a skim if runtime power management is an area you want to work in.

A reasonable starting project is to take a driver you wrote during the book and add runtime power management to it. Even though the driver may not have a real hardware device to exercise the low-power states on, the exercise of adding the correct state machine, the reference counting, and the wake handlers is valuable.

### 38.6.5 3.5 SMP and NUMA-Aware Drivers

A fifth area is the intersection of driver writing with symmetric multiprocessing (SMP) and non-uniform memory access (NUMA) tuning. The book has covered the basics of locking and concurrency throughout Part 3, and you have been writing SMP-safe drivers since then. What the book did not cover in depth is how to write drivers that are not just SMP-safe but also SMP-scalable, and how to handle NUMA topology explicitly.

An SMP-safe driver is one that will not crash or corrupt state on a multiprocessor machine. That is a baseline requirement. An SMP-scalable driver is one whose throughput grows reasonably as you add more CPUs. That is a much harder target. It requires careful attention to cache-line sharing, to the granularity of locks, to per-CPU data structures, and to the flow of work between processors. Most of the high-performance drivers in FreeBSD, particularly network drivers for 10 gigabit and faster interfaces, use advanced techniques to achieve scalability.

NUMA awareness is the next layer. On a NUMA machine, different regions of physical memory are closer to different CPUs. A driver that pins its DMA buffers and its interrupt handlers to the same NUMA node will be faster than one that does not. The FreeBSD NUMA subsystem under `/usr/src/sys/vm/` provides the mechanisms, and the `numa_setaffinity(2)` system call and the `cpuset(2)` interfaces are the starting points.

The advanced network drivers under `/usr/src/sys/dev/ixgbe/`, `/usr/src/sys/dev/ixl/`, and related directories are good examples of SMP-scalable and NUMA-aware driver design. Reading them is a graduate course in this area. The `iflib` framework under `/usr/src/sys/net/iflib.c` and the adjoining headers provides the primary scaffolding for modern network drivers of this class.

A useful starting project in this area is to take a driver you wrote during the book, add per-CPU counters, and benchmark it on a multi-CPU system. Even if the driver does not need SMP scalability in practice, the exercise of adding per-CPU state and measuring the difference is a valuable introduction to the thinking.

### 38.6.6 3.6 Additional Areas Worth Naming

Beyond the five topics above, several other areas of the FreeBSD kernel are worth knowing about, even if this chapter cannot cover them in detail.

**Jails and bhyve integration.** The jail subsystem and the bhyve hypervisor each have implications for driver work. A driver that can be used inside a jail, or that participates in bhyve's I/O virtualisation, has requirements

that ordinary drivers do not. The relevant sources are under `/usr/src/sys/kern/kern_jail.c` and `/usr/src/sys/amd64/vmm/`.

**Audit and MAC frameworks.** FreeBSD has a sophisticated audit framework, implemented through `auditd(8)`, and a mandatory access control (MAC) framework implemented through MAC policy modules. Drivers that need to participate in security audit trails, or that need to enforce MAC policies, have additional interfaces available. The `audit(8)` manual page and the `mac(9)` manual page are the entry points.

**Cryptographic framework.** The FreeBSD kernel has a built-in cryptographic framework under `/usr/src/sys/opencrypto/` that drivers can register with to expose hardware cryptographic acceleration. If your target hardware includes a crypto engine, this is the integration path. The `crypto(9)` manual page describes the interface.

**GPIO and I2C buses.** Embedded drivers often need to talk to GPIO lines and I2C peripherals. FreeBSD has first-class support for both, with manual pages `gpio(4)` and `iic(4)` and source under `/usr/src/sys/dev/gpio/` and `/usr/src/sys/dev/iicbus/`.

**Sound drivers.** The audio subsystem has its own conventions, defined in `/usr/src/sys/dev/sound/`. It is a bus-like framework with its own concepts of a PCM stream, a mixer, and a virtual sound card. Writing a sound driver is an interesting specialty and a reasonable next step for someone who enjoyed the character driver work of Part 2.

**DRM and graphics.** Graphics drivers in FreeBSD have traditionally been ports of the Linux DRM framework, living in the `drm-kmod` port. Writing or maintaining a graphics driver is a very different activity from writing a typical device driver, and it is a specialised field. The `drm-kmod` project has its own documentation and its own mailing list.

Each of these areas is a direction you could go. None of them is a required next step. The right next step is the one that interests you enough to sustain the work.

### 38.6.7 3.7 Exercise: Pick One, Read One Manpage, Write One Paragraph

Here is a small exercise that has disproportionate value. Pick one of the areas above, exactly one, that sounds interesting to you. Read the relevant FreeBSD manual page. This means opening a terminal, typing something like `man 9 vfs` or `man 4 usb`, and reading what you find. Expect it to take twenty to forty minutes.

After you finish reading, close the manual page. On a blank page in your notebook or on a fresh text file, write a one-paragraph summary of what the interface is for, what the main data structures are, and what a driver author would use it for. Do not refer back to the manual page while writing. The point is to test your own understanding, not to produce a polished description.

Then open the manual page again and compare. The places where your paragraph was vague or wrong are the places where you actually did not understand yet. Revise. Write a better paragraph. Save it.

This exercise is valuable for three reasons. First, it gives you hands-on practice with FreeBSD manual pages, which are an underused resource and one of the best technical documents in the system. Second, it trains the skill of summarising a technical interface in your own words, which is the foundation of understanding. Third, the paragraph itself is something you can keep as a reference. Over time, a collection of such paragraphs becomes a personal glossary of the kernel areas you have explored.

### 38.6.8 3.8 Wrapping Up Section 3

This section has given you a map of advanced topics rather than a curriculum. The map shows where the book's coverage ends and where further study begins. For each topic, we named the topic, described briefly what it covers, pointed to the relevant parts of the source tree and manual pages, and suggested a starting project.

The most important thing about this section is the suggestion that you not try to study all of these topics at once, and not try to study any of them at all unless you actually find yourself interested. Depth of understanding comes from sustained attention to one topic over time, not from a whirlwind survey of many topics. The list above is a menu, not a curriculum.

The next section turns from advanced topics to the practical work of building yourself a reusable development toolkit. That toolkit is the scaffolding that makes whatever specialised area you pursue easier to pursue, because it frees you from the friction of starting from scratch on every new project. The toolkit and the advanced topics together are the practical engine of your continued growth.

## 38.7 4. Building Your Own Development Toolkit

Every experienced driver developer has a set of tools and templates they reach for reflexively. A starter driver project that captures the patterns they always use. A virtual lab that boots in seconds and lets them try things without fear of breaking anything. A set of scripts that handle the tedious parts of testing. A habit of writing regression tests before submitting patches. These tools are not provided by the kernel, and they are not covered in any specific chapter of the book. They are built up over time by each developer, and they pay for themselves many times over.

This section walks through building that toolkit. The examples directory for this chapter contains starter templates, and you should treat the templates as a first draft that you then modify to suit your own working style. The point is not to use the templates verbatim; the point is to have something to start from, and then to evolve it over the next several projects into something that fits how you actually work.

### 38.7.1 4.1 Setting Up a Reusable Driver Template

The first tool in your toolkit is a driver project template. When you start a new driver, you should not begin with a blank file. You should begin by copying a template that already contains the copyright header you use, the standard includes, the Newbus method table shape, the probe-attach-detach skeleton, the softc convention, and the Makefile that builds it all into a loadable module.

The template should be opinionated. It should reflect your own style choices within the constraints of FreeBSD's `style(9)` guidelines. If you always use a particular locking pattern, the template should include it. If you always define a `*_debug sysctl`, the template should include it. If you always keep your register definitions in a separate header, the template should include an empty one named correctly.

The template does not need to be sophisticated. Five files is enough for most purposes: a main `.c` file with the driver skeleton, a `.h` file for internal declarations, a `reg.h` file for register definitions, a `Makefile` for the module build, and a manual page stub. The whole thing fits in a few hundred lines. You can iterate on it.

The companion directory for this chapter contains a working template you can start from. Copy it, place it under version control, date it, and start making it your own. Every time you finish a driver project and notice a pattern

you reached for repeatedly, consider whether the pattern should go into the template. Over the course of several projects, the template becomes a compressed record of your accumulated style.

There is a subtle trap worth avoiding. The template should be kept simple enough that you can type it from memory if you had to. If the template becomes so elaborate that you depend on it for patterns you could not reproduce manually, you have moved from having a useful tool to having a crutch. The tool helps you move faster; the crutch hides what you know and do not know. Keep the template on the useful side of that line.

A second subtle consideration is licensing. Your template should contain the copyright header you use for your own code. If you typically write drivers under the BSD-2-Clause license, as is standard in FreeBSD, the template should have that header. If you sometimes write drivers under a different license for professional reasons, keep separate templates for each license. Getting the license right at the start of a project is easier than changing it later, and a template that starts with the correct license is one fewer thing to remember on each new project.

### 38.7.2 4.2 Building a Reusable Virtual Lab

The second tool in your toolkit is a virtual lab. This is the environment where you load your drivers, test them, crash them, and iterate. It should be separate from any machine you care about, it should be easy to rebuild, and it should be fast enough that you do not dread turning it on.

FreeBSD provides two primary virtualisation paths for this purpose: bhyve and QEMU. Bhyve is the native FreeBSD hypervisor, and it is an excellent choice for a lab when your host is FreeBSD. QEMU is a portable emulator that runs on many host operating systems, and it is the right choice if your host is Linux, macOS, or Windows. Both are capable of running FreeBSD guests with good performance, and both have communities and documentation around them.

A reasonable lab setup has the following properties. It boots in under thirty seconds. It exposes a serial console rather than a graphical one, because serial consoles are much easier to automate and to log. It shares a source directory with the host so that you can edit code on the host and build it in the guest without transferring files manually. It has a snapshot of a known-good state so that you can recover quickly after a panic. It is configured to dump its memory on panic so that you can attach kgdb to the crash dump.

Setting up such a lab is a one-time investment of a few hours, and the payoff is an environment you will use for every future driver project. The companion directory for this chapter contains example bhyve and QEMU configurations, along with a short script that creates a disk image, installs FreeBSD into it, and configures the guest for driver development work.

For some drivers, you will want a slightly more elaborate lab. If you are writing a GPIO driver, you will want an attached simulator that can model GPIO transitions. If you are writing a USB driver, you will want the ability to pass a USB device through from the host to the guest, which both bhyve and QEMU support. If you are writing a network driver, you will want virtual network interfaces connecting the guest to the host and possibly to other guests. Each of these is a refinement of the base lab, and each of them takes an afternoon to set up properly.

One useful pattern is to keep your lab configuration in a version-controlled repository. Write the bhyve or QEMU command line in a script rather than typing it from memory each time. Store the disk image and the snapshots somewhere you can find them. Document the guest's network configuration in a README. The lab is code, and it should be treated that way.

### 38.7.3 4.3 Loopback Testing With User-Mode Helpers

A particular lab pattern worth highlighting is loopback testing with user-mode helpers. Many drivers can be exercised fully by a userland program that exercises them. A network driver can be tested by a program that opens a socket to the driver's interface and sends packets. A character driver can be tested by a program that opens the device node and performs a sequence of operations. A sysctl-controlled driver can be tested by a script that sets sysctl values and checks for expected behaviour.

The pattern is to pair every driver with a small testing helper. The helper is usually a userland program in C or a shell script that invokes `sysctl`, `devstat`, or custom userland tools. The helper should cover at least the happy path: the driver loads, responds to normal operations, and unloads cleanly. A more thorough helper also covers edge cases: error paths, concurrent access, resource exhaustion.

Writing the helper alongside the driver, rather than afterwards, has a subtle benefit. It forces you to think about how the driver will be used from userland as you design the driver. If the helper is hard to write, that is a signal that the driver's userland interface is hard to use, and the time to redesign the interface is during development rather than after submission. This is one of the small engineering habits that separates drivers that are easy to maintain from drivers that are hard to maintain.

The companion directory contains an example helper that uses the standard character-driver operations. It is a template rather than a complete test suite, but it illustrates the pattern and gives you something to evolve.

### 38.7.4 4.4 Creating Regression Tests for Your Driver

The third tool in your toolkit is regression testing. A regression test is an automated check that a specific driver behaviour works correctly. You run the regression tests before submitting a patch, you run them after pulling in upstream changes, and you run them any time you are uncertain whether something you changed broke something else.

FreeBSD has a first-class testing framework called `kyua`(1), defined under `/usr/src/tests/`. The framework provides a way to declare test programs, group them into test suites, run them, and report the results. Driver tests can be written as Kyua tests, and the infrastructure handles all the plumbing: isolating tests from each other, capturing their output, and producing reports.

For a driver that exposes a userland interface through a device node, a reasonable test suite covers the following kinds of cases. It tests that the driver loads without warnings. It tests that the device node appears in the expected location. It tests that the standard operations produce the expected results. It tests that edge cases (zero-length writes, reads at end-of-file, concurrent opens) produce the expected errors rather than panics. It tests that the driver unloads cleanly.

A more thorough test suite also covers stress cases. It might run a hundred concurrent writers against a driver that is supposed to serialise correctly. It might repeatedly load and unload the driver to check for leaks. It might use `kttr`(9) tracing or DTrace probes to verify that particular code paths are exercised.

The companion directory contains a regression-test script skeleton that illustrates the pattern. It is not a complete test suite, but it is enough to show the structure. Extending it for a specific driver is a matter of adding specific test cases, and the Kyua documentation under `/usr/share/examples/atf/` shows the idiomatic way to structure them.

One important habit to develop is to write the regression test for a bug before you fix the bug. This is the discipline that regression tests exist to support. A test that does not exist before the fix is a test that may never exist, because once the fix is in, the motivation to write the test is gone. A test written first captures the bug in a concrete, reproducible form, and then the fix turns the failing test into a passing test. The test stays in the suite forever, and if the bug is ever reintroduced, the test catches it. This is an old discipline in software engineering, and it works as well in FreeBSD kernel work as in any other setting.

### **38.7.5 4.5 Lightweight Continuous Integration**

The fourth tool in your toolkit is lightweight continuous integration. This does not need to be a complex system. A single script that runs on each commit or each push, that builds your driver and runs its regression tests, is enough for most purposes.

The script can be as simple as a shell script that invokes the build and the tests in sequence. If a step fails, the script exits with a non-zero status, and you know to investigate. Over time, the script can grow to include style checks, manual-page linting, and cross-architecture builds. Each addition is incremental, and each addition catches a class of mistake that you would otherwise discover only in review.

If you have access to a continuous-integration system, such as GitHub Actions, GitLab CI, or a self-hosted runner, you can wire the script up to run on every push to your repository. The feedback cycle becomes: push a change, wait a few minutes, see whether it broke anything. This feedback cycle catches mistakes much earlier than manual testing catches them, and it frees your own time for thinking rather than rote checking.

A warning about CI complexity. It is tempting to build elaborate CI pipelines with many stages, caches, artifacts, and notification systems. For a solo developer on a small driver project, elaborate CI is usually a time sink. Start with a script that does the minimum. Add to it only when you notice a specific mistake that the current pipeline missed. Let the pipeline grow in response to real needs, not imagined ones.

The companion directory contains an example CI script that builds a driver, runs the style check, lints the manual page, and performs a basic load/unload cycle. You can adapt it to your repository of choice.

### **38.7.6 4.6 Package Your Driver With Documentation and Test Scripts**

A related habit worth cultivating is to package every driver you write with its documentation and its test scripts from the very beginning. Each driver in your repository should have the following files, at minimum: the source code, a module Makefile, a manual page, a README that explains what the driver does and how to use it, and a set of test scripts. If the driver is for specific hardware, the README should name the hardware. If the driver has known limitations, the README should name them.

The habit of packaging takes a little extra discipline, but it pays off in two ways. First, anyone who encounters your driver, including future-you, can understand it and use it without having to reconstruct the context. Second, the act of writing the README forces you to articulate what the driver does, and that articulation often reveals inconsistencies or missing features that you would not have noticed otherwise.

A small tip about READMEs. Write them in the second person, as instructions for a reader. “To load this driver, run `kldload mydev`.” This style is the standard for FreeBSD documentation, and it is easier to read than other styles, especially for someone skimming the file to learn how to use the driver.

### **38.7.7 4.7 Exercise: Package a Driver End-to-End**

Pick one of the drivers you wrote during the book. It should be one that is substantial enough to be worth packaging but small enough to finish the exercise in a weekend. The async character driver from Chapter 35, or the network driver from Chapter 28, or a Newbus driver from Part 6 are all reasonable candidates.

Create a new directory for the driver, separate from the book's examples directory. Copy the driver source in. Build the Makefile from scratch, using your driver template if you have one. Write a short manual page. Write a README. Write at least three regression tests. Write a load/unload script. Commit everything to a git repository.

When you are done, the directory should be self-contained. Hand it to a colleague and they should be able to build, load, test, unload, and understand the driver without needing to ask you questions. If they need to ask questions, those are gaps in your packaging that you can address.

This exercise is valuable beyond the specific driver. It is a rehearsal of the packaging habit, and packaging habits scale. Once you have packaged one driver well, the second one is easier, and the tenth one is automatic. Each time you do it, the quality of your packaging improves, and so does your sense of what makes a driver easy or hard to use.

### **38.7.8 4.8 Wrapping Up Section 4**

This section has walked through the practical toolkit that experienced FreeBSD developers build up over time: a driver project template, a virtual lab, loopback testing, regression tests, lightweight CI, and packaging habits. None of these is strictly necessary for writing a driver, but each of them makes the work easier, more reliable, and more durable.

The companion directory contains starter artifacts for all of them. You can adopt them verbatim or use them as a reference for building your own. Either path is valid, and the important thing is that you take some version of this toolkit into whatever driver work you do next.

The next section turns to the community of FreeBSD developers. A toolkit makes you productive. A community connects your productivity to the rest of the world and, over time, shapes you into a better engineer than solo work alone would produce.

## **38.8 5. Giving Back to the FreeBSD Community**

The FreeBSD Project is a community. It is not an abstraction; it is a set of people who read each other's patches, answer each other's questions, show up at conferences, argue about design choices, and together produce an operating system that has been evolving for over thirty years. This section is about how to become part of that community, how to give back to it, and how the engagement shapes you as a professional engineer.

### **38.8.1 5.1 Why Community Engagement Matters**

Let us start with the question of why this is worth discussing at all. A reader who has finished this book has the technical skills to write and maintain drivers in relative isolation. Does it really matter whether they engage with the community?

It does, and the reasons fall into several categories.

Community engagement is how your skills grow past the point a book can take them. Books cover patterns that are well understood enough to be written down. Community mailing lists, code review threads, and conference talks cover patterns that are emerging, controversial, or specialised. If you stop reading after the book, you stop growing in a specific way that the community would continue to develop in you.

Community engagement is how your work reaches other people. A driver in your personal repository serves you and a few people who happen to find your repository. A driver submitted upstream, discussed on a mailing list, and maintained in the project serves every FreeBSD user who encounters the hardware. The amplification is enormous, and you unlock it through engagement.

Community engagement is how you find the work that matters. Some of the most interesting projects in a large open-source ecosystem are not visible from the outside. They are discussed on mailing lists, at conferences, in IRC channels, and in informal chats. If you are in those conversations, you will hear about them. If you are not, you will miss them.

Community engagement is how you become someone the project trusts. Commit rights, mentorship opportunities, and leadership positions are not handed out; they are earned through a long history of visible, substantive engagement. The technical skill is the prerequisite. The community engagement is the path from prerequisite to actual standing.

None of these are obligations. You can finish this book, write drivers for your own purposes, and never engage with the community in any way. That is a legitimate path. But if you are curious about what deeper involvement looks like, the rest of this section shows you how to start.

### 38.8.2 5.2 Participating in Mailing Lists

The primary forum for FreeBSD development discussions is mailing lists. The project has many of them, each focused on a different area or audience. The ones most relevant to a driver developer are:

- **freebsd-hackers@**: general kernel development discussion. Broader than driver-specific topics, and the best starting point if you want a general sense of what the project is working on.
- **freebsd-drivers@**: focused on device driver topics. Lower volume than **freebsd-hackers** and more directly relevant if your interests are in driver work.
- **freebsd-current@**: discussion about the development branch of FreeBSD. Useful if you want to track recent changes and the discussions around them.
- **freebsd-stable@**: discussion about the stable branches. Lower volume, more release-focused.
- **freebsd-arch@**: architectural discussions about major changes to the system. Low volume, high signal-to-noise.

Subscribing to one or two of these is a reasonable first step. Start with **freebsd-hackers** or **freebsd-drivers**, and read for a few weeks before posting. The goal of the initial reading is to get a sense of the tone, the typical topics, and the people who participate regularly. Once you have that sense, you will know how to participate in a way that fits the culture.

Posting to a mailing list is a skill. A good post has a clear subject line, a concise body, and a specific question or contribution. A poor post wanders, asks several questions at once, or lacks enough context for anyone to help. When you are ready to post, take the time to draft the message carefully. Most experienced mailing-list

users spend more time on their posts than newcomers expect, and the investment shows up as higher-quality discussion.

A subtle skill is replying. Mailing list replies should quote just enough of the previous message to provide context, should address the specific point being made, and should avoid top- posting. These are conventions, not rules, but following them signals familiarity with the culture and makes your posts easier to follow. The RFC-style quoting convention, where you reply below each quoted paragraph, is the preferred style in FreeBSD mailing lists.

There is an etiquette around asking for help that is worth internalising. Before asking a question on a mailing list, you should have already read the manual pages, checked the source tree, searched the mailing list archives, and tried a few obvious solutions. When you do ask, include the information a reader would need: what FreeBSD version you are using, what hardware, what you tried, what you expected, and what actually happened. A well-formed question gets a helpful answer. A poorly-formed question often gets no answer, not because the community is hostile but because the community cannot help without more information.

### **38.8.3 5.3 Using Bugzilla**

FreeBSD tracks bugs in Bugzilla, which lives at <https://bugs.freebsd.org/bugzilla/>. It is the project's primary tool for recording defects, tracking progress, and coordinating fixes. A driver developer will interact with Bugzilla in several ways.

The first is reporting bugs. If you encounter a bug in a driver or in the kernel, you can file a PR (problem report) in Bugzilla. A good PR includes the FreeBSD version, the hardware, a clear description of the problem, reproduction steps, and any relevant output such as `dmesg` excerpts or crash dumps. The clearer the report, the more likely someone can fix the bug.

The second is triaging existing bugs. Bugzilla has a backlog of reports, some of which are not well-categorised or well- understood. A new contributor can add value by reading through unassigned PRs in the driver-related categories, reproducing the bugs on their own systems, and adding clarifying information to the reports. This kind of work is not glamorous, but it is genuinely valuable, and the contributors who do it learn a great deal about the shape of problems that drivers encounter in the wild.

The third is fixing bugs. When you find a bug you can fix, Bugzilla is the tool that coordinates the fix. You attach a patch to the PR, mark it for review, and follow the review through to commit. The process is not very different from the upstream submission workflow you learned in Chapter 37, except that it is targeted at a specific existing issue rather than at a new feature.

One useful habit is to subscribe to the Bugzilla product that covers drivers, or to a specific component you care about. The subscription gives you email notifications when bugs are filed, updated, or resolved. Over time, this subscription becomes a lightweight way of staying aware of what is going wrong in the area you maintain.

### **38.8.4 5.4 Contributing to Documentation**

Not all contributions are code. FreeBSD's documentation is a first-class part of the project, and it needs continuous work to stay current. For a new contributor, documentation work is one of the most accessible entry points.

The FreeBSD Handbook is the primary end-user document. It covers installation, administration, development, and specific subsystems. Its source lives in a separate Git repository at <https://git.freebsd.org/doc.git>, which you can browse online at <https://cgит.freebsd.org/doc/>. The documentation is written in AsciiDoc and rendered into HTML by Hugo; earlier generations of the documentation used DocBook XML, and you will still find references to that history in some older material.

Contributing to the Handbook is as simple as identifying a section that is outdated, incomplete, or confusing, writing an improvement, and submitting it. The documentation team welcomes such contributions and is usually quick to review them. The workflow is similar to code submission: clone the repository, make a change, generate a patch or pull request, and submit.

Manual pages are a second documentation target. Every driver should have a manual page, and every new FreeBSD feature should be documented in a manual page. The format is `mdoc`, defined in `mdoc(7)`, and the style guide lives in `style.mdoc(5)`. Writing good manual pages is a specialised skill, and a contributor who develops it is valuable to the project beyond their code contributions.

A specific area where manual-page work is always welcome is fixing outdated examples. Over time, manual pages accumulate references to options, files, or behaviours that have changed. Walking through a manual page, testing each example, and updating the ones that no longer work is useful, repeatable work that does not require deep kernel knowledge. It also teaches you the interfaces the manual page describes, which is its own benefit.

### 38.8.5 5.5 Translating Documentation

A third form of documentation contribution is translation. The FreeBSD Project maintains translations of the Handbook and other documents into many languages, coordinated through <https://docs.freebsd.org/> and the translation tools under <https://translate-dev.freebsd.org/>. If you are fluent in a language other than English and are willing to spend time on translation, the project has real, unmet needs for this work.

Translation is not simple substitution. A good translation requires understanding the technical content, understanding the conventions of the target language, and understanding the idiomatic expression of technical ideas in that language. It is serious work, and good translators are appreciated in proportion to how rare they are.

Working on translations puts you in contact with the FreeBSD Documentation Engineering Team, a small group of committers who maintain the documentation infrastructure. That contact is valuable beyond the immediate work, because it connects you to people who can help you understand the rest of the project.

### 38.8.6 5.6 Mentoring Other Beginners

A fourth form of contribution, and one that does not require commit rights or any specific standing in the project, is mentoring. Somewhere in the world, there is a reader who is at Chapter 5 of this book, struggling with kernel C, and wondering whether they should give up. If you can help that reader, you are contributing to the project in a way that matters more than almost any code patch could.

Mentoring happens in many forms. You can answer questions on the forums at <https://forums.freebsd.org/>. You can respond to questions on IRC in `#freebsd` or `#freebsd-hackers` on Libera Chat. You can participate in the Discord or Telegram channels that some parts of the community run. You can write blog posts that answer questions you struggled with when you were at that stage. You can give talks at local BSD user groups.

You can review someone else's first patch and offer suggestions in the tone you would have wanted when you were first reviewed.

The specific channels matter less than the habit of being available to help. Every person who finishes this book becomes, by that fact alone, someone who can help a reader who has not yet finished it. That is a real contribution to the sustainability of the FreeBSD community. The community grows when its senior members teach its junior members, and the senior/junior distinction here is measured in chapters completed, not in years of experience.

A useful pattern for mentoring is to focus on a specific channel and be reliably present there. If you answer questions on `freebsd-questions@` once a week for a year, you become a known face to the people who ask questions. If you respond to every driver-related question on the forums that you can answer, you become someone that newcomers look for when they have questions. Consistency matters more than intensity.

Be patient with beginners. Some of the questions will be things you remember finding hard, and some will be things you no longer remember finding hard because they have become obvious to you. Answer the obvious-to-you questions with the same care as the hard-for-you questions. That is what good mentoring looks like.

### **38.8.7 5.7 Contributing Driver Fixes**

A fifth form of contribution is driver fixes specifically. The FreeBSD tree contains hundreds of drivers, and at any given time several of them have known bugs or limitations. A new contributor with the skills from this book can fix some of these.

Finding driver bugs to fix is not hard. You can look at the open PRs in Bugzilla filtered by the `kern` or driver-specific products. You can read the mailing lists for reports of bugs that have not been fixed. You can use drivers yourself and report or fix the bugs you find. Any of these paths leads to real work the project needs.

Fixing a driver bug has several benefits beyond the fix itself. It teaches you how that particular driver works, which is an education in itself. It gives you practice with the upstream review workflow on real code that real users depend on. It builds a small history of contributions that, over time, adds up to a visible profile in the project.

One specific category of work worth mentioning is driver cleanup. Many older drivers in the tree have accumulated style issues, deprecated API usage, or missing manual pages over the years. Cleaning them up is not glamorous work, but it is exactly the kind of work the project needs and often welcomes. A contributor who is willing to do careful cleanup work on several older drivers develops a reputation for careful work very quickly, because careful work is always scarce.

### **38.8.8 5.8 Translating Knowledge to Other BSDs**

A sixth and less-commonly discussed form of contribution is carrying knowledge between the BSDs. OpenBSD and NetBSD share much of their ancestry with FreeBSD, and patterns that work in one often work in the others with adjustments. A driver developer who knows FreeBSD well can, with some additional study, contribute to OpenBSD or NetBSD as well.

The idioms are different in important ways. OpenBSD has its own locking conventions, its own interrupt handling patterns, and a strong emphasis on security and simplicity. NetBSD shares many patterns with FreeBSD

but has its own approach to things like device-tree integration and autoconfiguration. Each of these is a living system with its own community, and each of them has driver needs that a FreeBSD-trained developer can address.

The value of cross-BSD contribution goes beyond the individual commits. It keeps the three projects aware of each other, spreads good ideas between them, and prevents each from accumulating bugs that the others have already fixed. In an era where the BSD community is smaller than it once was, this cross-pollination is particularly valuable.

If this interests you, the starting point is to pick a driver you know well in FreeBSD and to look at whether OpenBSD or NetBSD supports the same hardware. If they do not, you have a clear porting target. If they do, you can still contribute by reading their version of the driver, comparing, and noting any improvements or fixes that could be shared. Either way, the engagement deepens your understanding of all three systems.

### **38.8.9 5.9 Exercise: Write a Thank-You Message**

This subsection's exercise is small and unusual. Send a thank-you message to someone whose code or documentation helped you during this book.

It could be the maintainer of a specific driver whose source you read closely. It could be the author of a manual page that clarified something for you. It could be a committer whose talk at a conference you watched on YouTube. It could be the person who wrote the book's foreword if one exists, or the person who reviewed it. Whoever helped you, in whatever way, say thank you.

The message does not need to be long. A few sentences will do. Name the specific piece of work that helped you. Explain briefly how it helped. Say thank you. Send the message by email or post it to the appropriate mailing list.

This exercise is valuable for two reasons. First, open-source work is often thankless, and maintainers who receive thank-you messages are more likely to keep contributing. You are, through the act of thanking, investing in the ecosystem's sustainability. Second, the act of writing the message will make you think specifically about how someone else's work helped you. That thinking, in turn, will make you more aware of how your own work might help someone else, and that awareness is the foundation of becoming a contributor yourself.

### **38.8.10 5.10 The Relationship Between Contribution and Growth**

There is a deeper point about community engagement that is worth naming explicitly. Contributing to the FreeBSD Project, in any of the forms above, is not just a way of giving back. It is a way of growing.

When you answer a beginner's question on a mailing list, you learn what was unclear about the topic. When you review someone else's patch, you learn patterns you would not have encountered in your own code. When you fix a bug in an area you did not write, you learn that area's conventions and history. When you write a manual page, you learn the discipline of precise technical explanation. Each act of contribution is also an act of education, and over time the education accumulates into a depth of understanding that solo work cannot produce.

The most senior FreeBSD developers are often the most prolific contributors precisely because contribution is how they continued to grow. They did not arrive at their current depth and then start contributing. They started

contributing, which led to their current depth. If you want to continue growing in the way they did, the path is visible and well-trodden.

This is not a moral argument. It is a practical observation about how expertise develops in open-source ecosystems. The people who engage deeply grow deeply. The people who stay on the periphery stay at whatever level the materials they consume took them to. Both paths are valid; if you want the former, the chapter has now shown you how to start.

### 38.8.11 5.11 Wrapping Up Section 5

This section has walked through the many forms of community contribution available to a reader of this book: mailing-list participation, Bugzilla engagement, documentation work, translation, mentoring, driver fixes, and cross-BSD contribution. Each of these is a legitimate way to be part of the FreeBSD community, and all of them are valuable beyond the specific work they involve.

The key takeaway is that contribution is broader than committing driver code. A reader who thinks of contribution only as “write a driver and send it upstream” is missing most of the contribution surface. Some of the most important work in the project is done by people who rarely commit code but who contribute in other ways.

The next and final major section of the chapter turns from the community to the living system itself. The FreeBSD kernel is under active development, and staying connected to that development is its own skill. How do you follow changes? How do you notice when something you rely on is about to change? How do you stay current without drowning in the volume of daily activity?

## 38.9 6. Staying Up to Date With FreeBSD Kernel Development

The FreeBSD kernel is a moving target. The version you learned against was 14.3, and by the time you read this at a later date, there will already be a 14.4, or a 15.0, or both. Each release brings new subsystems, deprecates old ones, changes internal APIs, and shifts conventions in small ways. A driver developer who writes a driver once and walks away will find, returning a few years later, that the driver may not build against the current tree. A driver developer who stays engaged with the kernel’s development watches those changes happen in real time and adjusts along the way.

This section is about how to stay engaged. Like the community section before it, the advice here is optional. You can finish this book, write drivers against FreeBSD 14.3, and never update your knowledge; your drivers will work for a while and then gradually stop working, and that is a legitimate relationship to have with the kernel. But if you want your drivers to keep working, or if you want to grow beyond the snapshot of knowledge that this book gave you, the habits in this section are what make that possible.

### 38.9.1 6.1 Where to Follow FreeBSD Development

There are several primary sources for following FreeBSD development, and a well-calibrated developer watches a few of them regularly without trying to watch them all.

**The FreeBSD Git repository.** The source tree itself lives at <https://git.freebsd.org/src.git>. Every commit to the tree is visible there, along with its commit message, its author, and its review history. You can

clone the repository and run `git log` to see the recent activity. You can use `git log --since=1.week` to filter to recent changes. You can use `git log --grep=driver` to look at driver-related commits.

For most developers, the Git repository is the primary source of truth. The commit logs are where the project's day-to-day engineering happens, and reading them regularly is one of the most direct ways to stay aware of what is changing and why.

**Commit notification mailing lists.** The project publishes commit messages to mailing lists such as `svn-src-all@` (historically, when the project used Subversion) and their Git-era equivalents. Subscribing to these gives you a high-volume stream of every commit to the tree. This is too much information for most purposes, but it is useful for a narrow audience: developers who want to watch every change.

A lower-volume alternative is to watch only the head branch's commit messages for a specific subsystem. You can do this with Git's `--author` or `--grep` flags, or by setting up a custom filter on your mail client.

**freebsd-current@ and freebsd-stable@.** These mailing lists are where discussions about the development and stable branches take place. Subscribing to them gives you early awareness of proposed changes, migration questions, and breakage. They are moderate volume and often high signal.

**The Release Notes.** Every FreeBSD release has release notes that describe significant changes since the previous release. The notes are published on the project's website at <https://www.freebsd.org/releases/>. Reading the release notes for each new release is an efficient way to catch up on changes you may have missed in the day-to-day volume.

**UPDATING.** The `/usr/src/UPDATING` file in the source tree contains important notices about changes that may affect users or developers. If a subsystem is being deprecated, or if an API is changing incompatibly, UPDATING is where the notice lives. Developers should check UPDATING after any significant tree update, and specifically before updating from one major release to another.

### 38.9.2 6.2 Developer Summits and BSD Conferences

FreeBSD has a rich conference culture, and attending or watching recordings of these conferences is one of the most efficient ways to stay connected to the project.

**BSDCan.** An annual conference held in Ottawa, Canada, usually in June. It draws developers from FreeBSD, OpenBSD, NetBSD, and DragonFly BSD. The presentations cover a mix of development updates, architectural discussions, and deep technical talks. Many of the talks are recorded and published on the conference website.

**EuroBSDcon.** An annual European BSD conference, held at a rotating location each September or October. The focus is similar to BSDCan, with a more European-centric participant list.

**Asia BSDCon.** An Asia-Pacific BSD conference, held annually in Tokyo. Smaller than BSDCan or EuroBSDcon but with a distinct set of participants and topics.

**The FreeBSD Developer Summit.** Held twice a year, once co-located with BSDCan and once with EuroBSDcon. The summit is where the project's committers meet face-to-face to discuss architectural direction, plan releases, and coordinate on major changes. Summaries of the summit sessions are published on the wiki, and the summit is one of the places where the project's internal planning becomes visible to the broader community.

**Regional BSD user groups.** Local BSD user groups exist in many cities and often host talks, meetups, and workshops. These are much lower-key than the international conferences but are often the most accessible entry point for someone who is new to the community.

For readers who cannot attend in person, many conference talks are recorded and posted online. The BSD Channel on YouTube, the BSDNow podcast, and the AsiaBSDCon recordings are all valuable resources. A habit of watching one conference talk per month is a low-effort way to stay connected to the project's current thinking.

### 38.9.3 6.3 Tracking API and Driver Model Changes Across Releases

Beyond following commits and attending conferences, there is a specific skill worth naming: tracking how the APIs and driver model change from release to release. This is the skill that keeps drivers buildable over time, and it is one of the least discussed aspects of long-term kernel work.

The basic pattern is this. When a new FreeBSD release comes out, you ask: what changed in the subsystem my driver touches? You answer the question by diffing the relevant parts of the source tree between the previous release and the new one. You read the release notes for anything flagged. You check UPDATING. You rebuild the driver against the new release and see what warnings or errors appear.

The tools that help with this are the standard Unix tools. `git log` with a path argument shows the history of a specific file or directory. `git diff` between two tags shows the difference. `grep` with the right patterns finds usage of a specific API. Each of these is elementary, but putting them together into a checking habit is a skill that repays itself many times over.

A specific example. Suppose your driver uses `bus_alloc_resource_any` and you want to know whether its semantics have changed between FreeBSD 14.0 and 14.3. You can run:

```
$ git log --oneline releng/14.0..releng/14.3 -- sys/kern/subr_bus.c
```

in a clone of the FreeBSD source tree. The output is the list of commits that modified `subr_bus.c` between those two releases. You can read each commit message to see whether the changes affect your usage. If something looks relevant, you can investigate with `git show` to see the actual change.

This pattern is fundamental to long-term driver maintenance. It is not glamorous, but it is reliable, and it catches problems before they become silent breakage.

### 38.9.4 6.4 Tools for Comparing Kernel Trees

Beyond `git log` and `git diff`, a few other tools help with the work of following kernel changes.

**diff -ruN.** The classic recursive diff between two directories. Useful when you have checked out two versions of the tree and want to compare them systematically. The output is large but readable, and it catches changes that `git log` alone might miss.

**git grep.** The Git-aware grep. Faster than external grep on large repositories because it knows about Git's index. Useful for finding all usages of a specific function or macro.

**diffoscope.** A more elaborate diffing tool that handles many file formats intelligently. Useful when you want to compare compiled objects, images, or other non-text artifacts.

**The FreeBSD source-code search at <https://cgит.freebsd.org/>.** A web-based interface to the Git repository that lets you browse the tree, view commits, and search for identifiers. Often faster for casual browsing than a local clone.

**Bugzilla's search interface.** Useful for finding whether a specific issue has been reported, and often for finding the commit that fixed it.

Becoming fluent with these tools is a matter of a few hours of practice. Once they are in your fingers, you can answer questions about the tree's history that would otherwise take days of manual reading.

### 38.9.5 6.5 A Monthly Rhythm for Staying Current

Readers often ask how to make “staying current” a sustainable habit rather than a vague good intention. Here is a monthly rhythm that works for many developers.

**Weekly.** Read the `freebsd-hackers` or `freebsd-drivers` mailing list digest (or equivalent summary) once a week. Read one or two threads that catch your interest. Reply to one if you have something to contribute. This is an hour of work per week.

**Monthly.** Pull the latest FreeBSD source tree. Run your personal driver's test suite against it. Investigate any failures. Read the most recent conference talk you have not yet watched. This is an afternoon per month.

**Quarterly.** Skim the commit log of the subsystem your driver touches since the last time you looked. Check whether any of the changes affect your driver. Read the most recent committer summary or project update. Review your personal learning goals and adjust them if the landscape has shifted. This is a day per quarter.

**Annually.** Read the release notes for the latest FreeBSD release, top to bottom. Consider whether you should upgrade your development environment. Attend or watch at least one conference worth of talks. Review your driver portfolio and consider whether any of the older drivers need maintenance work.

This rhythm is not a rigid schedule. It is an illustration of how regular, low-intensity attention can keep you current without becoming a second job. Most developers who stay engaged long-term follow something like this pattern, sometimes denser and sometimes looser.

### 38.9.6 6.6 Exercise: Subscribe and Read

This subsection's exercise is a small commitment. Subscribe to `freebsd-hackers@` or `freebsd-drivers@`, whichever seems more appropriate for your interests. Commit to reading one thread per week for four weeks. At the end of the four weeks, decide whether the subscription is worth keeping.

The point of the exercise is not to learn a specific technical thing. It is to build the habit of being aware of what the project is discussing. If after four weeks you find the traffic unhelpful, unsubscribe. If you find it useful, keep reading. The experiment is small and reversible.

A few practical tips. Filter the mailing-list messages into a separate folder in your mail client, so they do not pollute your regular inbox. Read in batches rather than as individual messages arrive. Be willing to ignore threads that are not about topics you care about. The goal is sustainable attention, not exhaustive coverage.

### 38.9.7 6.7 Watching for Deprecation Notices

A particular skill worth cultivating is watching for deprecation notices. Deprecation is how the project signals that a specific API, subsystem, or behaviour is going to change or be removed in a future release. Developers

who miss deprecation notices find out about the removal later, when their code no longer builds, and the fix is often more painful at that point than it would have been during the deprecation period.

Deprecation notices appear in several places. UPDATING is the primary one. Release notes mention them. Commit messages for deprecation changes often contain the word “deprecate” (with the ambiguous spelling to catch both “deprecate” and “deprecated”). Mailing list discussions often precede deprecation changes and give early warning.

A practical habit is to grep the recent commit log for deprecation keywords once a month:

```
$ git log --oneline --since=1.month --grep=deprecate
```

The output is usually short and scannable, and it catches most deprecations before they become problems.

### 38.9.8 6.8 Engaging When You See a Change That Affects You

When you spot a change that affects code you maintain, you have several options. You can adapt your code immediately, rebuilding and testing against the new behaviour. You can comment on the commit or the associated review, asking about the migration path. You can engage with the author on the relevant mailing list. You can file a PR in Bugzilla if you encounter a problem you think needs tracking.

The engagement itself is valuable beyond the specific change. Each time you reach out about a change, you are both contributing to the project’s awareness of downstream effects and building a relationship with the author. Over time, those relationships are one of the most valuable aspects of being part of the community.

One specific pattern worth highlighting. If a change is about to break your driver, and you find the change while it is still under review, commenting on the review is dramatically more valuable than commenting after the change is committed. Reviewers actively want to know about downstream effects, and a well-formed comment at review time often leads to adjustments that make the change less disruptive. Waiting until after commit means the change lands, downstream users discover the breakage, and the fix becomes a second patch that somebody else has to coordinate.

### 38.9.9 6.9 A Curated Reading List for Continued Study

The single most common request from readers who finish a book like this one is “what should I read next?” The honest answer is that the best reading depends on where you want to go. A reader headed toward filesystem work will have a very different list from one headed toward network drivers or toward embedded development. What follows is a curated starting list, organised by area, with one or two recommendations in each direction. The list is deliberately short. A long list would overwhelm. A short list lets you finish what you start.

For general FreeBSD kernel background, the most useful single source is still the FreeBSD source tree itself. Read `/usr/src/sys/kern/kern_synch.c` for an example of careful kernel engineering, read `/usr/src/sys/kern/vfs_subr.c` for a sense of how a large subsystem organises its internal interfaces, and read `/usr/src/sys/dev/null/null.c` once more at the end of the book to see how much richer the file reads now than it did in Chapter 1. The manual pages in section 9 remain the most authoritative reference for kernel interfaces; skim the list of section-9 pages with `apropos -s 9` and read anything that catches your eye.

For filesystem work, the classic reference is Kirk McKusick's "The Design and Implementation of the FreeBSD Operating System." Pay attention to the VFS chapters. Then read `/usr/src/sys/ufs/ffs/` carefully, choosing one file at a time and tracing how its functions are called from the layers above and below. If you prefer talks to books, the BSDCan archive contains several filesystem-focused talks from Kirk McKusick, Chuck Silvers, and others; watch them in chronological order to see how the system evolved.

For networking, start with the `netmap(4)` manual page and the sources under `/usr/src/sys/dev/netmap/`, then widen out to the stack proper under `/usr/src/sys/net/` and `/usr/src/sys/netinet/`. Read `if.c` first, then `if_ether.subr.c`, then pick a specific protocol family and follow its packets through. The `iflib(9)` manual page is essential for modern Ethernet drivers. For deeper coverage, the TCP/IP Illustrated series by Stevens remains the canonical reference; chapters 2 and 3 translate almost directly to FreeBSD's implementation.

For embedded and ARM work, read through the Device Tree sources under `/usr/src/sys/contrib/device-tree/src/` for your board, then study `/usr/src/sys/dev/fdt/` to see how FreeBSD consumes those trees. Warner Losh's conference talks on arm64 and RISC-V support are excellent complements. The `fdt(4)` manual page is short but dense; reread it after a month's practice.

For debugging and profiling, read the `kgdb(1)`, `ddb(4)`, `dtrace(1)`, and `hwpmc(4)` manual pages in sequence. Then pick a DTrace provider (io, vfs, sched) and write one meaningful script using it. Brendan Gregg's DTrace book remains relevant; most of its examples still apply to FreeBSD directly.

For security and hardening, read the `capsicum(4)`, `mac(4)`, and `jail(8)` manual pages carefully. The Capsicum papers from Watson and others are worth reading in full. `/usr/src/sys/kern/sys_capability.c` and `/usr/src/sys/kern/subr_capability.c` are the implementation worth tracing. The FreeBSD security advisory archive on the project website is a useful record of how real bugs have played out.

For USB work, start with the USB controller drivers in `/usr/src/sys/dev/usb/controller/` and the core files under `/usr/src/sys/dev/usb/` such as `usb_process.c` and `usb_request.c`. The USB specification is large but accessible; read only the chapters you need when you need them, and use the existing FreeBSD drivers as worked examples.

For virtualisation and bhyve, the bhyve manual page is the starting point, followed by the bhyve source under `/usr/src/usr.sbin/bhyve/`. John Baldwin's BSDCan talks provide excellent context. If you plan to use bhyve as a test harness for driver development, focus on the PCI passthrough and virtio sections.

For general craft, three books are worth owning: Kernighan and Ritchie's "The C Programming Language" for the language itself, Kernighan and Pike's "The Practice of Programming" for the habits, and McKusick and Neville-Neil's "The Design and Implementation of the FreeBSD Operating System" for the system. If you already know C well, the first book can be skimmed. If you have ever felt that your code "works but could be better," the second book will address that feeling directly.

For community culture and history, read the FreeBSD Handbook's introduction and then the archives of the FreeBSD project on the Internet Archive. The project has existed for decades and its culture is documented in its correspondence as much as in its code. Understanding how the project thinks about itself will help you contribute in a way the community welcomes.

One final recommendation: take the list above and mark, with a pencil, the one item in each area that you are most likely to actually complete in the next three months. Then close this book and start on those items, not all of them, just the marked ones. A small finished list beats a long unfinished list every time.

### 38.9.10 6.10 Wrapping Up Section 6

This section has walked through how to stay connected to the FreeBSD kernel’s ongoing development: where to watch for changes, which conferences to follow, how to track API drift, and what habits turn “staying current” from a vague aspiration into a sustainable practice.

The overarching idea is that staying current is not a task you do once. It is a rhythm you develop. The rhythm does not need to be intense; it needs to be regular. A weekly mailing-list glance, a monthly build test, a quarterly review of your code, and an annual walk through the release notes are together enough to keep most driver maintainers in sync with the project.

We have now covered the six main sections of the chapter: celebrating what you have accomplished, understanding where you stand, exploring advanced topics, building your toolkit, giving back to the community, and staying current. The remaining material of the chapter is hands-on: labs to apply what you have read, challenges to push your practice further, and planning artifacts you can keep as a record of the reflection you did here.

## 38.10 7. Hands-On Reflection Labs

The labs in this chapter are reflection labs rather than coding labs. They ask you to apply what the chapter has discussed to your own circumstances, using the companion files as templates where helpful. Each lab produces a concrete artifact you can keep, and the artifacts together form a record of where you were at the moment you finished this book.

Treat the labs as time well spent. A reader who does the labs will leave the book with a set of personal documents that shape the next few months of their work. A reader who skips the labs will have read the chapter but not applied it, and the difference shows up three months later when the one reader has a plan and the other is drifting.

### 38.10.1 7.1 Lab 1: Complete a Self-Assessment Worksheet

**Goal.** Produce a written self-assessment that captures where you stand at the end of the book.

**Time.** Two to three hours, spread across one or two sittings.

**Materials.** The `self-assessment.md` template in `examples/part-07/ch38-final-thoughts/`. A notebook or text editor. Access to the book’s chapters as a reference.

**Steps.**

1. Copy the self-assessment template into a directory you control, such as a personal Git repository or a folder in your home directory.
2. Date the file. Use ISO 8601 format (YYYY-MM-DD) in the filename or in the header, so you can sort multiple assessments chronologically when you redo the exercise later.
3. For each topic in the template, give yourself a confidence rating on a one-to-five scale. The topics are drawn from the book’s coverage: C for kernels, debugging and profiling, device tree integration, reverse engineering, userland interfaces, concurrency and synchronisation, DMA and interrupts, upstream submission, and the specific core APIs like `bus_space(9)`, `sysctl(9)`, `dtrace(1)`, `devfs(5)`, `poll(2)`, and `kqueue(2)`.

4. For each topic, write one sentence explaining why you chose that rating. A rating without a reason is just a number. A rating with a reason is a diagnosis.
5. At the end, identify the three topics where you most want to invest more practice. Explain why for each.
6. Save the file. Back it up. Put a calendar reminder for six months from now to redo the assessment and compare.

**Deliverable.** The completed self-assessment worksheet, saved with the current date.

**What to notice.** The act of forcing a specific confidence rating on each topic will reveal surprising distinctions. You may find that you rate yourself higher than you expected on some topics and lower on others. The surprises are where the diagnostic value lives.

### 38.10.2 7.2 Lab 2: Draft a Personal Learning Roadmap

**Goal.** Produce a written plan for the next three to six months of your FreeBSD learning.

**Time.** Two hours, in one focused sitting.

**Materials.** The `learning-roadmap.md` template in `examples/part-07/ch38-final-thoughts/`. The output of Lab 1. The advanced-topics section of this chapter.

**Steps.**

1. Copy the learning-roadmap template into your working directory.
2. Based on your self-assessment from Lab 1, choose the one technical area you most want to deepen over the next three months. The choice should be specific: not “the network stack,” but “the `ifnet` layer and its interaction with `iflib`.”
3. Break the three-month goal into monthly milestones. Each milestone should be concrete enough to be recognisable when it is done. Examples: “By end of month one, I have read `/usr/src/sys/net/if.c` in full and can explain the lifecycle of an `ifnet`.” “By end of month two, I have written a minimal pseudo-interface that implements the `ifnet` API.” “By end of month three, I have submitted the pseudo-interface for review.”
4. Identify the resources you will use. Manual pages. Specific source files. Specific conference talks. Specific people whose code you will read. Be concrete enough that you can start immediately, without additional research.
5. Identify the practice cadence. Will you work on this every day for an hour? Every weekend for a few hours? Twice a week? The cadence matters more than the intensity, and a sustainable cadence is better than an ambitious one.
6. Add secondary goals. A toolkit improvement. A community engagement goal (join a mailing list, answer N questions on the forums). A currency goal (watch M conference talks, follow commit logs for a specific subsystem).
7. Commit the roadmap to a Git repository or save it somewhere stable. Put a calendar reminder at the end of each month to review progress and adjust.

**Deliverable.** The completed learning roadmap, saved with the current date.

**What to notice.** A good roadmap feels slightly uncomfortable. If it feels easy and safe, it is probably not ambitious enough. If it feels impossible, it is probably not sustainable. The sweet spot is a roadmap that is visibly more than you can do in a weekend but visibly within reach over three months of consistent practice.

### 38.10.3 7.3 Lab 3: Set Up Your Driver Template

**Goal.** Produce a personal driver template that reflects your style choices.

**Time.** Two to four hours, in one or two sittings.

**Materials.** The `template-driver/` directory in `examples/part-07/ch38-final-thoughts/`. The book's chapters on Newbus, `bsd.kmod.mk`, and driver anatomy as reference. Your text editor.

**Steps.**

1. Copy the `template-driver` directory into a personal Git repository. Rename the files to something generic, such as `skeleton.c`, `skeleton.h`, `skeletonreg.h`, and adjust the Makefile accordingly.
2. Adjust the copyright header to match your name, email, and preferred license.
3. Adjust the include ordering to match your preferences, while still conforming to `style(9)`.
4. Add any standard patterns you reach for reflexively: a debug `sysctl`, a locking macro, a module event handler skeleton, a probe-attach-detach pattern you always use.
5. Remove any patterns you do not use. The goal is a minimal template, not a comprehensive one.
6. Write a short README explaining what the template is for and how to start a new driver from it. A paragraph or two is enough.
7. Commit the template to your Git repository. Tag the commit with a version number such as `template-v1.0`.

**Deliverable.** A personal, versioned driver template in a Git repository you control.

**What to notice.** The first version of your template will feel over- or under-specified in particular ways. That is normal. The template will evolve over the next several projects as you notice patterns you always add or patterns you always remove. Version it. Let it grow.

### 38.10.4 7.4 Lab 4: Subscribe to a Mailing List

**Goal.** Establish a connection to the FreeBSD community through a specific mailing list.

**Time.** Twenty minutes to subscribe; one hour per week for four weeks to read.

**Materials.** A working email account. Internet access.

**Steps.**

1. Choose a mailing list. For driver-focused readers, `freebsd-drivers@` is a natural choice. For readers who want a broader view of kernel development, `freebsd-hackers@` is appropriate. For readers who want to track the current branch specifically, `freebsd-current@` is the list.
2. Visit the project's mailing-list page at <https://lists.freebsd.org/> and follow the subscription instructions for the list you chose.

3. Set up a mail filter that moves the list's messages to a dedicated folder, so they do not overwhelm your inbox.
4. For each of the next four weeks, block out an hour to read the list. Read at least one full thread per week. Take notes on any threads that touch areas you care about or surprise you.
5. If you have something to contribute to a thread (a correction, a data point, an answer to a question), reply. If not, just read. Lurking is fine.
6. At the end of four weeks, decide whether to keep the subscription. If the list is not useful for your purposes, unsubscribe. If it is useful, keep it and let it become part of your routine.

**Deliverable.** A record of the subscription, a mail filter set up, and four weeks of at least one thread read per week.

**What to notice.** Mailing lists are a slow medium. Nothing happens quickly, and it can take several weeks for the value to become clear. Give the exercise the full four weeks before judging it.

### 38.10.5 7.5 Lab 5: Review a Manual Page You Have Not Read

**Goal.** Deepen your familiarity with FreeBSD's reference documentation by reading a manual page you have not yet read.

**Time.** One hour.

**Materials.** Access to the FreeBSD manual pages, either through `man(1)` on a FreeBSD system or through the web at <https://man.freebsd.org/>. A notebook or text editor.

**Steps.**

1. Pick a manual page you have not read. It should be relevant to areas you might want to study further. Good candidates: `vnode(9)`, `crypto(9)`, `iflib(9)`, `audit(4)`, `mac(9)`, `kproc(9)`.
2. Read the manual page in full. Expect it to take twenty to forty minutes if the page is substantive.
3. After reading, close the manual page. On a blank piece of paper or in a text file, write a one-paragraph summary in your own words. Cover: what the interface is for, what its main data structures and functions are, and what a hypothetical driver would use it for.
4. Reopen the manual page and compare your paragraph to the reference. Where is your paragraph vague or inaccurate? Revise it.
5. Save the paragraph in your personal knowledge directory, labelled by the manual page name and the date.

**Deliverable.** A written paragraph summarising a manual page you have newly read, saved for future reference.

**What to notice.** Writing your own summary forces understanding at a level that passive reading does not. A paragraph you can write well is a topic you understand. A paragraph you struggle with is a topic that needs more study. The paragraphs accumulate over time into a personal glossary of the kernel.

### 38.10.6 7.6 Lab 6: Build a Regression Test for a Driver You Wrote

**Goal.** Produce a regression test suite for one of your drivers from the book.

**Time.** Three to four hours.

**Materials.** A driver you wrote during the book. The `regression-test.sh` skeleton in `examples/part-07/ch38-final-thoughts/scripts/`. A FreeBSD development VM.

**Steps.**

1. Pick a driver. The async I/O driver from Chapter 35 is a good candidate because it has enough complexity to make regression testing worthwhile.
2. Copy the regression-test skeleton into a tests directory alongside the driver.
3. Identify three behaviours that the driver should reliably exhibit. Example for the async driver: “loads without warnings,” “accepts a write and allows it to be read back,” “unloads cleanly after being loaded and exercised.”
4. Translate each behaviour into an automated check. A check is a shell command that produces a predictable output or exit code if the behaviour holds, and an unpredictable one if it does not. Use `kldload`, `kldunload`, `dd`, `sysctl`, and similar tools as building blocks.
5. Wire the checks together in the script. A good script runs each check, reports the result, and exits with a non-zero status if any check failed.
6. Run the script. Verify it passes against the current driver. Verify it fails when you deliberately break the driver (add a line that aborts in the module init, for example) and then remove the deliberate break.
7. Commit the script alongside the driver in your Git repository.

**Deliverable.** A working regression-test script for a driver you wrote, committed to your repository.

**What to notice.** Regression tests are often harder to write than the code they test, especially for kernel modules. The difficulty is exactly why they are valuable: they force you to articulate what “correct behaviour” means in a way that can be checked automatically. A driver without regression tests is a driver whose correctness claims are verbal; a driver with regression tests has those claims encoded in something reproducible.

### 38.10.7 7.7 Lab 7: File or Triage a Bugzilla PR

**Goal.** Interact with the FreeBSD Bugzilla in a concrete, small way.

**Time.** One to two hours.

**Materials.** A FreeBSD Bugzilla account (free to create). Your FreeBSD 14.3 development system.

**Steps.**

1. Create a Bugzilla account at <https://bugs.freebsd.org/bugzilla/> if you do not have one.
2. Option A (triage path): Browse the open PRs in the `kern` product or a driver component you care about. Find a PR that has not been updated in at least six months and whose status is unclear. Attempt to reproduce the issue on your system. Add a comment to the PR with your findings: what you tried, what you observed, whether you can reproduce the issue.

3. Option B (reporting path): If you have encountered a bug in a driver or in the kernel during the book, and you have not yet reported it, file a PR. Include the FreeBSD version, the hardware, clear reproduction steps, and any relevant output from `dmesg`, `uname -a`, or the driver's own diagnostics.
4. Whatever option you choose, write the PR or comment in the clear, specific style that Bugzilla interactions reward. Avoid vague statements. Be specific. Include details someone else could act on.
5. Save the URL of the PR or comment. Add it to your contribution log if you keep one.

**Deliverable.** A PR you filed or a comment you added on an existing PR, in the FreeBSD Bugzilla.

**What to notice.** Bugzilla interactions have a specific style that is different from mailing-list posts and different from code-review comments. Clarity, reproducibility, and specificity are the main virtues. A well-formed PR gets attention; a poorly-formed one does not.

### 38.10.8 7.8 Lab 8: Set Up Your Virtual Lab

**Goal.** Produce a reproducible virtual lab you can boot quickly for future driver work.

**Time.** Half a day.

**Materials.** A host system with bhyve (on FreeBSD) or QEMU (on any host). A FreeBSD 14.3 installation image.

**Steps.**

1. Create a working directory for your lab. Initialise a Git repository in it for the scripts and configuration files.
2. Write a shell script that creates a disk image of at least 20 GB. Use `truncate(1)` or an equivalent to create a sparse file.
3. Write a shell script that runs the chosen hypervisor with the appropriate command-line arguments to boot from the FreeBSD installation image and install FreeBSD into the disk image. Document every flag.
4. After installation, take a snapshot of the disk image (copy it, or use the hypervisor's snapshot mechanism). Label the snapshot with the FreeBSD version and the date.
5. Write a shell script that boots the installed system. It should use a serial console, mount a shared directory for source code if your hypervisor supports it, and configure networking so that you can SSH into the guest.
6. Boot the guest. SSH into it. Verify you can build a trivial kernel module (a “hello world” module is fine) in the guest.
7. Commit all the scripts and the documentation to your Git repository. Tag the commit with the FreeBSD version and the date.

**Deliverable.** A Git repository containing your lab's configuration, along with a known-good snapshot of an installed system.

**What to notice.** The lab setup is a one-time investment that pays off on every subsequent project. If the lab takes ten minutes to boot, you will reach for it only for serious work. If it takes thirty seconds to boot, you will reach for it constantly, and the pace of your driver work will be much faster.

### 38.10.9 7.9 Wrapping Up the Reflection Labs

These eight labs have walked you through producing a set of personal artifacts: a self-assessment, a learning roadmap, a driver template, a mailing-list subscription, a manual-page summary, a regression-test script, a Bugzilla interaction, and a virtual lab. Together they constitute a snapshot of your current state and a starting position for the next phase of your work.

None of the artifacts is especially elaborate. Each one could be produced by someone who had finished this book. But together, they represent a surprisingly large amount of infrastructure that supports ongoing FreeBSD driver work. Without them, you start from zero every time. With them, you start from ground already cleared.

Keep the artifacts. Revisit them. Evolve them. Over the course of the next year, they will shape how your work proceeds in ways that are easier to recognise in retrospect than in prospect.

## 38.11 8. Challenge Exercises

The challenges in this section are longer, more open-ended than the labs, and designed for readers who want to go further than the main chapter material. There is no single correct way to complete any of them, and you may find that your approach differs substantially from another reader's. That is fine. The challenges are invitations, not puzzles.

### 38.11.1 8.1 Challenge 1: Write a Real Driver for Real Hardware

**Description.** Pick a piece of hardware you own, verify that FreeBSD does not already support it adequately, and write a driver for it. Go through the full cycle: acquisition, investigation, implementation, documentation, testing, and consideration for upstream submission.

**Scope.** This is a multi-week or multi-month project. A reasonable target is a relatively simple device: a USB serial adapter using an unsupported chipset, a PCI card for a niche application, a GPIO-connected sensor. Avoid ambitious targets for a first independent project; graphics cards and wireless chipsets are notoriously hard.

**Milestones.**

1. Identify the hardware. Confirm that FreeBSD does not support it, or supports it incompletely.
2. Gather documentation. Vendor datasheets, Linux or NetBSD drivers, chipset specs, whatever is available.
3. Set up a development environment. Configure your virtual lab to talk to the real hardware if your hypervisor supports passthrough, or plan to build and test on a physical FreeBSD system.
4. Write an initial probe and attach sequence. Confirm that FreeBSD can at least identify and attach to the hardware.
5. Implement the main driver functionality, one feature at a time, with tests for each.
6. Write a manual page.
7. Consider submission. Follow the Chapter 37 workflow if you decide to submit.

**What you will learn.** Independent driver development at a level the book's exercises did not require. The experience of a real, non-trivial project with its own friction and its own surprises.

### 38.11.2 8.2 Challenge 2: Fix a Real Bug in a Real Driver

**Description.** Find an open bug in a driver in the FreeBSD tree, reproduce it, understand it, fix it, and submit the fix upstream.

**Scope.** A couple of weekends, depending on the bug. Some bugs are one-line fixes; others require substantial investigation.

**Milestones.**

1. Browse the FreeBSD Bugzilla for open driver bugs. Filter by “kern” or by specific drivers. Look for bugs that have clear reproduction steps and are not obviously abandoned.
2. Pick a bug that matches your skill level. A good first bug is one where the reporter has already done some investigation and where the fix is likely to be small.
3. Reproduce the bug on your system. This step is essential and often takes longer than expected.
4. Investigate. Read the relevant driver source. Add diagnostic printouts or KTR traces if needed. Form a hypothesis about the cause.
5. Write a fix. Test it. Verify that the bug is resolved.
6. Check that you have not introduced new bugs.
7. Submit the fix, following the Chapter 37 workflow.

**What you will learn.** Reading and understanding code written by other people, working within existing conventions, and experiencing the full upstream workflow with a real, accepted contribution.

### 38.11.3 8.3 Challenge 3: Port a Linux or NetBSD Driver to FreeBSD

**Description.** Pick a driver that exists in Linux or NetBSD but not in FreeBSD (or is incomplete in FreeBSD). Study the existing driver, understand the hardware interface, and write an equivalent FreeBSD driver.

**Scope.** A serious multi-month project. Only attempt this if you have a specific piece of hardware in mind and enough interest to sustain the work.

**Milestones.**

1. Choose the target hardware and the source driver. Verify the source driver’s license is compatible with your intended license for the FreeBSD driver.
2. Read the source driver in full. Understand what it does at the interface level: how it probes, how it handles interrupts, what data structures it uses, how it handles DMA.
3. Design your FreeBSD driver architecture. It will not be a line-by-line port. FreeBSD’s conventions differ from Linux’s, and a well-ported driver respects FreeBSD’s conventions.
4. Write the driver, using the source driver as a reference for what the hardware does but writing the code from scratch in FreeBSD style.
5. Test against the real hardware.
6. Document the driver and submit.

**What you will learn.** Cross-system driver translation is a serious craft. You will learn FreeBSD idioms more deeply by contrasting them with Linux or NetBSD idioms. You will also learn the discipline of writing fresh code from an understanding of a specification rather than from cut-and-paste.

#### 38.11.4 8.4 Challenge 4: Write a Deep Technical Blog Post

**Description.** Write a thorough, carefully researched blog post about a FreeBSD kernel topic you want to understand better. The goal is not to produce a perfect post for a large audience; it is to use the act of writing to deepen your own understanding.

**Scope.** A weekend or two. Longer if you have a particularly complex topic.

**Milestones.**

1. Pick a topic. It should be something you partly understand but want to understand better. Good examples: “How FreeBSD’s epoch interface works,” “The lifecycle of an interrupt in FreeBSD,” “How `iflib` abstracts hardware for network drivers.”
2. Read everything you can find on the topic. Manual pages, source code, previous blog posts, conference talks.
3. Draft the post. Aim for three to five thousand words.
4. Revise. Cut the parts that are wrong or unclear. Sharpen the parts that are strong.
5. Ask a friend or colleague to read the draft. If they are a FreeBSD developer, all the better. If they are not, their questions will reveal gaps in your explanation.
6. Publish the post. Your own blog, the FreeBSD forum, or dev.to are all reasonable venues.

**What you will learn.** Teaching is one of the deepest forms of learning. The act of writing a careful explanation forces you to confront everything you do not yet understand, and resolving those gaps is how understanding grows.

#### 38.11.5 8.5 Challenge 5: Become a Reviewer

**Description.** Pick a specific area of the FreeBSD tree (driver-related for readers of this book) and commit to reviewing every Phabricator review that touches that area for one month.

**Scope.** Depending on the area’s activity, this could be a few reviews a week or several per day. A month of regular reviewing will give you experience at the craft of review without overwhelming other obligations.

**Milestones.**

1. Choose an area. A specific driver or subsystem is ideal.
2. Set up notifications for Phabricator reviews in that area. The Phabricator interface supports this.
3. For each review, read the proposed change carefully. Understand what it is trying to do. Test it locally if the change is small enough.
4. Post your review comments. Be specific. Be constructive. Ask questions when you are uncertain rather than asserting things you are not sure of.

5. Respond to replies. Engage in the review discussion until the review is resolved.
6. At the end of the month, reflect on what you learned.

**What you will learn.** Code review is a different skill from code writing. It requires reading carefully, understanding intent, and articulating suggestions productively. Developers who review well are among the most valuable members of any project, and the skill is one you can develop with practice.

### 38.11.6 8.6 Challenge 6: Run a Study Group

**Description.** Organise a small group of peers to work through a challenging topic together. The topic should be something none of you feel confident about individually, where working together will produce a shared understanding faster than working alone.

**Scope.** A group of three to six people, meeting weekly for two to three months.

**Milestones.**

1. Find the peers. They can be former colleagues, members of a local BSD user group, participants in an online forum. Three to six is the right size.
2. Choose a topic together. The VFS layer, `iflib`, the ACPI subsystem, or `netgraph` are all reasonable candidates.
3. Agree on a cadence and a format. A weekly video call with a shared reading list is a standard format. Each member prepares a section each week and presents it.
4. Meet regularly. Take notes. Share what you learn between meetings.
5. Produce a group artifact at the end. A shared notes document, a blog post summarising the study, or a presentation to a local user group.

**What you will learn.** Collaborative study is among the most effective ways to learn complex material. You will also learn how to organise and sustain a group, which is a leadership skill in its own right.

### 38.11.7 8.7 Challenge 7: Contribute a Non-Code Artifact

**Description.** Contribute something to the FreeBSD Project that is not code and not driver-specific. A documentation patch, a translation, a manual-page improvement, a test-case addition, a diagram for the handbook, whatever has a clear value.

**Scope.** A weekend.

**Milestones.**

1. Find a non-code artifact that needs improvement. Outdated manual pages, incomplete handbook sections, missing translations, or gaps in the test suite are common candidates.
2. Improve it. Write the new version carefully. Test it if it is testable.
3. Submit it through the appropriate workflow. For documentation, this means the documentation Git repository. For manual pages, the main source tree. For translations, the translation system.
4. Respond to review feedback until the contribution is accepted.

**What you will learn.** Non-code contributions have their own submission flows and their own community expectations. Going through one end-to-end broadens your sense of what it means to contribute.

### 38.11.8 8.8 Challenge 8: Sustain a Personal Practice for Six Months

**Description.** The most difficult challenge in this chapter is not technical. It is the challenge of sustaining your practice after the book is closed. Many readers finish technical books with enthusiasm and then let the momentum fade within weeks. This challenge is to resist that pattern deliberately, by committing to a specific, sustained practice for six months.

**Scope.** Commit to a small, regular practice. Not a heroic one. Examples of a sustainable cadence: two hours of kernel work every Saturday morning, or one hour every weekday evening, or every second weekend dedicated to a single driver project. Whatever you choose, write it down and stick to it.

**Milestones.**

1. Define the practice in a single sentence you can quote from memory. If you cannot state it cleanly, it is not specific enough.
2. Name a concrete project that will run through the full six months. The project must be small enough to complete but meaningful enough to sustain your interest.
3. Track your sessions in a plain log. Date, duration, one sentence on what you did. The log's existence matters more than its length.
4. At month three, review the log honestly. If you are behind, adjust the cadence downward rather than giving up. A smaller sustained practice is worth more than a larger abandoned one.
5. At month six, write a short reflection on what you produced, what you learned, and what you will do next.

**What you will learn.** Sustaining a practice is itself a skill, and it compounds across every area of a long career. Readers who learn to sustain their own practice in the months after this book will, in the long run, go much further than readers whose enthusiasm was bright but brief. This challenge exists specifically to help you build that habit on the other side of the book's last page.

### 38.11.9 8.9 Wrapping Up the Challenges

The challenges above range from small to substantial. None of them is required. A reader who completes one will have deepened their practice in a specific direction. A reader who completes several will be approaching the level of a working junior FreeBSD developer. A reader who completes all of them will be approaching the level at which commit rights become a meaningful possibility.

Pick the one or two that align with your interests and your available time. Execute them carefully. Let them inform the next iteration of your learning roadmap.

## 38.12 9. Personal Planning and Checklists

This section presents a few checklists and planning artifacts that you can use as templates. They are deliberately short and tactical, not elaborate frameworks. Each of them answers a specific practical question.

### 38.12.1 9.1 A Contribution Checklist

Use this checklist the first time you send a patch to the FreeBSD Project, and every time after that.

- ☐ My patch addresses a specific, well-defined issue or adds a specific, well-defined feature.
- ☐ I have verified that the patch applies cleanly to the current tip of the relevant branch.
- ☐ I have built the patch on amd64 and verified it compiles without warnings.
- ☐ I have built the patch on at least one other architecture (typically arm64) and verified it compiles without warnings.
- ☐ I have run the pre-submission test script from Chapter 37 and all steps pass.
- ☐ I have written or updated the relevant manual page.
- ☐ I have run `mandoc -Tlint` on the manual page and it is silent.
- ☐ I have written a commit message that explains what the change does and why.
- ☐ I have verified that no proprietary information, internal company URLs, or private correspondence appear in the patch.
- ☐ I have identified the reviewer(s) I will request.
- ☐ I have chosen the appropriate submission channel: Phabricator for structured review, GitHub or mailing list otherwise.
- ☐ I have a plan for responding to review feedback within a reasonable time.
- ☐ I have subscribed to notifications for the review so I will see comments quickly.
- ☐ I understand that merging the patch is a beginning, not an end, and I am prepared to maintain the code.

### 38.12.2 9.2 A Stay-Current Checklist

Use this checklist on a monthly cadence to keep yourself current with FreeBSD development.

- ☐ I have pulled the latest FreeBSD source tree.
- ☐ I have built my personal drivers against the latest source and investigated any warnings or errors.
- ☐ I have run my regression tests against the latest source and investigated any failures.
- ☐ I have read the commit log for the subsystems I care about since the last time I looked.
- ☐ I have checked UPDATING for new notices.
- ☐ I have read at least one thread on `freebsd-hackers@` or `freebsd-drivers@` since the last check.
- ☐ I have watched at least one conference talk or read at least one blog post about FreeBSD development.
- ☐ I have thought about whether any of the changes I saw affect my ongoing work.
- ☐ I have noted any TODO items for next month's review.

### 38.12.3 9.3 A Self-Assessment Worksheet

Use this worksheet every three to six months to track your growth.

**Date:** \_\_\_\_\_

**FreeBSD version last built:** \_\_\_\_\_

**Confidence rating (1-5) and one-sentence rationale:**

- C for kernel programming: \_\_\_\_\_
- Kernel debugging and profiling: \_\_\_\_\_

- Device tree integration: \_\_\_\_\_
- Reverse engineering and embedded development: \_\_\_\_\_
- Userland interfaces (ioctl, sysctl, poll, kqueue): \_\_\_\_\_
- Concurrency and synchronisation: \_\_\_\_\_
- DMA, interrupts, and hardware interaction: \_\_\_\_\_
- Upstream submission and review readiness: \_\_\_\_\_
- bus\_space(9): \_\_\_\_\_
- sysctl(9): \_\_\_\_\_
- dtrace(1): \_\_\_\_\_
- devfs(5): \_\_\_\_\_
- Newbus (device\_t, DEVMETHOD, DRIVER\_MODULE): \_\_\_\_\_
- Locking (mutexes, sx, rmlocks, condition variables): \_\_\_\_\_

**Three topics I most want to deepen in the next six months:**

1. \_\_\_\_\_
2. \_\_\_\_\_
3. \_\_\_\_\_

**One concrete project I will start this month:**

\_\_\_\_\_

**One community action I will take this month:**

\_\_\_\_\_

### 38.12.4 9.4 A Learning Roadmap Template

Use this template to plan each three-to-six-month learning cycle.

**Period:** \_\_\_\_\_ to \_\_\_\_\_

**Primary focus area:** \_\_\_\_\_

**Why this area, now:** \_\_\_\_\_

**Monthly milestones:**

- Month 1: \_\_\_\_\_
- Month 2: \_\_\_\_\_
- Month 3: \_\_\_\_\_

**Resources I will use:**

- Manual pages: \_\_\_\_\_
- Source files: \_\_\_\_\_
- Conference talks: \_\_\_\_\_
- Books and papers: \_\_\_\_\_

- People I will learn from: \_\_\_\_\_

**Practice cadence:**

- Frequency: \_\_\_\_\_
- Duration per session: \_\_\_\_\_

**Secondary goals:**

- Toolkit improvement: \_\_\_\_\_
- Community engagement: \_\_\_\_\_
- Currency: \_\_\_\_\_

**Review date:** \_\_\_\_\_

### 38.12.5 9.5 A Code Review Checklist

Sooner or later, whether you are reviewing another developer's patch or reviewing your own code before submitting it, you will benefit from a consistent mental pass over the same set of concerns. Use this checklist when you sit down to review a change. It applies equally to your own work and to work you review for others.

- ☐ I understand what the change is trying to accomplish and can restate its purpose in one sentence.
- ☐ The change is scoped appropriately: not too large to review carefully, not so small that the context is missing.
- ☐ The commit message explains the "why" clearly and will still make sense in five years.
- ☐ The change does not mix unrelated concerns (cleanup plus feature, refactor plus bug fix) without a strong reason.
- ☐ Every function added or modified has a clear responsibility and a clear contract.
- ☐ Error paths are handled, not silently swallowed.
- ☐ Resources allocated in `attach()` are released in `detach()` in reverse order.
- ☐ Any new locks are named clearly, their scope is explicit, and their lock order is consistent with existing code.
- ☐ The change does not introduce potential use-after-free, leaked references, or double-free paths.
- ☐ The change passes `checkstyle9.pl` without warnings.
- ☐ The change compiles on at least two architectures with no new warnings.
- ☐ Any manual pages or documentation affected by the change have been updated.
- ☐ Any `sysctl` or `dev.` names introduced are named consistently with existing conventions.
- ☐ The change behaves correctly under load and unload cycles.
- ☐ The change does not break any in-tree test.
- ☐ The change has a test case or a clear reason why no test is possible.

When reviewing other people's code, add one more item: have I been respectful, specific, and helpful, rather than abrupt or dismissive? Code review is one of the most visible forms of community participation, and the tone matters as much as the substance.

### 38.12.6 9.6 A Debugging Journal Entry Template

When you run into a hard bug, write it down before, during, and after the debugging session. The journal serves two purposes: it helps you think clearly while the bug is fresh, and it gives you something to return to the next time you hit a similar problem. Over time, these entries become a personal reference that saves you hours.

Use this template for each bug you spend more than a single short session on.

**Date:** \_\_\_\_\_

**Module or driver:** \_\_\_\_\_

**Kernel version:** \_\_\_\_\_

**One-line description of the symptom:**

\_\_\_\_\_

**What I observed first:**

\_\_\_\_\_

**First hypothesis:**

\_\_\_\_\_

**How I tested the first hypothesis:**

\_\_\_\_\_

**What happened instead:**

\_\_\_\_\_

**Second hypothesis (if applicable):**

\_\_\_\_\_

**What the root cause turned out to be:**

\_\_\_\_\_

**What specifically fixed it:**

\_\_\_\_\_

**What I learned that I did not know before:**

---

**What I would look at sooner next time:**

---

**Relevant source paths and line numbers:**

---

**Relevant mailing-list threads, commits, or bug IDs:**

---

The act of filling in the last two fields (“what I learned” and “what I would look at sooner next time”) is the most valuable part. Those fields compound across entries and gradually turn a developer who solves each bug individually into one who recognises patterns across bugs.

### 38.12.7 9.7 A Driver Handoff Checklist

A driver is rarely owned by the same person forever. Whether you are handing a driver off to a new maintainer, leaving a company, or simply transferring stewardship to a colleague, there is a short list of things that make the handoff successful. Use this checklist when the handoff is planned, and use it as a self-review when you suspect a handoff may become necessary.

- ☐ The driver has a current manual page that reflects its real behaviour.
- ☐ The driver has a short design document that explains the non-obvious decisions and the hardware-specific quirks.
- ☐ The driver has a regression test suite that the new maintainer can run on their own hardware.
- ☐ The driver has a working build from a clean tree, with no local modifications required.
- ☐ The driver has been tested against at least two FreeBSD releases, and the compatibility range is documented.
- ☐ All TODOs, known bugs, and planned work are recorded in an issue tracker or a text file in the repository.
- ☐ The `sysctl` variables and `dev.` names are documented with their meaning and their expected range of values.
- ☐ Any vendor-specific documentation, datasheets, or NDAs that affect the driver are recorded, either with the driver or in a known location.
- ☐ The hardware required to test the driver is described in enough detail that the new maintainer can acquire or borrow it.
- ☐ The new maintainer has been introduced to the relevant mailing list discussions and to any community members who have contributed.
- ☐ Any outstanding patches, reviews, or conversations have been surfaced to the new maintainer.
- ☐ The commit history does not contain any proprietary information that would prevent further public development.

If a driver cannot cleanly meet this checklist, the handoff will leave debt for the next maintainer. Spend the time before the handoff closing the gaps. The cleaner the handoff, the more likely the driver continues to receive care after you step away.

### 38.12.8 9.8 A Quarterly Review Template

Every three months, take an hour or two to review your broader trajectory, not just your immediate projects. The quarterly review is different from the monthly stay-current rhythm. The monthly rhythm keeps you in touch with the kernel as a living system. The quarterly review keeps you in touch with your own growth as a developer.

Use this template for each quarterly review. Keep the filled copies together in your `freebsd-learning` repository so you can read them in sequence.

**Quarter:** Q\_\_ of \_\_

**Start date:** \_\_\_\_\_

**End date:** \_\_\_\_\_

**What I worked on this quarter, at a glance:**

\_\_\_\_\_

**What I consider the most significant thing I learned:**

\_\_\_\_\_

**A specific moment I am proud of:**

\_\_\_\_\_

**A specific moment that was harder than I expected:**

\_\_\_\_\_

**Progress against my learning roadmap:**

- Milestones I completed: \_\_\_\_\_
- Milestones I missed: \_\_\_\_\_
- Milestones I changed or abandoned, and why: \_\_\_\_\_

**Community engagement this quarter:**

- Patches submitted: \_\_\_\_\_
- Reviews performed: \_\_\_\_\_
- Mailing-list replies: \_\_\_\_\_
- Conference talks watched: \_\_\_\_\_
- Bug reports filed or triaged: \_\_\_\_\_

**Toolkit improvements this quarter:**

- New scripts or templates I added: \_\_\_\_\_
- Existing scripts I improved: \_\_\_\_\_

- Scripts I retired: \_\_\_\_\_

**What I want to prioritise next quarter:**

1. \_\_\_\_\_
2. \_\_\_\_\_
3. \_\_\_\_\_

**What I want to stop doing, or do less of, next quarter:**

\_\_\_\_\_

**Who I would like to learn from next quarter:**

\_\_\_\_\_

**One small, concrete commitment for the coming month:**

\_\_\_\_\_

Filling in this template takes real time. It is tempting to skip it when you are busy with other work, but skipping it is a false economy. A quarterly review is one of the cheapest forms of long-term self-correction available to a working engineer, and an hour of honest reflection prevents many hours of drifted effort later.

### 38.12.9 9.9 Where to Keep These Artifacts

A practical question: where should these artifacts live? The answer depends on your working style, but a few options work well.

A personal Git repository is ideal. Create a repository called something like `freebsd-learning` or `kernel-work` and commit each artifact as you produce it. The version history becomes its own record of your growth. If you use a hosted Git service, make the repository private unless you are comfortable sharing your progress publicly; both choices are legitimate.

A folder in your home directory works if you prefer not to use Git. Organise it by date so that you can see the chronology. Back it up regularly.

A paper notebook works for some readers. The constraint it imposes (one-way revision, no text search) is a feature for some kinds of thinking, and paper notebooks have their own durability advantages. The downside is that you cannot easily share the contents with others or sync them across devices.

Whatever you choose, choose consistently. Scattered artifacts across multiple systems tend to become unreachable over time. A single, stable location where your learning record lives is much more useful.

### 38.12.10 9.10 Wrapping Up Section 9

The checklists and templates in this section are small tactical tools. They will not change your life individually, but used regularly, they help structure the ongoing work of professional growth. Copy them, adapt them to your circumstances, and treat them as living documents that evolve as you learn.

The chapter is now approaching its end. What remains is the wrapping-up material of the chapter itself, and the final closing words of the book.

## 38.13 Wrapping Up

This chapter has walked through the full reflective arc of the book's ending: a recognition of what you accomplished, an honest assessment of where you stand, a map of the advanced topics that remain beyond the book, a practical toolkit for continued work, a careful treatment of community engagement, a rhythm for staying current with kernel development, hands-on reflection labs, challenge exercises, and planning artifacts. Each section has had its own closing bridge, and the reflection labs have produced concrete artifacts that you will keep beyond the book.

A few themes run through the chapter and deserve a final explicit summary.

The first theme is that finishing the book is a milestone, not an endpoint. The milestone is real. The journey from no kernel experience to competent driver author is a substantial one, and you have completed it. The endpoint is something different: mastery is never reached in kernel work, because the kernel keeps changing and the depth of understanding keeps deepening. A finished book is a useful checkpoint, not a final destination.

The second theme is that independence grows from practice, not from reading. You have the knowledge to write drivers. The knowledge is necessary but not sufficient. What turns knowledge into independent capability is repeated practice on real problems, and the book can only gesture toward that practice; it cannot substitute for it. The chapter has suggested many specific paths for that practice, and the right one for you is whichever you are most likely to follow through on.

The third theme is that the FreeBSD community is a resource, a destination, and a teacher. You can finish this book and continue as a solo developer, and that is a legitimate path. But if you engage with the community, you will grow faster, reach further, and encounter ideas you could not have found alone. The community is not an obligation. It is an invitation, and the chapter has shown you many specific doors through which you can enter.

The fourth theme is that staying current is a rhythm, not a task. The FreeBSD kernel changes constantly, and a developer who stops paying attention will find their knowledge slowly rotting. A developer who maintains a weekly glance, a monthly rebuild, and a quarterly review will stay in step with the project over decades. The rhythm is sustainable, the benefits compound, and the chapter has shown you exactly what that rhythm looks like in practice.

The fifth theme is that contribution takes many forms. A reader who thinks of contribution only as committing driver code will miss most of the ways to be useful to the project. Mailing list help, documentation work, translations, mentoring, bug triage, code review, and test-case contributions are all real contributions, and all of them are valued. The chapter has named each of them and pointed you toward the channels where they happen.

The sixth theme is that a development toolkit pays for itself. The driver template, the virtual lab, the regression tests, the CI scripts, and the packaging habits are not glamorous. Each of them takes a few hours to set up and a few more hours to maintain. But together they turn each new driver project from a clean-slate effort into a refinement of an existing pipeline, and the compounding gain is large. The chapter has given you starter artifacts for each part of the toolkit, and the companion directory contains the templates.

The seventh and perhaps most important theme is that you are, now, in the practical sense, a FreeBSD device-driver developer. Not a senior one. Not yet a committer. But a working developer who can write, debug, test, and submit drivers. That identification is not a small one. It took work to earn it, and it deserves to be acknowledged.

Take a moment to appreciate what has changed in your toolkit over the course of the book. Before Chapter 1, the FreeBSD kernel may have been an opaque system that ran below your applications. Now it is a readable piece of software, with familiar patterns, known subsystems, and a predictable layout. Before Chapter 1, writing a driver may have been a distant aspiration. Now it is a concrete activity with a known workflow. Before Chapter 1, the FreeBSD community may have been an abstraction. Now it is a set of specific channels where specific kinds of work happen.

That transformation is the quiet kind of change that long books produce. It is not the dramatic transformation of a single chapter, but the slow accumulation of many chapters over many hours. Its value is measured in the difference between the person who started and the person who finished. By that measure, you are not the same reader who opened Chapter 1, and neither is the book.

Before the book closes, the final words are directed to the larger journey of which this book has been only a part.

## 38.14 Part 7 Checkpoint

Part 7 spent ten chapters turning a capable driver author into one who can ship work into the wider FreeBSD world. Before the book's final pages, it is worth pausing to confirm that the mastery topics have settled, because nothing after Chapter 38 will remind you of them again.

By the end of Part 7 you should be comfortable refactoring a driver so that its hardware-facing code sits behind a small backend interface, compiling it against both a simulation backend and a real one, and running the resulting module under bhyve, inside a VNET jail, or behind VirtIO without changing its core. You should be comfortable hardening a driver against hostile or careless input, which means bounds-checking every copy, zeroing buffers before copyout, applying privilege checks through `priv_check`, rate-limiting logs, and carrying a safe detach all the way through `MOD_QUIESCE` and resource teardown. You should be able to measure a driver's behaviour with the right instrument for the question at hand: DTrace and SDT probes for function-level tracing, `pmcstat` and `hwpmc` for CPU-level events, per-CPU counters and cache-aligned `softc` fields for contention relief, and `kgdb` with a core dump or the GDB stub for bugs that survive `INVARIANTS` and `WITNESS`. And you should be able to extend a driver's user-space contract with `poll(2)`, `kqueue(2)`, and `SIGIO` support, approach an undocumented device through safe probing and reverse-engineering discipline, and prepare a submission that reviewers will actually accept, from KNF-clean source through the manual page to the cover letter and the Phabricator review.

If any of those still feels soft, the labs to revisit are:

- Portability and backend separation: Lab 3 (Extract the Backend Interface) and Lab 5 (Add a Simulation Backend) in Chapter 29.
- Virtualisation and jails: Lab 3 (A Minimal Character Device Driver Inside a Jail) and Lab 6 (Building and Loading the vtedu Driver) in Chapter 30.
- Security discipline: Lab 2 (Bounds-Check the Buffer), Lab 4 (Add Privilege Checks), and Lab 6 (Safe Detach) in Chapter 31.
- Embedded and Device Tree work: Lab 2 (Build and Deploy an Overlay) and Lab 4 (Build the edled Driver End to End) in Chapter 32.
- Performance and profiling: Lab 2 (DTrace perfdemo) and Lab 4 (Cache Alignment and Per-CPU Counters) in Chapter 33.
- Advanced debugging: Lab 2 (Capturing and Analyzing a Panic With kgdb) and Lab 5 (Catching a Use-After-Free With memguard) in Chapter 34.
- Asynchronous I/O: Lab 2 (Adding poll() Support), Lab 3 (Adding kqueue Support), and Lab 6 (The Combined v2.5-async Driver) in Chapter 35.
- Reverse engineering: Lab 3 (Building a Safe Register Probing Module) and Lab 5 (Building a Safe Probing Wrapper) in Chapter 36.
- Upstreaming: Lab 1 (Prepare the File Layout), Lab 4 (Draft the Manual Page), and Lab 6 (Generate a Submission Patch) in Chapter 37.

Part 7 has no successor part. What it does have is the practice that follows the book: real hardware, real review cycles, real bugs, and the long-running rhythm of staying current that Chapter 38 has already named. The baseline the rest of your career assumes is exactly what these chapters taught, a driver that is portable, hardened, measured, debuggable, and submittable, written by an author who knows when to reach for each tool and when to step away from the keyboard. If the ideas above feel like habits rather than lookups, the book's work is done. What remains is yours.

## 38.15 Final Closing Words for the Book

This book began with a story about a chemistry student in Brazil in 1995, who found FreeBSD in a university library and slowly, over years, turned that curiosity into a career. That story was not offered as a model to follow; it was offered as evidence that curiosity is enough to start, even when the starting conditions are difficult.

Your starting conditions, whatever they were, brought you to the last pages of a technical book about an operating system that is now more than thirty years old. The operating system is still being developed, still being used in places that matter, and still welcoming new contributors. The ability to write device drivers for it is a skill that remains valuable and will continue to be valuable for as long as the project continues. By finishing this book, you have acquired that skill to a working level. What you do with it from here is entirely yours to decide.

There is a specific hope I have for the readers of this book, and I want to name it clearly. The hope is that at least some of you will find, in the months after finishing, that the book unlocked something you did not know was possible. That you will write a driver for a device you care about, or fix a bug that has been bothering you, or answer a question on a mailing list that helps a stranger, or begin a conversation with the project that leads somewhere you could not have anticipated. That the skills this book has given you become the beginning of a longer relationship with FreeBSD than the book's pages can contain.

The kernel is not magic. Over the course of this book, you have come to see that more clearly. A kernel is software, written by people, available for anyone to read, and modifiable by anyone with the patience to

understand it. The difference between a reader who finds kernels mysterious and a reader who finds them approachable is, in the end, whether they have actually sat down and looked. You have looked. You have looked carefully, across many chapters and many hours, and the mystery has receded.

That receding is permanent. You cannot un-know the shape of a driver now. You cannot un-know what a `softc` is, or what a `device_method_t` array does, or what the `_IOWR` macro means. Those pieces of knowledge will be with you for the rest of your career. They will help you read other systems, write other software, and reason about problems that are nothing like drivers. The investment you made in learning them has a return that extends well beyond FreeBSD.

There is also something the book has tried to convey without saying it directly. Systems engineering is a craft, and crafts are learned in a particular way: through long practice with specific materials, under the guidance of people who have done the work before. Books are one part of that guidance, but they are not the whole of it. The rest of the guidance comes from source code read carefully, from bugs debugged patiently, from mailing-list threads followed through to their conclusions, from conference talks watched with attention, and from the slow accumulation of intuitions that cannot be explicitly written down. This book has pointed you toward that larger guidance. The larger guidance is what will carry you forward from here.

If you choose to engage with FreeBSD after this book, you will find a community that has been remarkably stable across decades of technology change. The faces change, but the culture persists: an emphasis on careful engineering, on clear documentation, on long-term thinking, on the value of doing things well rather than quickly. Joining that culture is a privilege, and the culture welcomes newcomers who approach it with respect for its traditions.

If you do not choose to engage further, that is also fine. Many readers of this book will use what they learned for their own purposes, inside their own companies or on their own hardware, and never contribute publicly. Those readers have not wasted their time. They have acquired a skill, and the skill is useful in many contexts. The FreeBSD community is large enough to welcome those who engage and patient enough to let others benefit from the work without engaging. Both relationships are legitimate, and the book has tried not to pressure you toward either one.

A few last specific things deserve to be said.

If you submit a driver upstream, and it takes three rounds of review to land, that is normal. Do not be discouraged. Most first submissions go through several rounds, and the reviewers are helping you rather than judging you. Patience is the discipline that completes a submission; impatience is the discipline that abandons one. You have both disciplines available to you. Choose the first.

If you hit a bug you cannot figure out, and you have looked at it for an hour without progress, stop. Step away. Come back in a few hours or the next day. Fresh eyes see what tired eyes miss. The kernel is patient. Your bug will still be there tomorrow, and you will likely see its cause within the first few minutes of the next session. This is one of the most consistent patterns in debugging work, and it applies to kernel work as fully as to any other kind.

If you get discouraged, and at some point you probably will, remember why you started. Most people who finish a book like this finished it because something about FreeBSD caught their imagination. Return to that something. Reread the chapter that excited you most, or return to the driver you wrote that worked first, or watch a conference talk about a topic that made you curious. The return to the source of excitement is how you sustain a long career, and the sustenance matters more than the speed.

If you teach someone else what you learned, your own understanding will deepen in ways that solitary practice cannot produce. The slower, less efficient-feeling work of explaining to a newcomer what a device-method table does, or how `copyin` protects the kernel from userland pointers, or why locking order matters, is one of the most potent forms of learning there is. If you ever have the chance to help a future reader through the material you just worked through, take it. You will be doing them a favour, but you will be doing yourself a larger one.

This book has been a long journey, and every long one deserves a formal ending. Thank you for reading it. Thank you for working through the labs, the challenges, and the reflections. Thank you for caring enough about your own learning to see the book through. Your time is the most limited resource you have, and you spent a substantial portion of it on the pages of this book. I hope the return on that investment is large, and I hope you carry forward both the technical knowledge and the habits of thought that the book tried to convey.

The FreeBSD kernel is not going anywhere. It will still be here next year, and the year after, and ten years from now. It will still have drivers that need writing, bugs that need fixing, and documentation that needs updating. Whenever you are ready to return to the kernel, whether that is tomorrow or a decade from now, it will be waiting for you, and the community around it will still welcome the careful, curious work that you have learned to do.

Close the book now. Take a moment to notice that you have done something substantial. Then, when you are ready, open a terminal, type `cd /usr/src/sys/dev/`, and look around. You know what you are looking at. You know how to read it. You know how to change it. You know how to make it your own.

Good luck, and welcome to the community.

The kernel was never magic.

You just learned how to work with it.

## 39 Appendix A: FreeBSD Kernel API Reference

### 39.1 How to Use This Appendix

This appendix is the companion lookup table for everything the book has taught you to use inside a FreeBSD driver. The main chapters build each API carefully, show it in a working driver, and explain the mental model behind it. This appendix is the short, scannable counterpart you keep open while coding, debugging, or reading someone else's driver.

It is deliberately written to be a reference and not a tutorial. It does not try to teach any subsystem from scratch. Each entry assumes you have already met the API somewhere in the book, or that you are willing to read the manual page before you use it. What the entry gives you is the vocabulary to navigate: what the API is for, the small set of names that actually matter, the mistakes you are likely to make, where it typically fits in the driver lifecycle, and which chapter teaches it in full. If the entry is doing its job, you can answer four questions in under a minute:

1. Which API family do I need for the problem in front of me?
2. What is the exact name of the function, macro, or type I want?
3. What caveat should I check before I trust it?
4. Which manual page or chapter should I open next?

Nothing more is promised. Every detail below was verified against the FreeBSD 14.3 source tree and the corresponding manual pages in `man 9`. Where a distinction is important but deferred to another part of the book, the entry points forward rather than pretending to resolve it here.

#### 39.1.1 How the Entries Are Organised

The appendix groups APIs by the problem they solve, not alphabetically. A driver rarely reaches for a name in isolation. It reaches for a whole family: memory with its flags, a lock with its sleep rules, a callout with its cancellation story. Keeping those families together makes the appendix more useful for real lookup tasks.

Within each family, every entry follows the same short pattern:

- **Purpose.** What the API is for, in one or two sentences.
- **Typical use in drivers.** When a driver reaches for it.
- **Key names.** The functions, macros, flags, or types you actually call or declare.
- **Header(s).** Where the declarations live.
- **Caveats.** The handful of mistakes that cause real bugs.
- **Lifecycle phase.** Where in probe, attach, normal operation, or detach the API usually appears.
- **Manual pages.** The `man 9` entries to read next.
- **Where the book teaches this.** Chapter references for full context.

Keep this pattern in mind when you scan. If you only need the name of a flag, look at **Key names**. If you only need the manual page, look at **Manual pages**. If you have forgotten why the API exists at all, read **Purpose** and stop there.

### 39.1.2 What This Appendix Is Not

This appendix is not a replacement for `man 9`, not a replacement for the book's teaching chapters, and not a replacement for reading real drivers under `/usr/src/sys/dev/`. It is short on purpose. The canonical reference remains the manual page; the canonical mental model remains the chapter that introduced the API; the canonical truth remains the source tree. This appendix helps you find all three quickly.

It also does not cover every kernel interface. The kernel is large, and a full reference would repeat material that belongs in Appendix E (FreeBSD Internals and Kernel Reference) or in focused chapters such as Chapter 16 (Accessing Hardware), Chapter 19 (Handling Interrupts), and Chapter 20 (Advanced Interrupt Handling). The goal here is coverage of the APIs that a driver author actually uses in day-to-day work, at the level of detail a driver author actually needs.

## 39.2 Reader Guidance

You can use this appendix in three different ways, and they each call for a different reading strategy.

If you are **writing new code**, treat it as a checklist. Pick the family that matches your problem, skim the entries, note the key names, and jump to the manual page or the chapter for the details. Time investment: one or two minutes per lookup.

If you are **debugging**, treat it as a map of assumptions. When a driver misbehaves, the bug is almost always in a caveat that the author overlooked: a mutex held across a sleepable copy, a callout stopped but not drained, a resource freed before the interrupt was torn down. The **Caveats** line of each entry is where those assumptions live. Read them in order and ask whether your driver honours each one.

If you are **reading an unfamiliar driver**, treat it as a translator. When you see a function or macro you do not recognise, find its family in this appendix, read the **Purpose**, and move on. The full understanding can come later from the chapter or the manual page. The goal during exploration is to keep moving and to form an initial mental model of what the driver is doing.

A few conventions used throughout:

- All source paths are shown in book-facing form, `/usr/src/sys/...`, matching the layout on a standard FreeBSD system.
- Manual pages are cited in the usual FreeBSD style: `mtx(9)` means section 9 of the manual. You can read any of them with, for example, `man 9 mtx`.
- When a family has no dedicated manual page, the entry says so and points to the closest available documentation.
- When the book defers a topic to a later chapter or to Appendix E, the entry points forward rather than fabricating detail here.

With that in mind, we can open the appendix proper. The first family is memory: where drivers get the bytes they need, how they give them back, and which flags control the behaviour along the way.

## 39.3 Memory Allocation

Every driver allocates memory, and every allocation carries rules about when you may block, where the memory is physically located, and how it is returned. The kernel provides three main allocators: `malloc(9)` for general-purpose allocation, `uma(9)` for high-frequency fixed-size objects, and `contigmalloc(9)` for physically contiguous ranges that hardware can address. Below you will find each one at a glance, plus the small vocabulary of flags they share.

### 39.3.1 `malloc(9)` / `free(9)` / `realloc(9)`

**Purpose.** General-purpose kernel memory allocator. Gives you a byte buffer of any size, tagged by a `malloc_type` so you can account for it later with `vmstat -m`.

**Typical use in drivers.** Softc allocation, small variable-size buffers, temporary scratch space, anything where a fixed-size zone would be overkill.

**Key names.**

- `void *malloc(size_t size, struct malloc_type *type, int flags);`
- `void free(void *addr, struct malloc_type *type);`
- `void *realloc(void *addr, size_t size, struct malloc_type *type, int flags);`
- `MALLOC_DEFINE(M_FOO, "foo", "description for vmstat -m");`
- `MALLOC_DECLARE(M_FOO);` for use in headers.

**Header.** `/usr/src/sys/sys/malloc.h`.

**Flags that matter.**

- `M_WAITOK`: the caller may block until memory is available. The allocation will succeed or the kernel will panic.
- `M_NOWAIT`: the caller must not block. The allocation may return `NULL`. Always check for `NULL` with `M_NOWAIT`.
- `M_ZERO`: zero the returned memory before handing it back. Combine with either wait flag.
- `M_NODUMP`: exclude the allocation from crash dumps.

**Caveats.**

- `M_WAITOK` must not be used while holding a spin mutex, in an interrupt filter, or in any context that cannot sleep.
- `M_NOWAIT` callers must check the return value. Failing to handle `NULL` is one of the most common driver crashes in review.
- Never mix allocator families. Memory returned by `malloc(9)` must be freed by `free(9)`; `uma_zfree(9)` and `contigfree(9)` are not interchangeable.
- The `struct malloc_type` pointer must match between `malloc` and the corresponding `free`.

**Lifecycle phase.** Most commonly in `attach` (softc, buffers) and `detach` (release). Smaller allocations can appear in normal I/O paths as long as the context permits the chosen flag.

**Manual page.** `malloc(9)`.

**Where the book teaches this.** Introduced in Chapter 5 alongside kernel-specific C idioms; used in Chapter 7 when your first driver allocates its softc; revisited in Chapter 10 when I/O buffers become real, and again in Chapter 11 when allocation flags must obey locking rules.

### 39.3.2 uma(9) Zones

**Purpose.** Fixed-size object cache, highly optimised for allocations that are frequent, uniform, and performance-sensitive. Reuses objects instead of repeatedly hitting the general allocator.

**Typical use in drivers.** Network mbuf-like structures, per-packet state, per-request descriptors, anything where you allocate and free millions of identical small objects per second.

**Key names.**

- `uma_zone_t uma_zcreate(const char *name, size_t size, uma_ctor, uma_dtor, uma_init, uma_fini, int align, uint32_t flags);`
- `void uma_zdestroy(uma_zone_t zone);`
- `void *uma_zalloc(uma_zone_t zone, int flags);`
- `void uma_zfree(uma_zone_t zone, void *item);`

**Header.** `/usr/src/sys/vm/uma.h`.

**Flags.**

- `M_WAITOK`, `M_NOWAIT`, `M_ZERO` on allocation, identical in meaning to `malloc(9)`.
- Creation-time flags such as `UMA_ZONE_ZINIT`, `UMA_ZONE_NOFREE`, `UMA_ZONE_CONTIG`, and alignment hints (`UMA_ALIGN_CACHE`, `UMA_ALIGN_PTR`, and so on) tune behaviour for specific workloads.

**Caveats.**

- Zones must be created before they can be used and must be destroyed before the module unloads. Forgetting `uma_zdestroy` in `detach` leaks the entire zone.
- Constructors and destructors run on allocation and free respectively, not on zone creation and destruction; use the `init` and `fini` callbacks for once-per-slab work.
- A zone is expensive to create. Create one per object type per module, not per instance.
- There is no dedicated `uma(9)` manual page. The authoritative reference is the header and the existing users under `/usr/src/sys/`.

**Lifecycle phase.** `uma_zcreate` in module load or early attach; `uma_zalloc` and `uma_zfree` in I/O paths; `uma_zdestroy` in module unload.

**Manual page.** None dedicated. Read `/usr/src/sys/vm/uma.h` and look at `/usr/src/sys/kern/kern_mbuf.c` and `/usr/src/sys/net/netisr.c` for realistic use.

**Where the book teaches this.** Mentioned briefly in Chapter 7 as an alternative to `malloc(9)`; revisited when high-rate drivers need it in Chapter 28 (networking) and Chapter 33 (performance tuning).

### 39.3.3 contigmalloc(9) / contigfree(9)

**Purpose.** Allocate a physically contiguous range of memory within a specified address window. Required when hardware must DMA into memory without an IOMMU and therefore needs contiguous physical pages.

**Typical use in drivers.** DMA buffers for devices that cannot scatter-gather, and only after confirming that `bus_dma(9)` is not a better fit.

**Key names.**

- `void *contigmalloc(unsigned long size, struct malloc_type *type, int flags, vm_paddr_t low, vm_paddr_t high, unsigned long alignment, vm_paddr_t boundary);`
- `void contigfree(void *addr, unsigned long size, struct malloc_type *type);`

**Header.** `/usr/src/sys/sys/malloc.h`.

**Caveats.**

- Fragmentation after boot makes large contiguous allocations fail. Do not assume success.
- For almost all modern hardware, prefer the `bus_dma(9)` framework. It handles tags, maps, bouncing, and alignment in a portable way.
- `contigmalloc` allocations are a scarce system resource; free them as soon as possible.

**Lifecycle phase.** Typically in `attach`; freed in `detach`.

**Manual page.** `contigmalloc(9)`.

**Where the book teaches this.** Mentioned alongside `bus_dma(9)` in Chapter 21 when DMA first becomes a real concern.

### 39.3.4 Allocation Flag Cheat Sheet

| Flag                  | Meaning                                                      |
|-----------------------|--------------------------------------------------------------|
| <code>M_WAITOK</code> | Caller may block until memory is available.                  |
| <code>M_NOWAIT</code> | Caller must not block; returns <code>NULL</code> on failure. |
| <code>M_ZERO</code>   | Zero the allocation before returning.                        |
| <code>M_NODUMP</code> | Exclude the allocation from crash dumps.                     |

Use `M_WAITOK` only where sleeping is permitted. When in doubt, the safe answer is `M_NOWAIT` plus a `NULL` check.

## 39.4 Synchronisation Primitives

If memory is the raw material of a driver, synchronisation is the discipline that prevents two execution contexts from corrupting it at the same time. FreeBSD gives you a small, well-designed toolkit. The names below are the ones you will meet most often. Full teaching lives in Chapters 11, 12, and 15, with interrupt-context nuances in Chapters 19 and 20; this appendix collects the vocabulary.

### 39.4.1 mtx(9): Mutexes

**Purpose.** The default kernel mutual-exclusion primitive. A thread acquires the lock, enters the critical section, and releases the lock.

**Typical use in drivers.** Protecting softc fields, circular buffers, reference counts, and any shared state whose critical section is short and does not sleep.

**Key names.**

- `void mtx_init(struct mtx *m, const char *name, const char *type, int opts);`
- `void mtx_destroy(struct mtx *m);`
- `mtx_lock(m), mtx_unlock(m), mtx_trylock(m).`
- `mtx_assert(m, MA_OWNED | MA_NOTOWNED | MA_RECURSED | MA_NOTRECURSED);` for invariants.
- Sleep-on-mutex helpers: `msleep(9)` and `mtx_sleep(9)`.

**Header.** `/usr/src/sys/sys/mutex.h`.

**Options.**

- `MTX_DEF`: the default sleepable-on-contention mutex. Use this for almost everything.
- `MTX_SPIN`: pure spinlock. Required for interrupt-filter context and other places where blocking is impossible. Rules are stricter.
- `MTX_RECURSE`: allow the same thread to acquire the lock multiple times. Use with caution; it often hides design mistakes.
- `MTX_NEW`: force `mtx_init` to treat the lock as newly created. Useful with `WITNESS`.

**Caveats.**

- Never sleep while holding an `MTX_DEF` or `MTX_SPIN` mutex. `uiomove(9)`, `copyin(9)`, `copyout(9)`, `malloc(9, M_WAITOK)`, and most bus primitives can sleep. Audit carefully.
- Always pair `mtx_init` with `mtx_destroy`. Forgetting the destroy leaks internal state and annoys `WITNESS`.
- Lock order matters. Once the kernel has seen you acquire lock A before lock B, it will warn if you ever reverse the pair. Plan your lock hierarchy in advance.
- `MTX_SPIN` disables preemption; hold it for as short a time as possible.

**Lifecycle phase.** `mtx_init` in attach; `mtx_destroy` in detach. Lock and unlock operations everywhere in between.

**Manual pages.** `mutex(9)`, `mtx_pool(9)`, `msleep(9)`.

**Where the book teaches this.** First treatment in Chapter 11, deepened in Chapter 12 with lock-order and `WITNESS` discipline, and revisited in Chapter 19 for interrupt-safe variants (`MTX_SPIN`).

### 39.4.2 sx(9): Sleepable Shared-Exclusive Locks

**Purpose.** A reader-writer lock where either the reader or the writer may block. Use when multiple readers are common, writers are rare, and the critical section may sleep.

**Typical use in drivers.** Configuration state read by many paths and modified infrequently. Not for fast-path data.

**Key names.**

- `void sx_init(struct sx *sx, const char *desc);`
- `void sx_destroy(struct sx *sx);`
- `sx_slock(sx), sx_sunlock(sx)` for shared access.
- `sx_xlock(sx), sx_xunlock(sx)` for exclusive access.
- `sx_try_slock, sx_try_xlock, sx_upgrade, sx_downgrade.`
- `sx_assert(sx, SA_SLOCKED | SA_XLOCKED | SA_LOCKED | SA_UNLOCKED);`

**Header.** `/usr/src/sys/sys/sx.h`.

**Caveats.**

- `sx` allows sleeping inside the critical section, unlike `mtx`. That flexibility is the whole point; make sure you actually need it.
- `sx` locks are more expensive than mutexes. Do not use them as a default.
- Avoid mixing `sx` and `mtx` in the same lock order without thinking through the implications.

**Lifecycle phase.** `sx_init` in `attach`; `sx_destroy` in `detach`.

**Manual page.** `sx(9)`.

**Where the book teaches this.** Chapter 12.

### 39.4.3 `rmlock(9)`: Read-Mostly Locks

**Purpose.** Extremely fast reader path, slower writer path. Readers do not contend with each other. Designed for data that is read on every operation but written only rarely.

**Typical use in drivers.** Routing-like tables, configuration state used in fast paths, structures where writer overhead is acceptable because writes are rare.

**Key names.**

- `void rm_init(struct rmlock *rm, const char *name);`
- `void rm_destroy(struct rmlock *rm);`
- `rm_rlock(rm, tracker), rm_runlock(rm, tracker).`
- `rm_wlock(rm), rm_wunlock(rm).`

**Header.** `/usr/src/sys/sys/rmlock.h`.

**Caveats.**

- Each reader needs its own struct `rm_priotracker`, typically on the stack. Do not share one.
- Readers may not sleep unless the lock was initialised with `RM_SLEEPABLE`.
- The writer path is heavy; if writes are frequent, `sx` or `mtx` is a better choice.

**Lifecycle phase.** `rm_init` in `attach`; `rm_destroy` in `detach`.

**Manual page.** `rmlock(9)`.

**Where the book teaches this.** Introduced briefly in Chapter 12 and used in later chapters where read-mostly patterns arise.

### 39.4.4 `cv(9)` / `condvar(9)`: Condition Variables

**Purpose.** A named wait channel. One or more threads sleep until another thread signals that the condition they are waiting for has become true.

**Typical use in drivers.** Waiting for a buffer to drain, for hardware to finish a command, or for a specific state transition. Use instead of bare `wakeup(9)` channels when you want the wait reason to be explicit.

**Key names.**

- `void cv_init(struct cv *cv, const char *desc);`
- `void cv_destroy(struct cv *cv);`
- `cv_wait(cv, mtx), cv_wait_sig(cv, mtx), cv_wait_unlock(cv, mtx).`
- `cv_timedwait(cv, mtx, timo), cv_timedwait_sig(cv, mtx, timo).`
- `cv_signal(cv), cv_broadcast(cv), cv_broadcastpri(cv, pri).`

**Header.** `/usr/src/sys/sys/condvar.h`.

**Caveats.**

- The mutex passed to `cv_wait` must be held by the caller; `cv_wait` drops it while sleeping and reacquires it on return.
- Always recheck the predicate after `cv_wait` returns. Spurious wakeups and signals are possible.
- `cv_signal` wakes one waiter; `cv_broadcast` wakes all. Pick based on the design, not on instinct.

**Lifecycle phase.** `cv_init` in `attach`; `cv_destroy` in `detach`.

**Manual page.** `condvar(9)`.

**Where the book teaches this.** Chapter 12, with interruptible and timed waits revisited in Chapter 15.

### 39.4.5 `sema(9)`: Counting Semaphores

**Purpose.** A counting semaphore with `wait` and `post` operations. Less common than mutexes or condition variables.

**Typical use in drivers.** Producer-consumer patterns where a counted resource must be tracked, such as a fixed pool of command slots.

**Key names.**

- `void sema_init(struct sema *sema, int value, const char *desc);`
- `void sema_destroy(struct sema *sema);`
- `sema_wait(sema), sema_trywait(sema), sema_timedwait(sema, timo).`
- `sema_post(sema).`

**Header.** `/usr/src/sys/sys/sema.h`.

**Caveats.**

- Semaphores are appropriate for counting. For one-thread-in-critical-section patterns, use `mtx` instead.
- `sema_wait` may return early on signal; check return values.

**Manual page.** sema(9).

**Where the book teaches this.** Chapter 15, as part of the advanced synchronisation toolkit.

### 39.4.6 atomic(9): Atomic Operations

**Purpose.** Single-word, interruption-free read-modify-write operations. Faster than any lock, and strictly limited in expressiveness.

**Typical use in drivers.** Counters, flags, and compare-and-swap patterns where the critical section fits in one integer.

**Key names.**

- atomic\_add\_int, atomic\_subtract\_int, atomic\_set\_int, atomic\_clear\_int.
- atomic\_load\_int, atomic\_store\_int, with acquire and release variants.
- atomic\_cmpset\_int, atomic\_fcmpset\_int for compare-and-swap.
- Width variants: \_8, \_16, \_32, \_64, and pointer-sized \_ptr.
- Barrier helpers: atomic\_thread\_fence\_acq(), atomic\_thread\_fence\_rel(), atomic\_thread\_fence\_acq\_rel()

**Header.** /usr/src/sys/sys/atomic\_common.h plus machine/atomic.h for architecture-specific pieces.

**Caveats.**

- Atomic operations give you one word of mutual exclusion. Any invariant that spans two fields still needs a lock.
- Memory ordering matters. The plain operations are relaxed; use the \_acq, \_rel, and \_acq\_rel variants when one access must become visible before or after another.
- For per-CPU counters that are read rarely, counter(9) scales better.

**Lifecycle phase.** Any. Cheap enough to use in interrupt filters.

**Manual page.** atomic(9).

**Where the book teaches this.** Chapter 11, with counter(9) introduced alongside for per-CPU patterns.

### 39.4.7 epoch(9): Read-Mostly Lock-Free Sections

**Purpose.** Lightweight reader protection for data structures where readers vastly outnumber writers and latency must be minimal. Writers wait for all current readers to leave before freeing memory.

**Typical use in drivers.** Network stack fast paths, read-mostly lookup tables in high-performance drivers. Not a general-purpose primitive.

**Key names.**

- epoch\_t epoch\_alloc(const char \*name, int flags);
- void epoch\_free(epoch\_t epoch);
- epoch\_enter(epoch), epoch\_exit(epoch).
- epoch\_wait(epoch) for writers to block until readers drain.
- NET\_EPOCH\_ENTER(et) and NET\_EPOCH\_EXIT(et) wrappers for the network stack.

**Header.** `/usr/src/sys/sys/epoch.h`.

**Caveats.**

- Readers must not block, sleep, or call any function that does, while inside an epoch section.
- Freeing protected memory must be deferred until `epoch_wait` returns.
- Epoch sections are a tool of last resort, not a default primitive. Choose locks first.

**Manual page.** `epoch(9)`.

**Where the book teaches this.** Introduced briefly in Chapter 12; used in depth only where real drivers in later chapters require it.

### 39.4.8 Lock Decision Cheat Sheet

| You want to...                                        | Reach for                                      |
|-------------------------------------------------------|------------------------------------------------|
| Protect a short, non-sleeping critical section        | <code>mtx(9)</code> with <code>MTX_DEF</code>  |
| Protect state in an interrupt filter                  | <code>mtx(9)</code> with <code>MTX_SPIN</code> |
| Allow many readers, rare writers, may sleep           | <code>sx(9)</code>                             |
| Allow many readers, rare writers, no sleep in readers | <code>rmlock(9)</code>                         |
| Sleep until a named condition holds                   | <code>cv(9)</code> with a mutex                |
| Increment or compare-and-swap a single word           | <code>atomic(9)</code>                         |
| Lock-free reader path for read-mostly data            | <code>epoch(9)</code>                          |

When a row does not obviously match the problem, the full discussion in Chapters 11, 12, and 15 is the place to resolve it.

## 39.5 Deferred Execution and Timers

Drivers often need to run work later, periodically, or from a context that can sleep. The kernel gives you three tools for that: `callout(9)` for one-shot and periodic timers, `taskqueue(9)` for deferred work that may sleep, and `kthread(9)` or `kproc(9)` for long-running background threads. They overlap in some situations; the rule of thumb is that callouts run from the timer interrupt context (fast, no sleeping), taskqueues run in a worker thread (can sleep, can grab sleepable locks), and kthreads are whole threads you own.

### 39.5.1 `callout(9)`: Kernel Timers

**Purpose.** Schedule a function to run after a time delay. The callback runs in soft-interrupt context by default and must not sleep.

**Typical use in drivers.** Watchdog timers, polling intervals, retry delays, idle timeouts.

**Key names.**

- `void callout_init(struct callout *c, int mpsafe);` plus `callout_init_mtx` and `callout_init_rm`.
- `int callout_reset(struct callout *c, int ticks, void (*func)(void *), void *arg);`
- `int callout_stop(struct callout *c);`
- `int callout_drain(struct callout *c);`
- `int callout_pending(struct callout *c);`, `callout_active(struct callout *c);`

**Header.** `/usr/src/sys/sys/callout.h`.

**Caveats.**

- `callout_stop` does not wait for a running callback. Use `callout_drain` before freeing the softc in detach.
- A callout can fire even after you think you cancelled it if the timer was already dispatched. Guard the callback with a flag or use the `_mtx` and `_rm` variants to integrate cancellation with your lock.
- Running tickless kernels means ticks are abstract. Convert real time with `hz` or use `callout_reset_sbt` for subsecond precision.

**Lifecycle phase.** `callout_init` in attach; `callout_drain` in detach; `callout_reset` whenever the next firing time needs to be set.

**Manual page.** `callout(9)`.

**Where the book teaches this.** Chapter 13.

### 39.5.2 taskqueue(9): Deferred Work in a Worker Thread

**Purpose.** Hand off work from a context that cannot sleep, or that should not hold a lock for long, to a worker thread. Tasks queued on the same taskqueue run in order.

**Typical use in drivers.** Interrupt post-processing, hardware command completion handlers, reset and recovery paths that may need to allocate memory or grab sleepable locks.

**Key names.**

- `struct taskqueue *taskqueue_create(const char *name, int mflags, taskqueue_enqueue_fn, void *context);`
- `void taskqueue_free(struct taskqueue *queue);`
- `TASK_INIT(struct task *t, int priority, task_fn_t *func, void *context);`
- `int taskqueue_enqueue(struct taskqueue *queue, struct task *task);`
- `void taskqueue_drain(struct taskqueue *queue, struct task *task);`
- `void taskqueue_drain_all(struct taskqueue *queue);`
- Global queues such as `taskqueue_thread`, `taskqueue_swi`, `taskqueue_fast`.

**Header.** `/usr/src/sys/sys/taskqueue.h`.

**Caveats.**

- Enqueuing the same task twice before it runs is a no-op by design. If you need a new request every time, that is fine; if you expect two runs, use distinct tasks.
- `taskqueue_drain` waits for the task to finish; call it before freeing anything the task uses.

- Private taskqueues are cheap but not free. Reuse global taskqueues (`taskqueue_thread`, `taskqueue_fast`) unless you have a reason to own one.

**Lifecycle phase.** `taskqueue_create` (if private) and `TASK_INIT` in `attach`; `taskqueue_drain` and `taskqueue_free` in `detach`.

**Manual page.** `taskqueue(9)`.

**Where the book teaches this.** Chapter 14.

### 39.5.3 `kthread(9)` and `kproc(9)`: Kernel Threads and Processes

**Purpose.** Create a dedicated kernel thread or process that runs your function. Useful when the workload is long-lived, needs its own scheduling policy, or needs to be explicitly addressable.

**Typical use in drivers.** Rare. Most driver work is served better by a taskqueue or a callout. Kernel threads appear in subsystems with genuine long-running loops, such as housekeeping daemons.

**Key names.**

- `int kthread_add(void (*func)(void *), void *arg, struct proc *p, struct thread **td, int flags, int pages, const char *fmt, ...);`
- `int kproc_create(void (*func)(void *), void *arg, struct proc **procp, int flags, int pages, const char *fmt, ...);`
- `void kthread_exit(void);`
- `kproc_exit`, `kproc_suspend_check`.

**Header.** `/usr/src/sys/sys/kthread.h`.

**Caveats.**

- Creating a thread is heavier than queuing a task. Prefer `taskqueue(9)` unless the workload is genuinely long-running.
- Cleanly shutting down a `kthread` requires cooperation: set a stop flag, wake the thread, and wait for it to exit. Forgetting any step leaks the thread across module unloads.
- A `kthread` must exit by calling `kthread_exit`, not by returning.

**Manual pages.** `kthread(9)`, `kproc(9)`.

**Where the book teaches this.** Mentioned in Chapter 14 as the heavier alternative to taskqueues.

### 39.5.4 Deferred Work Decision Cheat Sheet

| You need to...                                      | Reach for                 |
|-----------------------------------------------------|---------------------------|
| Fire a function after a delay, briefly, no sleeping | <code>callout(9)</code>   |
| Defer work that may sleep or grab sleepable locks   | <code>taskqueue(9)</code> |
| Run a persistent background loop                    | <code>kthread(9)</code>   |
| Convert short periodic polling into real interrupts | See Chapter 19            |

## 39.6 Bus and Resource Management

The bus layer is where a driver meets hardware. Newbus introduces the driver to the kernel; `rman(9)` hands out the resources that represent MMIO regions, I/O ports, and interrupts; `bus_space(9)` accesses them portably; `bus_dma(9)` lets devices DMA safely.

### 39.6.1 Newbus: `DRIVER_MODULE`, `DEVMETHOD`, and Related Macros

**Purpose.** Register a driver with the kernel, bind it to a device class, declare the entry points the kernel should call, and publish version and dependency information.

**Typical use in drivers.** Every kernel module that owns a device. This is the scaffolding that turns a pile of C code into something `kldload` can attach to hardware.

**Key names.**

- `DRIVER_MODULE(name, bus, driver, devclass, evh, evharg);`
- `MODULE_VERSION(name, version);`
- `MODULE_DEPEND(name, busname, vmin, vpref, vmax);`
- `DEVMETHOD(method, function)` and `DEVMETHOD_END` for the method table.
- `device_method_t` entries such as `device_probe`, `device_attach`, `device_detach`, `device_shutdown`, `device_suspend`, `device_resume`.
- Types: `device_t`, `devclass_t`, `driver_t`.

**Header.** `/usr/src/sys/sys/module.h` and `/usr/src/sys/sys/bus.h`.

**Caveats.**

- `DRIVER_MODULE` expands into a module event handler; do not declare your own `module_event_t` table by hand unless you know exactly why.
- `MODULE_DEPEND` is how you make the loader bring in your prerequisites. Forgetting it produces ugly symbol-resolution failures at load time.
- `DEVMETHOD_END` terminates the method table. Without it the kernel will walk past the end.
- `device_t` is opaque; use accessors such as `device_get_softc`, `device_get_parent`, `device_get_name`, and `device_printf`.

**Lifecycle phase.** Declaration only. The macros expand into `module-init` and `module-fini` glue that is run on `kldload` and `kldunload`.

**Manual pages.** `DRIVER_MODULE(9)`, `MODULE_VERSION(9)`, `MODULE_DEPEND(9)`, `module(9)`, `DEVICE_PROBE(9)`, `DEVICE_ATTACH(9)`, `DEVICE_DETACH(9)`.

**Where the book teaches this.** Full treatment in Chapter 7, with the anatomy first sketched in Chapter 6.

### 39.6.2 `devclass(9)` and Device Accessors

**Purpose.** A `devclass_t` groups instances of the same driver so the kernel can find them, number them, and iterate over them. In drivers, you mostly use the accessors, not the `devclass` directly.

**Key names.**

- `device_t device_get_parent(device_t dev);`
- `void *device_get_softc(device_t dev);`
- `int device_get_unit(device_t dev);`
- `const char *device_get_nameunit(device_t dev);`
- `int device_printf(device_t dev, const char *fmt, ...);`
- `devclass_find`, `devclass_get_device`, `devclass_get_devices`, `devclass_get_count` when you truly need to walk a class.

**Header.** `/usr/src/sys/sys/bus.h`.

#### Caveats.

- `device_get_softc` assumes the `softc` was registered through the driver structure. Rolling your own `device_t`-to-state mapping is almost always wrong.
- Direct `devclass` manipulation is rare in drivers. If you find yourself reaching for it, check whether the question belongs in a bus-level interface instead.

**Manual pages.** `devclass(9)`, `device(9)`, `device_get_softc(9)`, `device_printf(9)`.

**Where the book teaches this.** Chapter 6 and Chapter 7.

### 39.6.3 `rman(9)`: Resource Manager

**Purpose.** A uniform view over MMIO regions, I/O ports, interrupt numbers, and DMA channels. Your driver asks for resources by type and RID and gets back a `struct resource *` with useful accessors.

#### Key names.

- `struct resource *bus_alloc_resource(device_t dev, int type, int *rid, rman_res_t start, rman_res_t end, rman_res_t count, u_int flags);`
- `struct resource *bus_alloc_resource_any(device_t dev, int type, int *rid, u_int flags);`
- `int bus_release_resource(device_t dev, int type, int rid, struct resource *r);`
- `int bus_activate_resource(device_t dev, int type, int rid, struct resource *r);`
- `int bus_deactivate_resource(device_t dev, int type, int rid, struct resource *r);`
- `rman_res_t rman_get_start(struct resource *r);`, `rman_get_end`, `rman_get_size`.
- `bus_space_tag_t rman_get_bustag(struct resource *r);`, `rman_get_bushandle`.
- Resource types: `SYS_RES_MEMORY`, `SYS_RES_IOPORT`, `SYS_RES_IRQ`, `SYS_RES_DRQ`.
- Flags: `RF_ACTIVE`, `RF_SHAREABLE`.

**Header.** `/usr/src/sys/sys/rman.h`.

#### Caveats.

- The `rid` parameter is a pointer and may be rewritten by the allocator. Pass the address of a real variable.
- Release every allocated resource in detach in reverse order of allocation. Leaking a resource almost always corrupts the next attach.
- `RF_ACTIVE` is the common case. Do not forget it, or you will get a handle that cannot be used with `bus_space(9)`.
- Always check the return value. A failed allocation is common on hardware with quirks.

**Lifecycle phase.** Allocation in attach; release in detach. If the driver has exotic needs, `bus_activate_resource` and `bus_deactivate_resource` can manage activation separately.

**Manual pages.** `rman(9)`, `bus_alloc_resource(9)`, `bus_release_resource(9)`, `bus_activate_resource(9)`.

**Where the book teaches this.** Chapter 16.

### 39.6.4 `bus_space(9)`: Portable Register Access

**Purpose.** Read and write device registers through a (tag, handle, offset) triple that hides whether the underlying access is memory-mapped, port-based, big-endian, little-endian, or indexed.

**Typical use in drivers.** Every MMIO or I/O port access. Do not dereference `rman_get_virtual` yourself; use `bus_space`.

**Key names.**

- Types: `bus_space_tag_t`, `bus_space_handle_t`.
- Reads: `bus_space_read_1(tag, handle, offset), _2, _4, _8`.
- Writes: `bus_space_write_1(tag, handle, offset, value), _2, _4, _8`.
- Multi-register helpers: `bus_space_read_multi_N`, `bus_space_write_multi_N`, `bus_space_read_region_N`, `bus_space_write_region_N`.
- Barriers: `bus_space_barrier(tag, handle, offset, length, flags)` with `BUS_SPACE_BARRIER_READ` and `BUS_SPACE_BARRIER_WRITE`.

**Header.** `/usr/src/sys/sys/bus.h`, with machine-specific details in `machine/bus.h`.

**Caveats.**

- Never touch device registers through a raw pointer. Portability and debugging both depend on `bus_space`.
- Barriers are not automatic. When two writes must occur in order, insert `bus_space_barrier` between them.
- The width used in `bus_space_read_N` or `bus_space_write_N` must match the register's natural size. Mismatches cause silent corruption on some architectures.

**Lifecycle phase.** Any time the driver talks to the device.

**Manual page.** `bus_space(9)`.

**Where the book teaches this.** Chapter 16.

### 39.6.5 `bus_dma(9)`: Portable DMA

**Purpose.** Describe DMA constraints with a tag, load a buffer through a map, and let the framework handle alignment, bouncing, and coherency. Required for any serious device that moves data.

**Key names.**

- `int bus_dma_tag_create(bus_dma_tag_t parent, bus_size_t alignment, bus_addr_t boundary, bus_addr_t lowaddr, bus_addr_t highaddr, bus_dma_filter_t *filtfunc, void *filtfuncarg, bus_size_t maxsize, int nsegments, bus_size_t maxsegsz, int flags, bus_dma_lock_t *lockfunc, void *lockfuncarg, bus_dma_tag_t *dmat);`

- `int bus_dma_tag_destroy(bus_dma_tag_t dmat);`
- `int bus_dmamap_create(bus_dma_tag_t dmat, int flags, bus_dmamap_t *mapp);`
- `int bus_dmamap_destroy(bus_dma_tag_t dmat, bus_dmamap_t map);`
- `int bus_dmamap_load(bus_dma_tag_t dmat, bus_dmamap_t map, void *buf, bus_size_t buflen, bus_dmamap_callback_t *callback, void *arg, int flags);`
- `void bus_dmamap_unload(bus_dma_tag_t dmat, bus_dmamap_t map);`
- `void bus_dmamap_sync(bus_dma_tag_t dmat, bus_dmamap_t map, bus_dmasync_op_t op);`
- `int bus_dmamem_alloc(bus_dma_tag_t dmat, void **vaddr, int flags, bus_dmamap_t *mapp);`
- `void bus_dmamem_free(bus_dma_tag_t dmat, void *vaddr, bus_dmamap_t map);`
- Flags: `BUS_DMA_WAITOK`, `BUS_DMA_NOWAIT`, `BUS_DMA_ALLOCNOW`, `BUS_DMA_COHERENT`, `BUS_DMA_ZERO`.
- Sync operations: `BUS_DMASYNC_PREREAD`, `BUS_DMASYNC_POSTREAD`, `BUS_DMASYNC_PREWRITE`, `BUS_DMASYNC_POSTWRITE`.

**Header.** `/usr/src/sys/sys/bus_dma.h`.

#### Caveats.

- Tags form a tree. Child tags inherit parent constraints; create them in the right order.
- `bus_dmamap_load` may complete asynchronously. Always use the callback, even for synchronous buffers.
- `bus_dmamap_sync` is not decoration. Without the right sync direction, caches and device memory will disagree.
- On platforms with IOMMUs the framework does the right thing. Do not skip it just because your development hardware is coherent.

**Lifecycle phase.** Tag creation and mapping setup in `attach`; load and sync in I/O paths; unload and destroy in `detach`.

**Manual page.** `bus_dma(9)`.

**Where the book teaches this.** Chapter 21.

## 39.6.6 Interrupt Setup

**Purpose.** Attach a filter or handler to an IRQ resource so the kernel can deliver interrupts to the driver.

#### Key names.

- `int bus_setup_intr(device_t dev, struct resource *r, int flags, driver_filter_t *filter, driver_intr_t *handler, void *arg, void **cookiep);`
- `int bus_teardown_intr(device_t dev, struct resource *r, void *cookie);`
- Flags: `INTR_TYPE_NET`, `INTR_TYPE_BIO`, `INTR_TYPE_TTY`, `INTR_TYPE_MISC`, `INTR_MPSAFE`, `INTR_EXCL`.

#### Caveats.

- Provide a filter when the fast-path decision is cheap and the driver can honour filter-context restrictions (no sleeping, no sleepable locks). Provide a handler when the work needs a thread.

- `INTR_MPSAFE` is mandatory for new drivers. Without it, the kernel serialises the handler on the Giant lock, which is almost always wrong.
- Tear down before freeing the resource. The order is: `bus_tear_down_intr`, then `bus_release_resource`.

**Lifecycle phase.** `bus_setup_intr` at the end of `attach`, after the rest of the softc is ready; `bus_tear_down_intr` at the start of `detach`, before any resource is released.

**Manual page.** `BUS_SETUP_INTR(9)`, `bus_alloc_resource(9)` for the resource side.

**Where the book teaches this.** Chapter 19, with advanced patterns in Chapter 20.

## 39.7 Device Nodes and Character-Device I/O

Once hardware is bound, drivers most often expose themselves to userland through a device node in `/dev/`. The APIs below build and tear down those nodes, and the associated switch table declares how the kernel should dispatch `read`, `write`, `ioctl`, and `poll`.

### 39.7.1 `make_dev_s(9)` and `destroy_dev(9)`

**Purpose.** Create a new device node under `/dev/`, connected to a `cdevsw` that holds the function pointers the kernel will call.

**Key names.**

- `int make_dev_s(struct make_dev_args *args, struct cdev **cdev, const char *fmt, ...);`
- `void destroy_dev(struct cdev *cdev);`
- Fields in `struct make_dev_args`: `mda_si_drv1`, `mda_devsw`, `mda_uid`, `mda_gid`, `mda_mode`, `mda_flags`, `mda_unit`.
- Legacy helper `make_dev(struct cdevsw *, int unit, uid_t, gid_t, int mode, const char *fmt, ...)` still exists but `make_dev_s` is preferred in new code.

**Header.** `/usr/src/sys/sys/conf.h`.

**Caveats.**

- Always use `make_dev_s`. The older `make_dev` swallows errors and does not let you set all the arguments.
- Set `mda_si_drv1` to the softc so the `cdev` carries a pointer back to driver state without a separate lookup.
- `destroy_dev` waits for all active threads to leave the `cdev` before returning, making it safe to free the softc afterwards.

**Lifecycle phase.** `make_dev_s` at the end of `attach`; `destroy_dev` at the start of `detach`, before any backing state is torn down.

**Manual page.** `make_dev(9)`.

**Where the book teaches this.** Chapter 8.

### 39.7.2 cdevsw: Character-Device Switch Table

**Purpose.** Declare the entry points the kernel should call when a process opens, reads, writes, or otherwise interacts with the device node.

**Key names.**

- struct cdevsw fields: d\_version, d\_flags, d\_name, d\_open, d\_close, d\_read, d\_write, d\_ioctl, d\_poll, d\_kqfilter, d\_mmap, d\_mmap\_single.
- d\_version must be D\_VERSION.
- Common flags: D\_NEEDGIANT (legacy), D\_TRACKCLOSE, D\_MEM.

**Header.** /usr/src/sys/sys/conf.h.

**Caveats.**

- Always set d\_version = D\_VERSION. The kernel refuses to attach a switch table with a missing or stale version.
- d\_flags default of zero is fine for modern MPSAFE drivers. Do not add D\_NEEDGIANT unless you genuinely need it.
- Unused entries can be left as NULL; the kernel substitutes defaults. Do not point them at stubs that do nothing.

**Lifecycle phase.** Declared statically at module scope. Referenced by struct make\_dev\_args.

**Manual page.** make\_dev(9) covers the structure in the context of make\_dev\_s.

**Where the book teaches this.** Chapter 8.

### 39.7.3 ioctl(9) Dispatch

**Purpose.** Provide out-of-band commands to a device, addressed by a numeric command and an argument buffer.

**Key names.**

- Entry point: d\_ioctl\_t with signature `int (*)(struct cdev *, u_long cmd, caddr_t data, int fflag, struct thread *td);`
- Command encoding macros: \_IO, \_IOR, \_IOW, \_IOWR.
- Copy helpers: copyin(9) and copyout(9) for pointer-carrying ioctls.

**Caveats.**

- Use \_IOR, \_IOW, or \_IOWR to declare commands. They encode size and direction, which matters for cross-architecture compatibility.
- Validate command arguments before acting on them. An ioctl is a trust boundary.
- Never dereference a user pointer directly. Use copyin(9) and copyout(9).

**Lifecycle phase.** Normal operation.

**Manual page.** ioctl(9) (conceptual); the entry point is documented alongside cdevsw in make\_dev(9).

**Where the book teaches this.** Chapter 24 (Section 3), with further patterns in Chapter 25.

### 39.7.4 `devfs_set_cdevpriv(9)`: Per-Open State

**Purpose.** Attach a driver-private pointer to an open file descriptor. The pointer is freed by a callback when the last close occurs.

**Key names.**

- `int devfs_set_cdevpriv(void *priv, d_priv_dtor_t *dtor);`
- `int devfs_get_cdevpriv(void **datap);`
- `void devfs_clear_cdevpriv(void);`

**Header.** `/usr/src/sys/sys/conf.h`.

**Caveats.**

- Per-open state is the right tool for per-descriptor settings, cursors, or pending transactions. Do not store per-open state in the softc.
- The destructor runs in the context of the last close. Keep it short and non-blocking.

**Manual page.** `devfs_set_cdevpriv(9)`.

**Where the book teaches this.** Chapter 8.

## 39.8 Process and User-Space Interaction

Userland cannot be trusted with kernel addresses, and the kernel cannot be trusted to follow userland pointers without care. The APIs below cross the trust boundary safely.

### 39.8.1 `copyin(9)`, `copyout(9)`, `copyinstr(9)`

**Purpose.** Move bytes between kernel and user address spaces with address validation. These are the only safe way to touch a user pointer from kernel code.

**Key names.**

- `int copyin(const void *uaddr, void *kaddr, size_t len);`
- `int copyout(const void *kaddr, void *uaddr, size_t len);`
- `int copyinstr(const void *uaddr, void *kaddr, size_t len, size_t *done);`
- Related: `fuword`, `fuword`, `subyte`, `suword`, documented under `fetch(9)` and `store(9)`.

**Header.** `/usr/src/sys/sys/system.h`.

**Caveats.**

- All three may sleep. Do not call them while holding a non-sleepable mutex.
- They return `EFAULT` on a bad address, not zero. Always check the return value.
- `copyinstr` distinguishes truncation from success via its `done` argument; do not ignore it.

**Lifecycle phase.** `d_ioctl`, `d_read`, `d_write`, and anywhere else userland is the source or destination.

**Manual pages.** `copy(9)`, `fetch(9)`, `store(9)`.

**Where the book teaches this.** Chapter 9.

### 39.8.2 uio(9): I/O Descriptor for Read and Write

**Purpose.** The kernel's own description of an I/O request. Hides the difference between user and kernel buffers, between scatter-gather and contiguous transfers, and between read and write directions.

**Key names.**

- `int uiomove(void *cp, int n, struct uio *uio);`
- `int uiomove_nofault(void *cp, int n, struct uio *uio);`
- Fields in `struct uio`: `uio_iov`, `uio_iovcnt`, `uio_offset`, `uio_resid`, `uio_segflg`, `uio_rw`, `uio_td`.
- Segment flags: `UIO_USERSPACE`, `UIO_SYSSPACE`, `UIO_NOCOPY`.
- Direction: `UIO_READ`, `UIO_WRITE`.

**Header.** `/usr/src/sys/sys/uio.h`.

**Caveats.**

- Use `uiomove` in `d_read` and `d_write` entry points. It is the right tool even when the userland buffer is a simple contiguous region.
- `uiomove` may sleep. Drop non-sleepable mutexes before calling it.
- After `uiomove` returns, `uio_resid` has been updated. Do not maintain your own byte count in parallel; read it from `uio_resid`.

**Lifecycle phase.** Normal I/O.

**Manual page.** `uio(9)`.

**Where the book teaches this.** Chapter 9.

### 39.8.3 proc(9) and Thread Context for Drivers

**Purpose.** Access to the calling thread and its process, primarily for credential checks, signal state, and diagnostic printing.

**Key names.**

- `curthread`, `curproc`, `curthread->td_proc`.
- `struct ucred *cred = curthread->td_ucred;`
- `int priv_check(struct thread *td, int priv);`
- `pid_t pid = curproc->p_pid;`

**Header.** `/usr/src/sys/sys/proc.h`.

**Caveats.**

- Direct use of process internals is rare. When you need it, it is usually for a credential check, which should go through `priv_check(9)`.
- Do not store `curthread` across sleeps. The thread that re-enters the driver may be a different one.

**Manual page.** No single page; see `priv(9)` and `proc(9)`.

**Where the book teaches this.** Referenced in Chapter 9 and Chapter 24 when `ioctl` handlers need credentials.

## 39.9 Observability and Notification

A driver that cannot be observed is a driver that cannot be trusted. The kernel provides several ways for userland to peek at driver state, subscribe to events, and wait for readiness. The APIs below are the most common.

### 39.9.1 `sysctl(9)`: Read-and-Write Configuration Nodes

**Purpose.** Publish driver state and tunables under a hierarchical name so tools like `sysctl(8)` and monitoring scripts can read or modify them.

**Key names.**

- Static declarations: `SYSCTL_NODE`, `SYSCTL_INT`, `SYSCTL_LONG`, `SYSCTL_STRING`, `SYSCTL_PROC`, `SYSCTL_OPAQUE`.
- Dynamic context API: `sysctl_ctx_init`, `sysctl_ctx_free`, `SYSCTL_ADD_NODE`, `SYSCTL_ADD_INT`, `SYSCTL_ADD_PROC`.
- Handler helpers: `sysctl_handle_int`, `sysctl_handle_long`, `sysctl_handle_string`.
- Access flags: `CTLFLAG_RD`, `CTLFLAG_RW`, `CTLFLAG_TUN`, `CTLFLAG_STATS`, `CTLTYPE_INT`, `CTLTYPE_STRING`.

**Header.** `/usr/src/sys/sys/sysctl.h`.

**Caveats.**

- For anything tied to a specific device instance, use the dynamic API. `device_get_sysctl_ctx` and `device_get_sysctl_tree` give you the right context.
- Handlers run in user context. They may sleep and may fail.
- Publish tunables sparingly. Every knob is a contract with future users.

**Lifecycle phase.** Static declarations are module-wide. Dynamic declarations are created in attach and destroyed automatically in detach through the context.

**Manual pages.** `sysctl(9)`, `sysctl_add_oid(9)`, `sysctl_ctx_init(9)`.

**Where the book teaches this.** Introduced in Chapter 7, with deeper treatment in Chapter 24 (Section 4) when the driver starts exposing metrics to userland.

### 39.9.2 `eventhandler(9)`: In-Kernel Publish-Subscribe

**Purpose.** Register for kernel-wide events such as mount, unmount, low memory, and shutdown. The kernel invokes registered callbacks in response.

**Key names.**

- `EVENTHANDLER_DECLARE(name, type_t);`
- `eventhandler_tag EVENTHANDLER_REGISTER(name, func, arg, priority);`
- `void EVENTHANDLER_DEREGISTER(name, tag);`
- `void EVENTHANDLER_INVOKE(name, ...);`
- Priority constants: `EVENTHANDLER_PRI_FIRST`, `EVENTHANDLER_PRI_ANY`, `EVENTHANDLER_PRI_LAST`.

**Header.** `/usr/src/sys/sys/eventhandler.h`.

**Caveats.**

- Handlers run synchronously. Keep them short.
- Always deregister before module unload. A dangling handler will panic when the event fires.

**Manual page.** `EVENTHANDLER(9)`.

**Where the book teaches this.** Referenced in Chapter 24 when drivers integrate with kernel-wide notifications such as shutdown and low-memory events.

### 39.9.3 `poll(2)` and `kqueue(2)`: Readiness Notification

**Purpose.** Let userland wait for driver-owned readiness events. `poll(2)` is the older interface; `kqueue(2)` is the modern one with richer filters.

**Key names.**

- Entry point for `poll`: `int (*d_poll)(struct cdev *, int events, struct thread *)`;
- Entry point for `kqueue`: `int (*d_kqfilter)(struct cdev *, struct knote *)`;
- Wait-list management: `struct selinfo`, `selrecord(struct thread *td, struct selinfo *sip)`, `selwakeup(struct selinfo *sip)`.
- `kqueue` support: `struct knote`, `knote_enqueue`, `knlist_init_mtx`, `knlist_add`, `knlist_remove`.
- Event bits: `POLLIN`, `POLLOUT`, `POLLERR`, `POLLHUP` for `poll`; `EVFILT_READ`, `EVFILT_WRITE` for `kqueue`.

**Headers.** `/usr/src/sys/sys/selinfo.h`, `/usr/src/sys/sys/event.h`, `/usr/src/sys/sys/poll.h`.

**Caveats.**

- `d_poll` must call `selrecord` when no events are ready and report current readiness when they are.
- `selwakeup` must be called with no mutex held that might invert against the scheduler. This is a common lock-order bug.
- `kqueue` support is richer but also more code. When the driver already has a clean `poll` path, extending it to `kqueue` is often the right next step rather than a rewrite.

**Lifecycle phase.** Setup in `attach`; tear down in `detach`; actual dispatch in `d_poll` or `d_kqfilter`.

**Manual pages.** `selrecord(9)`, `kqueue(9)`, and the userland pages `poll(2)` and `kqueue(2)`.

**Where the book teaches this.** Chapter 10 introduces `poll(2)` integration in full; `kqueue(2)` is referenced there and explored in depth in Chapter 35.

## 39.10 Diagnostics, Logging, and Tracing

Driver correctness does not just live in the code. It lives in the ability to observe, assert, and trace. The APIs below are how you make a driver tell the truth about itself.

### 39.10.1 `log(9)` and `printf(9)`

**Purpose.** Emit messages to the kernel log so they appear in `dmesg` and in `/var/log/messages`.

**Key names.**

- `void log(int level, const char *fmt, ...);`
- Standard kernel `printf` family: `printf`, `vprintf`, `uprntf`, `tprintf`.
- Per-device helper: `device_printf(device_t dev, const char *fmt, ...);`
- Priority constants from `syslog.h`: `LOG_EMERG`, `LOG_ALERT`, `LOG_CRIT`, `LOG_ERR`, `LOG_WARNING`, `LOG_NOTICE`, `LOG_INFO`, `LOG_DEBUG`.

**Headers.** `/usr/src/sys/sys/systm.h`, `/usr/src/sys/sys/syslog.h`.

**Caveats.**

- Do not log at `LOG_INFO` on the I/O fast path. It floods the console and masks real issues.
- `device_printf` automatically prepends the device name, which makes logs easy to filter. Prefer it over bare `printf`.
- Log once for each distinct event class, not once per packet.

**Lifecycle phase.** Any.

**Manual pages.** `printf(9)`.

**Where the book teaches this.** Chapter 23.

### 39.10.2 `KASSERT(9)`: Kernel Assertions

**Purpose.** Declare invariants that must be true. When the kernel is built with `INVARIANTS`, a violated assertion panics with a descriptive message. Without `INVARIANTS`, the assertion compiles away.

**Key names.**

- `KASSERT(expression, (format, args...));`
- `MPASS(expression);` for simpler message-free assertions.
- `CTASSERT(expression);` for compile-time assertions on constants.

**Header.** `/usr/src/sys/sys/kassert.h`, included transitively by `/usr/src/sys/sys/systm.h`.

**Caveats.**

- The expression must be cheap and free of side effects. The compiler does not optimise it into place; you write the invariant.
- The message is a parenthesised `printf` argument list. Include enough context to diagnose a failure from the panic alone.
- Use `KASSERT` for conditions that indicate a programmer error, not for normal runtime conditions.

**Lifecycle phase.** Wherever an invariant must be documented and enforced.

**Manual page.** `KASSERT(9)`.

**Where the book teaches this.** Chapter 23 introduces `INVARIANTS` and assertion use; Chapter 34 Section 2 treats `KASSERT` and diagnostic macros in depth.

### 39.10.3 WITNESS: Lock-Order Verifier

**Purpose.** A kernel option that tracks the order in which each thread acquires locks and warns when a later thread reverses a previously observed order.

**Key names.**

- Built into `mtx(9)`, `sx(9)`, `rm(9)`, and the locking macros. No separate API call is needed.
- Kernel options: `WITNESS`, `WITNESS_SKIPSPIN`, `WITNESS_COUNT`.
- Assertions that cooperate with `WITNESS`: `mtx_assert`, `sx_assert`, `rm_assert`.

**Caveats.**

- `WITNESS` is a debugging option. Build a debug kernel to enable it; it is too expensive for production.
- Warnings are not noise. If `WITNESS` complains, there is a bug.
- Lock-order warnings reference the lock names passed to `mtx_init`, `sx_init`, and so on. Give each lock a meaningful name.

**Manual page.** No single page. See `lock(9)` and `locking(9)`.

**Where the book teaches this.** Chapter 12 (Section 6), with reinforcement in Chapter 23.

### 39.10.4 ktr(9): Kernel Trace Facility

**Purpose.** A low-overhead ring buffer for event tracing inside the kernel. `ktr` records are emitted by macros and can be dumped with `ktrdump(8)`.

**Key names.**

- `CTR0(class, fmt)`, `CTR1(class, fmt, a1)`, up to `CTR6` with increasing argument counts.
- Trace classes: `KTR_GEN`, `KTR_NET`, `KTR_DEV`, and many others in `sys/ktr_class.h`.
- Kernel option: `KTR` with per-class masks.

**Header.** `/usr/src/sys/sys/ktr.h`.

**Caveats.**

- `ktr` must be enabled at kernel build time; check for `KTR` in the configuration.
- Each record is small. Do not try to log entire structures.
- For user-facing diagnostics, `dttrace(1)` is often a better answer.

**Manual page.** `ktr(9)`.

**Where the book teaches this.** Chapter 23.

### 39.10.5 DTrace Static Probes and Major Providers

**Purpose.** Static and dynamic tracing infrastructure that lets userland attach to probe points in the running kernel without a recompile.

**Key names.**

- Statically defined tracing: `SDT_PROVIDER_DECLARE`, `SDT_PROVIDER_DEFINE`, `SDT_PROBE_DECLARE`, `SDT_PROBE_DEFINE`, `SDT_PROBE`.
- Common providers on FreeBSD: `sched`, `proc`, `io`, `vfs`, `fbt` (function boundary tracing), `sdt`.
- Headers: `/usr/src/sys/sdt.h`, `/usr/src/sys/cddl/dev/dtrace/...`

#### Caveats.

- `fbt` requires no change to the driver, but `sdt` probes give you named, stable points that survive future refactoring.
- A disabled probe has negligible cost. Do not worry about adding several of them.
- DTrace scripts themselves are userland code; the driver only defines the probe points that the scripts can attach to.

**Manual pages.** `SDT(9)`, `dtrace(1)`, `dtrace(8)`.

**Where the book teaches this.** Chapter 23.

## 39.11 Cross-Reference by Driver Lifecycle Phase

The same APIs show up in different phases of a driver's life. The table below is a quick reverse index: when you are writing a particular phase, here are the families that usually belong there.

### 39.11.1 Module Load

- `MODULE_VERSION`, `MODULE_DEPEND`, `DEV_MODULE` (if the module is a pure cdev).
- Static `MALLOC_DEFINE`, `SYSCTL_NODE`, `SDT_PROVIDER_DEFINE` declarations.
- Event-handler registration that must survive before any device attaches.

### 39.11.2 Probe

- `device_get_parent`, `device_get_nameunit`, `device_printf`.
- Return values: `BUS_PROBE_DEFAULT`, `BUS_PROBE_GENERIC`, `BUS_PROBE_SPECIFIC`, `BUS_PROBE_LOW_PRIORITY`, `ENXIO` on no match.

### 39.11.3 Attach

- `device_get_softc`, `malloc(9)` for `softc` fields, `MALLOC_DEFINE` tags.
- Locking initialisation: `mtx_init`, `sx_init`, `rm_init`, `cv_init`, `sema_init`.
- Resource allocation: `bus_alloc_resource` or `bus_alloc_resource_any`.
- `bus_space` setup through `rman_get_bustag` and `rman_get_bushandle`.
- DMA scaffolding: `bus_dma_tag_create`, `bus_dmamap_create`.
- `callout_init`, `TASK_INIT`, taskqueue creation when needed.
- Interrupt setup: `bus_setup_intr`.
- Device node creation: `make_dev_s`.
- `sysctl` tree: `device_get_sysctl_ctx`, `SYSCTL_ADD_*`.

- `uma_zcreate` for high-frequency objects.
- Eventhandler registration tied to this driver.

### 39.11.4 Normal Operation

- `d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl`, `d_poll`, `d_kqfilter`.
- `uiomove`, `copyin`, `copyout`, `copyinstr`.
- `bus_space_read_*`, `bus_space_write_*`, `bus_space_barrier`.
- `bus_dmamap_load`, `bus_dmamap_sync`, `bus_dmamap_unload`.
- Locking: `mtx_lock`, `mtx_unlock`, `sx_slock`, `sx_xlock`, `cv_wait`, `cv_signal`, `atomic_*`.
- Deferred work: `callout_reset`, `taskqueue_enqueue`.
- Diagnostics: `device_printf`, `log`, `KASSERT`, `SDT_PROBE`.

### 39.11.5 Detach

- Tear-down in reverse attach order.
- `bus_tearardown_intr` before any resource is released.
- `destroy_dev` before the softc fields it references are torn down.
- `callout_drain` before freeing the callout structure.
- `taskqueue_drain_all` and `taskqueue_free` for private taskqueues.
- `bus_dmamap_unload`, `bus_dmamap_destroy`, `bus_dma_tag_destroy`.
- `bus_release_resource` for every resource allocated in attach.
- `cv_destroy`, `sx_destroy`, `mtx_destroy`, `rm_destroy`, `sema_destroy`.
- `uma_zdestroy` for every zone the driver owns.
- Eventhandler deregistration.
- Final `free` or `contigfree` of anything allocated.

### 39.11.6 Module Unload

- Verify that no device instance is still attached. Newbus usually handles this, but defensive `DRIVER_MODULE` event handlers should refuse unload if state remains.

## 39.12 Quick-Reference Checklists

These checklists are meant to be read in five minutes or less. They do not replace the teaching in the chapters; they remind you of the things that experienced driver authors no longer forget.

### 39.12.1 Locking Discipline Checklist

- Every shared field in the softc has exactly one lock that protects it, documented in a comment near the field.
- No mutex is held across `uiomove`, `copyin`, `copyout`, `malloc(9, M_WAITOK)`, or `bus_alloc_resource`.
- Lock order is declared in a comment at the top of the file and respected everywhere.

- `mtx_assert` or `sx_assert` appears on functions that require a particular lock to be held on entry.
- `WITNESS` is enabled in the development kernel and its warnings are treated as bugs.
- Every `mtx_init` has a matching `mtx_destroy`, and so on for every lock type.

### 39.12.2 Resource Lifetime Checklist

- `bus_setup_intr` is the last thing in `attach`; `bus_tearardown_intr` is the first thing in `detach`.
- Every allocated resource has a matching release, in reverse order, in `detach`.
- `callout_drain` is called before the structure it points at is freed.
- `taskqueue_drain_all` or `taskqueue_drain` is called before the task structures or their arguments are freed.
- `destroy_dev` is called before the `softc` fields referenced by `mda_si_drv1` are torn down.

### 39.12.3 User-Space Safety Checklist

- No user pointer is dereferenced directly. Every cross-boundary access goes through `copyin`, `copyout`, `copyinstr`, or `uiomove`.
- All return values from the copy helpers are checked. `EFAULT` is propagated rather than ignored.
- `_IOR`, `_IOW`, and `_IOWR` are used for `ioctl` command numbers.
- `Ioctl` handlers validate arguments before acting on them.
- Credentials are checked with `priv_check(9)` when the operation is privileged.

### 39.12.4 Diagnostic Coverage Checklist

- Every major branch that should never be taken carries a `KASSERT`.
- Logs use `device_printf` for instance context.
- At least one DTrace SDT probe marks entry to the main I/O paths.
- `sysctl` exposes the driver's counters in a stable, documented tree.
- The driver has been built and exercised under `INVARIANTS` and `WITNESS` before it is considered done.

## 39.13 Wrapping Up

This appendix is a reference, not a chapter. It becomes more useful the more you use it. Keep it within reach while you are writing, debugging, or reading driver code, and turn to it whenever you want a fast reminder about a flag, a manual page, or a caveat you almost remember.

Three suggestions for getting the most out of it over time.

First, treat the **Manual pages** line as the canonical next step for any API you only half remember. The manual pages in section 9 are maintained with the tree; they age well. Opening one of them costs nothing and pays back every time.

Second, treat the **Caveats** line as a debugging companion. Most driver bugs are not unknown unknowns. They are documented caveats that the author skipped under time pressure. When you are stuck, read the caveats for every API the problem area touches. It is unglamorous but effective.

Third, when you find a missing entry or a correction to make, write it down. This appendix improves as drivers improve. The FreeBSD kernel is alive and so is the reference. If a new primitive appears, or an old one is retired, the appendix that matches reality is the one you will actually trust.

From here you can jump in several directions. Appendix E covers FreeBSD internals and subsystem behaviour at a depth this reference deliberately avoids. Appendix B collects the algorithms and systems-programming patterns that recur throughout the kernel. Appendix C grounds the hardware concepts that the bus and DMA families depend on. And every chapter in the main book still has source code you can read, labs you can run, and questions you can answer by opening `/usr/src/` and looking at the real thing.

Good reference material is quiet. It stays out of the way while you work, and it is there when you need it. That is the role this appendix is meant to play for the rest of your driver-writing life with FreeBSD.

## 40 Appendix B: Algorithms and Logic for Systems Programming

### 40.1 How to Use This Appendix

The main chapters teach the primitives a driver author uses day to day. Alongside those primitives there is a second layer of knowledge that the book assumes without always naming it: the small catalogue of data structures, control-flow shapes, and reasoning patterns that show up in nearly every driver you will read. A red-black tree in a virtual-memory subsystem, a STAILQ of pending requests on the side of a softc, a goto out ladder that unwinds an attach routine, a switch on a state enum that drives a protocol handshake. None of these ideas is hard in isolation. What makes them feel hard is meeting them for the first time embedded in real kernel code, where the pattern is implicit and the name is nowhere on the page.

This appendix is that missing name. It is a short, practical field guide to the algorithmic patterns that recur across FreeBSD kernel and driver code, organised so that you can recognise a pattern when you see it and decide which pattern fits when you have to write one. It is not a computer-science textbook, and it is not a replacement for the chapters that already teach the specific pieces you will use most. What it provides is a middle layer: enough pattern recognition to let you read driver code confidently, enough mental modelling to pick the right structure when the blank page stares back at you, and enough caveat awareness to avoid the mistakes that every driver author eventually makes once.

#### 40.1.1 What You Will Find Here

The appendix is organised by problem family, not by abstract taxonomy. Each family collects a few related patterns with a consistent short structure:

- **What it is.** One or two sentences.
- **Why drivers use it.** The concrete role in kernel or driver code.
- **Use this when.** A compact decision hint.
- **Avoid this when.** The other side of the same decision.
- **Core operations.** The handful of names you need in muscle memory.
- **Common traps.** The mistakes that actually cost people time.
- **Where the book teaches it.** A pointer back to the main chapters.
- **What to read next.** A manual page or a realistic source-tree example.

When a pattern has a real FreeBSD implementation with a stable interface, the entry uses those names directly. When the pattern is generic, the entry still grounds itself in how FreeBSD drivers actually apply it.

### 40.1.2 What This Appendix Is Not

It is not a first course in algorithms. If you have never met a linked list or a state machine before, this appendix will feel too compressed; read Chapters 4 and 5 first, then come back. It is not a deep theoretical reference either. You will find almost no asymptotic analysis here, because driver authors rarely choose between  $O(\log n)$  and  $O(n)$  on paper. They choose between patterns whose trade-offs are mostly about locking, cache behaviour, and invariants. Finally, it is not a replacement for Appendix A (which covers the APIs), Appendix C (which covers hardware concepts), or Appendix E (which covers kernel subsystems). If the pattern you want points you there, go there and come back.

## 40.2 Reader Guidance

Three ways to read this appendix, each calling for a different strategy.

If you are **writing new code**, skim the problem family that matches your situation, read the one or two entries that apply, glance at the **Common traps** line, and close the appendix. Thirty seconds is enough. Start from the pattern, not from the code.

If you are **reading someone else's driver**, treat the appendix as a translator. When you see an unfamiliar idiom, find the family that names it, read **What it is** and **Core operations**, and keep moving. Full understanding can come later; right now the goal is to form a mental model of what the driver is doing.

If you are **debugging**, read the **Common traps** lines in the pattern family around the bug. Most driver bugs that look mysterious are ordinary caveats the author did not honour. A ring buffer with a stale full check, an unwind ladder that frees in the wrong order, a state machine that forgot a transient state. The traps in this appendix are not exhaustive, but they cover the ones that recur.

A few conventions apply throughout:

- Source paths are shown in the book-facing form, `/usr/src/sys/...`, matching a standard FreeBSD system.
- Manual pages are cited in the usual FreeBSD style. For the data-structure macros, the authoritative pages live in section 3: `queue(3)`, `tree(3)`, `bitstring(3)`. For kernel services such as `hashinit(9)`, `buf_ring(9)`, `refcount(9)`, the pages live in section 9. The distinction matters only when you type `man` at the prompt.
- When an entry points to real source as a reading example, it points to a file that a beginner can open and navigate. Larger subsystems exist that also use the pattern; those are mentioned only when they are the canonical place to see a pattern in practice.

With that in mind, we start with the structures a driver uses to hold state.

## 40.3 Data Structures in the Kernel

A driver without state is rare. Almost every non-trivial driver keeps a collection of something: pending requests, open handles, per-CPU statistics, per-channel configuration, per-client contexts. The question is which collection shape matches the access pattern. The kernel ships a small toolkit of header-file data structures that you

should reach for by default instead of rolling your own. Each of them solves a different problem; confusing them is one of the most common category errors in driver design.

### 40.3.1 The `<sys/queue.h>` Family

**What it is.** A family of intrusive linked-list macros. You define a head and an entry, embed the entry inside your element structure, and the macros give you insertion, removal, and traversal without heap allocation for list nodes.

The header defines four flavours:

- `SLIST` is a singly linked list. Cheapest, forward only,  $O(n)$  removal of arbitrary elements.
- `LIST` is a doubly linked list. Forward and backward traversal,  $O(1)$  removal of an arbitrary element.
- `STAILQ` is a singly linked tail queue. Forward only, but with fast insertion at the tail. Classic FIFO.
- `TAILQ` is a doubly linked tail queue. Every operation you can reasonably want, at the cost of two pointers per element.

**Why drivers use them.** Almost every per-driver collection in the tree is one of these. Pending commands, open file handles, registered callbacks, child devices. They are predictable, allocation-free at the list level, and the macros make the code read almost like pseudocode.

**Use this when** you have a collection of objects you already allocate yourself, and you want standard list operations without inventing them. The intrusive design means an object can live in several lists at once; that is a feature, not a bug.

**Avoid this when** you need ordered lookup by key. A list is  $O(n)$  to search. Reach for a tree or a hash table instead.

#### Choosing among the four.

- Start with `TAILQ` unless you have a reason not to. It is the most common and the most flexible.
- Drop to `STAILQ` when you know you only ever push and pop like a queue. You save one pointer per element.
- Use `LIST` when you want doubly linked behaviour but do not need a tail pointer. Unordered sets of independent elements, for example.
- Use `SLIST` when every byte counts and the list is short or traversal is linear anyway. Fast paths in hot structures sometimes justify it.

**Core operations.** The macros are uniform across flavours. Insertion: `TAILQ_INSERT_HEAD`, `TAILQ_INSERT_TAIL`, `TAILQ_INSERT_BEFORE`, `TAILQ_INSERT_AFTER`. Removal: `TAILQ_REMOVE`. Traversal: `TAILQ_FOREACH`, plus the `_SAFE` variant when you may remove the current element. The same operations exist with `LIST_`, `STAILQ_`, and `SLIST_` prefixes. Field storage is an embedded `TAILQ_ENTRY(type)` in your struct.

#### Common traps.

- Using the non-`_SAFE` foreach while removing elements. Plain `TAILQ_FOREACH(var, head, field)` expands to a for loop that reads `TAILQ_NEXT(var, field)` at the end of each iteration. If the body freed `var`, the next step dereferences freed memory. `TAILQ_FOREACH_SAFE(var, head, field, tmp)` caches the next pointer into `tmp` before the body runs, and is always the right answer when the loop body may remove `var`.

- Forgetting that the list is intrusive. The same element cannot be in two TAILQs through the same entry field at once. If you need that, define two TAILQ\_ENTRY fields with different names.
- Mixing flavours on the same head. SLIST\_INSERT\_HEAD on a TAILQ\_HEAD compiles but produces silent corruption. Keep the macros consistent with the head type.

**Where the book teaches this.** Introduced briefly in Chapter 5 as part of the kernel dialect of C and revisited whenever a driver in later parts of the book needs an internal collection.

**What to read next.** `queue(3)` for the full macro catalogue, and any real driver that keeps pending work. `/usr/src/sys/net/if_tuntap.c` uses these idioms extensively.

### 40.3.2 Red-Black Trees via `<sys/tree.h>`

**What it is.** A set of macros that generate a self-balancing binary search tree inlined into your types. FreeBSD's implementation is rank-balanced, but it exposes the historical RB\_ prefix and behaves like a red-black tree for all practical purposes.

**Why drivers use them.** When you need  $O(\log n)$  ordered lookup by a key and the key is not a small integer, a red-black tree is the default. Virtual-memory maps, scheduler run-queues in some subsystems, and per-subsystem registries of named objects all use this header.

**Use this when** you have a collection of objects indexed by a key, the set grows to hundreds or thousands of entries, and you care about ordered traversal as well as lookup.

**Avoid this when** the set is small (a dozen elements) or the key space is small and dense. A linear scan on a cache-hot array usually beats a tree in both cases, because the constant factor of a pointer chase is much higher than a sequential read.

**Core operations.** `RB_HEAD(name, type)` defines the head type, `RB_ENTRY(type)` defines the embedded node field, `RB_PROTOTYPE` and `RB_GENERATE` instantiate the function family (insert, remove, find, min, max, next, prev, foreach). You also write a comparison function that returns negative, zero, or positive the way `strcmp(3)` does. A variant `SPLAY_` family in the same header gives splay trees when locality of reference is important.

#### Common traps.

- Calling `RB_GENERATE` in a header. That produces multiple definitions at link time. Keep `RB_GENERATE` in exactly one .c file and `RB_PROTOTYPE` in the header that declares the type.
- Forgetting that the tree is intrusive. An element cannot live in two trees through the same entry, and removing from the wrong tree silently corrupts both.
- Holding a pointer across an insert. Balance rotations do not move nodes, but the comparator must be consistent; if your key changes while the node is in the tree, you have invalidated the search structure and every subsequent lookup is undefined.

**Where the book teaches this.** Not taught as a dedicated pattern in the book. The reader meets it through example when Appendix E walks the virtual-memory subsystem and when advanced drivers in Part 7 reach for ordered lookup.

**What to read next.** `tree(3)` for the macro catalogue, and any subsystem that keeps an ordered set of named things.

### 40.3.3 Radix Trees via `<net/radix.h>`

**What it is.** A kernel-specific radix (or Patricia) tree, primarily used by the routing table to match addresses against prefixes. A radix tree differs from a red-black tree in that it keys on prefix length rather than total order, which is precisely what longest-prefix-match needs. The header lives at `/usr/src/sys/net/radix.h`, alongside the rest of the networking code, rather than under `/usr/src/sys/sys/`.

**Why drivers use them.** Rarely, directly. The radix tree exists because the networking stack needs it, and the machinery is specialised to that use. A driver almost never creates its own radix tree. You may meet one as a caller in network-adjacent code, or you may see the related LinuxKPI radix-tree shim in compatibility layers.

**Use this when** you genuinely need prefix matching over keys of varying length. Routing, ACL tables, prefix-based policy.

**Avoid this when** what you actually need is ordered lookup by exact key. Use `<sys/tree.h>` instead.

**Core operations.** `rn_inithead`, `rn_addroute`, `rn_delete`, `rn_lookup`, `rn_match`, `rn_walktree`. These are specialised enough that the routing subsystem is the canonical reference.

**Common traps.** The header and the routines are tightly coupled to the routing-table abstraction. Attempting to reuse the radix tree for non-routing data structures is almost always a mistake; the abstraction will leak in uncomfortable ways. The LinuxKPI radix tree in `/usr/src/sys/compat/linuxkpi/common/include/linux/radix-tree.h` is a different structure and should not be confused with the native one.

**Where the book teaches this.** Only mentioned in Appendix E alongside the routing table. This appendix names it so you can recognise it in passing.

**What to read next.** The routing-table code under `/usr/src/sys/net/`.

### 40.3.4 Bitmaps and Bit-Strings via `<sys/bitstring.h>`

**What it is.** A compact set-of-bits abstraction backed by an array of machine words. You allocate a bit-string of *N* bits, then set, clear, test, and scan individual bits.

**Why drivers use them.** Any time you have a dense finite universe and want to track boolean state for each element. Free-slot bitmaps for a fixed pool of hardware descriptors, interrupt allocations, minor numbers, per-channel enable flags. A bitmap uses one bit per element and supports efficient first-free searches.

**Use this when** the universe is dense, known in advance, and you track boolean state per element. Bitmaps are particularly effective when you need “find the first free slot” or “how many are set”.

**Avoid this when** the universe is sparse. A set of a few thousand used slot numbers in a 32-bit key space does not belong in a bitmap; use a hash table or a tree.

**Core operations.** `bit_alloc` (kernel allocator variant) and `bit_decl` (stack), `bit_set`, `bit_clear`, `bit_test`, `bit_nset`, `bit_nclear` for ranges, `bit_ffs` for first-set, `bit_ffc` for first-clear, `bit_foreach` for iteration. Sizes are computed with `bitstr_size(nbits)`.

**Common traps.**

- Forgetting that bit indices are zero-based and that the `bit_ffs` / `bit_ffc` macros do not return a value; they write the found index into `*_resultp` and set it to `-1` when nothing matched. Always check `if (result < 0)` before using the index.

- Race conditions under concurrent modification. `bitstring(3)` is not atomic; if two contexts can set or clear bits concurrently, they need a lock or a coordinated handoff.
- Allocating the wrong size. Use `bitstr_size(nbits)` rather than doing the division by hand.

**Where the book teaches this.** Not taught directly. A driver that needs a free-slot bitmap will reach for this header, and this entry is the pointer.

**What to read next.** `bitstring(3)`.

### 40.3.5 Hash Tables with `hashinit(9)`

**What it is.** A small helper pattern for building hash tables out of `<sys/queue.h>` lists. `hashinit(9)` allocates a power-of-two array of `LIST_HEAD` buckets and gives you back the array and a mask. Your code hashes the key to a 32-bit value, ANDs it with the mask, and walks the resulting bucket.

**Why drivers use them.** When you need unordered lookup by key and the set is large enough that a linear scan is too slow. File-system name caches, open-file tables per-process, and any driver that maintains a registry keyed by hashable identifier all use this shape.

**Use this when** the set is large, lookups are frequent, and ordering does not matter. A hash table beats a tree on average-case lookup and is easier to lock coarsely (one lock per bucket, or one lock for the whole table if writes are rare).

**Avoid this when** the set is small (a tree or a list is simpler) or you need ordered traversal (`RB_FOREACH` is the answer, not hashing).

**Core operations.** `void *hashinit(int elements, struct malloc_type *type, u_long *hashmask);` returns the bucket array and writes the mask to `*hashmask`. Each bucket is a `LIST_HEAD`, so you insert and iterate with the usual `LIST_` macros. `hashdestroy` tears it down. `hashinit_flags` takes an extra flags word (`HASH_WAITOK` or `HASH_NOWAIT`) when you need the non-sleeping variant; `hashinit` itself is equivalent to `HASH_WAITOK`. `phashinit` and `phashinit_flags` give you a prime-sized table when you prefer modulo arithmetic to masking, and write the chosen size (not a mask) through the out-pointer. A small `<sys/hash.h>` header provides basic hash functions such as `hash32_buf` and `hash32_str`, along with `jenkins_hash` and `murmur3_32_hash`; the Fowler-Noll-Vo family lives in `<sys/fnv_hash.h>`.

#### Common traps.

- Hashing a pointer directly. Pointer low bits are usually aligned and produce poor bucket distribution. Use a proper hash function on the contents or on the shifted pointer.
- Assuming `hashinit` uses your requested size. It rounds down to the nearest power of two and returns the mask for that size. A request for 100 elements produces a 64-bucket table, not 100.
- Forgetting the lock story. A bare hash table is not thread-safe. Decide up front whether you want a single lock, per-bucket locks, or something fancier, and document it in the softc.

**Where the book teaches this.** Briefly referenced in Part 7 drivers that maintain a per-client registry. This entry gives the scaffolding for when you need to build one yourself.

**What to read next.** `hashinit(9)`, and the implementation in `/usr/src/sys/kern/subr_hash.c`.

## 40.4 Circular and Ring Buffers

Rings appear everywhere in a driver that mediates between hardware and software. A NIC hands out a ring of descriptors for packet transmission. A UART buffers characters between the interrupt that receives them and the process that consumes them. A command driver batches requests into a ring for the hardware engine to pick up. The shape is always the same: a fixed-size array plus a producer index and a consumer index that wrap around. What varies is who is concurrent with whom, which primitives you use, and whether the ring needs to be lock-free.

### 40.4.1 Single-Producer Single-Consumer Ring Buffers

**What it is.** A fixed-size circular buffer where exactly one context produces and exactly one context consumes. The producer advances a head (or tail) index after writing; the consumer advances a tail (or head) index after reading; neither ever writes the other's index.

**Why drivers use them.** The interrupt handler produces data (a received character, a completion event), and a thread consumes it. That is the prototypical SPSC shape. It is lock-free by construction, because no two contexts modify the same variable.

**Use this when** you have exactly one producer and exactly one consumer, and you want to avoid a lock. Character device ring buffers are the classic case.

**Avoid this when** more than one thread can produce, or more than one thread can consume. Adding a second producer breaks the invariant; you need a lock, or you need `buf_ring(9)`.

**Core operations and invariants.** The usual invariants are:

- head advances only by the producer; tail advances only by the consumer.
- $(\text{head} - \text{tail}) \bmod \text{capacity}$  is the number of occupied slots.
- $\text{capacity} - (\text{head} - \text{tail}) \bmod \text{capacity}$  is the number of free slots (minus one, depending on the encoding).
- The buffer is empty when `head == tail`.
- The buffer is full when  $(\text{head} + 1) \bmod \text{capacity} == \text{tail}$ . The one sacrificed slot is how you distinguish full from empty.

The alternative encoding uses a separate count variable or uses free-running indices modulo the capacity with a mask (`head & mask`, `tail & mask`). Free-running indices make full-versus-empty a signed comparison and avoid the sacrificed slot.

#### Common traps.

- Mixing up full and empty without the one-slot convention. Every ring design must have a clear answer; pick one and write it at the top of the file.
- Not ordering memory properly. On modern CPUs, writes can become visible out of order. The producer must make sure the buffer contents are visible to the consumer before the updated head is. In the kernel that means an explicit memory barrier (`atomic_thread_fence_rel` on the producer, `atomic_thread_fence_acq` on the consumer), or using the atomic store-release and load-acquire variants.

- Assuming capacity is a power of two when the code does not enforce it. Masking requires a power of two; modulo does not. The code and the invariant must agree.

**Where the book teaches this.** Chapter 10 builds a circular buffer for the `myfirst` driver's character device and teaches the head/tail/full/empty discipline from first principles. Revisited in Chapters 11 and 12 when the ring meets synchronisation.

**What to read next.** The circular-buffer example from Chapter 10 in the companion `examples/` tree, and any small character-device driver that uses a ring to bridge interrupt and process context.

#### 40.4.2 `buf_ring(9)` for MPMC Rings

**What it is.** FreeBSD's kernel ring-buffer library. `buf_ring` provides a multi-producer multi-consumer ring with lock-free enqueue and both single-consumer and multi-consumer dequeue paths. It is used heavily by `iflib`, networking drivers, and elsewhere in the tree.

See Chapter 11 for the introduction and the `buf_ring(9)` man page for the authoritative concurrency contract.

**Why drivers use them.** When more than one context can enqueue (several CPUs pushing packets onto the same transmit queue) or more than one context can dequeue (several worker threads draining the same work queue), you cannot get away with the SPSC invariants. `buf_ring` does the atomic compare-and-swap work for you and hides the memory-ordering details behind a stable interface.

**Use this when** you have multiple producers or multiple consumers and you want a lock-free path. Network-adjacent drivers are the canonical case.

**Avoid this when** you truly have one producer and one consumer. The SPSC ring is simpler, cheaper, and easier to reason about.

**Core operations.** `buf_ring_alloc(count, type, flags, lock)` and `buf_ring_free` at setup and teardown. `buf_ring_enqueue(br, buf)` enqueues, returning 0 on success or `ENOBUFFS` when full. `buf_ring_dequeue_mc(br)` dequeues safely under multiple consumers; `buf_ring_dequeue_sc(br)` is faster when the caller guarantees single-consumer semantics. `buf_ring_peek`, `buf_ring_count`, `buf_ring_empty`, `buf_ring_full` give you inspection without removing.

##### Common traps.

- Calling `buf_ring_dequeue_sc` from multiple consumers at once. The SC path assumes only one consumer is running; violating that corrupts the tail index silently.
- Treating `ENOBUFFS` as a hard error. `buf_ring_enqueue` returning `ENOBUFFS` is an ordinary back-pressure signal; the caller must either retry, drop, or queue on a slower path.
- Forgetting that `buf_ring_count` and `buf_ring_empty` are advisory. Another CPU may enqueue or dequeue the moment after you check. Design the caller around eventual consistency, not instantaneous truth.

**Where the book teaches this.** Named in Chapter 10 as the production-grade counterpart to the pedagogical SPSC ring. Used in Part 5 networking chapters when driver examples need real ring semantics.

**What to read next.** `buf_ring(9)`, and the header itself at `/usr/src/sys/sys/buf_ring.h`. For a real user, browse `iflib` or any high-performance NIC driver under `/usr/src/sys/dev/`.

### 40.4.3 Wrap-Around Arithmetic and the Full-vs-Empty Problem

Every ring has to distinguish full from empty. The two states satisfy `head == tail` or are one slot apart, and the encoding you pick decides which comparison to use. The two common conventions are worth naming so you can spot them in code.

- **Sacrificed slot.** The ring holds `capacity - 1` usable slots. Empty is `head == tail`. Full is `(head + 1) mod capacity == tail`. Simple, cheap, works with any capacity.
- **Free-running indices.** `head` and `tail` count every operation since the ring was created and never wrap. The modular index for array access is `head & mask` (which requires `capacity` to be a power of two). Occupied count is `head - tail` as unsigned arithmetic; full is `occupied == capacity`; empty is `occupied == 0`. The advantage is that you never sacrifice a slot; the cost is that you must write `(uint32_t)(head - tail)` carefully.

Both conventions are correct. Pick one and make it a one-sentence comment at the top of the file. Readers who know ring buffers will know what to look for; readers who do not will have the comment.

## 40.5 Sorting and Searching

Drivers sort and search less often than they list, ring, or tree things. But when they do, a small toolkit covers almost every case, and knowing which tool is appropriate saves time.

### 40.5.1 In-Kernel `qsort` and `bsearch`

**What it is.** The kernel provides the familiar `qsort` and `bsearch` from the standard library, declared in `/usr/src/sys/sys/libkern.h`. A thread-safe variant `qsort_r` passes a user context pointer through to the comparator.

**Use this when** you need to sort an array in place once or occasionally, or when you need binary search over a sorted array. Device ID tables, compatibility matching, and sorted snapshots all fit here.

**Avoid this when** the collection is long-lived and changes frequently. In that case you want a tree, not a sort-and-search pair. Also avoid `qsort` on hot paths: the function-call overhead of the comparator dominates for small arrays.

**Core operations.** `qsort(base, nmemb, size, cmp)` and `qsort_r(base, nmemb, size, cmp, thunk)` for sorting; `bsearch(key, base, nmemb, size, cmp)` for searching. The comparator returns negative, zero, or positive in the `strcmp(3)` style. All three are declared in `libkern.h` and have section-3 manual pages (`qsort(3)`, `bsearch(3)`).

#### Common traps.

- Non-stable comparisons. `qsort` is not guaranteed stable. If ordering among equal keys matters, add a tiebreaker to the comparator.
- Passing a comparator that tests with subtraction (`a->x - b->x`) when the fields are wide. Integer overflow can make a negative look positive. Use explicit comparisons (`a->x < b->x ? -1 : a->x > b->x ? 1 : 0`).

**Where the book teaches this.** Referenced in Chapter 4 (the C tour) and in Part 7 where specific drivers sort a table once at attach.

**What to read next.** `qsort(3)`, `bsearch(3)`.

### 40.5.2 Binary Search Over Device ID Tables

**What it is.** A specialised application of `bsearch`. A driver maintains a sorted table of (vendor, device) or compatible-string keys, and the probe path does a binary search to decide whether the hardware is one it supports.

**Why drivers use it.** A PCI driver may match dozens of device IDs. A scan through the table is fine at attach time; doing it linearly works. Doing it with `bsearch` is a small, readable, fast improvement when the table grows.

**Use this when** the ID table is longer than a handful of entries and ordering by key is easy. You can sort at compile time by declaring the table statically sorted, or once at module load with `qsort`.

**Avoid this when** the match is not a simple key comparison. PCI matching sometimes involves subclass and programming interface fields; express the matching logic directly rather than contorting it into a comparator.

**Common traps.** Sorting at runtime and then relying on the sort for ABI compatibility. If another piece of code reads the table by index, changing the order breaks it. Declare the table `const` and sort at build time when you can.

**Where the book teaches this.** Referenced in Chapter 18 (PCI) and in the device-matching discussion in Chapter 6.

**What to read next.** Any PCI driver's ID table and probe path. `/usr/src/sys/dev/uart/uart_bus_pci.c` is a readable example.

### 40.5.3 When Linear Search Wins

**What it is.** A reminder that for small collections, linear search on a cache-hot array is the fastest lookup you can write. CPU caches reward sequential reads and punish pointer chasing.

**Use this when** the collection has fewer than a few dozen entries. In practice, a linear scan on twenty items is faster than any tree lookup, because the tree walk takes several cache misses while the linear scan takes one.

**Avoid this when** the collection grows without bound, or when the hot-path latency requirement is tight and the worst case matters more than the average.

**Common traps.** Optimising the wrong side. Do not introduce a tree to cure “linear search is slow” before measuring. The real cost is usually elsewhere.

## 40.6 State Machines and Protocol Handling

Many drivers are state machines in disguise. A USB device probes, attaches, goes idle, resumes, suspends, detaches. A network driver goes through link-down, link-up, negotiation, steady-state, error recovery. When the state transitions are complicated, making the state explicit pays off immediately. When they are simple, an enum and a switch often do the job.

### 40.6.1 Explicit State Enum vs Implicit Flag Bits

**What it is.** Two ways to represent state. An enum says “this device is in exactly one of N states”. A flag word says “this device has any combination of N independent booleans”.

**Use the enum when** the conditions are mutually exclusive and naming the transitions matters. A link is one of `LINK_DOWN`, `LINK_NEGOTIATING`, or `LINK_UP`. A command is one of `CMD_IDLE`, `CMD_PENDING`, `CMD_RUNNING`, or `CMD_DONE`. An enum forces every transition to be explicit; you cannot accidentally be in two states at once.

**Use flag bits when** the conditions are independent and can be combined. “Interrupt enabled”, “autonegotiation allowed”, “in promiscuous mode”. Mixing mutually exclusive and independent conditions in the same flag word is the usual mistake; separate them into an enum for the first and a flag word for the second.

**Common traps.**

- Encoding a state machine as bit flags and then having to decide what “both `CMD_PENDING` and `CMD_DONE` set” means. That never means anything useful. Switch to an enum.
- Encoding independent booleans as a single packed state. You will reinvent bitwise OR, badly.

### 40.6.2 Switch-Based FSMs

**What it is.** The simplest explicit state machine: an enum for the state, a switch in a function that takes an event, and a body per case that updates the state and performs the action.

**Use this when** the state space is small (perhaps ten states) and the transitions are shallow. A switch is easy to read, easy to extend, and the compiler catches missing cases if you enable the right warning flag.

**Avoid this when** the switch grows to hundreds of lines or the same transition logic is duplicated across several states. That is the signal to move to a table-driven FSM.

**Common traps.**

- Forgetting a state. Compile with `-switch-enum` so the compiler tells you.
- Doing non-trivial work inside the switch. Keep the switch as a dispatcher; delegate the real work to named helper functions.

**Where the book teaches this.** The pattern appears naturally in many driver examples. Chapter 5 introduces it in its simplest form.

### 40.6.3 Table-Driven FSMs

**What it is.** The state machine expressed as a two-dimensional table indexed by (state, event). Each cell holds the next state and, typically, a function pointer for the action to run on that transition.

**Use this when** the FSM has many states and many events and you want the transition logic to be data, not code. Visualising the matrix is often easier than chasing a giant switch. Protocol stacks, bus enumeration logic, and suspend-resume state machines are classic uses.

**Avoid this when** the FSM is small. A five-state switch is easier to read than a five-by-five matrix.

**Core operations.** Define the state enum, the event enum, and a transition struct containing `next_state` and `action_fn`. Declare the table as a static constant two-dimensional array. The driver steps the machine with `table[current_state][event]`.

**Common traps.**

- Null action pointers without a check. Either the table must be dense (every cell is a valid transition) or the dispatcher must treat a null action as “ignore”, and the convention must be consistent.
- Embedding locks inside the action functions without a clear discipline. The state transition is a critical section; decide whether the caller holds the lock or the dispatcher takes it, and stick to that.

#### 40.6.4 Function-Pointer Dispatch

**What it is.** A lighter alternative to a full state table. The current “mode” of the driver is a pointer to a set of handler functions; switching state is as simple as reassigning the pointer.

**Use this when** the “state” is really a set of methods the driver performs differently depending on mode. A link that comes up has a different receive path than a link that is still negotiating. A device that is booting its firmware dispatches commands differently from one that is already running.

**Avoid this when** the state transitions are ad-hoc or numerous. A function-pointer swap is a coarse operation; reserving it for a few well-named modes keeps the code honest.

**Common traps.**

- Racing with the swap. If one CPU calls through the pointer while another is replacing it, the call may dispatch to stale code. The swap needs ordering. In the kernel, that usually means a lock or an RCU-style deferred free via `epoch(9)` for any state structure the old pointer referenced.
- Orphaned resources. When you swap the function-pointer table, make sure the resources the old mode owned are handed off or released cleanly. The switch itself does not free anything.

#### 40.6.5 Reentrancy and Partial Completion

**What it is.** A state-machine design concern rather than a data structure. Real drivers receive events in interleaved order: an interrupt fires while the driver is halfway through processing an `ioctl`; a completion arrives while the command that triggered it is still being posted; a detach races with an open. The state machine has to tolerate this.

**Design principles.**

- Make every transition a single, atomic update. Read current state, compute next state, commit with a lock or an atomic. Do not perform the action before committing the state; if you crash or return early, the state must match reality.
- Separate “what to do” from “who runs it”. The state transition decides what needs to happen; a taskqueue or a worker thread actually does the work. That way the transition can finish before the expensive work starts, and a second caller sees consistent state.
- Have a “transient” state for every transition that takes time. A command that is in the act of being sent is neither `IDLE` nor `RUNNING`; it is `SENDING`. A link that is bringing itself down is neither `UP` nor `DOWN`; it is `GOING_DOWN`. Transient states give concurrent callers something to wait for or retry on.

**Common traps.** Assuming events are serialised. They are not. An interrupt can arrive at any time, a detach can race with an open, a userspace close can race with a device's internal teardown. Build the state machine so that every event is handled from every state, even if the handling is just "reject" or "defer".

**Where the book teaches this.** Revisited in Chapter 11 (synchronisation), Chapter 14 (interrupts in depth), and Part 5 when real networking drivers hit these cases hard.

## 40.7 Error-Handling Patterns

A driver that gets the happy path right but gets the error path wrong will corrupt memory, leak resources, or panic the kernel. Good error handling in driver code is almost always about structure, not cleverness. The kernel has a strong, uniform idiom for it, and this section names that idiom.

### 40.7.1 The `goto out` Idiom

**What it is.** The canonical kernel cleanup pattern. At the top of the function, declare every resource to `NULL`. At each acquisition, check the result; on failure, `goto fail_N` where `fail_N` is a label that releases exactly the resources acquired so far. At the end of the function, the success path returns; the cleanup ladder runs in reverse order of acquisition and falls through every label down to the final return.

**Why drivers use it.** Because it works. The ladder makes it impossible to forget a release, and the order-of-release is visually identical to the reverse of the order of acquisition. The pattern is pervasive in the FreeBSD tree.

**Use this when** a function acquires more than one resource. Three is usually the threshold where a ladder is cleaner than nested `if`.

**Avoid this when** the function is simple. A single acquisition, a single release, and a single error path do not need a ladder; a straight-line function with two returns is clearer.

**The shape.**

```
int
my_attach(device_t dev)
{
 struct my_softc *sc;
 struct resource *mem = NULL;
 void *ih = NULL;
 int error, rid;

 sc = device_get_softc(dev);
 sc->dev = dev;

 rid = 0;
 mem = bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE);
 if (mem == NULL) {
 device_printf(dev, "cannot allocate memory window\n");
 }
}
```

```
 error = ENXIO;
 goto fail_mem;
 }

 error = bus_setup_intr(dev, sc->irq, INTR_TYPE_MISC | INTR_MPSAFE,
 NULL, my_intr, sc, &ih);
 if (error != 0) {
 device_printf(dev, "cannot setup interrupt: %d\n", error);
 goto fail_intr;
 }

 sc->mem = mem;
 sc->ih = ih;
 return (0);

fail_intr:
 bus_release_resource(dev, SYS_RES_MEMORY, rid, mem);
fail_mem:
 return (error);
}
```

The shape is what matters. Each label releases exactly the resources acquired between it and the start of the function. Falling through is intentional; the labels are stacked in the order a human would read them from the top of the function.

### Variants.

- A single out: label with conditional checks (`if (mem != NULL) bus_release_resource(...)`) works for short functions. For long ones, the numbered-label variant is easier to audit because it encodes the order directly.
- Some code names the labels `err_mem`, `err_intr` instead of `fail_mem`, `fail_intr`. The prefix does not matter; consistency within a file does.

### Common traps.

- Freeing in the wrong order. Always free in reverse order of allocation. The ladder's visual order is a reminder, not a proof; review the labels when you add a new resource.
- Initialising pointers to something other than `NULL`. If a ladder conditionally frees, the condition has to be reliable. Uninitialised pointers are undefined; free of uninitialised memory is a panic.
- Returning on the success path with a partial state. The success path at the end should either hand full ownership to the caller or return an error and unwind. There is no third option.

**Where the book teaches this.** Chapter 5 introduces the pattern explicitly and the book uses it consistently from Chapter 7 onward.

**What to read next.** Real attach functions under `/usr/src/sys/dev/`. Almost any driver shows the pattern in action.

### 40.7.2 Return-Code Conventions

**What it is.** The kernel convention: integer return codes where 0 means success and a positive errno value means failure. 1 is not an error; it is a truthy return that would be confusing next to EPERM (which is also 1). Always return 0 on success.

**Core conventions.**

- 0 on success, a positive errno (EINVAL, ENOMEM, ENXIO, EIO, EBUSY, EAGAIN) on failure.
- Never return a negative error code. That is a Linux convention and does not match the rest of FreeBSD.
- Propagate error codes upwards unchanged unless you can make them more specific.
- When a function returns a pointer, convention is to return NULL on failure and set a separate int if the caller needs to distinguish why.
- Probe routines follow a different rule: they return BUS\_PROBE\_DEFAULT and friends on success and ENXIO on no-match. See Appendix A for the full list.

**Common traps.**

- Returning -1 from a kernel function. That is a userspace idiom; do not do it in kernel code.
- Overloading a single return value to mean both “an error” and “a resource count”. Use a separate output pointer parameter if you need both.
- Swallowing errors. An error code from a lower-level call is a contract; either handle it or propagate it. Returning 0 after a failed copyin is how kernel panics are born.

**Where the book teaches this.** Chapter 5 again, alongside the cleanup ladder.

### 40.7.3 Resource Acquisition and Release Ordering

**What it is.** The discipline that says: every resource you acquire in attach must be released in detach, in reverse order. Every lock you take must be released along every exit path. Every reference you add must be released before you drop the last one. The cleanup ladder above is a local expression of this principle; the whole driver is a global one.

**Core principles.**

- Attach acquires in order A, B, C. Detach releases in order C, B, A. The two are mirror images.
- Every error path inside attach unwinds what has been acquired so far, in reverse. That is the ladder.
- Locks are held for as short a time as possible and released along every exit, including the error paths. A goto ladder that unwinds memory but forgets the mutex is still wrong.
- Ownership should be local. One function acquires; the same function releases, or it hands ownership explicitly to the caller. A function that “leaks” ownership to a parameter side-effect is almost always a bug waiting to happen.

**Where the book teaches this.** Chapter 7 introduces the mirror-image discipline for a first driver, and every driver chapter afterwards repeats it.

## 40.8 Concurrency Patterns

Two threads touching the same state is where kernel bugs are born. The synchronisation primitives in Appendix A are the tools; this section collects the patterns that use those tools well. The goal here is pattern recognition, not a full concurrency course.

### 40.8.1 Producer-Consumer with Condition Variables

**What it is.** One context produces data (fills a buffer, posts a command, receives a character), and another consumes it. A shared state protected by a mutex, and a condition variable that the consumer waits on when the state is empty.

**Mental model.**

- The mutex protects the shared state. That is non-negotiable.
- The consumer checks the state under the mutex. If there is nothing to do, it sleeps on the condition variable via `cv_wait`. `cv_wait` atomically drops the mutex while sleeping and reacquires it on return.
- The producer also holds the mutex while it modifies the state, then signals the condition variable.
- The consumer re-checks the state after waking, because spurious wakeups and shared signals are possible. The check is always a loop, not an `if`.

**The shape.**

```
/* Producer. */
mtx_lock(&sc->lock);
put_into_buffer(sc, item);
cv_signal(&sc->cv);
mtx_unlock(&sc->lock);

/* Consumer. */
mtx_lock(&sc->lock);
while (buffer_is_empty(sc))
 cv_wait(&sc->cv, &sc->lock);
item = take_from_buffer(sc);
mtx_unlock(&sc->lock);
```

**Common traps.**

- Using `if` instead of `while` around `cv_wait`. Spurious wakeups are real; always re-check.
- Signalling without holding the lock. FreeBSD permits it, but it is almost always easier to reason about if you signal while holding the lock.
- `cv_signal` when you meant `cv_broadcast`. `cv_signal` wakes exactly one waiter; if several waiters are waiting on different preconditions, only one of them will be unblocked, possibly the wrong one.
- Sleeping under a spinlock. `cv_wait` is sleepable; you need a normal mutex (`MTX_DEF`), not a spin mutex (`MTX_SPIN`).

**Where the book teaches this.** Chapter 10 builds the pattern implicitly around the circular buffer; Chapters 11 and 12 formalise it.

### 40.8.2 Reader-Writer: `rmlock(9)` vs `sx(9)`

**What it is.** Two different read-write locks, with different cost profiles.

- `sx(9)` is a sleepable shared-exclusive lock. Readers block writers; writers block readers. Both sides may sleep inside the critical section.
- `rmlock(9)` is a read-mostly lock with an extremely cheap reader path (essentially a per-CPU indicator) and a much more expensive writer path (the writer must wait for every reader to drain).

**Choosing between them.**

- If reads are frequent, writes are rare, and the reader path must not sleep, choose `rmlock`.
- If reads are frequent, writes are occasional, and the reader path needs to sleep (for example, it calls `copyout`), choose `sx`.
- If reads and writes are roughly balanced or if the critical section is short, neither is right. Use a plain mutex.

**Core operations.**

- `sx`: `sx_slock`, `sx_sunlock` for shared; `sx_xlock`, `sx_xunlock` for exclusive; `sx_try_slock`, `sx_try_xlock`.
- `rmlock`: `rm_rlock(rm, tracker)`, `rm_runlock(rm, tracker)` for readers (each reader needs its own struct `rm_priotracker`, typically on the stack); `rm_wlock(rm)`, `rm_wunlock(rm)` for writers.

**Common traps.**

- Using `rmlock` for a balanced workload. The writer path is genuinely slow; use it only when reads dwarf writes.
- Letting an `rmlock` reader sleep without initialising with `RM_SLEEPABLE`. The default `rmlock` forbids sleeping in the read path.
- Upgrading a shared lock to an exclusive one. Neither `sx` nor `rmlock` supports a lock-free upgrade. Drop the shared lock, acquire the exclusive one, and re-check state.

**Where the book teaches this.** Chapter 12.

### 40.8.3 Reference Counting with `refcount(9)`

**What it is.** A kernel-blessed pattern for counting how many contexts still use an object. An atomic counter, `refcount_acquire` to bump it, `refcount_release` to drop it and return `true` when the count reaches zero (so the caller can free).

**Why drivers use it.** Whenever an object can outlive the operation that produced it. A `cdev` that is being closed while a read is in flight; a `softc` whose detach races an `ioctl`; a buffer passed to hardware that must not be freed until the hardware is done.

**Use this when** you have shared ownership and no single place that can reliably free the object. If one piece of code unambiguously owns the object, skip the reference count and free it there.

**Core operations.** `refcount_init(count, initial)`, `refcount_acquire(count)` returning the previous value, `refcount_release(count)` returning `true` if the count reached zero (caller must free). There are

`_if_gt` and `_if_not_last` variants for conditional acquisition, and `refcount_load` for read-only inspection.

### Common traps.

- Using `refcount` for resources with a real ownership hierarchy. Refcounts are for genuinely shared ownership, not for laziness about who frees what.
- Freeing before the release. `refcount_release` returning `true` is your permission to free; do it inside that branch, not before.
- Mixing refcounts with locks. Refcount operations are lock-free, but “increment the refcount then dereference” is a race if another thread may drop the last reference between the two steps. The usual fix is to hold a lock while you decide to acquire.

**Where the book teaches this.** Mentioned in Appendix A, with the concurrency context built up through Chapters 11 and 12.

**What to read next.** `refcount(9)`, and any subsystem that manages shared lifetime.

## 40.9 Decision Aids

The compact tables below are meant to be glanceable. They are not decision oracles; they are reminders of which family to look inside. The real decision is always local to the problem.

### 40.9.1 Collection Shape

| You have...                                | Reach for                                                                       |
|--------------------------------------------|---------------------------------------------------------------------------------|
| A small collection, no ordered lookup      | <code>TAILQ_</code> or <code>LIST_</code> from <code>&lt;sys/queue.h&gt;</code> |
| A FIFO queue with no arbitrary removal     | <code>STAILQ_</code>                                                            |
| A collection ordered by a key, grows large | <code>RB_</code> from <code>&lt;sys/tree.h&gt;</code>                           |
| A dense universe of boolean flags          | <code>bit_*</code> from <code>&lt;sys/bitstring.h&gt;</code>                    |
| Unordered lookup on a large set            | <code>hashinit(9)</code> plus <code>LIST_</code>                                |
| Prefix-matching networking keys            | <code>radix.h</code> (you usually do not write this yourself)                   |

### 40.9.2 Ring Buffer Shape

| You have...                                    | Reach for                                                   |
|------------------------------------------------|-------------------------------------------------------------|
| One producer, one consumer, lock-free          | SPSC ring with head/tail indices                            |
| Many producers, many consumers                 | <code>buf_ring(9)</code>                                    |
| Producer is an interrupt, consumer is a thread | SPSC ring plus condition variable or <code>selrecord</code> |

---

| You have...                                | Reach for                                                                 |
|--------------------------------------------|---------------------------------------------------------------------------|
| Soft queue with back-pressure to userspace | SPSC ring plus <code>poll(2)</code> or <code>kqueue(2)</code> integration |

---

### 40.9.3 State Representation

---

| Your state is...                              | Reach for                 |
|-----------------------------------------------|---------------------------|
| A handful of mutually exclusive modes         | enum plus switch          |
| Many states, many events, complex transitions | Table-driven FSM          |
| Coarse modes that change the driver's methods | Function-pointer dispatch |
| Independent boolean facts                     | Flag bits in an integer   |

---

### 40.9.4 Cleanup Strategy

---

| Your function...                   | Reach for                                                             |
|------------------------------------|-----------------------------------------------------------------------|
| Acquires one resource              | Single early return, single release                                   |
| Acquires two or three              | <code>goto out:</code> with conditional <code>if (ptr != NULL)</code> |
| Acquires many, order-sensitive     | Numbered <code>goto fail_N:</code> ladder                             |
| Has to roll back a mid-way success | Same ladder with explicit “rollback” label                            |

---

### 40.9.5 Concurrency Pattern

---

| You have...                                        | Reach for                                      |
|----------------------------------------------------|------------------------------------------------|
| Short critical section, no sleeping                | <code>mtx(9)</code> with <code>MTX_DEF</code>  |
| Short critical section in an interrupt filter      | <code>mtx(9)</code> with <code>MTX_SPIN</code> |
| Many readers, occasional writer, may sleep         | <code>sx(9)</code>                             |
| Many readers, rare writer, no sleep in readers     | <code>rmlock(9)</code>                         |
| One producer, one consumer, waiting on an event    | mutex plus <code>cv(9)</code>                  |
| Shared ownership of an object with no single freer | <code>refcount(9)</code>                       |
| A counted resource (pool of slots)                 | <code>sema(9)</code>                           |
| One-word counter or flag                           | <code>atomic(9)</code>                         |

---

## 40.10 Wrapping Up: How to Recognise These Patterns in Real Code

Recognising a pattern in someone else's driver is a different skill from writing the pattern yourself. The easy part is spotting the API: `TAILQ_FOREACH`, `buf_ring_enqueue`, `goto fail_mem`. The harder part is spotting the pattern when the author has not used an API at all, because the pattern is pure control flow.

Three habits help.

The first is asking what invariant the author is trying to preserve. A ring buffer preserves “the interrupt and the thread never write the same index”. A state machine preserves “we are always in exactly one state”. A cleanup ladder preserves “every resource is released exactly once, in reverse order”. When you read new code, naming the invariant first gives the rest of the code somewhere to attach to.

The second is reading the comment at the top of the file. Most FreeBSD drivers include a short block comment explaining the locking discipline, the state machine, or the ring conventions they use. That comment exists precisely because a reader cannot recover it from the code alone. Read it before you read the code, and read it again when the code surprises you.

The third is letting the patterns in this appendix colonise your vocabulary. When you find yourself writing “the ring buffer”, be able to say whether it is SPSC or MPMC, whether the indices are sacrificed-slot or free-running, where the barrier belongs. When you find yourself writing “the state machine”, be able to name the states, the events, and the transient states. When you find yourself writing “the cleanup path”, be able to list the resources in reverse order of acquisition. The appendix becomes useful once these words come to mind automatically.

From here you can move in several directions. Appendix A has the detailed API entries for every primitive named above. Appendix C grounds the hardware-side patterns (DMA rings, descriptor arrays, and the discipline of coherency) that sit just below these software ones. Appendix E covers the kernel subsystems that many of these patterns were born inside. And every chapter of the book has labs where these patterns appear in a working driver, so that the next time you meet one in the wild you recognise it without slowing down. That is all pattern recognition really is: the confidence to keep reading.

# 41 Appendix C: Hardware Concepts for Driver Developers

## 41.1 How to Use This Appendix

The main chapters teach the driver-facing side of FreeBSD: how to write a softc, how to declare a cdev, how to set up an interrupt, how to walk a PCI BAR into a bus\_space handle, how to tame a DMA engine with bus\_dma(9). Underneath every one of those topics there is a quiet layer of hardware knowledge that the book keeps using without always naming. What a physical address really is. Why the CPU cannot simply read a device register through an ordinary pointer. Why PCI and I2C feel like completely different worlds even though both carry bytes between a CPU and a peripheral. Why an interrupt is not a function call. Why DMA changes how you write a driver from top to bottom.

This appendix is that quiet layer, written down. It is a concept guide, not an electronics textbook. It is shaped by what a driver author actually needs to believe about the machine in order to write correct code, and deliberately stops short of full computer-architecture teaching. If you have ever written a bus\_space\_read\_4 call and wondered what the tag and the handle really represent, or set up an MSI-X vector and wondered what is being signalled across which wires, or debugged a DMA transfer that worked on your desk and broke on a different board, you are in the right place.

### 41.1.1 What You Will Find Here

The appendix is organised by driver relevance, not by abstract hardware taxonomy. Each topic follows the same compact rhythm:

- **What it is.** One or two sentences of plain definition.
- **Why this matters to driver writers.** The concrete place where the concept shows up in your code.
- **How this shows up in FreeBSD.** The API, header, or convention that names the idea.
- **Common trap.** The misunderstanding that actually costs people time.
- **Where the book teaches this.** A pointer back to the chapter that uses it in context.
- **What to read next.** A manual page, a header, or a real driver you can open.

Not every topic uses every label; the shape is a guide, not a template.

### 41.1.2 What This Appendix Is Not

It is not a first course in electronics. It assumes you can accept “a wire carries a signal” and move on. It is not a computer-architecture textbook either; there is no discussion of pipelines, caches beyond what a driver author must know, or branch prediction. It is not a replacement for the focused chapters: Chapter 16 teaches

`bus_space(9)`, Chapter 18 teaches PCI, Chapter 19 teaches interrupts, Chapter 20 teaches MSI and MSI-X, and Chapter 21 teaches DMA in depth. This appendix is what you keep open beside those chapters when you want a mental-model anchor instead of a full walkthrough.

It also does not overlap with the other appendices. Appendix A is the API reference; Appendix B is the algorithmic-pattern field guide; Appendix D is the operating-systems-concepts companion; Appendix E is the kernel-subsystem reference. If the question you want answered is “what does this macro call do” or “what algorithm fits this problem” or “how does the scheduler schedule”, you want a different appendix.

## 41.2 Reader Guidance

Three ways to use this appendix, each calling for a different strategy.

If you are **learning the main chapters**, open the appendix alongside them. When Chapter 16 mentions memory barriers, flip to the memory section here. When Chapter 18 talks about BARs, flip to the PCI section. When Chapter 19 introduces edge versus level triggering, flip to the interrupt section. The appendix is designed to be a mental-model companion, not a linear read. Thirty minutes from start to finish is realistic for a first pass; a few minutes at a time is more common in daily use.

If you are **reading real driver code**, use the appendix as a translator for unfamiliar terminology. When the header comment says “coherent DMA memory” or “message-signalled interrupt” or “BAR at offset 0x10”, find the concept here and keep going. Full understanding can come later; the first job is to form a mental picture of what the driver is doing against what kind of hardware.

If you are **designing a new driver**, read the sections that match your hardware. A PCI NIC will touch the memory model, PCI, interrupts (probably MSI-X), and DMA, so those four sections are your warm-up. An I2C sensor will touch the I2C section and the interrupt section and almost nothing else. An embedded driver on a system-on-chip will touch everything except PCI. Match the hardware to the sections, then skim only those.

A few conventions apply throughout:

- Source paths are shown in the book-facing form, `/usr/src/sys/...`, matching a standard FreeBSD system. You can open any of them on your lab machine.
- Manual pages are cited in the usual FreeBSD style. The kernel-facing pages live in section 9: `bus_space(9)`, `bus_dma(9)`, `pci(9)`, `malloc(9)`, `intr_event(9)`. Device overviews usually live in section 4: `pci(4)`, `usb(4)`, `iicbus(4)`.
- When an entry points to real source as reading material, the file is one a beginner can navigate in one sitting. Larger subsystems exist that also use the pattern; those are mentioned only when they are the canonical example.

With that in mind, we start with memory: the single concept that separates a working driver from a puzzling one.

## 41.3 Memory in the Kernel

A driver that misunderstands memory will write perfect-looking code that crashes on real hardware. Memory in the kernel is not the same as memory in a C tutorial. There are at least two address spaces in play (physical

and virtual), there are constraints the hardware enforces (DMA addressing limits, page boundaries), and there are regions where even an ordinary read has side effects (device registers). This section builds the mental model that every later topic in the appendix depends on.

### 41.3.1 Physical vs Virtual Memory

**What it is.** A physical address is the number the memory controller uses to select a real location in RAM, or the number the I/O fabric uses to select a register on a peripheral. A virtual address is the number a running thread sees when it dereferences a pointer; the memory-management unit (MMU) translates it to a physical address on the fly, using the page tables that the kernel maintains.

**Why this matters to driver writers.** Every pointer in your driver is virtual. The CPU never sees a physical address when it executes your C code. The kernel and the `pmap(9)` layer keep the page tables so that kernel virtual addresses map to wherever in physical memory the kernel has decided to put the corresponding pages. A driver that “knows” a physical address cannot simply cast it to `(void *)` and dereference; the translation might not exist, the permissions might forbid it, or the attributes might be wrong for the kind of access you need.

Hardware is on the opposite side of the mirror. A peripheral device lives somewhere in a physical address space (its registers are physical addresses, and when it does DMA it emits physical addresses on the bus). A device never dereferences a virtual pointer. If your driver hands the device a kernel virtual address and expects it to read the data there, the device will read some unrelated physical location and you will spend a long afternoon figuring out why.

**How this shows up in FreeBSD.** Two places. First, `bus_space(9)` encodes the translation for register access: a tag describes the kind of physical address space, a handle describes the virtual mapping the kernel has set up, and the `bus_space_read_*` and `bus_space_write_*` accessors use the handle to reach the device through that mapping. Second, `bus_dma(9)` mediates DMA: the `bus_dmamap_load` call walks a buffer and produces the list of bus addresses the device should use, which are not necessarily the same as either the virtual addresses or the physical addresses, because an IOMMU may sit in between.

**Common trap.** Casting a physical address returned by firmware or a BAR register to a pointer and reading from it directly. On some architectures and some builds this compiles and may even return something, but it is never correct. Always map through `bus_space`, `pmap_mapdev`, or an established FreeBSD API.

**Where the book teaches this.** Chapter 16 establishes the distinction and shows why raw pointer arithmetic is not enough for device memory. Chapter 21 returns to it when DMA makes the physical side visible.

**What to read next.** `bus_space(9)`, `pmap(9)`, and the early parts of `/usr/src/sys/kern/subr_bus_dma.c`.

### 41.3.2 The MMU, Page Tables, and Device Mappings

**What it is.** The MMU is the hardware unit that translates virtual addresses into physical addresses using a tree of page tables. Each page-table entry holds a physical page number and a small set of attribute bits: readable, writable, executable, cacheable, user-accessible. The same physical page can be mapped at several virtual addresses with different attributes; the same virtual address can point at different physical pages at different times.

**Why this matters to driver writers.** Device memory is not ordinary RAM, and the CPU must know that. A register may change on its own (a status bit that sets when the device finishes a transfer), it may have side effects

on read (a read-to-clear flag), and it may require that writes become visible in a specific order. If the CPU caches a device register the way it caches an integer in RAM, the code reads a stale value forever. The MMU solves this by letting the kernel map device regions with different attributes: typically uncached, strongly ordered, and sometimes write-combining. A driver does not usually choose those attributes by hand. `bus_space` and `bus_alloc_resource` do it on your behalf.

**How this shows up in FreeBSD.** When `bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE)` returns, the kernel has already mapped the device region with the right attributes for MMIO. The struct `resource` \* you get back carries a `bus_space_tag_t` and `bus_space_handle_t` pair that the accessors use. You should never manipulate the underlying page table yourself. In practice the access is two lines:

```
uint32_t val = bus_space_read_4(rman_get_bustag(res),
 rman_get_bushandle(res), STATUS_REG_OFFSET);
```

Each `bus_space_read_4` / `bus_space_write_4` call goes through the MMIO mapping the kernel set up for you; no pointer dereference, no cached load.

**Common trap.** Mixing cacheable and uncacheable views of the same physical region. A DMA buffer allocated with `bus_dmamem_alloc` and then cast to a different virtual mapping will give you two incoherent views of the same bytes. Use the mapping the allocator returned, not a mapping you build on the side.

**Where the book teaches this.** Chapter 16 touches the MMU indirectly when it explains why the `bus_space` abstraction exists. Chapter 21 makes it explicit when DMA coherence becomes the topic.

**What to read next.** `pmap(9)`, `bus_space(9)`, and `/usr/src/sys/vm/vm_page.h` for the kernel's representation of a physical page (`vm_page_t`).

### 41.3.3 Why Hardware Cannot Simply See Kernel Pointers

**What it is.** A short way of stating the most important consequence of the previous two subsections. The kernel lives in virtual memory. Peripherals live in physical (and sometimes I/O-virtual) memory. A kernel pointer has no meaning to a device.

**Why this matters to driver writers.** Every time you give a device a memory address, you must give it a bus address, not a virtual pointer. The bus address is what the device sees; it may be the physical address, or it may be an I/O-virtual address remapped by an IOMMU. You do not compute it yourself. The DMA infrastructure computes it for you when you load a map.

**How this shows up in FreeBSD.** `bus_dmamap_load` takes a virtual buffer and produces `bus_dma_segment_t` entries whose `ds_addr` is the address the device must use. You copy that value into the descriptor you are about to hand the hardware. The moment you find yourself wanting to pass the output of `vtophys` or a raw BAR value to the device, stop and reach for `bus_dma` instead.

**Common trap.** Writing `(uint64_t)buffer` into a device descriptor because it works in a toy test on one machine. It will fail on any machine where the kernel address is not the same as the bus address, which is most real machines.

**Where the book teaches this.** Chapter 21. The whole chapter is about honouring this separation.

**What to read next.** `bus_dma(9)`, and the DMA section below.

### 41.3.4 Kernel Memory Allocation in One Page

The kernel provides three main ways to get memory, each with a different purpose. Drivers reach for them constantly, and picking the wrong one is a classic beginner mistake. The point here is the conceptual difference; the full API reference is in Appendix A.

- **malloc(9)** is the general-purpose allocator. It returns kernel-virtual memory that is perfectly fine for softc structures, lists, command buffers for your own bookkeeping, and anything else that stays inside the driver's data. It is not automatically physically contiguous, and it is not automatically suitable for DMA. Use it for control data.
- **uma(9)** is the zone allocator. It is a fast cache for fixed-size objects that the driver allocates and frees often, such as per-request structures or per-packet state. It is a specialisation of general-purpose allocation; it does not change the physical-vs-virtual story.
- **contigmalloc(9)** returns a physically contiguous range, with options for alignment and an upper address limit. A driver calls it directly only when it truly needs a single contiguous physical block and the `bus_dma` layer is not a better fit. In modern drivers, `bus_dma` almost always is the better fit. The call shape is telling on its own:

```
void *buf = contigmalloc(size, M_DEVBUF, M_WAITOK | M_ZERO,
 0, BUS_SPACE_MAXADDR, PAGE_SIZE, 0);
```

The `low`, `high`, `alignment`, and `boundary` arguments are exactly the DMA constraints a `bus_dma_tag_create` call would express, which is why `bus_dma(9)` is almost always the better place to encode them.

- **bus\_dmamem\_alloc(9)** is the DMA-aware allocator. It returns a buffer that is usable for DMA under a given tag, properly aligned, optionally coherent, and paired with a `bus_dmamap_t` you can load. This is the call you want in almost every DMA scenario.

**Why this matters to driver writers.** The question to ask yourself is always “who is going to read or write this memory?”. If only the CPU ever touches it, `malloc(9)` is fine. If the device needs to read or write it, you want `bus_dmamem_alloc(9)` under a `bus_dma(9)` tag that expresses the device's addressing constraints. Mixing the two is the source of an entire genus of driver bugs.

**Common trap.** Allocating a buffer with `malloc(9)`, handing its virtual address to the device, and wondering why the device reads garbage. The fix is rarely to patch around the symptoms; it is to rewrite the allocation through `bus_dma(9)`.

**Where the book teaches this.** Chapter 5 introduces `malloc(9)` in a kernel-C context, and the driver chapters from Chapter 7 onward use it repeatedly for softc and bookkeeping memory. Chapter 21 introduces `bus_dmamem_alloc`. Appendix A lists the full API and flags.

**What to read next.** `malloc(9)`, `contigmalloc(9)`, `uma(9)`, `bus_dma(9)`.

### 41.3.5 IOMMUs and Bus Addresses

**What it is.** An IOMMU is a hardware unit (sometimes the `amdvi` or `intel-iommu` unit; on ARM, the SMMU) that sits between devices and main memory and translates the addresses devices emit into physical addresses. It is the device-side analogue of the MMU.

**Why this matters to driver writers.** When an IOMMU is present, the address the device uses on the bus (a bus address or I/O-virtual address) is not the same as the physical address of the underlying memory. The IOMMU lets the kernel give each device a restricted view of memory, which is good for safety and isolation, and it lets the kernel use scatter-gather where the device would otherwise demand contiguous physical pages.

**How this shows up in FreeBSD.** Transparently, for most drivers. When the kernel is built with the IOMMU option and one of the architecture backends (the Intel and AMD drivers under `/usr/src/sys/x86/iommu/` on amd64, the SMMU backend under `/usr/src/sys/arm64/iommu/` on arm64), the `busdma_iommu` layer in `/usr/src/sys/dev/iommu/` bridges `bus_dma(9)` and the IOMMU automatically, without changing the driver's code. You still allocate a tag, create a map, load the map, and read the `ds_addr` of each segment; the number you get is the address the device should use, IOMMU or not. You do not need to know whether an IOMMU is present.

**Common trap.** Assuming `ds_addr` is a physical address and logging it that way. On IOMMU systems the number is an I/O-virtual address and will not match anything you see in `/dev/mem`. The right mental model is “the address the device uses”, not “the physical address”.

**Where the book teaches this.** Chapter 21 mentions IOMMU integration briefly and sticks to the common case where `bus_dma` hides it.

**What to read next.** `bus_dma(9)`, `/usr/src/sys/dev/iommu/busdma_iommu.c` for the bridge code, and `/usr/src/sys/x86/iommu/` or `/usr/src/sys/arm64/iommu/` for the per-architecture backends.

### 41.3.6 Memory Barriers in One Paragraph

On modern CPUs, memory operations may become visible to other agents (other CPUs, other devices) in an order different from the one in which the code issued them. For ordinary RAM the kernel's locking primitives hide this from you. For device registers, though, ordering matters: writing to a “start” register before writing to the “data” register produces a different outcome from the reverse. The kernel provides explicit barriers for both sides. For register access, `bus_space_barrier(tag, handle, offset, length, flags)` is the right tool; for DMA buffers, `bus_dmamap_sync(tag, map, op)` is the right tool. You will meet both again later in this appendix. For now, internalise the rule: when the order of two accesses matters to the hardware, say so with a barrier. Do not rely on the code order alone.

## 41.4 Buses and Interfaces

A bus is a physical and logical pathway that carries commands, addresses, and data between a CPU and peripherals. FreeBSD treats every bus as a specialised tree in the Newbus framework: the bus has a driver that enumerates its children, each child is a `device_t`, and each child can in turn be a bus for further children. The concept of “a bus” is uniform at the Newbus level. The concepts of “the electrical, protocol, and enumeration rules of a particular bus” are not uniform at all, and a driver author must understand which one they are writing for.

This section gives the mental models for the four buses the book cares about: PCI (and PCIe), USB, I2C, and SPI. Their chapters are later; this is the shared vocabulary you need first.

### 41.4.1 PCI and PCIe at a Driver-Relevant Level

**What it is.** PCI is the canonical bus for attaching peripherals to a CPU complex. Classical PCI was parallel and shared; modern PCI Express is a set of point-to-point serial lanes that a switch fabric organises into a tree. From a driver's perspective, the electrical difference is mostly invisible: you still see a configuration space, you still see Base Address Registers, you still see interrupts, and you still write probe-and-attach code. Unless stated otherwise, "PCI" in this book means "PCI and PCIe together".

A PCI device is identified by a Bus:Device:Function (B:D:F) tuple and by a configuration space that the firmware and the kernel populate. The configuration space holds the vendor and device identifiers, the class code that describes what kind of peripheral this is, the Base Address Registers (BARs) that describe the device's memory and I/O windows, and a linked list of capability structures that advertise optional features like MSI, MSI-X, and power management.

**Why this matters to driver writers.** Every PCI driver does roughly the same dance. Read `pci_get_vendor(dev)` and `pci_get_device(dev)` during probe, compare them to a table of devices the driver supports, return a `BUS_PROBE_*` value on a match. In attach, allocate each BAR with `bus_alloc_resource_any(dev, SYS_RES_MEMORY, &rid, RF_ACTIVE)`, pull the `bus_space_tag_t` and `bus_space_handle_t` out with `rman_get_bustag` and `rman_get_bushandle`, allocate the interrupt with `bus_alloc_resource_any(dev, SYS_RES_IRQ, ...)` (or `pci_alloc_msix/pci_alloc_msi` for message-signalled interrupts), wire the handler with `bus_setup_intr`, and you are in business.

Capabilities are where the PCI driver meets the features of the specific device family. `pci_find_cap(dev, PCIY_MSIX, &offset)` finds the MSI-X capability; `pci_find_extcap(dev, PCIZ_AER, &offset)` finds the extended capability for Advanced Error Reporting. A driver usually only walks the capabilities it cares about.

**How this shows up in FreeBSD.** The PCI bus driver lives under `/usr/src/sys/dev/pci/`. The key header is `/usr/src/sys/dev/pci/pci.h` for register constants and `/usr/src/sys/dev/pci/pcivar.h` for functions a client driver calls. Every PCI driver you will write starts with a `device_probe_t` and a `device_attach_t`, with `DRIVER_MODULE(name, pci, driver, 0, 0)` at the bottom of the file. The last two arguments are the per-module event handler and its argument, which are normally left as `0, 0` (or `NULL, NULL`); the separate `devclass_t` slot that older books mention was removed from the macro some releases ago.

**Common trap.** Forgetting to call `pci_enable_busmaster(dev)` before expecting the device to DMA. The chip can live in a quiet state where MMIO works and DMA silently does nothing. Enabling bus-mastering in attach is part of the usual sequence.

**Where the book teaches this.** Chapter 18 is the full chapter on PCI driver writing. Chapter 20 extends it with MSI-X.

**What to read next.** `pci(4)`, `pci(9)`, and a compact real example such as `/usr/src/sys/dev/uart/uart_bus_pci.c`. The PCI bus itself is implemented in `/usr/src/sys/dev/pci/pci.c`.

### 41.4.2 USB at a Driver-Relevant Level

**What it is.** USB is a host-controlled tiered bus, in which a host controller talks to devices through a tree of hubs. Unlike PCI, the bus is strictly hierarchical and polling-like: the host schedules every transaction. A device

does not “speak” on the bus without being asked. USB speed classes (low, full, high, super) share the same conceptual model; the protocol details change.

A USB device exposes a set of endpoints. Each endpoint is a one-way data channel with a specific transfer type: control, bulk, interrupt, or isochronous. Control is the setup channel every device has. Bulk is high-throughput with no timing guarantees. Interrupt is small, periodic, low-latency (mice, keyboards, sensors). Isochronous is real-time streaming (audio, video) that trades reliability for timing.

**Why this matters to driver writers.** A FreeBSD USB driver attaches to a `device_t` whose parent is a USB bus, not a PCI bus. The identification model is different: instead of vendor/device IDs and class codes in configuration space, a USB driver matches on a USB Vendor ID (VID), Product ID (PID), device class, subclass, and protocol. The FreeBSD USB stack gives you a structured probe against those fields. At run time, a USB driver opens specific endpoints through the USB framework and issues transfers whose lifetime is managed by the host controller; you do not write to registers the way a PCI driver does.

**How this shows up in FreeBSD.** The USB stack lives under `/usr/src/sys/dev/usb/`. A class driver uses `usbd_transfer_setup` to describe the endpoints it wants, `usbd_transfer_start` to initiate transfers, and callback functions to handle completion. Transfer-type constants live in `/usr/src/sys/dev/usb/usb.h` (`UE_CONTROL`, `UE_ISOCHRONOUS`, `UE_BULK`, `UE_INTERRUPT`).

**Common trap.** Thinking in terms of registers and interrupts. A USB device driver is event-driven around transfer completion callbacks, not around device-register reads. A register-oriented mindset leads to fighting the framework instead of using it.

**Where the book teaches this.** Chapter 26 is the full chapter on USB and serial drivers. This appendix is the concept-level primer; the chapter is where your first USB driver lives.

**What to read next.** `usb(4)`, `usbdi(9)`, and the headers under `/usr/src/sys/dev/usb/`.

### 41.4.3 I2C at a Driver-Relevant Level

**What it is.** I2C (Inter-Integrated Circuit) is a slow, two-wire, master-slave bus designed to connect low-bandwidth peripherals on a board: temperature sensors, power management controllers, EEPROMs, small displays. Each slave has a seven-bit or ten-bit address. A master initiates every transaction by asserting a start condition, sending the address, sending or receiving bytes, and asserting a stop condition.

Speeds are typically 100 kHz (standard), 400 kHz (fast), 1 MHz (fast-plus), and higher variants on newer devices. The bus supports multiple masters, but most embedded systems use a single master; in that case the driver only has to worry about the master-to-slave interaction.

**Why this matters to driver writers.** An I2C driver in FreeBSD comes in two flavours. An I2C *controller* driver implements the master side of a specific controller chip and hangs under the Newbus tree as an I2C bus. An I2C *device* driver is a client that uses the `iicbus` layer to talk to a slave device without knowing the controller details. The second form is what most driver authors write. You ask `iicbus_transfer` to perform a short sequence of `struct iic_msg` operations, and the `iicbus` layer takes care of arbitration and timing.

There are no interrupts or BARs to allocate in the client driver. There is no DMA. Each transfer is short and blocking, typically a few bytes; long reads are broken into a series of transfers.

**How this shows up in FreeBSD.** The framework lives under `/usr/src/sys/dev/iicbus/`. The client interface centres on `iicbus_transfer(dev, msgs, nmsgs)` and the `struct iic_msg` type. FreeBSD discovers

I2C buses through FDT on embedded platforms and ACPI on x86 laptops that expose an I2C controller.

**Common trap.** Writing an I2C driver that busy-waits. Even at 1 MHz, a transfer is several tens of microseconds; a driver that pins a CPU through a polling loop wastes resources. The `iicbus` layer handles the waiting for you.

**Where the book teaches this.** The book does not dedicate a full chapter to I2C; this appendix is the primary concept treatment, and the embedded chapter (Chapter 32) revisits it in the context of device-tree bindings. For a concrete client you can read front-to-back, open `/usr/src/sys/dev/iicbus/icee.c`.

**What to read next.** `iicbus(4)`, `/usr/src/sys/dev/iicbus/iicbus.h`, and an example client such as `/usr/src/sys/dev/iicbus/icee.c` (an EEPROM driver).

#### 41.4.4 SPI at a Driver-Relevant Level

**What it is.** SPI (Serial Peripheral Interface) is a simple, fast, full-duplex, master-slave bus. It has no addressing in the bus itself; each slave has a dedicated chip-select line, and the master asserts that line to begin a transaction. Four wires are typical: `SCLK` (clock), `MOSI` (master-out slave-in), `MISO` (master-in slave-out), and `SS/CS` (slave-select). Speeds commonly range from a few MHz to tens of MHz.

Unlike I2C, SPI has no protocol beyond the electrical one: the master shifts bits out on `MOSI` while simultaneously shifting bits in on `MISO`. What those bits mean is entirely up to the device.

**Why this matters to driver writers.** As with I2C, FreeBSD separates the controller from the client. A controller driver knows how the SPI master in a particular chip is programmed; a client driver uses the `spibus` interface to send and receive bytes without knowing the controller. The client calls `spibus_transfer` or `spibus_transfer_ext` with a `struct spi_command` that describes a single transaction, including the chip-select to assert and the buffers to shift.

**How this shows up in FreeBSD.** The framework lives under `/usr/src/sys/dev/spibus/`. The typical client driver hangs under an `spibus` parent in Newbus and uses the same `probe/attach` shape as any other device. `/usr/src/sys/dev/spibus/spigen.c` is a generic character-device client that exposes raw SPI to userland; reading it is a good way to see the client side of the framework.

**Common trap.** Expecting SPI to carry data with any built-in framing. It does not. The device datasheet tells you what bytes mean; the bus tells you nothing.

**Where the book teaches this.** The book does not dedicate a full chapter to SPI; this appendix is the primary concept treatment, and the embedded chapter (Chapter 32) revisits it in the context of device-tree bindings. For a concrete example you can read front-to-back, open `/usr/src/sys/dev/spibus/spigen.c`.

**What to read next.** `/usr/src/sys/dev/spibus/spibus.c`, `/usr/src/sys/dev/spibus/spigen.c`, and the device datasheet for whatever SPI peripheral you are driving.

#### 41.4.5 A Compact Comparison of the Four Buses

A small reference is often easier than a long description. This table compares the buses along the axes that actually affect driver design. It is not a full electrical comparison.

| Aspect           | PCI / PCIe            | USB                        | I2C                        | SPI                     |
|------------------|-----------------------|----------------------------|----------------------------|-------------------------|
| Topology         | Tree (PCIe switches)  | Strict host/hub tree       | Multi-drop, addressed      | Multi-drop, chip-select |
| Typical speed    | Gigabytes/s per lane  | Kilobytes/s to gigabytes/s | 100 kHz - 1 MHz            | 1 MHz - tens of MHz     |
| Identification   | Vendor/Device + class | VID/PID + class            | 7- or 10-bit slave address | None (chip-select)      |
| Protocol framing | PCI TLPs, invisible   | Packets + transfer types   | Start/address/data/stop    | Raw bits                |
| Interrupts       | INTx or MSI / MSI-X   | Transfer callbacks         | Rare; bus is polled        | Rare; bus is polled     |
| DMA              | Yes, device-driven    | Host controller does it    | No                         | No                      |
| Driver role      | Register-level        | Framework client           | iicbus client              | spibus client           |
| Enumeration      | Firmware + pci(4)     | Hub/device descriptors     | FDT / ACPI / hand-wired    | FDT / ACPI / hand-wired |

The pattern you should take away is that PCI and USB are complex enough to need their own enumeration stacks and transaction machinery, while I2C and SPI are simple enough that a short transaction struct is the whole API. A driver author's workload looks different on each side of that split.

## 41.5 Interrupts

An interrupt is how a device tells the CPU that something has happened. Without interrupts, drivers would have to poll, burning CPU cycles to discover events the hardware already knows about. With interrupts, the CPU does other work until the hardware signals; then the kernel dispatches a handler in a narrow, well-defined context. This section explains what that signal actually is, what distinguishes the common forms, and why interrupt discipline is one of the most demanding skills in driver work.

### 41.5.1 What an Interrupt Actually Is

**What it is.** At the hardware level, an interrupt is a signal the device raises to request CPU attention. On classical parallel buses, the signal is a line that the device pulls high or low. On modern PCIe, the signal is a memory-write transaction carrying a small payload that the interrupt controller recognises. In both cases, the interrupt controller maps the signal to a CPU vector, the CPU saves just enough state to switch context, and the kernel's low-level entry code decides which driver to call.

What the driver sees is a function call: the interrupt handler runs with a small stack, in a special scheduling context, usually with preemption disabled or highly constrained. The hardware model is “a device raised a line”; the software model is “the kernel ran your callback”.

**Why this matters to driver writers.** Interrupts are not ordinary function calls. They happen asynchronously, possibly on a different CPU from the one your driver is running on, and they can arrive in the middle of almost any code path. That is why interrupt handlers must be short, must avoid sleeping, and must not touch shared state without a lock that is safe in that context. Most of the discipline a driver learns about locking, ordering, and deferred work exists because of this one fact.

**How this shows up in FreeBSD.** Interrupts reach drivers through `intr_event(9)`. A driver calls `bus_setup_intr(dev, irq_resource, flags, filter, ithread, arg, &cookie)` to register up to two callbacks: a *filter* that runs first, in interrupt context, with only spin locks available, and optionally an *ithread* (interrupt thread) that runs as a kernel thread and may use sleep locks. The filter's return value decides what happens next: `FILTER_HANDLED` (fully handled, acknowledge at the controller), `FILTER_STRAY` (not mine, do nothing), or `FILTER_SCHEDULE_THREAD` (the ithread should run now). Those constants live in `/usr/src/sys/sys/bus.h`.

**Common trap.** Doing real work in the filter. The filter is there to decide ownership, acknowledge the device quickly if possible, and either handle a trivially small amount of work or schedule the thread. Long processing belongs in the ithread or on a taskqueue, not in the filter.

**Where the book teaches this.** Chapter 19 is the dedicated chapter on interrupts. Chapter 20 adds MSI and MSI-X. Chapter 14 (taskqueues) explains how to defer heavy work out of the interrupt path.

**What to read next.** `intr_event(9)`, `bus_setup_intr(9)`, and the filter/ithread documentation in `/usr/src/sys/sys/bus.h` around the `FILTER_` and `INTR_` constants.

## 41.5.2 Edge-Triggered vs Level-Triggered

**What it is.** Two ways the hardware signal can mean “there is something new”.

- **Edge-triggered.** The device asserts a transition (a rising or falling edge) to signal an event. If the driver does not record that an interrupt happened, the event is lost. The edge is a moment, not a state.
- **Level-triggered.** The device holds the line (or the signal) active as long as the condition persists. The interrupt controller keeps firing until the driver acknowledges the device and the line deasserts. The level is a state, not a moment.

**Why this matters to driver writers.** Edge-triggered interrupts are unforgiving: if the driver has a race and a second edge arrives while the first is being processed without being recorded, the second event is forgotten. Level-triggered interrupts are self-healing: if the line is still asserted when you return, the controller will fire again. Legacy PCI INTx lines are level-triggered and shared, which is why driver handlers must read the device's status register and check whether “this interrupt” is really theirs before claiming it. MSI and MSI-X are effectively edge-like: each message is a discrete event.

**How this shows up in FreeBSD.** The distinction is mostly handled below your driver. Legacy INTx registration with `SYS_RES_IRQ` and `rid 0` gets you level-triggered, shared interrupts; `pci_alloc_msi` and `pci_alloc_msix` give you message-signalled interrupts that are per-vector and not shared with unrelated drivers. Your filter still has to behave well; but the sharing concern goes away.

**Common trap.** Writing a filter that returns `FILTER_HANDLED` without actually checking the device. On level-triggered INTx, this hangs the system because the line stays asserted and the controller fires forever.

**Where the book teaches this.** Chapter 19 teaches the classical case; Chapter 20 teaches the message-signalled case.

**What to read next.** The legacy interrupt discussion in `/usr/src/sys/dev/pci/pci.c` around `pci_alloc_msi`, and the filter examples in Chapter 19.

### 41.5.3 MSI and MSI-X Without the Acronyms

**What it is.** Message-Signalled Interrupts. Instead of asserting a shared interrupt line, a PCI Express device sends a small memory-write transaction to a special address that the interrupt controller watches. The payload of the write identifies which interrupt has fired. MSI supports a handful of vectors per device (typically up to 32); MSI-X supports thousands, each with its own address and data, and per-vector CPU affinity.

**Why this matters to driver writers.** Two things change when a driver uses MSI or MSI-X instead of legacy INTx. First, the interrupts are no longer shared, so the filter does not need to coexist with unrelated drivers (it still has to confirm the event came from its own hardware). Second, you can have more than one interrupt per device. A NIC can have one interrupt per receive queue, another per transmit queue, another for the management path, and you can bind each one to a different CPU. That changes how you structure the driver: each queue has its own softc substructure, its own lock, and its own handler.

**How this shows up in FreeBSD.** `pci_msi_count(dev)` and `pci_msix_count(dev)` tell you how many vectors are available. `pci_alloc_msi(dev, &count)` and `pci_alloc_msix(dev, &count)` reserve them; the call updates `count` with the number actually allocated. You then allocate each vector with `bus_alloc_resource_any(dev, SYS_RES_IRQ, &rid, RF_ACTIVE)` using `rid = 1, 2, ..., count`. CPU affinity is set with `bus_bind_intr(dev, res, cpu_id)`. Teardown mirrors the sequence: per-vector `bus_teardown_intr` and `bus_release_resource`, then a single `pci_release_msi(dev)`.

**Common trap.** Requesting too many vectors and assuming the system will give them all. `pci_alloc_msix` may return fewer than requested, even on hardware that advertises plenty; the driver must adapt its queue structure to the number actually allocated. A fallback ladder (MSI-X, then MSI, then INTx) is the standard shape.

**Where the book teaches this.** Chapter 20.

**What to read next.** `pci(9)` for the function list, and `/usr/src/sys/dev/pci/pci.c` for the implementation.

### 41.5.4 Why Interrupt Discipline Matters

**What it is.** The set of rules that keep a driver correct under interrupts. Most of it follows from three facts: the filter runs with very few primitives available, the filter can race with every other path in the driver, and late acknowledgement produces wedged systems.

#### Core rules.

- Keep the filter short and allocation-free. No `malloc`, no sleeping, no calls that might sleep, no complex logic.
- Acknowledge at the device before returning `FILTER_HANDLED`, or make sure the device continues to assert until your `ithread` runs.

- Use spin locks (MTX\_SPIN) to protect state the filter and a CPU path share. Sleep locks cannot be taken in the filter.
- Defer real work to an ithread, a taskqueue, or a callout. The filter's job is to move data off the critical path.
- Count your interrupts. A `sysctl` counter per vector is cheap and often the first clue when the driver misbehaves.

**Common trap.** Holding a sleep lock across a path that could be re-entered from the filter. A thread that owns a sleep mutex cannot be preempted by an interrupt on the same CPU; the kernel's `witness(9)` diagnostic will catch many of these before production, but only if the scenario is actually exercised.

**Where the book teaches this.** Chapter 11 introduces the discipline in general; Chapter 19 makes it concrete for real hardware.

**What to read next.** The locking summary in Appendix A and the filter/ithread split in `/usr/src/sys/sys/bus.h`.

## 41.6 DMA

DMA (Direct Memory Access) is how a peripheral reads or writes memory without the CPU copying every byte. It exists because the alternative (the CPU reading a register, placing the byte in RAM, and looping) is too slow for any modern device. DMA is also the most hardware-aware part of a driver, because it is where the driver must speak the bus's address language instead of the kernel's virtual-pointer language. A driver that is not disciplined about DMA will produce data corruption that is almost impossible to diagnose from user space.

### 41.6.1 What DMA Is and Why It Exists

**What it is.** A transfer in which the device reads from or writes to system memory under its own control, using bus addresses the driver has handed it in advance. The CPU sets up the transfer and goes on with other work; the device signals completion, usually by raising an interrupt. There is no per-byte CPU involvement during the data movement itself.

**Why this matters to driver writers.** Everything about how you allocate, load, synchronise, and release memory changes the moment DMA enters the picture. You no longer own the buffer exclusively; the device owns it during the transfer. You must tell the kernel which parts of the buffer are being read or written and when, so that cache coherence, alignment, and address remapping can be handled correctly.

**How this shows up in FreeBSD.** `bus_dma(9)` is the whole machinery. The driver author's workflow is consistent across every DMA-capable device:

1. Create a `bus_dma_tag_t` in `attach`, describing the device's addressing constraints (alignment, boundary, `lowaddr`, `highaddr`, maximum segment size, number of segments, and so on). The tag captures the device's truth.
2. Allocate a DMA-capable buffer with `bus_dmamem_alloc(tag, &vaddr, flags, &map)`, or allocate an ordinary buffer and load it later.
3. Load the buffer with `bus_dmamap_load(tag, map, vaddr, length, callback, arg, flags)`. The callback receives one or more `bus_dma_segment_t` entries whose `ds_addr` fields are the bus addresses to hand the device.

4. Before the device reads, `bus_dmamap_sync(tag, map, BUS_DMASYNC_PREWRITE)`. Before the CPU reads what the device wrote, `bus_dmamap_sync(tag, map, BUS_DMASYNC_POSTREAD)`. The flags are defined in `/usr/src/sys/sys/bus_dma.h`.
5. When the transfer is complete, `bus_dmamap_unload(tag, map)` releases the mapping; `bus_dmamem_free(tag, vaddr, map)` releases the buffer; `bus_dma_tag_destroy(tag)` releases the tag (usually in detach).

**Common trap.** Forgetting the PREWRITE or POSTREAD sync. On coherent architectures (amd64 with IOMMU, for example), the driver often works without it; on non-coherent architectures (some ARM systems), it silently corrupts data. Write the sync calls every time, even when you are developing on a forgiving platform.

**Where the book teaches this.** Chapter 21 is the full-length dedicated treatment.

**What to read next.** `bus_dma(9)` and `/usr/src/sys/kern/subr_bus_dma.c`.

### 41.6.2 The Mental Model: Tags, Maps, Segments, Sync

A short refresher in the shape of a diagram. The pieces fit together like this:

Each arrow is a responsibility. The tag expresses what the device can tolerate. The map expresses one particular set of segments the device will actually touch. The sync calls bracket the device's use of the buffer. Miss any one of them and the transfer is undefined.

### 41.6.3 Why Synchronisation and Mapping Matter

**What it is.** Two concerns that together explain why `bus_dma` is not just an address translator.

- **Mapping.** The device needs a bus address, not a virtual one. On IOMMU systems, the mapping is a real I/O-virtual range; on non-IOMMU systems, it is the physical address, possibly through a bounce buffer if the device cannot reach where the memory actually lives. The driver does not choose which; `bus_dma` chooses based on the tag.
- **Synchronisation.** The CPU has caches. The device may have its own. The kernel has ordering rules. The sync calls translate the driver's intent ("I am about to hand this buffer to the device for reading") into whatever cache flushes, invalidations, or memory barriers the architecture requires.

**Why this matters to driver writers.** Skipping synchronisation is the single most common source of subtle data corruption in a DMA driver. The code appears to work because the CPU caches happen to be flushed by other activity; then a kernel update changes cache behaviour slightly and the driver begins to fail. Writing every sync call every time is the only reliable habit.

**How this shows up in FreeBSD.** The four sync flags are `BUS_DMASYNC_PREREAD`, `BUS_DMASYNC_PREWRITE`, `BUS_DMASYNC_POSTREAD`, and `BUS_DMASYNC_POSTWRITE` (values 1, 4, 2, 8 in `/usr/src/sys/sys/bus_dma.h`). "PRE" runs before the device touches the buffer; "POST" runs after. The "READ" and "WRITE" halves follow the wording in `bus_dma(9)`: `PREREAD` is "the device is about to update host memory, and the CPU will later read what was written"; `PREWRITE` is "the CPU has updated host memory, and the device is about to access it". In the pair of directions a driver usually thinks about, `PREWRITE` covers the CPU-writes-buffer-then-device-reads case, and `PREREAD` covers the device-writes-buffer-then-CPU-reads case.

**Common trap.** Reading the flag names as if they described the device's own action. If the device is about to write to memory, and the CPU will later read what the device wrote, you call `BUS_DMASYNC_PREREAD` first (because the CPU will later read this memory), not `BUS_DMASYNC_PREWRITE`. The flag pairs track the memory operation the CPU is part of, not the direction the device happens to move data on the wire.

**Where the book teaches this.** Chapter 21 spends substantial space on the sync semantics because they are easy to get wrong.

**What to read next.** `bus_dma(9)` and the header comments in `/usr/src/sys/sys/bus_dma.h`.

### 41.6.4 DMA Buffers vs Control Buffers

**What it is.** A final distinction that keeps the memory section and the DMA section in step. Not every buffer in a DMA-capable driver is a DMA buffer.

- **DMA buffers** are the ones the device reads from or writes to. They go through `bus_dma(9)`: allocated with `bus_dmamem_alloc` or `malloc` plus `bus_dmamap_load`, loaded, synchronised, unloaded.
- **Control buffers** are the ones only the CPU touches: ring indices, per-request bookkeeping, command structures the driver inspects but the hardware does not. They live in ordinary `malloc(9)` memory.

**Why this matters to driver writers.** Both kinds of buffer usually exist in the same driver, often side by side inside the same softc. Keeping them straight makes the code much easier to review. A pointer that the device reads should be labelled and allocated unambiguously; a pointer the device never sees should be labelled and allocated just as unambiguously. Confusing the two usually produces hard-to-reproduce bugs.

**Where the book teaches this.** Chapter 21 revisits the split when it walks a complete descriptor-ring driver.

## 41.7 Quick-Reference Tables

The compact tables below are meant for scanning. They do not replace the sections above; they help you point at the right section fast.

### 41.7.1 Address Spaces at a Glance

| You have...                | It lives in...                         | How you get it                                                                               | Who can dereference it                           |
|----------------------------|----------------------------------------|----------------------------------------------------------------------------------------------|--------------------------------------------------|
| A C pointer in kernel code | Kernel virtual memory                  | <code>malloc</code> , <code>uma_zalloc</code> ,<br>stack, <code>softc</code>                 | CPU                                              |
| A device register          | Physical I/O space                     | <code>bus_alloc_resource(SYS_CHS_MEMORY, space_*</code><br><code>+ bus_space_handle_t</code> | CPU                                              |
| A DMA buffer               | Kernel virtual, plus a bus view        | <code>bus_dmamem_alloc</code>                                                                | CPU via virtual, device via <code>ds_addr</code> |
| A device-side bus address  | Bus address space (maybe IOMMU-mapped) | <code>bus_dmamap_load</code><br>callback                                                     | Device only                                      |

### 41.7.2 When to Use Which Allocator

| Purpose                                        | Call                                                              |
|------------------------------------------------|-------------------------------------------------------------------|
| <code>Softc</code> , lists, control structures | <code>malloc(9)</code> with <code>M_DRIVER_NAME</code>            |
| Frequent fixed-size objects                    | <code>uma(9)</code> zone                                          |
| DMA buffer with tag constraints                | <code>bus_dmamem_alloc(9)</code> under a <code>bus_dma</code> tag |
| Physically contiguous block, no DMA tag        | <code>contigmalloc(9)</code> (rarely)                             |
| Stack temporary, small and bounded             | Plain C stack                                                     |

### 41.7.3 Interrupt vs Polling

| You should use...                      | When...                                                   |
|----------------------------------------|-----------------------------------------------------------|
| A hardware interrupt                   | The event rate is moderate and latency matters            |
| Polling inside an <code>ithread</code> | The event rate is very high and interrupts would dominate |

| You should use...                            | When...                                        |
|----------------------------------------------|------------------------------------------------|
| A taskqueue triggered by interrupts          | The work is heavy and cannot run in the filter |
| A timer (callout) plus occasional interrupts | The device is slow and state is simple         |

#### 41.7.4 Bus at a Glance (Driver-Writer View)

| Bus        | Driver form                       | Identification                       | Main API call                                                          |
|------------|-----------------------------------|--------------------------------------|------------------------------------------------------------------------|
| PCI / PCIe | Full Newbus driver with registers | Vendor/Device ID + class             | <code>bus_alloc_resource_any</code> ,<br><code>bus_setup_intr</code>   |
| USB        | Framework class driver            | VID/PID +<br>class/subclass/protocol | <code>usbd_transfer_setup</code> ,<br><code>usbd_transfer_start</code> |
| I2C        | <code>iicbus</code> client        | Slave address                        | <code>iicbus_transfer</code>                                           |
| SPI        | <code>spibus</code> client        | Chip-select line                     | <code>spibus_transfer</code>                                           |

#### 41.7.5 DMA Sync Quick Check

| You are about to...                                        | Call this                                                         |
|------------------------------------------------------------|-------------------------------------------------------------------|
| Hand a buffer to the device for the device to <i>read</i>  | <code>bus_dmamap_sync( . . . , BUS_DMASYNC_PREWRITE )</code>      |
| Hand a buffer to the device for the device to <i>write</i> | <code>bus_dmamap_sync( . . . , BUS_DMASYNC_PREREAD )</code>       |
| Read from a buffer the device just wrote                   | <code>bus_dmamap_sync( . . . , BUS_DMASYNC_POSTREAD )</code>      |
| Reuse a buffer after the device read it                    | <code>bus_dmamap_sync( . . . ,<br/>BUS_DMASYNC_POSTWRITE )</code> |

The “PRE” calls fence the CPU writes or cache lines before the device looks at the buffer. The “POST” calls fence the device’s completion before the CPU looks at what changed.

### 41.8 Wrapping Up: How to Keep Relating Hardware Concepts to Driver Code

The hardware concepts in this appendix are not a separate subject from driver writing. Every one of them shows up in code. The sequence the reader will use, over and over, is always the same:

1. The device exists in physical address space. Its registers are at physical addresses.
2. The kernel gives the driver a `bus_space` handle that maps those registers with the right attributes.
3. The device raises interrupts on events, and the driver handles them through a filter (fast, small, spin-lock safe) and optionally an `ithread` (slower, sleep-lock safe).

4. When the device needs to move data, the driver uses `bus_dma(9)` to produce bus addresses that the device can use, and it brackets every transfer with sync calls.
5. The driver never hands a kernel virtual pointer to the device, and never treats a `ds_addr` as if it were a physical address the CPU can read directly.

If you keep that sequence in mind, the hardware concepts here stop being a separate subject and become a running commentary on the code you are writing. When you are about to cast a pointer and hand it to hardware, stop and translate the action into the sequence: in which address space is this, who is going to read it, what attributes does that view need. The sequence never changes. The details change with every device family.

Three habits that reinforce the model.

The first is reading the header comment of a real driver before reading its code. Most FreeBSD drivers open with a block that explains the locking discipline, the MSI-X structure, or the ring layout. That comment is there because the code alone cannot communicate it. When the comment says “the receive ring uses the per-queue lock; the filter acknowledges the device and schedules a taskqueue”, read it carefully. It is a condensed map of the hardware-to-software bridge for that driver.

The second is naming the bus every time. When you read an unfamiliar driver, find the `DRIVER_MODULE` line. The bus name in that line (`pci`, `usb`, `iicbus`, `spibus`, `acpi`, `simplebus`) tells you which hardware model applies before you read a single function. A driver attached to `pci` is register-oriented and interrupt-driven; a driver attached to `iicbus` is transaction-oriented and polled at the bus level. The same C code reads differently when you know which bus is behind it.

The third is keeping a short companion sheet with your driver notes. The files under `examples/appendices/appendix-c-hardware-concepts-for-driver-developers/` are meant for exactly this. A bus-comparison cheatsheet you can glance at when you open a new datasheet. A DMA mental-model checklist you can walk when you suspect a sync is missing. A physical-vs-virtual diagram you can annotate with the particular tag and handle pair you are working with today. The teaching is in this appendix; the application is in those sheets.

With that, the hardware side of the book has a consolidated home. The chapters keep teaching; the appendix keeps naming; the examples keep reminding. When a reader closes this appendix and opens a real driver, the vocabulary is ready.

## 42 Appendix D: Operating System Concepts

### 42.1 How to Use This Appendix

The main chapters teach the reader how to write a FreeBSD device driver: how to declare a softc, how to probe and attach to a bus, how to register a character device, how to set up an interrupt, how to do DMA. Beneath all of that there is a running assumption that the reader has a working mental model of what an operating system kernel actually is, how it differs from userland, what a driver is *inside* that kernel, and how the machine gets from power-on to a kernel that is ready to load and run that driver. The book introduces each piece of this model in the chapter where it first becomes relevant, but the pieces never appear in one place together.

This appendix is that one place. It is a concept companion for the operating-system ideas the rest of the book keeps reusing: the kernel/user boundary, the definition of a driver, the handful of data structures you will see again and again in FreeBSD source, and the boot-to-init sequence that sets the stage for everything a driver can do. It is deliberately short. The goal is to consolidate the mental model, not to teach operating-systems theory, and not to repeat what the chapters already teach at length.

#### 42.1.1 What You Will Find Here

The appendix is organised by driver relevance, not by textbook taxonomy. Four sections, each with a small set of entries. Each entry follows the same compact rhythm:

- **What it is.** One or two sentences of plain definition.
- **Why this matters to driver writers.** The concrete place where the concept shows up in your code.
- **How this shows up in FreeBSD.** The API, header, subsystem, or convention that names the idea.
- **Common trap.** The misunderstanding that actually costs people time.
- **Where the book teaches this.** A pointer back to the chapter that uses it in context.
- **What to read next.** A manual page, a header, or a real source file you can open.

Not every entry uses every label; the shape is a guide, not a template.

#### 42.1.2 What This Appendix Is Not

It is not an introduction to operating-systems theory. If you have never met the idea of a process or an address space before, pick up a general operating-systems textbook first and come back. It is not a systems-programming tutorial either; the early chapters of the book already handle that. And it does not overlap with the other appendices. Appendix A is the API lookup. Appendix B is the algorithmic-pattern field guide. Appendix C is the hardware-concepts companion. Appendix E is the kernel-subsystem reference. If the question you want answered is “what does this macro call do”, “what data structure should I use”, “what is a BAR”, or “how does the scheduler work”, you want a different appendix. This one keeps its focus on the operating-system mental model that makes driver work make sense.

## 42.2 Reader Guidance

Three ways to use this appendix, each with a different reading strategy.

If you are **learning the main chapters**, keep this appendix open as a companion. When Chapter 3 discusses the UNIX division between the kernel and userland, glance at Section 1 here for the driver-relevant summary. When Chapter 6 introduces Newbus and the driver lifecycle, Section 2 compresses the same story into a one-page mental model. When Chapter 11 walks you through your first mutex, Section 3 names the family. A first pass through the whole appendix should take about twenty-five minutes; daily use looks more like two or three minutes at a time.

If you are **reading unfamiliar kernel code**, treat the appendix as a translator. Kernel source assumes the reader already knows why `copyin(9)` exists, what a `softc` is, when a `TAILQ` is better than a `LIST`, and where `SYSINIT` chains come from. If any of those words feel fuzzy when you meet them in code, the entry here names the concept in one page and points to the chapter that teaches it in full.

If you are **coming back to the book after time away**, read the appendix as a consolidation. The concepts here are the recurring spine of driver work. Re-reading them is a low-cost way to reload the mental model before you open an unfamiliar driver.

A few conventions apply throughout:

- Source paths are shown in the book-facing form, `/usr/src/sys/...`, matching a standard FreeBSD system. You can open any of them on your lab machine.
- Manual pages are cited in the usual FreeBSD style. Kernel-facing pages live in section 9 (`intr_event(9)`, `mtx(9)`, `kld(9)`). Userland system calls live in section 2 (`open(2)`, `ioctl(2)`). Device overviews live in section 4 (`devfs(4)`, `pci(4)`).
- When an entry points to real source as reading material, the file is one a beginner can navigate in a single sitting.

With that framing in place, we start where every driver must start: by understanding which side of the kernel/user line it lives on.

## 42.3 Section 1: What Is a Kernel, and What Does It Do?

A kernel is the program that owns the machine. It is the only program that runs in the CPU's most privileged mode, the only program that may touch physical memory directly, the only program that may talk to hardware, and the only program that may decide which other programs run and when. Everything else (shells, compilers, web browsers, daemons, your own programs) runs in a less privileged mode and asks the kernel for the things it cannot do itself. A driver is kernel code. That single fact changes the rules the code must follow, and the rest of this section explains why.

### 42.3.1 Kernel Responsibilities in One Page

**What it is.** The FreeBSD kernel is responsible for a small, well-defined set of jobs: managing the CPU (processes, threads, scheduling, interrupts), managing memory (virtual address spaces, page tables, allocation), managing I/O (talking to devices through drivers), managing files and filesystems (through VFS and GEOM), and

managing the network stack. It also mediates security boundaries, handles signals, and serves as the only entry point for every system call.

**Why this matters to driver writers.** A driver is not a free-standing program. It is a participant in each of those jobs. A network driver participates in the networking subsystem. A storage driver participates in the I/O and filesystem subsystems. A sensor driver participates in the I/O subsystem and sometimes in the event-handler subsystem. When you write a driver, you are extending the kernel, not sitting beside it. The kernel's invariants become your invariants, and every convention the kernel relies on (locking discipline, memory discipline, error-return conventions, cleanup ordering) becomes a convention you must honour.

**How this shows up in FreeBSD.** The kernel source tree under `/usr/src/sys/` is organised by responsibility: `/usr/src/sys/kern/` holds the machine-independent core (process management, scheduling, locking, VFS), `/usr/src/sys/vm/` holds the virtual-memory system, `/usr/src/sys/dev/` holds the device drivers, `/usr/src/sys/net/` and `/usr/src/sys/netinet/` hold the network stack, and `/usr/src/sys/amd64/` (or `arm64/`, `i386/`, `riscv/`) holds the machine-dependent code. When you read a driver, you are reading code that ties together pieces from several of these directories.

**Common trap.** Treating the kernel as a passive library that drivers “call into”. The kernel is the running program; your driver lives inside it. A crash, a memory leak, or a held lock in your driver is a crash, a memory leak, or a held lock for the whole system.

**Where the book teaches this.** Chapter 3 introduces the UNIX and FreeBSD picture. Chapter 5 sharpens the distinction at the level of kernel-space C. Chapter 6 grounds it in driver anatomy.

**What to read next.** `intro(9)` for the top-level kernel overview, and the directory listing of `/usr/src/sys/` itself. Spend five minutes reading folder names and you will already have a rough map.

### 42.3.2 Kernel Space vs User Space

**What it is.** Two distinct execution environments inside the same machine. Kernel space runs with full CPU privileges, shares one address space among all kernel threads, and has direct access to hardware. User space runs with reduced privileges, lives in per-process virtual address spaces that the kernel sets up and protects, and has no direct access to hardware. A single machine is always running code from both environments; the CPU switches between them many times per second.

**Why this matters to driver writers.** Almost every rule that makes kernel programming feel different from user programming comes from this separation. A kernel pointer is not addressable from user space, and a user pointer is not safely addressable from kernel space. User memory may be swapped, paged, or unmapped at any moment; kernel memory is stable within its allocation lifetime. The kernel must never blindly dereference a pointer that came from userland; it must always use the dedicated copy primitives. And because one kernel address space is shared by every thread in the kernel, any kernel bug that stomps memory can corrupt every subsystem at once.

**How this shows up in FreeBSD.** Three places in driver code are visible every time the boundary is crossed:

- `copyin(9)` and `copyout(9)` move fixed-size data between a user buffer and a kernel buffer, returning an error on a bad user address instead of panicking.
- `copyinstr(9)` does the same for NUL-terminated strings with a caller-supplied length cap.
- `uiomove(9)` walks a `struct uio` (user I/O descriptor) through either direction of a read or write system call, handling the buffer list and the direction flag for you.

Under the hood, each of these routines uses machine-dependent helpers that know how to catch a fault from a bad user address and convert it into an `EFAULT` return rather than a kernel panic.

**Common trap.** Dereferencing a user pointer directly inside a syscall handler or an `ioctl` implementation. The code may appear to work when the user passes a valid pointer and the page happens to be resident. It will panic or silently misbehave the moment the user passes something bad (either by mistake or deliberately), and that is one of the easier bugs to turn into a security problem.

**Where the book teaches this.** Chapter 3 sets up the distinction. Chapter 5 covers it in kernel C. Chapter 9 walks the boundary in character-driver code.

**What to read next.** `copyin(9)`, `copyout(9)`, `uiomove(9)`, and the header `/usr/src/sys/sys/uio.h` for `struct uio`.

### 42.3.3 System Calls: The Door Between the Two Sides

**What it is.** A system call is the disciplined mechanism a user-space program uses to ask the kernel to do something on its behalf. The user program invokes a special instruction (`syscall` on amd64, `svc` on arm64, with equivalent traps on every other architecture FreeBSD supports), which causes the CPU to trap into kernel mode, switch to the kernel stack of the current thread, and dispatch to the implementation the kernel has registered for that system-call number.

**Why this matters to driver writers.** Most driver interaction with userland happens because a userland program issued a system call. When the user runs `cat /dev/mydevice`, `cat(1)` invokes `open(2)`, `read(2)`, and `close(2)` against that device node. Each of those system calls eventually reaches your driver through the `cdev` switch table you registered with `make_dev_s(9)`: `open(2)` becomes `d_open`, `read(2)` becomes `d_read`, `ioctl(2)` becomes `d_ioctl`. Your driver's entry points are therefore system-call entry points in disguise, which is exactly why the copy primitives above matter so much.

**How this shows up in FreeBSD.** Two pieces. First, the system-call table itself and the trap-handling path, which live in the machine-independent core and in the architecture-specific backends. Second, the driver-visible structures that a system call hands you: a `struct thread *` for the calling thread, a `struct uio *` for the buffer list on `read/write`, an argument pointer for `ioctl`, and a set of flags that describe the mode of the call. The driver does not see the trap; it sees a function call that arrives already in kernel context.

**Common trap.** Assuming the calling thread can be treated as an ordinary kernel thread. A thread that entered the kernel through a system call is temporarily running kernel code on behalf of a user process. It may be killed if the process is killed, its priority may be different from an internal kernel thread, and it is usually the wrong thread to own long-lived work. Long work belongs on a taskqueue or a kernel thread the driver owns.

**Where the book teaches this.** Chapter 3 names the mechanism. Chapter 9 exercises it in a working `read/write` path.

**What to read next.** `syscall(2)` for the userland view, `uiomove(9)` for the kernel entry shape, and `/usr/src/sys/kern/syscalls.master` if you are curious about the actual system-call numbering table.

### 42.3.4 Why Kernel Mistakes Have System-Wide Consequences

**What it is.** A short way of stating what the previous entries imply. A kernel thread can read and write any kernel memory; there is no per-module address space inside the kernel. A kernel bug is therefore free to damage any

data structure, including data structures that belong to other subsystems. A kernel crash takes the whole machine down. A kernel deadlock can wedge threads across every driver at once.

**Why this matters to driver writers.** The blast radius of a kernel bug is the whole system. That is why the book repeats the same disciplines in every chapter: balanced allocate/free pairs, balanced lock acquire/release pairs, consistent cleanup ladders on error, defensive validation of any pointer that comes from userland, and careful ordering at boundaries (interrupts, DMA, device registers). None of these disciplines are about heroics; they are about acknowledging that the cost of a kernel mistake is paid by every process on the machine, not only by the driver that made it.

**How this shows up in FreeBSD.** Directly, in the tools the kernel offers you to catch mistakes before they escape. `witness(9)` verifies lock ordering. `KASSERT(9)` lets you encode invariants that compile away in production but fire loudly in a development build. `INVARIANTS` and `INVARIANT_SUPPORT` in the kernel config turn on extra self-checks. `DTrace` lets you watch driver behaviour under real load. Your development lab should always be running a kernel with these diagnostics enabled; your production target should not.

**Common trap.** Testing only on a release-build kernel and discovering the bugs in production. The development kernel is the one that finds the problem cheaply. Use it.

**Where the book teaches this.** Chapter 2 walks you through building a diagnostics-enabled lab kernel. Chapter 5 makes the discipline concrete at the C level. Every chapter from Chapter 11 onward depends on these habits.

**What to read next.** `witness(9)`, `kassert(9)`, `ddb(4)`, and the kernel-debugging options in `/usr/src/sys/conf/NOTES`.

### 42.3.5 How Drivers Participate in Kernel Responsibilities

The previous entries describe the kernel as an abstract entity. The role a driver plays inside that kernel is concrete and limited. A driver is the component that makes a specific piece of hardware, or a specific pseudo-device, usable through the kernel's existing subsystems. A storage driver exposes a disk through GEOM and the buffer cache so that filesystems can use it. A network driver exposes a NIC through `ifnet` so that the network stack can use it. A character driver exposes a device node in `/dev` so that userland programs can use it through ordinary file system calls. Drivers do not invent interfaces; they implement the ones the kernel already publishes.

That framing is worth keeping close while you read a new driver. Finding the two ends, the hardware end (registers, interrupts, DMA) and the subsystem end (the `ifnet`, the `cdev`, the GEOM provider), is the single best way to orient yourself in an unfamiliar driver. Section 2 puts more shape on the subsystem end.

## 42.4 Section 2: What Is a Device Driver?

A device driver is the piece of kernel code that makes a particular device, real or virtual, usable through the operating system's regular interfaces. It lives on two fronts at once. On one side it speaks the hardware's language: register accesses, interrupts, DMA descriptors, protocol sequences. On the other side it speaks one of FreeBSD's standard subsystem interfaces: `cdevsw` for character devices, `ifnet` for network interfaces, GEOM for storage. A driver's job is to translate between those two sides, correctly and safely, for the lifetime of the device.

This section names the driver types the book cares about, the role the driver plays in the hardware-to-userland path, and the mechanics by which FreeBSD loads a driver and binds it to a device.

### 42.4.1 Driver Types: Character, Block, Network, Pseudo

**What it is.** A classification by the subsystem interface the driver publishes. The vocabulary is older than FreeBSD and the historical category names still appear, but on modern FreeBSD the exact boundaries differ from the textbook picture.

- A **character device driver** exposes the hardware as a stream through a `cdev` node in `/dev`. It registers a `struct cdevsw` with entry points such as `d_open`, `d_close`, `d_read`, `d_write`, and `d_ioctl`, and the kernel routes corresponding system calls to those entry points. Pseudo-devices (drivers with no real hardware behind them, like `/dev/null` or `/dev/random`) are character devices too.
- A **block device driver** in the historical UNIX sense exposed a fixed-size disk through a block-oriented cache. In modern FreeBSD, disk-like devices are presented through GEOM, not through a separate block-`cdevsw`; the entries in `/dev` for a disk (`/dev/ada0`, `/dev/da0`) are still `cdev` nodes, but their substance is a GEOM provider, and filesystems talk to them through the BIO layer rather than through raw read/write.
- A **network driver** exposes a network interface through `ifnet`. It does not use `cdevsw` at all; it registers with the network stack, receives packets as `struct mbuf` chains, sends packets through the stack's transmit queues, and participates in link-state events.
- A **pseudo-device driver** is any driver with no real hardware behind it. It may be a character device (`/dev/null`, `/dev/random`), a network device (`tun`, `tap`, `lo`), or a storage provider (`md`, `gmirror`). The word “pseudo” refers only to the absence of hardware; the subsystem integration is the same as for a real device.

**Why this matters to driver writers.** The type of driver you are writing determines the interface you must implement. A character-device driver spends its time in `d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl`. A network driver spends its time in `if_transmit`, `if_input`, and interrupt-driven receive paths. A storage driver spends its time in GEOM start routines and BIO completion. Picking the right type early saves a rewrite; picking the wrong one is an expensive mistake.

**How this shows up in FreeBSD.** Three separate sets of headers and chapters of the tree handle the three main types:

- Character drivers register through `/usr/src/sys/sys/conf.h` (`struct cdevsw`, `make_dev_s`) and are implemented all across `/usr/src/sys/dev/`.
- Network drivers register through `/usr/src/sys/net/if.h` (`struct ifnet`) and have their stack integration in `/usr/src/sys/net/` and `/usr/src/sys/netinet/`.
- Storage drivers register through the GEOM framework under `/usr/src/sys/geom/` and use `struct bio` for I/O requests.

**Common trap.** Reaching for `cdevsw` to expose a disk. The “everything is a file” intuition is half right, but a modern FreeBSD disk is a GEOM provider; a raw `cdevsw` interface skips the cache, the partitioning layer, and the transforms the rest of the system expects.

**Where the book teaches this.** Chapter 6 names the categories and positions them inside Newbus. Chapter 7 writes the first character driver from scratch. Chapter 27 covers storage and GEOM. Chapter 28 covers network drivers.

**What to read next.** `cdevsw(9)`, `ifnet(9)`, and a compact pseudo-device such as `/usr/src/sys/dev/null/null.c`. Read the `null` driver in one sitting; it is the cleanest example of a complete character driver in the tree.

### 42.4.2 The Role of a Driver in Hardware Communication

**What it is.** The driver is the only kernel code that talks to its hardware. Nothing else in the kernel accesses the device's registers, arms its interrupts, or queues its DMA transfers. All other subsystems reach the device through the driver.

**Why this matters to driver writers.** This exclusivity is why the driver must be trustworthy. The network stack cannot double-check whether a packet was really transmitted; it trusts the network driver. The filesystem cannot double-check whether a block really reached the disk; it trusts the storage driver. When the driver lies (by completing a transfer before the hardware is finished, for example), the rest of the system believes the lie and carries on. Most catastrophic failures in real systems come from this class of subtle driver dishonesty, not from outright crashes.

**How this shows up in FreeBSD.** In the shape of the driver's public functions. A character driver's `d_read` returns only after the data is really in the user buffer or an error has occurred. A network driver's `if_transmit` tells the stack whether the packet is owned by the driver now or still by the stack. A storage driver's `g_start` takes responsibility for completing the `bio` through `biodone(9)` eventually. Every one of those contracts is a promise the driver is making on behalf of the hardware.

**Common trap.** Returning early from a completion path because "the hardware usually works". On a good day, nothing fails. On a bad day, the stack thinks a packet was sent that was not, a filesystem thinks a block was written that was not, and the resulting corruption is impossible to track back to its source.

**Where the book teaches this.** Chapter 6 sets up the contract. Chapter 19 makes it rigorous for interrupt-driven completion. Chapter 21 does the same for DMA.

**What to read next.** `biodone(9)`, and the transmit/receive path of a small NIC driver.

### 42.4.3 How Drivers Are Loaded and Bound to Devices

**What it is.** FreeBSD drivers reach a running kernel in one of two ways. Either they are compiled into the kernel binary (built-in drivers, activated during boot) or they are built as kernel-loadable modules (`.ko` files) that the administrator loads at run time with `kldload(8)`. Once a driver is present in the kernel, Newbus offers it the devices it claims.

The binding dance is the *probe/attach* cycle. Every bus enumerates its children at boot or on hot-plug and asks each registered driver whether it can handle each child. The driver's `probe` function examines the child (vendor/device ID for PCI, VID/PID for USB, FDT compatibility string for embedded systems, a class register for generic buses) and returns a priority value saying how confident it is. The bus picks the highest-priority match and calls that driver's `attach` function. From that point on, the device belongs to the driver, and the driver's `softc` holds the device's state.

**Why this matters to driver writers.** Every FreeBSD driver ends with a short block of boilerplate that registers it for this dance. The boilerplate is the contract between the driver and the rest of the kernel. Get it wrong and the driver never attaches; get it right and the kernel will attach, detach, suspend, resume, and unload your driver at the moments it chooses.

**How this shows up in FreeBSD.** Five pieces, all compact:

- A `device_method_t` array that lists the driver's implementations of the standard device methods, ending with `DEVMETHOD_END`.

- A `driver_t` structure that binds a driver name, the method table, and a softc size.
- A `DRIVER_MODULE(name, busname, driver, evh, arg)` invocation at the bottom of the file, which registers the driver with the named bus. The `evh` and `arg` fields pass an optional event handler; most drivers leave them as `0, 0`.
- A `MODULE_VERSION(name, version)` invocation to advertise the module's ABI version.
- Optional `MODULE_DEPEND(name, other, min, pref, max)` lines if the driver depends on another module.

These live in `/usr/src/sys/sys/module.h` and `/usr/src/sys/sys/bus.h`. The `DEVMETHOD` macro hooks the driver's `probe`, `attach`, `detach`, and optional `suspend/resume/shutdown` functions into the `kobj` method dispatcher that Newbus uses internally.

**Common trap.** Forgetting `MODULE_VERSION`. The module may load and work on your machine, and then fail to load on someone else's because the kernel has no way to check ABI compatibility. The version declaration is not ceremonial; it is how the module loader keeps pieces compatible.

**Where the book teaches this.** Chapter 6 introduces the Newbus tree. Chapter 7 writes the full boilerplate end to end and uses `kldload(8)` to exercise it.

**What to read next.** `DRIVER_MODULE(9)`, `MODULE_VERSION(9)`, `kld(9)`, `kldload(8)`, and the compact `/usr/src/sys/dev/null/null.c` as a complete example.

#### 42.4.4 Connecting Hardware, Kernel Subsystems, and Userland

**What it is.** A short way of stating what a driver does viewed from the top. Hardware is on one side. Userland is on the other. In between are the kernel subsystems (`VFS`, `GEOM`, `ifnet`, `cdev`). The driver is the component that lets bytes flow through that sandwich.

A rough picture, in one direction:

| userland | kernel subsystems                  | driver                         | hardware   |
|----------|------------------------------------|--------------------------------|------------|
| -----    | -----                              | -----                          | -----      |
| cat(1)   | -> open(2) / read(2)               |                                |            |
|          | -> cdev switch                     |                                | ADC, NIC,  |
|          | (d_read)                           | -> driver entry point          | disk, etc. |
|          |                                    | -> register read, MMIO, DMA    |            |
|          |                                    |                                | -> bytes   |
|          |                                    | <- sync, interrupt, completion |            |
|          | <- mbuf chain / bio / uiomove back |                                |            |
|          | <- read(2) returns                 |                                |            |

The picture is not literal code. It is the shape of responsibility. Every driver fits some variant of it.

**Why this matters to driver writers.** When you are unsure where a piece of code belongs, ask which layer of the sandwich is responsible for the current concern. A user-pointer validation belongs at the subsystem boundary. A register access belongs in the driver. A per-device state update belongs in the softc. Once the layer is clear, the names and primitives follow.

**Where the book teaches this.** Chapter 6 draws the picture for character drivers. Chapter 27 redraws it for GEOM. Chapter 28 redraws it for `ifnet`. The shape is always recognisable.

**What to read next.** The top of `/usr/src/sys/dev/null/null.c` for a minimal character variant, and the top of `/usr/src/sys/net/if_tuntap.c` for a minimal network variant.

## 42.5 Section 3: Kernel Data Structures You Will See Often

Certain shapes appear in nearly every FreeBSD driver. A linked list of pending requests. A buffer that crosses the kernel/user boundary. A lock around the softc. A condition variable waited on from one thread and signalled from another. None of these is complicated in isolation, but meeting them for the first time inside real code is where the mental model often breaks down. This section names the families, explains what role they play, and points you back to the chapter that teaches them in full. Appendix A has the detailed APIs; Appendix B has the algorithmic patterns. This section is the one-page orientation.

### 42.5.1 Lists and Queues from `<sys/queue.h>`

**What it is.** A header-only family of intrusive-list macros. You embed a `TAILQ_ENTRY`, `LIST_ENTRY`, or `STAILQ_ENTRY` inside your element structure, define a head, and the macros give you insertion, removal, and traversal without any heap allocation for list nodes. Four flavours exist: `SLIST` (singly linked), `LIST` (doubly linked, insertion at head), `STAILQ` (singly linked with fast tail insertion), and `TAILQ` (doubly linked with tail insertion and  $O(1)$  arbitrary removal).

**Why this matters to driver writers.** Almost every per-driver collection in the tree is one of these. Pending commands, open file handles, registered callbacks, queued bio requests. Picking the right flavour for the access pattern produces code that is short, predictable, and lockable with a single mutex. Picking the wrong one produces needless pointer bookkeeping or surprise  $O(n)$  removal.

**How this shows up in FreeBSD.** The macros live in `/usr/src/sys/sys/queue.h`. A softc often holds its queue heads as ordinary fields. Every traversal is wrapped by the driver's lock. The safe-against-removal variants (`TAILQ_FOREACH_SAFE`, `LIST_FOREACH_SAFE`) are the ones you want any time the body of the loop might unlink the current element.

**Common trap.** Using a plain `LIST_FOREACH` while freeing elements inside the loop body. The iterator dereferences the element's link pointer after you have already freed it. Switch to the `_SAFE` variant or rearrange the loop.

**Where the book teaches this.** Chapter 5 introduces the macros in kernel C. Chapter 11 uses them with locking. Appendix B has the full pattern-oriented treatment.

**What to read next.** `queue(3)`, `/usr/src/sys/sys/queue.h`, and any driver softc that holds an in-flight request list.

### 42.5.2 Kernel Buffers: mbuf, buf, and bio

**What it is.** Three buffer representations that appear in specific subsystems. `struct mbuf` is the networking packet-representation type, a linked list of small fixed-size units that together hold a packet and its metadata. `struct buf` is the storage buffer-cache unit, used by the VFS and the legacy block layer. `struct bio` is the GEOM I/O-request structure, the modern unit of storage I/O that a storage driver completes with `biodone(9)`.

**Why this matters to driver writers.** You will not meet all three at once. A network driver thinks in mbuf chains. A storage driver thinks in bio requests and, at the VFS layer, in buf entries. A character driver rarely sees any of them; it uses `struct uio` instead. Knowing which buffer type your subsystem uses tells you which completion convention applies and which headers to include. Mixing them up is a signal that the driver type is wrong or that a layer boundary is being violated.

**How this shows up in FreeBSD.** `struct mbuf` is defined in `/usr/src/sys/sys/mbuf.h`. `struct buf` is defined in `/usr/src/sys/sys/buf.h`. `struct bio` is defined in `/usr/src/sys/sys/bio.h`. Each has its own allocation, reference-counting, and completion rituals; the driver never invents a substitute.

**Common trap.** Allocating a plain byte buffer for network transmit because it looks easier. The network stack hands you an mbuf; the network stack expects an mbuf back. Converting in and out of the right type is almost always a mistake, and it breaks zero-copy fast paths that the stack relies on.

**Where the book teaches this.** Chapter 27 introduces bio in the storage context. Chapter 28 introduces mbuf in the network context. Appendix E will have deeper entries for each.

**What to read next.** `mbuf(9)`, `bio(9)`, `buf(9)`.

### 42.5.3 Locking: Mutex, Spin Mutex, Sleep Lock, Condition Variable

**What it is.** A family of kernel primitives for ordering access to shared data. Four kinds matter at the appendix level:

- A **default mutex** (`mtx(9)` with `MTX_DEF`) is the everyday sleep-capable mutex. A thread that cannot immediately acquire it goes to sleep until the owner releases. It is the right default for almost every softc field.
- A **spin mutex** (`mtx(9)` with `MTX_SPIN`) is an interrupt-safe busy-wait lock. A thread that cannot immediately acquire it spins. Spin mutexes are used in the tiny set of contexts where sleeping is forbidden (interrupt filters and a few scheduler paths). They are not a performance optimisation; they are a correctness tool for a narrow case.
- A **sleepable shared/exclusive lock** (`sx(9)`) is the right choice for long read-mostly critical sections that may sleep while holding the lock. It is used by code that performs operations the kernel might block on (for example, allocating memory with `M_WAITOK` while holding the lock).
- A **condition variable** (`cv(9)`) is a synchronisation primitive for waiting on a predicate. A thread holds a mutex, checks a condition, and if the condition is false, calls `cv_wait` which atomically drops the mutex, sleeps, and reacquires the mutex on wakeup. Another thread changes the predicate under the same mutex and calls `cv_signal` or `cv_broadcast`. A condition variable never exists without an accompanying mutex.

**Why this matters to driver writers.** Every non-trivial driver keeps shared state: the softc itself, an in-flight request list, a pending I/O counter, a reference count. Protecting that state correctly is the difference between a

driver that works under load and a driver that fails intermittently in ways nobody can reproduce. The FreeBSD locking primitives are the tools you reach for every time.

**How this shows up in FreeBSD.** The headers are `/usr/src/sys/sys/mutex.h` for the regular and spin mutexes, `/usr/src/sys/sys/sx.h` for the shared/exclusive lock, and `/usr/src/sys/sys/condvar.h` for condition variables. The convention is to store the lock inside the `softc` and name it after the `softc` field: a driver that protects its work queue usually has something like `mtx_init(&sc->sc_lock, device_get_nameunit(dev), NULL, MTX_DEF)` in `attach` and a matching `mtx_destroy` in `detach`.

**Common trap.** Two, both common. The first is taking a sleep mutex from an interrupt filter. A filter runs in a context that cannot sleep; a sleep mutex may block; the kernel detects this with `witness(9)` in a development build. The second is reading the state the condition variable guards *outside* the mutex. The mutex-predicate-wait pattern relies on the predicate and the wait being atomic with respect to the signaller; breaking that atomicity reintroduces the race the condition variable was supposed to eliminate.

**Where the book teaches this.** Chapter 11 introduces mutexes and spin mutexes. Chapter 12 adds condition variables and shared/exclusive locks. Appendix B collects the reasoning patterns.

**What to read next.** `mtx(9)`, `sx(9)`, `cv(9)`, `witness(9)`, and the top of a real driver's `softc` structure to see the lock and its users in one place.

#### 42.5.4 `softc`: The Per-Device Driver Structure

**What it is.** The per-device state structure that the driver defines and the kernel allocates on its behalf. “Softc” is short for “software context”. It holds everything the driver needs to know about one specific instance of the device it drives: the `device_t` back-pointer, the lock, the `bus_space` tag and handle for MMIO, the allocated resources, any in-flight state, counters, and `sysctl` nodes. When FreeBSD attaches a driver to a device, it allocates a `softc` of the size the driver declared in its `driver_t` and gives the driver a pointer to it through `device_get_softc(9)`.

**Why this matters to driver writers.** Every function in the driver reaches the `softc` the same way: `struct mydev_softc *sc = device_get_softc(dev)`. Everything specific to this particular device lives behind that pointer. A driver that attaches to three devices gets three independent `softcs`, each with its own lock, its own state, its own hardware view. Keeping the `softc` the single owner of per-device state is what makes the code reentrant across multiple devices.

**How this shows up in FreeBSD.** The pattern is uniform across the tree. In the driver:

- A `struct mydev_softc` definition at the top of the file.
- `.size = sizeof(struct mydev_softc)` in the `driver_t` initialiser.
- `struct mydev_softc *sc = device_get_softc(dev)` at the top of every function that receives a `device_t`.
- A `sc->sc_lock` field initialised in `attach` and destroyed in `detach`.

The kernel zeroes the `softc` before handing it to the driver, so a fresh `attach` always starts in a known state.

**Common trap.** Stashing state in file-scope globals because “there is only one device”. Then someone attaches two, or builds a VM with two, and the second device silently corrupts the first. Every driver, no matter how simple it looks, keeps state in the `softc`.

**Where the book teaches this.** Chapter 6 introduces the concept. Chapter 7 writes a full softc and uses it end to end. Every chapter from Chapter 8 onward assumes the pattern.

**What to read next.** `device_get_softc(9)`, the `softc` block at the top of `/usr/src/sys/dev/null/null.c`, and the `softc` of any small PCI driver.

### 42.5.5 Why These Structures Keep Reappearing

The families above (queues, buffers, locks, and the `softc`) recur because they correspond to the four questions every driver eventually has to answer. What pending work do I hold? What bytes am I moving? How do I serialise access to my own state? Where do I keep the state of one instance of my device? Once you recognise that framing, driver code starts to read very differently. The unfamiliar parts are the details of a specific device or bus; the familiar parts are the four answers, in four standard shapes, used by every driver in the tree.

## 42.6 Section 4: Kernel Compilation and Booting

A driver runs inside a kernel. That kernel did not appear from nothing; something had to compile it, something had to load it into memory, something had to call its entry point, and something had to set up the environment in which your driver's `attach` function eventually runs. This section traces that chain at concept level, so that when a bug happens early in the boot, you have a mental picture of what the system was trying to do.

### 42.6.1 The Boot Process Overview

**What it is.** The sequence of events from power-on to a running FreeBSD kernel with userland processes. On a typical x86 machine it is roughly: firmware (BIOS or UEFI), first-stage boot (`boot0` on BIOS, the UEFI boot manager on UEFI), the FreeBSD loader (`loader(8)`), the architecture-specific kernel entry (`hammer_time` on amd64, called from assembly), the machine-independent startup (`mi_startup`), the `SYSINIT` chain, and finally the first userland process (`/sbin/init`). On ARM64 and other architectures, the firmware and machine-dependent parts differ; the machine-independent kernel startup is the same.

**Why this matters to driver writers.** Two reasons. First, many driver failures happen during `SYSINIT` processing, before there is a console to print to, and you need to know where you are when that happens. Second, the order in which subsystems initialise determines when your driver's bus has enumerators, when memory allocators are available, when the root filesystem is mounted, and when it is safe to talk to userland. A driver that tries to allocate memory too early will fail; a driver that tries to open a file before the root filesystem is mounted will also fail. The `SYSINIT` mechanism names the stages explicitly so that ordering is visible in the code.

**How this shows up in FreeBSD.** Each stage has a file you can open. The boot loader lives under `/usr/src/stand/`; the amd64 early C entry is `hammer_time` in `/usr/src/sys/amd64/amd64/machdep.c` (called from `/usr/src/sys/amd64/amd64/locore.S`); the machine-independent startup is `mi_startup` in `/usr/src/sys/kern/init_main.c`; and `start_init` in the same file is what the `init` process runs when it is finally scheduled, execing `/sbin/init` as PID 1.

**Common trap.** Treating boot as opaque. The `SYSINIT` mechanism makes the stages explicit and inspectable, and a driver that understands its place in them is much easier to debug.

**Where the book teaches this.** Chapter 2 walks through boot in lab context. Chapter 6 connects the driver-loading sequence to the kernel's startup picture.

**What to read next.** `boot(8)`, `loader(8)`, `/usr/src/sys/kern/init_main.c`, and the `SYSINIT` section of `/usr/src/sys/sys/kernel.h`.

### 42.6.2 From Power-On to init: A Compact Timeline

A thumbnail picture of the whole sequence. The names on the right are the functions or manual pages you would open to look closer.

|                                                                                   |                                                                                     |  |
|-----------------------------------------------------------------------------------|-------------------------------------------------------------------------------------|--|
| Stage                                                                             | Where to look                                                                       |  |
| Firmware: BIOS / UEFI starts executing                                            | (hardware / firmware)                                                               |  |
| First-stage boot: <code>boot0</code> / UEFI boot manager                          | <code>/usr/src/stand/</code>                                                        |  |
| FreeBSD loader: selects kernel and modules                                        | <code>loader(8)</code> , <code>loader.conf(5)</code>                                |  |
| Kernel entry (amd64): <code>hammer_time()</code> + <code>locore</code>            | <code>sys/amd64/amd64/machdep.c</code> ,<br>  <code>sys/amd64/amd64/locore.S</code> |  |
| MI startup: <code>mi_startup()</code> drives <code>SYSINITs</code>                | <code>sys/kern/init_main.c</code>                                                   |  |
| <code>SYSINIT</code> chain: subsystems init in order                              | <code>sys/sys/kernel.h</code>                                                       |  |
| <code>SI_SUB_VM</code> , <code>SI_SUB_LOCK</code> , <code>SI_SUB_KLD</code> , ... |                                                                                     |  |
| <code>SI_SUB_DRIVERS</code> , <code>SI_SUB_CONFIGURE</code> , ...                 |                                                                                     |  |
| Bus probe and attach: drivers bind to devices                                     | <code>sys/kern/subr_bus.c</code>                                                    |  |
| <code>SI_SUB_CREATE_INIT</code> / <code>SI_SUB_KTHREAD_INIT</code> :              | <code>sys/kern/init_main.c</code>                                                   |  |
| <code>init</code> proc forked, then made runnable                                 |                                                                                     |  |
| <code>start_init()</code> mounts root, execs <code>/sbin/init</code>              | <code>sys/kern/init_main.c</code> ,                                                 |  |
| (PID 1)                                                                           | <code>sys/kern/vfs_mountroot.c</code>                                               |  |
| Userland startup: <code>rc(8)</code> , daemons, logins                            | <code>rc(8)</code> , <code>init(8)</code>                                           |  |

The table is a map, not a contract. Many details differ per architecture, and the boundaries between stages shift as the kernel evolves. What does not change is the direction: small, simple environment at the top, increasingly functional environment at the bottom, userland at the end.

### 42.6.3 Boot Loaders and Kernel Modules at Boot Time

**What it is.** The FreeBSD loader (`/boot/loader`) is a small program that the first-stage boot code hands control to. Its job is to read `/boot/loader.conf`, load the kernel (`/boot/kernel/kernel`), load any modules requested by configuration, hand tunables and hints to the kernel, and transfer control to the kernel's entry point. It also provides the boot menu, the ability to boot a different kernel for recovery, and the facility to load a module before the kernel starts.

**Why this matters to driver writers.** Some drivers must be present before the root filesystem is mounted (storage controllers, for example). Those drivers are either compiled into the kernel or loaded by the loader from `/boot/loader.conf`. A driver that is loaded after root mount (through `kldload(8)`) cannot drive the disk that holds `/`. Knowing the difference is part of planning when a driver should attach.

**How this shows up in FreeBSD.** `/boot/loader.conf` is the text file that lists modules to load at boot. `loader(8)` and `loader.conf(5)` describe the mechanism. The loader also provides facilities such as `kenv(2)` tunables that the kernel can read in early `SYSINIT` stages.

**Common trap.** Relying on boot-time loader variables from kernel code that runs after root mount. Those variables are available; they are just not the right place for runtime configuration. Use `sysctl(9)` tunables for runtime, `kenv` only for early init decisions.

**Where the book teaches this.** Chapter 2 uses the loader while setting up the lab. Chapter 6 introduces `kldload(8)` for run-time driver loading.

**What to read next.** `loader(8)`, `loader.conf(5)`, `kenv(2)`.

### 42.6.4 Kernel Modules and Driver Attachment

**What it is.** A kernel module is a compiled `.ko` file that the kernel can load at runtime (or that the loader can load before kernel entry). Modules are how most drivers reach the kernel during normal operation. The module framework handles symbol resolution, versioning (`MODULE_VERSION`), dependencies (`MODULE_DEPEND`), and the registration of any `DRIVER_MODULE` declarations the file contains.

**Why this matters to driver writers.** Most of your development cycle will look like this: edit source, run `make`, `kldload ./mydriver.ko`, test, `kldunload mydriver`, repeat. The module framework makes that cycle fast and safe, and it also makes the production deployment story clean (the same `.ko` that you test is what ships). The loader and the run-time `kldload(8)` use the same module format.

**How this shows up in FreeBSD.** Every driver file ends with `DRIVER_MODULE`, `MODULE_VERSION`, and optionally `MODULE_DEPEND`. The declarations register the driver's bus-attachment metadata and module-level metadata with the kernel. When the module is loaded, the kernel runs the module's event handler for `MOD_LOAD`, which (among other things) registers the driver with Newbus. Newbus then offers the driver each device of the right bus, calling `probe` on each.

**Common trap.** Forgetting to call `bus_generic_detach`, `bus_release_resource`, or `mtx_destroy` from `detach`. The module unload succeeds, the driver is gone, but the resources leak. Subsequent reloads accumulate leaks until something obvious breaks.

**Where the book teaches this.** Chapter 6 introduces the module/driver relationship. Chapter 7 exercises the full edit-build-load-test-unload cycle.

**What to read next.** `kld(9)`, `kldload(8)`, `kldstat(8)`, `DRIVER_MODULE(9)`, `MODULE_VERSION(9)`.

### 42.6.5 `init_main` and the `SYSINIT` Chain

**What it is.** `mi_startup` is the machine-independent entry point that the architecture-specific boot code calls after early assembly (on amd64, `hammer_time` returns to `locore.S`, which calls `mi_startup`). Its body is almost entirely a loop that walks a sorted list of `SYSINIT` records and calls each one. Each record is registered at compile time by a `SYSINIT(...)` macro and carries a subsystem identifier (`SI_SUB_*`) and an order within the subsystem (`SI_ORDER_*`). The linker collects them all into a single section; `mi_startup` sorts and runs them. The init process itself is created in a stopped state at `SI_SUB_CREATE_INIT`, made runnable at `SI_SUB_KTHREAD_INIT`, and once it is scheduled it runs `start_init`, which mounts the root filesystem and execs `/sbin/init` as PID 1.

**Why this matters to driver writers.** Most drivers never touch `SYSINIT` directly; `DRIVER_MODULE` wraps the right registration for them. But a few pieces of infrastructure (kernel threads that must exist before drivers attach, subsystem-wide initialisers, early event handlers) use `SYSINIT` directly, and when you read such code it helps to know what the declaration is registering. The `SI_SUB_*` names make the ordering auditable, and the numeric spacing between them leaves room for future stages.

**How this shows up in FreeBSD.** The `SYSINIT` macro and the `SI_SUB_*` constants are in `/usr/src/sys/sys/kernel.h`. The driver-relevant stages include `SI_SUB_VM` (virtual memory up), `SI_SUB_LOCK` (lock initialisation), `SI_SUB_KLD` (module system), `SI_SUB_DRIVERS` (early driver-subsystem init), `SI_SUB_CONFIGURE` (Newbus probe and attach), `SI_SUB_ROOT_CONF` (candidate root devices identified), `SI_SUB_CREATE_INIT` (init process forked), and `SI_SUB_KTHREAD_INIT` (init made runnable). `mi_startup` is in `/usr/src/sys/kern/init_main.c`, and `start_init` is in the same file.

**Common trap.** Assuming your driver's `attach` runs very early. It runs at `SI_SUB_CONFIGURE`, which is after locks, memory, and most subsystems are up. If you need to coordinate with something earlier, either use the event-handler system (`eventhandler(9)`) to hook a well-defined event, or place the work at the right `SYSINIT` stage.

**Where the book teaches this.** Chapter 2 introduces the picture at boot-time. Chapter 6 connects `DRIVER_MODULE` to the `SYSINIT` chain conceptually. Appendix E goes into the subsystem-stage detail for readers who need it.

**What to read next.** The `SYSINIT` definitions in `/usr/src/sys/sys/kernel.h`, the loop in `/usr/src/sys/kern/init_main.c`, and `/usr/src/sys/kern/subr_bus.c` for the Newbus side.

### 42.6.6 Kernel Compilation in One Paragraph

A FreeBSD kernel is built from source by the ordinary `make` system invoked from `/usr/src`. The build takes a kernel configuration file (typically under `/usr/src/sys/amd64/conf/GENERIC` or a customised file you keep alongside it), compiles the selected options and device entries, and links the result into `kernel` plus a set of `.ko` files for devices not statically included. The standard commands are `make buildkernel KERNCONF=MYCONF` and `make installkernel KERNCONF=MYCONF`, run from `/usr/src`. For out-of-tree modules, the build uses `bsd.kmod.mk`, a short Makefile fragment that knows how to compile one or more `.c` files into a `.ko` file with the right kernel flags. Chapter 2 walks through both paths in lab context; the details are not repeated here.

## 42.7 Quick-Reference Tables

The compact tables below are meant for scanning. They do not replace the sections above; they help you point at the right section fast.

### 42.7.1 Kernel Space vs User Space at a Glance

| Property                   | Kernel space                                      | User space                                      |
|----------------------------|---------------------------------------------------|-------------------------------------------------|
| Privilege                  | Full CPU privilege                                | Reduced, CPU-enforced                           |
| Address space              | One, shared by all kernel threads                 | One per process, isolated                       |
| Memory stability           | Stable while allocated                            | May be paged, unmapped, moved                   |
| Direct hardware access     | Yes                                               | No                                              |
| Failure blast radius       | Whole machine                                     | One process                                     |
| How to cross over          | System call trap                                  | <code>syscall</code> instruction (architecture) |
| Data copy primitive (into) | <code>copyin(9)</code> , <code>uiomove(9)</code>  | (no equivalent; kernel does the copy)           |
| Data copy primitive (out)  | <code>copyout(9)</code> , <code>uiomove(9)</code> | (no equivalent; kernel does the copy)           |

### 42.7.2 Driver Type Comparison

| Driver type        | Registers with                            | Main entry points                                                | Main buffer type         | Typical devices                                       |
|--------------------|-------------------------------------------|------------------------------------------------------------------|--------------------------|-------------------------------------------------------|
| Character          | <code>cdevsw</code> in <code>devfs</code> | <code>d_open</code> , <code>d_read</code> , <code>d_ioctl</code> | <code>struct uio</code>  | Serial, sensors, <code>/dev/*</code>                  |
| Network            | <code>ifnet</code>                        | <code>if_transmit</code> , receive path                          | <code>struct mbuf</code> | NICs, <code>tun</code> , <code>tap</code>             |
| Storage (GEOM)     | GEOM class/provider                       | <code>g_start</code> , <code>biodone(9)</code>                   | <code>struct bio</code>  | Disks, <code>md</code> , <code>geli</code>            |
| Pseudo (character) | <code>cdevsw</code> in <code>devfs</code> | Same as character                                                | <code>struct uio</code>  | <code>/dev/null</code> ,<br><code>/dev/random</code>  |
| Pseudo (network)   | <code>ifnet</code>                        | Same as network                                                  | <code>struct mbuf</code> | <code>tun</code> , <code>tap</code> , <code>lo</code> |

### 42.7.3 Locking Primitive Selection

| You need...                                | Use                                            |
|--------------------------------------------|------------------------------------------------|
| A default lock around softc fields         | <code>mtx(9)</code> with <code>MTX_DEF</code>  |
| A lock safe to hold in an interrupt filter | <code>mtx(9)</code> with <code>MTX_SPIN</code> |

| You need...                                | Use                                        |
|--------------------------------------------|--------------------------------------------|
| Many readers, occasional writer, may sleep | <code>sx(9)</code>                         |
| Wait for a predicate under a mutex         | <code>cv(9)</code> together with the mutex |
| Atomic single-word read-modify-write       | <code>atomic(9)</code>                     |

#### 42.7.4 softc Lifecycle Checkpoint

| Phase   | Typical softc actions                                                       |
|---------|-----------------------------------------------------------------------------|
| probe   | Read IDs, return <code>BUS_PROBE_*</code> . No softc allocation yet.        |
| attach  | <code>device_get_softc</code> , init lock, allocate resources, setup state. |
| Runtime | All operations dereference <code>sc</code> , all state updates under lock.  |
| suspend | Save volatile hardware state, stop pending work.                            |
| resume  | Restore state, restart work.                                                |
| detach  | Stop work, free resources in reverse order, destroy lock.                   |

#### 42.7.5 Boot-to-Init Quick Map

| Phase                                                              | Driver-relevant fact                                               |
|--------------------------------------------------------------------|--------------------------------------------------------------------|
| Firmware + loader                                                  | Kernel and preloaded modules reach memory.                         |
| Kernel entry ( <code>hammer_time</code> on amd64)                  | Machine-dependent early setup; no drivers yet.                     |
| <code>mi_startup</code> / <code>SYSINIT</code> chain               | Subsystems initialise in <code>SI_SUB_*</code> order.              |
| <code>SI_SUB_DRIVERS</code> / <code>SI_SUB_CONFIGURE</code>        | Buses enumerate; compiled-in and preloaded drivers probe / attach. |
| <code>SI_SUB_ROOT_CONF</code>                                      | Candidate root devices identified.                                 |
| <code>SI_SUB_CREATE_INIT</code> / <code>SI_SUB_KTHREAD_INIT</code> | Init process forked, then made runnable.                           |
| <code>start_init</code> runs                                       | Root filesystem mounted; <code>/sbin/init</code> execed as PID 1.  |
| Runtime <code>kldload(8)</code>                                    | Additional drivers attach after this point.                        |

### 42.8 Wrapping Up: How These OS Concepts Support Driver Development

Each of the concepts in this appendix is already in use somewhere in the book. The appendix only assembles the pieces so that the reader can glance at the whole picture when one part feels out of focus.

The kernel/user boundary is the reason driver code looks different from ordinary C. Every unusual rule, from `copyin(9)` to the short spin-safe interrupt filter, exists because the kernel runs in a privileged world that cannot afford to trust the less privileged one. Keep that framing and the rest follows.

The driver types name the contracts with the rest of the kernel. Character, network, and GEOM are not ornaments; they are the standard interfaces that let userland and other subsystems reach your device without learning anything about its hardware. When you begin a new driver, naming the type is the first architectural decision you make.

The recurring data structures name the shapes inside the driver. A queue for pending work. A buffer for bytes moving through the subsystem. A mutex around shared state. A `softc` that owns everything about one device. The shapes are small; the discipline they encode is what keeps the driver correct.

The boot sequence names the stage on which your driver performs. The kernel did not spring into existence; it was assembled by a chain of well-defined steps, and your driver enters during one specific step at `SI_SUB_CONFIGURE`. Understanding the order of the steps turns early-boot bugs from mysteries into ordinary kernel diagnostics.

Three habits keep these concepts active instead of dormant.

The first is asking which side of the boundary you are on. Before you touch a pointer, ask whether it is a user pointer, a kernel pointer, or a bus address; the correct primitive follows immediately.

The second is asking which subsystem you are speaking to. Before you reach for a buffer type, ask whether the code is in the character, network, or GEOM path; the right buffer follows immediately.

The third is keeping a short companion sheet for the concepts you use most. The files under `examples/appendices/appendix-d-operating-system-concepts/` are meant for exactly that. A kernel-vs-user-space cheatsheet, a driver-type comparison, a `softc` lifecycle checklist, a boot-to-init timeline, and a “where drivers fit in the OS” diagram. The teaching is in this appendix; the application is in those sheets.

With that, the operating-system side of the book has a consolidated home. The chapters keep teaching; this appendix keeps naming; the examples keep reminding. When a reader closes this appendix and opens an unfamiliar driver, the mental model is ready, and every line of kernel code has a place to attach to.

## 43 Appendix E: Navigating FreeBSD Kernel Internals

### 43.1 How to Use This Appendix

The main chapters teach you to build a FreeBSD device driver from the first `printf("hello")` module to a working PCI driver with DMA and interrupts. Underneath that progression is a large kernel with many moving parts, and the book cannot teach each of those parts from scratch without losing the thread of what you are actually trying to do. Most of the time you do not need to know every corner of the kernel. You just need to know where you are, which subsystem your current line of code is touching, which structure gives you the answer when you stop to look, and where in `/usr/src` the evidence lives.

This appendix is that map. It does not try to teach each subsystem from first principles. It takes the seven subsystems a driver author meets most often and, for each one, gives you the short version: what it is for, which structures matter, which APIs your driver is likely to cross, where to open a file and look, and what to read next. You can think of it as the field guide you keep next to the chapters, not a replacement for them.

#### 43.1.1 What You Will Find Here

Each subsystem is covered with the same small pattern, so that you can skim one and know where to look in the next.

- **What the subsystem is for.** A one-paragraph statement of the subsystem's responsibility.
- **Why a driver author should care.** The concrete reason your code meets this subsystem.
- **Key structures, interfaces, or concepts.** The short list of names that actually matter.
- **Typical driver touchpoints.** The specific places where a driver calls in, registers with, or receives a callback from the subsystem.
- **Where to look in `/usr/src`.** The two or three files that are worth opening first.
- **Manual pages and files to read next.** The next step when you want more depth.
- **Common beginner confusion.** The misunderstanding that costs people time.
- **Where the book teaches this.** Back-references into the chapters that use the subsystem in context.

Not every entry needs every label, and no entry tries to be exhaustive. The aim is pattern recognition, not a full subsystem manual.

#### 43.1.2 What This Appendix Is Not

It is not an API reference. Appendix A is the API reference and goes deeper into flags, lifecycle phases, and caveats for each call. When the question is *what does this function do* or *which flag is right*, Appendix A is the place to look.

It is not a concept tutorial either. Appendix D covers the operating-system mental model (kernel vs userland, driver types, the boot-to-init path), Appendix C covers the hardware model (physical memory, MMIO, interrupts, DMA), and Appendix B covers the algorithmic patterns (`<sys/queue.h>`, ring buffers, state machines, unwind ladders). If the question you want answered is “what is a process”, “what is a BAR”, or “which list macro should I use”, one of those appendices is the right destination.

It is also not a complete subsystem reference. A full tour of the VFS, the VM, or the network stack would be its own book. What you get here is the ten per cent of each subsystem a driver author actually meets, in the order in which a driver author meets it.

## 43.2 Reader Guidance

Three ways to use this appendix, each calling for a different reading strategy.

If you are **reading the main chapters**, keep the appendix open in a second window. When Chapter 5 introduces the kernel’s memory allocators, glance at the Memory Subsystem section here to see where those allocators sit relative to UMA and the VM system. When Chapter 6 walks through `device_t`, `softc`, and the probe/attach lifecycle, the Driver Infrastructure section shows where those types fit into the Newbus layer. When Chapter 24 discusses `SYSINIT`, `eventhandler(9)`, and taskqueues, the Boot and Module System and Kernel Services sections give you the surrounding context in one page each.

If you are **reading unfamiliar kernel code**, treat the appendix as a translator. When you see `struct mbuf` in a function signature, jump to the Network Subsystem section. When you see `struct bio`, jump to File and VFS. When you see `kobj_class_t` or `device_method_t`, jump to Driver Infrastructure. The goal during exploration is not to master the subsystem, just to name it.

If you are **designing a new driver**, scan the subsystems your driver will touch before you start. A character driver for a small peripheral will lean on Driver Infrastructure and File and VFS. A network driver will add the Network Subsystem. A storage driver will add the GEOM and buffer cache layers. An early-boot driver on an embedded board will add the Boot and Module System section. Knowing which subsystems you will touch helps you guess the right headers and the right chapters before you write a line of code.

A few conventions apply throughout:

- Source paths are shown in the book-facing form, `/usr/src/sys/...`, matching the layout on a standard FreeBSD system. You can open any of them on your lab machine.
- Manual pages are cited in the usual FreeBSD style. Kernel-facing pages live in section 9: `kthread(9)`, `malloc(9)`, `uma(9)`, `bus_space(9)`, `eventhandler(9)`. Userland interfaces live in section 2 or 3 and are mentioned where they matter.
- When an entry points at a reading example, the file is one a beginner can read in one sitting. Larger files exist that also use each pattern; those are mentioned only when they are the canonical reference.

With that in mind, we start with a one-page orientation to the whole kernel before drilling into subsystems one at a time.

### 43.3 How This Appendix Differs From Appendix A

A driver author ends up consulting two very different kinds of reference while working. One kind answers the question *what is the exact name of the function or flag I need*. That is Appendix A. The other kind answers the question *which subsystem am I in, and where does this piece fit*. That is this appendix.

Concretely, the difference shows up like this. When you want to know the signature of `malloc(9)`, the meaning of `M_WAITOK` versus `M_NOWAIT`, and which manual page to open, that is Appendix A. When you want to know that `malloc(9)` is a thin convenience on top of `UMA`, which in turn builds on the `vm_page_t` layer, which in turn depends on the per-architecture `pmap(9)`, that is this appendix.

Both appendices cite real source paths and real manual pages. The split is deliberate. Keeping the API lookup separate from the subsystem map makes each one short enough to actually use. If an entry here starts to look like Appendix A, it has drifted from its role, and the right move is to read Appendix A instead.

### 43.4 A Map of the Major Subsystems

Before you walk into any one subsystem, the shape of the whole kernel is worth naming. The FreeBSD kernel is large, but the pieces a driver author meets fit into a small set of families. The diagram below is the simplest honest picture.

Each of the labelled boxes above has a section below. The driver-infrastructure box in the middle is where every driver starts. The two boxes at the top are the subsystem entry points that a driver publishes to the rest of the kernel (character or storage on the left, network on the right). The two boxes in the middle rows are the horizontal services every driver relies on. The bottom boxes are the plumbing that gets the kernel running in the first place.

Most drivers touch only three or four of these boxes in detail. The appendix is organised so that you can read only the ones your driver actually uses.

## 43.5 Process and Thread Subsystem

### 43.5.1 What the subsystem is for

The process and thread subsystem manages every unit of execution inside FreeBSD. It owns the data structures that describe a running program, the scheduler that decides which thread runs next on which CPU, the machinery that creates and destroys kernel threads, and the rules that govern how a thread may block, sleep, or be preempted. Every line of kernel code, including your driver, is being executed by some thread, and the discipline the subsystem enforces is a direct constraint on what your driver is allowed to do.

### 43.5.2 Why a driver author should care

Three practical reasons. First, the context your code runs in (interrupt filter, `ithread`, taskqueue worker, syscall thread from userland, dedicated kernel thread you spawned) decides whether you may sleep, may allocate memory with `M_WAITOK`, or may hold a sleep lock. Second, any driver that needs background work (a polling loop, a recovery watchdog, a deferred command handler) will create a kernel thread or a `kproc` to host it. Third, any driver that looks at the caller's process credentials (for security checks in `d_ioctl`, for example) reaches into the process structure.

### 43.5.3 Key structures, interfaces, or concepts

- **struct proc** is the per-process descriptor. It records the process id, credentials, file-descriptor table, signal state, address space, and the list of threads that belong to the process.

- **struct thread** is the per-thread descriptor. It records the thread id, priority, run state, saved register context, the pointer to its owning struct proc, and the locks it currently holds. A FreeBSD kernel thread is also described by a struct thread; it simply has no userland side.
- **The ULE scheduler** is FreeBSD's default multi-processor scheduler. It assigns threads to CPUs, implements priority classes (real-time, time-sharing, idle), and honours interactivity and affinity hints. From a driver author's perspective, the most important fact about ULE is that it runs whichever thread is next, whenever a lock is released, a sleep ends, or an interrupt finishes; you cannot assume control of the CPU across such events.
- **kthread\_add(9)** creates a new kernel thread inside an existing kernel process. Use it when you want a lightweight worker that shares state with an existing kproc (for example, extra worker threads inside a driver-specific kproc).
- **kproc\_create(9)** creates a new kernel process, which comes with its own struct proc and one initial thread. Use it when you want an independent, top-level worker that ps -axH will show as a distinct name (for example, g\_event, usb, bufdaemon).

#### 43.5.4 Typical driver touchpoints

- Interrupt handlers and bus\_setup\_intr(9) callbacks run in kernel-thread context created by the interrupt framework.
- A driver that needs long-running background work calls kproc\_create(9) or kthread\_add(9) from its attach path and joins the thread from detach.
- A driver that takes action on behalf of a user process reads curthread or td->td\_proc to look at credentials, process id, or root-directory for validation.
- A driver that sleeps on a condition uses the sleep primitives, which record the sleeping thread and yield to the scheduler until woken.

#### 43.5.5 Where to look in /usr/src

- /usr/src/sys/sys/proc.h defines struct proc and struct thread and the macros that navigate between them.
- /usr/src/sys/sys/kthread.h declares the kernel-thread creation API.
- /usr/src/sys/kern/kern\_kthread.c contains the implementation.
- /usr/src/sys/kern/sched\_ule.c is the ULE scheduler source.

#### 43.5.6 Manual pages and files to read next

kthread(9), kproc(9), curthread(9), proc(9), and the header /usr/src/sys/sys/proc.h. If you want to see a driver that owns a kernel thread, /usr/src/sys/dev/random/random\_harvestq.c is a readable example.

#### 43.5.7 Common beginner confusion

The most frequent trap is assuming that the thread running your driver code is a driver-owned thread. It is not. Most of the time it is a user thread that entered the kernel through a syscall, or an ithread that the interrupt

framework created for you. Your driver only owns the threads it explicitly creates. Another recurring trap is reaching into `curthread->td_proc` from a context where `curthread` has nothing to do with the device (an interrupt `ithread`, for example); the process you find is not the process that asked for the operation.

### 43.5.8 Where the book teaches this

Chapter 5 introduces kernel execution context and the sleep-versus-atomic distinction. Chapter 11 returns to it when concurrency becomes real. Chapter 14 uses taskqueues as a way to offload work into a safely sleepable context. Chapter 24 shows a full `kproc` lifecycle inside a driver.

### 43.5.9 Further reading

- **In this book:** Chapter 11 (Concurrency in Drivers), Chapter 14 (Taskqueues and Deferred Work), Chapter 24 (Integrating with the Kernel).
- **Man pages:** `kthread(9)`, `kproc(9)`, `scheduler(9)`.
- **External:** McKusick, Neville-Neil, and Watson, *The Design and Implementation of the FreeBSD Operating System* (2nd ed.), chapters on process and thread management.

## 43.6 Memory Subsystem

### 43.6.1 What the subsystem is for

The virtual-memory (VM) subsystem manages every byte of memory the kernel can address. It owns the mapping from virtual addresses to physical pages, the allocation of pages to processes and to the kernel, the paging policy that reclaims pages under pressure, and the page-backing stores that hand pages in from disk, from devices, or from zero. A driver that allocates memory, exposes memory to userland through `mmap`, or does DMA is interacting with the VM subsystem whether it names it or not.

### 43.6.2 Why a driver author should care

Four practical reasons. First, every kernel allocation goes through this subsystem, directly or indirectly. Second, any driver that exports a memory-mapped view of a device (or of a software buffer) does so through a VM pager. Third, DMA involves physical addresses, and only the VM subsystem knows how virtual kernel addresses translate to them. Fourth, the subsystem defines the sleep rules for allocation: `M_WAITOK` may walk the VM's page-reclamation path, which is something you cannot do from an interrupt filter.

### 43.6.3 Key structures, interfaces, or concepts

- **`vm_map_t`** represents a contiguous collection of virtual address mappings belonging to one address space. The kernel has its own `vm_map_t`, and each user process has one. Drivers almost never walk a `vm_map_t` directly; higher-level APIs do the walking for them.
- **`vm_object_t`** represents a backing store: a set of pages that can be mapped into a `vm_map_t`. Objects are typed by the pager that produces their pages (anonymous, vnode-backed, swap-backed, device-backed).

- **vm\_page\_t** represents one physical page of RAM, together with its current state (wired, active, inactive, free) and the object it currently belongs to. All physical memory in the system is tracked by an array of **vm\_page\_t** records.
- **The pager layer** is the set of pluggable strategies that fill pages with data. The three most important ones for driver authors are the swap pager (anonymous memory), the vnode pager (file-backed memory), and the device pager (memory whose content is produced by a driver). When a driver implements **d\_mmap** or **d\_mmap\_single**, it is publishing a slice of the device pager.
- **pmap(9)** is the machine-dependent page-table manager. It knows how to translate virtual addresses into physical ones for the current CPU architecture. Drivers rarely call **pmap** directly. The portable way to see a physical view is through **bus\_dma(9)** (for DMA) or **bus\_space(9)** (for MMIO registers).
- **UMA** is FreeBSD's slab allocator for fixed-size objects, with per-CPU caches to avoid locking in the fast path. **malloc(9)** itself is implemented on top of UMA for common sizes. Drivers that allocate and free millions of identical small objects per second (network descriptors, per-request contexts) create their own UMA zone with **uma\_zcreate** and reuse objects instead of walking the general allocator.

#### 43.6.4 Typical driver touchpoints

- **malloc(9)**, **free(9)**, **contigmalloc(9)** for general control-plane memory.
- **uma\_zcreate(9)**, **uma\_zalloc(9)**, **uma\_zfree(9)** for high-rate fixed-size objects.
- **bus\_dmamem\_alloc(9)** and the rest of the **bus\_dma(9)** interface for DMA-capable memory; this is the driver-facing wrapper around the physical side of the VM.
- **d\_mmap(9)** or **d\_mmap\_single(9)** in a **cdevsw** method table to publish a device pager view of hardware memory to userland.
- **vm\_page\_wire(9)** and **vm\_page\_unwire(9)** only in the rare cases where the driver needs to pin pages of a user buffer across a long-running I/O.

#### 43.6.5 Where to look in /usr/src

- **/usr/src/sys/vm/vm.h** declares the **vm\_map\_t**, **vm\_object\_t**, and **vm\_page\_t** typedefs.
- **/usr/src/sys/vm/vm\_map.h**, **/usr/src/sys/vm/vm\_object.h**, and **/usr/src/sys/vm/vm\_page.h** hold the full type definitions.
- **/usr/src/sys/vm/swap\_pager.c**, **/usr/src/sys/vm/vnode\_pager.c**, and **/usr/src/sys/vm/device\_pager.c** are the three pagers most relevant to drivers.
- **/usr/src/sys/vm/uma.h** is the UMA public interface; **/usr/src/sys/vm/uma\_core.c** is the implementation.
- **/usr/src/sys/vm/pmap.h** is the machine-independent **pmap** interface; the machine-specific side lives under **/usr/src/sys/amd64/amd64/pmap.c**, **/usr/src/sys/arm64/arm64/pmap.c**, and similar files for each architecture.

#### 43.6.6 Manual pages and files to read next

**malloc(9)**, **uma(9)**, **contigmalloc(9)**, **bus\_dma(9)**, **pmap(9)**, and the header **/usr/src/sys/vm/uma.h**. For a readable driver that publishes a device pager, inspect **/usr/src/sys/dev/drm2/** or the framebuffer code under **/usr/src/sys/dev/fb/**.

### 43.6.7 Common beginner confusion

Two traps. First, conflating the three pointer flavours a DMA-capable driver sees: the kernel virtual address (what your pointer dereferences), the physical address (what the memory controller sees), and the bus address (what the device sees, which may go through an IOMMU). `bus_dma(9)` exists precisely to keep these separate. Second, assuming that a `bus_dmamem_alloc(9)` allocation is a generic memory allocation; it is a specialised allocation with stricter alignment, boundary, and segment rules dictated by the tag you passed in.

### 43.6.8 Where the book teaches this

Chapter 5 introduces kernel memory and the allocator flags. Chapter 10 revisits buffers in read/write paths. Chapter 17 introduces `bus_space` for MMIO access. Chapter 21 is the full DMA chapter and where the bus-versus-physical distinction becomes concrete.

### 43.6.9 Further reading

- **In this book:** Chapter 5 (Understanding C for FreeBSD Kernel Programming), Chapter 21 (DMA and High-Speed Data Transfer).
- **Man pages:** `malloc(9)`, `uma(9)`, `contigmalloc(9)`, `bus_dma(9)`, `pmap(9)`.
- **External:** McKusick, Neville-Neil, and Watson, *The Design and Implementation of the FreeBSD Operating System* (2nd ed.), chapter on memory management.

## 43.7 File and VFS Subsystem

### 43.7.1 What the subsystem is for

The file and VFS (Virtual File System) subsystem owns everything that userland sees through `open(2)`, `read(2)`, `write(2)`, `ioctl(2)`, `mmap(2)`, and the filesystem hierarchy in general. It dispatches operations to the correct filesystem through the vnode-operation vector, manages the buffer cache that sits between filesystems and storage drivers, and hosts the GEOM framework that lets storage drivers compose into stacks. For a driver author, this subsystem is either the main entry point (if you write a character or storage driver) or a quiet middle layer you are glad to let someone else worry about (if you write a network or embedded driver).

### 43.7.2 Why a driver author should care

Three practical reasons. First, every character driver publishes itself to VFS through a `cdevsw` and a `/dev` node created by `devfs`. Second, every storage driver plugs into the bottom of a stack that the VFS and GEOM layers assemble on top, and the unit of work you receive is a `struct bio`, not a user pointer. Third, even a non-storage driver may need to understand vnodes and `mmap` if it publishes its memory to userland.

### 43.7.3 Key structures, interfaces, or concepts

- **struct vnode** is the kernel's abstract file or device. It carries a type (regular file, directory, character device, block device, named pipe, socket, symbolic link), a pointer to its filesystem's `vop_vector`, the

mount it belongs to, a reference count, and a lock. Every file descriptor in userland ultimately resolves to a vnode.

- **struct vop\_vector** is the vnode-operation dispatch table: a pointer per operation (VOP\_LOOKUP, VOP\_READ, VOP\_WRITE, VOP\_IOCTL, and dozens more) that the filesystem or devfs implements. The vector is declared conceptually in `/usr/src/sys/sys/vnode.h` and generated from the operation list in `/usr/src/sys/kern/vnode_if.src`.
- **The GEOM framework** is FreeBSD's stackable storage layer. A GEOM *provider* is a storage surface; a *consumer* is something attaching to a provider. Drivers for storage hardware register as providers; classes such as `g_part`, `g_mirror`, or filesystems attach as consumers. The topology graph is dynamic and visible at runtime through `gpart show`, `geom disk list`, and `sysctl kern.geom`.
- **devfs** is the pseudo-filesystem that populates `/dev`. When your character driver calls `make_dev_s(9)`, devfs allocates a vnode-backed entry that forwards VFS operations into your `cdevsw` callbacks. devfs is the single layer between `open(2)` on a `/dev` path and `d_open` in your driver.
- **struct buf** is the traditional buffer-cache descriptor used by the old block-device path and by filesystems that layer on top of the buffer cache. It is still important because many filesystems drive I/O through `buf` objects before `buf_strategy()` funnels them into GEOM.
- **struct bio** is the modern per-operation descriptor that flows through GEOM. Every block read or write in GEOM is a `bio` with a command (`BIO_READ`, `BIO_WRITE`, `BIO_FLUSH`, `BIO_DELETE`), a range, a buffer pointer, and a completion callback. Your storage driver receives `bios` on its start routine and calls `biodone()` (or the GEOM equivalent) when it finishes them.

#### 43.7.4 Typical driver touchpoints

- A character driver fills a `struct cdevsw` with callbacks (`d_open`, `d_close`, `d_read`, `d_write`, `d_ioctl`, optionally `d_poll`, `d_mmap`) and calls `make_dev_s(9)` to attach it to `/dev`.
- A storage driver registers a GEOM class, implements a start routine that accepts `bios`, and calls `g_io_deliver()` when it finishes them.
- A driver that wants to be visible as a file (for reading telemetry, for example) may expose a character device whose `d_read` copies driver data out.
- A driver that publishes device memory to userland implements `d_mmap` or `d_mmap_single` to hand back a device pager object.

#### 43.7.5 Where to look in `/usr/src`

- `/usr/src/sys/sys/vnode.h` declares `struct vnode` and the vnode-operation plumbing.
- `/usr/src/sys/kern/vnode_if.src` is the source of truth for every VOP in the kernel; read it to see the operation list and the locking protocol.
- `/usr/src/sys/fs/devfs/` holds the devfs implementation; `devfs_devs.c` and `devfs_vnops.c` are the readable entry points.
- `/usr/src/sys/geom/geom.h` declares providers, consumers, and the GEOM class interface.
- `/usr/src/sys/sys/buf.h` and `/usr/src/sys/sys/bio.h` declare the block-I/O structures.
- `/usr/src/sys/dev/null/null.c` is the simplest character driver in the tree and the right first read.

### 43.7.6 Manual pages and files to read next

`vnode(9)`, `VOP_LOOKUP(9)` and the rest of the VOP family, `devfs(4)`, `devfs(5)`, `cdev(9)`, `make_dev(9)`, `g_attach(9)`, `geom(4)`, and the header `/usr/src/sys/sys/bio.h`.

### 43.7.7 Common beginner confusion

Three traps. First, expecting a character driver to deal with `struct buf` or `struct bio`. It does not; those live in the storage path. A character driver sees `struct uio` on its `d_read` and `d_write` callbacks and nothing more. Second, expecting a storage driver to create a `/dev` node itself. In modern FreeBSD the GEOM layer creates the `/dev` entries for block devices; your storage driver registers with GEOM, and `devfs` does the rest on the other side of GEOM. Third, assuming the `vnode` and the `cdev` are the same object. They are not. The `vnode` is the VFS-side handle to the open file; the `cdev` is the driver-side identity. `open(2)` on `/dev/foo` produces a `vnode` whose operations forward into your `cdevsw`.

### 43.7.8 Where the book teaches this

Chapter 7 writes the first character driver and the first `cdevsw`. Chapter 8 walks through `make_dev_s(9)` and `devfs` node creation. Chapter 9 connects `d_read` and `d_write` to `uio`. Chapter 27 is the storage chapter and introduces `struct bio`, GEOM providers and consumers, and the buffer cache.

### 43.7.9 Further reading

- **In this book:** Chapter 7 (Writing Your First Driver), Chapter 8 (Working with Device Files), Chapter 27 (Working with Storage Devices and the VFS Layer).
- **Man pages:** `vnode(9)`, `make_dev(9)`, `devfs(5)`, `geom(4)`, `g_bio(9)`.
- **External:** McKusick, Neville-Neil, and Watson, *The Design and Implementation of the FreeBSD Operating System* (2nd ed.), chapters on the I/O system and local filesystems.

## 43.8 Network Subsystem

### 43.8.1 What the subsystem is for

The network subsystem moves packets. It owns the data structures that represent a packet in flight (`mbuf` and friends), the per-interface state that represents a network device to the rest of the stack (`ifnet`), the routing tables that decide where a packet should go, the socket layer that userland sees, and the VNET infrastructure that lets multiple independent network stacks coexist in a single kernel. A network driver is the bottom layer of this stack: it hands packets up into the stack on receive, and the stack hands packets down into the driver on transmit.

### 43.8.2 Why a driver author should care

Two reasons. If you write a network driver, nearly every byte you touch is a field of one of the structures named below, and the shape of your code is set by the protocols they enforce. If you write any other kind of driver, you

still benefit from recognising `struct mbuf` and `struct ifnet` when you see them in code, because they turn up in many adjacent subsystems (packet filters, load-balancing helpers, virtual interfaces).

### 43.8.3 Key structures, interfaces, or concepts

- **struct mbuf** is the packet fragment. Packets are represented as chains of mbufs, linked by `m_next` for a single packet and by `m_nextpkt` for consecutive packets in a queue. An mbuf carries a small header and either a small inline data area or a pointer into an external storage cluster. The design is optimised for cheap prepending of headers.
- **struct m\_tag** is an extensible metadata tag attached to an mbuf. It lets the stack and drivers attach typed information to a packet (for example, hardware transmit-checksum offload, receive-side-scaling hash, filter decision) without enlarging the mbuf itself.
- **ifnet** (spelled `if_t` in modern APIs) is the per-interface descriptor. It carries the interface name and index, the flags, the MTU, a transmit function (`if_transmit`), the counters the stack increments, and the hooks that let higher layers deliver packets to the driver.
- **VNET** is the per-virtual-network-stack container. When `VIMAGE` is compiled in, every jail that enables VNET has its own routing table, its own set of interfaces, and its own protocol control blocks. Network drivers must be VNET-aware: they use `VNET_DEFINE` and `VNET_FOREACH` so that per-VNET state lives in the right place.
- **Routing** is the subsystem that selects a next-hop for an outbound packet. It owns the forwarding information base (FIB), a per-VNET radix tree of routes. Drivers rarely interact with routing directly; the stack has already chosen the interface before it reaches the driver.
- **The socket layer** is the kernel side of the socket(2) family of syscalls. For driver authors, the relevant fact is that a socket ultimately produces calls into `ifnet`, which produce calls into your driver. You do not implement sockets yourself.

### 43.8.4 Typical driver touchpoints

- The driver allocates and populates an `ifnet` in `attach`, registers a transmit function, and calls `ether_ifattach(9)` or `if_attach(9)` to announce itself to the stack.
- The driver's transmit function receives an mbuf chain, writes descriptors, kicks the hardware, and returns.
- The receive path handles an interrupt or a poll, wraps received bytes in mbufs, and calls `if_input(9)` on the interface to push them up into the stack.
- On detach, the driver calls `ether_ifdetach(9)` or `if_detach(9)` before freeing its resources.
- The driver registers for `ifnet_arrival_event` or `ifnet_departure_event` if it needs to react when peers appear or disappear (see `/usr/src/sys/net/if_var.h` for the declarations).

### 43.8.5 Where to look in `/usr/src`

- `/usr/src/sys/sys/mbuf.h` declares `struct mbuf` and `struct m_tag`.
- `/usr/src/sys/net/if.h` declares `if_t` and the public interface API.
- `/usr/src/sys/net/if_var.h` declares the interface-event eventhandlers and internal state.
- `/usr/src/sys/net/if_private.h` contains the full `struct ifnet` definition used inside the stack.
- `/usr/src/sys/net/vnet.h` declares the VNET infrastructure.

- `/usr/src/sys/net/route.h` and `/usr/src/sys/net/route/` hold the routing tables.
- `/usr/src/sys/sys/socketvar.h` declares `struct socket`.

### 43.8.6 Manual pages and files to read next

`mbuf(9)`, `ifnet(9)`, `ether_ifattach(9)`, `vnet(9)`, `route(4)`, and `socket(9)`. For a small, readable real network driver, `/usr/src/sys/net/if_tuntap.c` is the canonical reading example.

### 43.8.7 Common beginner confusion

Two traps. First, expecting a network driver to publish itself through `/dev`. It does not; it publishes itself through `ifnet` and becomes visible as `bge0`, `em0`, `igb0`, and so on, not through `devfs`. Second, holding onto an `mbuf` after handing it to the stack. Once you call `if_input` or return from `if_transmit`, the `mbuf` is no longer yours; using it afterwards corrupts the stack silently.

### 43.8.8 Where the book teaches this

Chapter 28 is the full network-driver chapter and the right place for the details. Chapters 11 and 14 provide the locking and deferred-work discipline the receive path needs. Chapter 24 covers `ifnet_arrival_event` and related event hooks at a driver-integration level.

### 43.8.9 Further reading

- **In this book:** Chapter 28 (Writing a Network Driver), Chapter 11 (Concurrency in Drivers), Chapter 14 (Taskqueues and Deferred Work).
- **Man pages:** `mbuf(9)`, `ifnet(9)`, `vnet(9)`, `socket(9)`.
- **External:** McKusick, Neville-Neil, and Watson, *The Design and Implementation of the FreeBSD Operating System* (2nd ed.), chapters on the network subsystem.

## 43.9 Driver Infrastructure (Newbus)

### 43.9.1 What the subsystem is for

Newbus is FreeBSD's driver framework. It owns the tree of devices in the system, matches drivers to devices through probe, manages the lifecycle of each attachment, routes resource allocations to the right bus, and provides the object-oriented dispatch that lets buses override and extend each other's behaviour. Every character driver, storage driver, network driver, and embedded driver in the tree is a Newbus participant. If the other subsystems in this appendix are the rooms, Newbus is the hallway that connects them.

### 43.9.2 Why a driver author should care

There is essentially no FreeBSD driver without Newbus. The types you meet first (`device_t`, `softc`, `driver_t`, `devclass_t`), the APIs you reach for in `attach` (`bus_alloc_resource_any`, `bus_setup_intr`), the macros

you wrap the whole driver in (`DRIVER_MODULE`, `DEVMETHOD`, `DEVMETHOD_END`) all belong here. Learning to navigate Newbus is the same thing as learning to navigate FreeBSD driver source.

### 43.9.3 Key structures, interfaces, or concepts

- **device\_t** is an opaque handle to a node in the Newbus device tree. You receive one in probe and attach, pass it into almost every bus API, and use it to fetch the softc with `device_get_softc(9)`.
- **driver\_t** is the descriptor for a driver: its name, its method table, and the size of its softc. You construct one for your driver and hand it to `DRIVER_MODULE(9)`, which registers it under a parent bus name.
- **devclass\_t** is the per-driver-class registry: the collection of `device_t` instances a driver has attached. It is how the kernel gives each instance a unit number.
- **kobj(9)** is the object-oriented machinery underneath Newbus. Method tables, method dispatch, and the ability for a bus to inherit another bus's methods are all kobj features. As a driver author you use the `DEVMETHOD` macros, which expand into kobj metadata; you rarely call kobj primitives directly.
- **softc** is the per-instance state of your driver, allocated by the kernel when it allocates the `device_t`. The kernel knows how large your softc is because you told it in the `driver_t`. `device_get_softc(9)` gives you back a pointer to it.
- **bus\_alloc\_resource(9)** and friends allocate memory windows, I/O ports, and interrupt lines from the parent bus on behalf of your driver. They are the portable way to get at a device's resources without caring which bus it sits on.

### 43.9.4 Typical driver touchpoints

- Declare a `device_method_t` array with `DEVMETHOD(device_probe, ...)`, `DEVMETHOD(device_attach, ...)`, `DEVMETHOD(device_detach, ...)`, terminated with `DEVMETHOD_END`.
- Declare a `driver_t` with your driver name, the methods, and `sizeof(struct mydev_softc)`.
- Use `DRIVER_MODULE(mydev, pci, mydev_driver, ...)` (or `usb`, `iicbus`, `spibus`, `simplebus`, `acpi`, `nexus`) to register the driver under its parent bus.
- In probe, decide whether this device is yours and, if so, return `BUS_PROBE_DEFAULT` (or a weaker/stronger value) and a description.
- In attach, allocate resources with `bus_alloc_resource_any(9)`, map registers with `bus_space(9)`, set up interrupts with `bus_setup_intr(9)`, and only then expose yourself to the rest of the kernel.
- In detach, undo everything in reverse order.

### 43.9.5 Where to look in /usr/src

- `/usr/src/sys/sys/bus.h` declares `device_t`, `driver_t`, `devclass_t`, `DEVMETHOD`, `DEVMETHOD_END`, `DRIVER_MODULE`, `bus_alloc_resource_any`, `bus_setup_intr`, and most of the rest.
- `/usr/src/sys/sys/kobj.h` declares the method-dispatch machinery.
- `/usr/src/sys/kern/subr_bus.c` holds the Newbus implementation.
- `/usr/src/sys/kern/subr_kobj.c` holds the kobj implementation.
- `/usr/src/sys/dev/null/null.c` and `/usr/src/sys/dev/led/led.c` are very small real drivers you can read in a sitting.

### 43.9.6 Manual pages and files to read next

`device(9)`, `driver(9)`, `DEVMETHOD(9)`, `DRIVER_MODULE(9)`, `bus_alloc_resource(9)`, `bus_setup_intr(9)`, `kobj(9)`, and `devinfo(8)` to see the running Newbus tree.

### 43.9.7 Common beginner confusion

Two traps. First, thinking that `device_t` and `softc` are the same object. `device_t` is the Newbus handle; `softc` is your driver's private state. You fetch `softc` from `device_t` with `device_get_softc(9)`. Second, forgetting that `DRIVER_MODULE`'s second argument is the parent bus name. A driver declared with `DRIVER_MODULE( . . . , pci, . . . )` can only attach under a PCI bus, no matter how many PCI-like boards exist elsewhere. If a driver must attach under multiple buses (for example, a chip that appears both as PCI and as ACPI), you register it twice.

### 43.9.8 Where the book teaches this

Chapter 6 is the full anatomy of a driver chapter and the canonical teaching location for everything above. Chapter 7 writes the first working driver against these APIs. Chapter 18 extends the picture for PCI. Chapter 24 returns to `DRIVER_MODULE`, `MODULE_VERSION`, and `MODULE_DEPEND` when kernel integration becomes the subject.

### 43.9.9 Further reading

- **In this book:** Chapter 6 (The Anatomy of a FreeBSD Driver), Chapter 7 (Writing Your First Driver), Chapter 18 (Writing a PCI Driver).
- **Man pages:** `device(9)`, `driver(9)`, `DRIVER_MODULE(9)`, `bus_alloc_resource(9)`, `bus_setup_intr(9)`, `kobj(9)`, `rman(9)`.

## 43.10 Boot and Module System

### 43.10.1 What the subsystem is for

The boot and module system is how the kernel gets into memory, how it initialises the hundreds of subsystems it depends on before anything can run, and how code that is not compiled into the kernel (loadable modules) is brought in, wired up, and eventually removed. From a driver author's perspective, the subsystem defines when your initialisation code runs relative to the rest of the kernel, and how your module-level `MOD_LOAD` and `MOD_UNLOAD` events interact with the kernel's internal initialisation order.

### 43.10.2 Why a driver author should care

Three reasons. First, if your driver can be loaded as a module, it may run on a kernel whose subsystems have been ordered differently than you expect, and you need to declare what you depend on. Second, if your driver must run early (for example, a console driver or a boot-time storage driver), you must understand `SYSINIT(9)`

subsystem IDs so that your code runs in the right slot. Third, even a plain driver relies on the module system to register itself, to declare ABI compatibility, and to fail cleanly if a dependency is missing.

### 43.10.3 Key structures, interfaces, or concepts

- **The boot sequence** follows a fixed arc: the loader reads the kernel from disk, hands control to the kernel entry point, which sets up the early CPU state and then calls `mi_startup()`. `mi_startup()` walks a sorted list of `SYSINIT` entries, invoking each one in order. When the list is exhausted, the kernel has enough services up to start `init(8)` as user process 1.
- **`SYSINIT(9)`** is the macro that registers a function to be called at a specific phase of kernel initialisation. Each entry has a subsystem ID (`SI_SUB_*`, coarse ordering) and an order-within-subsystem (`SI_ORDER_*`, fine ordering). The full list of legal subsystem IDs is in `/usr/src/sys/sys/kernel.h` and is worth skimming once. `SYSUNINIT(9)` is the matching teardown.
- **Module loading** is driven by the KLD framework. `kldload(8)` invokes the linker, which relocates the module, resolves its symbols against the running kernel, and invokes the module's event handler with `MOD_LOAD`. A matching `MOD_UNLOAD` runs when the module is removed. Drivers rarely write module event handlers by hand; `DRIVER_MODULE(9)` produces one for you.
- **`MODULE_DEPEND(9)`** declares that your module requires another module (`usb`, `miibus`, `pci`, `iflib`) to be present, and at which version range. The kernel refuses to load your module if the dependency is missing.
- **`MODULE_VERSION(9)`** declares the ABI version your module exports, so that other modules can depend on it with `MODULE_DEPEND`.

### 43.10.4 Typical driver touchpoints

- `DRIVER_MODULE(mydev, pci, mydev_driver, ...)` emits a module event handler that registers the driver on `MOD_LOAD` and deregisters it on `MOD_UNLOAD`.
- `MODULE_VERSION(mydev, 1)`; announces your module's ABI version.
- `MODULE_DEPEND(mydev, pci, 1, 1, 1)`; declares a `pci` dependency.
- A driver that must run before Newbus is available uses `SYSINIT(9)` to register a one-off setup hook at an early subsystem ID.
- A driver that wires a teardown hook at the last possible moment uses `SYSUNINIT(9)` with the matching ordering.

### 43.10.5 Where to look in `/usr/src`

- `/usr/src/sys/sys/kernel.h` defines `SYSINIT`, `SYSUNINIT`, `SI_SUB_*`, and `SI_ORDER_*`.
- `/usr/src/sys/kern/init_main.c` contains `mi_startup()` and the walk through the `SYSINIT` list.
- `/usr/src/sys/sys/module.h` declares `MODULE_VERSION` and `MODULE_DEPEND`.
- `/usr/src/sys/sys/linker.h` and `/usr/src/sys/kern/kern_linker.c` implement the KLD linker.
- `/usr/src/stand/` holds the loader and the boot-time code. (On older FreeBSD releases this lived under `/usr/src/sys/boot/`; FreeBSD 14 hosts it entirely under `/usr/src/stand/`.)

### 43.10.6 Manual pages and files to read next

`SYSINIT(9)`, `kld(9)`, `kldload(9)`, `kldload(8)`, `kldstat(8)`, `module(9)`, `MODULE_VERSION(9)`, and `MODULE_DEPEND(9)`. For a short real `SYSINIT` example, look near the top of `/usr/src/sys/dev/random/random_harvestq.c`.

### 43.10.7 Common beginner confusion

Two traps. First, assuming that `MOD_LOAD` is the moment your `attach` function runs. It is not. `MOD_LOAD` is the moment your *driver* is registered with Newbus; `attach` runs later, per device, whenever a bus offers a matching child. Second, using `SYSINIT` levels as if they were arbitrary. Each `SI_SUB_*` corresponds to a well-defined phase of kernel startup, and registering your hook at the wrong phase either makes it run too early (with half the kernel missing) or too late (after the event you cared about has passed).

### 43.10.8 Where the book teaches this

Chapter 6 introduces `DRIVER_MODULE`, `MODULE_VERSION`, and `MODULE_DEPEND` as part of driver anatomy. Chapter 24 covers kernel-integration topics including `SYSINIT`, subsystem IDs, and module teardown ordering. Chapter 32 returns to boot-time concerns on embedded platforms.

### 43.10.9 Further reading

- **In this book:** Chapter 24 (Integrating with the Kernel), Chapter 32 (Device Tree and Embedded Development).
- **Man pages:** `SYSINIT(9)`, `module(9)`, `MODULE_VERSION(9)`, `MODULE_DEPEND(9)`, `kldload(8)`, `kldstat(8)`.

## 43.11 Kernel Services

### 43.11.1 What the subsystem is for

The kernel ships a small set of general-purpose services that are not tied to any one subsystem but show up repeatedly in drivers: event notifications, deferred-work queues, timed callbacks, and subscription hooks. None of them teaches you how to write a driver, but all of them turn up in real driver code, and recognising them speeds up every code-reading session. This section collects the handful you are likely to meet.

### 43.11.2 Why a driver author should care

Drivers often need to react to system-wide events (shutdown, low memory, interface arrival, root filesystem mount), or to do work outside the context that delivered the event (away from an interrupt filter, away from a spin-locked critical section). The kernel services below are the standard FreeBSD answers to both needs. Using them means your driver integrates cleanly with the rest of the system; reimplementing them means you will eventually collide with a subsystem that expects your hooks to exist.

### 43.11.3 Key structures, interfaces, or concepts

- **eventhandler(9)** is the publish/subscribe system for kernel events. A publisher declares an event with `EVENTHANDLER_DECLARE`, a subscriber registers with `EVENTHANDLER_REGISTER`, and invocation with `EVENTHANDLER_INVOKE` fans out to every subscriber. Standard event tags defined in `/usr/src/sys/sys/eventhandler.h` include `shutdown_pre_sync`, `shutdown_post_sync`, `shutdown_final`, `vm_lowmem`, and `mountrout`; interface events (`ifnet_arrival_event`, `ifnet_departure_event`) are declared in `/usr/src/sys/net/if_var.h`. Drivers use these to clean up, to release memory, to react when a sibling interface appears, or to delay early work until the root filesystem is available.
- **taskqueue(9)** is a queue of deferred work items. A driver enqueues a task from a context that cannot sleep (for example, an interrupt filter) and the task later runs on a dedicated worker thread where sleeping and blocking are allowed. The kernel ships a small set of system-wide taskqueues (`taskqueue_swi`, `taskqueue_thread`, `taskqueue_fast`) and lets you create your own.
- **Grouped taskqueues (gtaskqueue)** extend taskqueue with CPU affinity and rebalancing; they are heavily used in `iflib` and in the high-rate network stack. The declarations live in `/usr/src/sys/sys/gtaskqueue.h`.
- **callout(9)** is the kernel's one-shot and periodic timer. A driver arms a callout with a future deadline and receives a callback when the deadline arrives. `callout(9)` replaces almost every ad-hoc “sleep for N ticks” loop a driver might otherwise write.
- **hooks(9)-style subsystem extension points.** A number of FreeBSD subsystems publish registration APIs that behave like eventhandlers but are specific to the subsystem (for example, packet filters register with `pfil(9)`; disk drivers can register with `disk(9)` events). These are not one unified interface, but the pattern is the same: a list of callbacks that a subsystem invokes at a well-defined moment.

### 43.11.4 Typical driver touchpoints

- `EVENTHANDLER_REGISTER(shutdown_pre_sync, mydev_shutdown, softc, SHUTDOWN_PRI_DEFAULT);` in `attach` so the driver flushes hardware before a reboot; `EVENTHANDLER_DEREGISTER` in `detach`. (The three standard priority constants for shutdown hooks are `SHUTDOWN_PRI_FIRST`, `SHUTDOWN_PRI_DEFAULT`, and `SHUTDOWN_PRI_LAST`, declared in `/usr/src/sys/sys/eventhandler.h`.)
- `taskqueue_create("mydev", M_WAITOK, ...); taskqueue_start_threads(...);` in `attach` to create a per-device worker; `taskqueue_drain_all` and `taskqueue_free` in `detach`.
- `callout_init_mtx(&sc->sc_watchdog, &sc->sc_mtx, 0)` in `attach` to arm a watchdog; `callout_drain` in `detach`.
- Grouped taskqueues are most visible inside `iflib`-based network drivers; a typical standalone driver rarely reaches for them directly.

### 43.11.5 Where to look in /usr/src

- `/usr/src/sys/sys/eventhandler.h` and `/usr/src/sys/kern/subr_eventhandler.c` for event handlers.
- `/usr/src/sys/sys/taskqueue.h` and `/usr/src/sys/kern/subr_taskqueue.c` for taskqueues.
- `/usr/src/sys/sys/gtaskqueue.h` and `/usr/src/sys/kern/subr_gtaskqueue.c` for grouped taskqueues.
- `/usr/src/sys/sys/callout.h` and `/usr/src/sys/kern/kern_timeout.c` for callouts.

### 43.11.6 Manual pages and files to read next

eventhandler(9), taskqueue(9), callout(9), and the header `/usr/src/sys/sys/eventhandler.h`. Look at `/usr/src/sys/dev/random/random_harvestq.c` for a driver that uses SYSINIT and a dedicated kproc cleanly; it is a good companion when reading about kernel services even though it does not itself exercise taskqueue(9) or callout(9).

### 43.11.7 Common beginner confusion

One important trap: forgetting that registration is half of the contract. Every `EVENTHANDLER_REGISTER` needs an `EVENTHANDLER_DEREGISTER` at the matching lifecycle moment, every `taskqueue_create` needs a `taskqueue_free`, and every armed callout needs a `callout_drain` before its memory is freed. A leaked registration keeps a dangling pointer into freed memory; the next invocation of the event will then crash the kernel in a subsystem that has nothing to do with your driver.

### 43.11.8 Where the book teaches this

Chapter 13 introduces callout(9). Chapter 14 is the taskqueue chapter. Chapter 24 is the kernel-integration chapter and covers eventhandler(9) and the SYSINIT/module cooperation in context.

### 43.11.9 Further reading

- **In this book:** Chapter 13 (Timers and Delayed Work), Chapter 14 (Taskqueues and Deferred Work), Chapter 24 (Integrating with the Kernel).
- **Man pages:** eventhandler(9), taskqueue(9), callout(9).

## 43.12 Cross-References: Structures and Their Subsystems

The table below is the fastest way to turn an unfamiliar type into a known subsystem. Use it when you are reading driver source, hit a struct name you do not recognise, and want to know which section of this appendix to open.

| Structure or type   | Subsystem          | Where declared                                                                    |
|---------------------|--------------------|-----------------------------------------------------------------------------------|
| struct proc, thread | Process and Thread | <code>/usr/src/sys/sys/proc.h</code>                                              |
| vm_map_t            | Memory (VM)        | <code>/usr/src/sys/vm/vm.h</code> and<br><code>/usr/src/sys/vm/vm_map.h</code>    |
| vm_object_t         | Memory (VM)        | <code>/usr/src/sys/vm/vm.h</code> and<br><code>/usr/src/sys/vm/vm_object.h</code> |
| vm_page_t           | Memory (VM)        | <code>/usr/src/sys/vm/vm.h</code> and<br><code>/usr/src/sys/vm/vm_page.h</code>   |
| uma_zone_t          | Memory (VM)        | <code>/usr/src/sys/vm/uma.h</code>                                                |

| Structure or type                                          | Subsystem                    | Where declared                                                                     |
|------------------------------------------------------------|------------------------------|------------------------------------------------------------------------------------|
| <code>struct vnode</code>                                  | File and VFS                 | <code>/usr/src/sys/sys/vnode.h</code>                                              |
| <code>struct vop_vector</code>                             | File and VFS                 | generated from<br><code>/usr/src/sys/kern/vnode_if.src</code>                      |
| <code>struct buf</code>                                    | File and VFS                 | <code>/usr/src/sys/sys/buf.h</code>                                                |
| <code>struct bio</code>                                    | File and VFS (GEOM)          | <code>/usr/src/sys/sys/bio.h</code>                                                |
| <code>struct g_provider</code>                             | File and VFS (GEOM)          | <code>/usr/src/sys/geom/geom.h</code>                                              |
| <code>struct cdev</code>                                   | File and VFS (devfs)         | <code>/usr/src/sys/sys/conf.h</code>                                               |
| <code>struct cdevsw</code>                                 | File and VFS (devfs)         | <code>/usr/src/sys/sys/conf.h</code>                                               |
| <code>struct mbuf, m_tag</code>                            | Network                      | <code>/usr/src/sys/sys/mbuf.h</code>                                               |
| <code>if_t, struct ifnet</code>                            | Network                      | <code>/usr/src/sys/net/if.h</code> ,<br><code>/usr/src/sys/net/if_private.h</code> |
| <code>struct socket</code>                                 | Network                      | <code>/usr/src/sys/sys/socketvar.h</code>                                          |
| <code>device_t</code>                                      | Driver Infrastructure        | <code>/usr/src/sys/sys/bus.h</code>                                                |
| <code>driver_t, devclass_t</code>                          | Driver Infrastructure        | <code>/usr/src/sys/sys/bus.h</code>                                                |
| <code>device_method_t</code>                               | Driver Infrastructure (kobj) | <code>/usr/src/sys/sys/bus.h</code> (kobj in<br><code>sys/kobj.h</code> )          |
| <code>struct resource</code>                               | Driver Infrastructure        | <code>/usr/src/sys/sys/rman.h</code>                                               |
| <code>SYSINIT, SI_SUB_*</code>                             | Boot and Module              | <code>/usr/src/sys/sys/kernel.h</code>                                             |
| <code>MODULE_VERSION,</code><br><code>MODULE_DEPEND</code> | Boot and Module              | <code>/usr/src/sys/sys/module.h</code>                                             |
| <code>eventhandler_tag</code>                              | Kernel Services              | <code>/usr/src/sys/sys/eventhandler.h</code>                                       |
| <code>struct taskqueue</code>                              | Kernel Services              | <code>/usr/src/sys/sys/taskqueue.h</code>                                          |
| <code>struct callout</code>                                | Kernel Services              | <code>/usr/src/sys/sys/callout.h</code>                                            |

When a type is not in the table, search `/usr/src/sys/sys/` or `/usr/src/sys/<subsystem>/` for its declaration; the comment near the definition usually names the subsystem outright.

### 43.13 Source-Tree Navigation Checklists

The FreeBSD source tree is organised by responsibility, and once you know the pattern you can guess where almost anything lives. The lists below are the five quick questions that turn “where in the tree” into “open this file”.

### 43.13.1 When you have a structure name

1. Is it a low-level primitive (proc, thread, vnode, buf, bio, mbuf, callout, taskqueue, eventhandler)? Look in /usr/src/sys/sys/ first.
2. Is it a VM type (vm\_\*, uma\_\*)? Look in /usr/src/sys/vm/.
3. Is it a network type (ifnet, if\_\*, m\_tag, route, socket, vnet)? Look in /usr/src/sys/net/, /usr/src/sys/netinet/, or /usr/src/sys/netinet6/.
4. Is it a device or bus type (device\_t, driver\_t, resource, rman, pci\_\*, usb\_\*)? Look in /usr/src/sys/sys/bus.h, /usr/src/sys/sys/rman.h, or the matching bus directory under /usr/src/sys/dev/.
5. Is it something else entirely? `grep -r 'struct NAME {' /usr/src/sys/sys/ /usr/src/sys/kern/ /usr/src/sys/vm/ /usr/src/sys/net/` usually finds it in one pass.

### 43.13.2 When you have a function name

1. If the name starts with vm\_, it lives under /usr/src/sys/vm/.
2. If it starts with bus\_, device\_, driver\_, devclass\_, resource\_, it lives in /usr/src/sys/kern/subr\_bus.c, /usr/src/sys/kern/subr\_rman.c, or one of the bus-specific directories.
3. If it starts with vfs\_, vn\_, or a VOP\_ prefix, it lives under /usr/src/sys/kern/vfs\_\*.c or one of the filesystems under /usr/src/sys/fs/.
4. If it starts with g\_, it is GEOM; look in /usr/src/sys/geom/.
5. If it starts with if\_, ether\_, or in\_, it is networking; look in /usr/src/sys/net/ or /usr/src/sys/netinet/.
6. If it starts with kthread\_, kproc\_, sched\_, or proc\_, it is the process/thread subsystem under /usr/src/sys/kern/.
7. If it starts with uma\_ or malloc, it is memory; look in /usr/src/sys/vm/uma\_core.c or /usr/src/sys/kern/kern\_malloc.c.
8. When nothing matches, `grep -rI '\bFUNC_NAME\s*( ' /usr/src/sys/` is slower but exhaustive.

### 43.13.3 When you have a macro name

1. SYSINIT, SYSUNINIT, SI\_SUB\_\*, SI\_ORDER\_\*: /usr/src/sys/sys/kernel.h.
2. DRIVER\_MODULE, DEVMETHOD, DEVMETHOD\_END, MODULE\_VERSION, MODULE\_DEPEND: /usr/src/sys/sys/bus.h and /usr/src/sys/sys/module.h.
3. EVENTHANDLER\_\*: /usr/src/sys/sys/eventhandler.h.
4. VNET\_\*, CURVNET\_\*: /usr/src/sys/net/vnet.h.
5. TAILQ\_\*, LIST\_\*, STAILQ\_\*, SLIST\_\*: /usr/src/sys/sys/queue.h.
6. VOP\_\*: generated from /usr/src/sys/kern/vnode\_if.src, visible in sys/vnode\_if.h once the kernel is built.

### 43.13.4 When you have a subsystem question

1. What initialises the kernel and in which order? /usr/src/sys/kern/init\_main.c.
2. What drivers does the tree contain? `ls /usr/src/sys/dev/` and its subdirectories.

3. Where are network-stack entry points? `/usr/src/sys/net/if.c`, `/usr/src/sys/netinet/`, and their siblings.
4. How does a specific syscall reach a driver? start in `/usr/src/sys/kern/syscalls.master`, follow the dispatcher into the relevant VFS or socket code, and keep reading until the dispatch lands in a `cdevsw`, a `vop_vector`, or an `ifnet`.

## 43.14 Manual Pages and Source Reading Itinerary

Pattern recognition across the kernel comes from reading it, not only from reading about it. A self-study plan that covers the subsystems in this appendix might look like this:

1. `intro(9)` plus a walk of `/usr/src/sys/sys/` file names, fifteen minutes total.
2. `kthread(9)`, `kproc(9)`, and `/usr/src/sys/sys/proc.h`.
3. `malloc(9)`, `uma(9)`, `bus_dma(9)`, and `/usr/src/sys/vm/uma.h`.
4. `vnode(9)`, `cdev(9)`, `make_dev(9)`, `devfs(4)`, and `/usr/src/sys/dev/null/null.c`.
5. `mbuf(9)`, `ifnet(9)`, `ether_ifattach(9)`, and `/usr/src/sys/net/if_tuntap.c`.
6. `device(9)`, `DRIVER_MODULE(9)`, `bus_alloc_resource(9)`, and `/usr/src/sys/dev/led/led.c`.
7. `SYSINIT(9)`, `kld(9)`, `module(9)`, and the top of `/usr/src/sys/kern/init_main.c`.
8. `eventhandler(9)`, `taskqueue(9)`, `callout(9)`, and `/usr/src/sys/dev/random/random_harvestq.c`.

The companion files in `examples/appendices/appendix-e-navigating-freebsd-kernel-internals/` collect the same itinerary in a form you can print, annotate, and keep next to the machine.

## 43.15 Wrapping Up: How to Keep Exploring the Kernel Safely

Exploring a kernel source tree can feel endless, and it is easy to lose a weekend chasing one interesting thread through ten subsystems. A small set of habits keeps the exploration productive.

Read in short sessions with a specific question. “What does `bus_setup_intr` actually do under the hood” is a good session. “Read the VM” is not.

Keep the map in view. When you jump from a driver into the VFS, remind yourself that you are now in the VFS and that the rules of the VFS apply. When you return to the driver, remind yourself that the VFS stopped at the function boundary. Each subsystem has its own invariants and its own locking discipline, and they rarely carry over.

Write down what you find. A short note like “`bus_alloc_resource_any` in `subr_bus.c` calls into `BUS_ALLOC_RESOURCE` via `kobj` dispatch, which the PCI bus method implements in `pci.c`” is worth more than an afternoon of passive reading. The appendix and its companion files are there to give you anchor points for exactly this kind of note-taking.

Use the safety rails. `/usr/src/sys/dev/null/null.c` and `/usr/src/sys/dev/led/led.c` are tiny. `/usr/src/sys/net/if_tuntap.c` is small enough to read in a sitting. `/usr/src/sys/dev/random/random_harvestq.c` uses real kernel services without hiding behind layers of abstraction. Start from these whenever a subsystem feels too large to approach directly.

And remember that the goal is not to memorise the kernel. It is to build enough pattern recognition that, the next time you open an unfamiliar driver or a new subsystem, the structures, the functions, and the source paths feel

like neighbourhoods you have already walked through. This appendix, together with Appendices A through D and the chapters that teach the pieces in context, is designed to make that feeling arrive sooner.

When the map here is not enough, the book is. When the book is not enough, the source is. And the source is already sitting on your FreeBSD machine, waiting to be read.

## 44 Appendix F: Benchmark Harness and Results

### 44.1 How to Use This Appendix

Several chapters in this book make performance claims. Chapter 15 gives order-of-magnitude timings for `mtx_lock`, `sx_slock`, condition variables, and semaphores. Chapter 28 notes that driver code typically shrinks by thirty to fifty percent when a network driver is converted to `iflib(9)`. Chapter 33 discusses the cost hierarchy of timecounter sources, with TSC at one end, HPET at the other, and ACPI-fast in the middle. Chapter 34 describes the run-time cost of debug kernels with INVARIANTS or WITNESS enabled, and of kernels with active DTrace scripts attached. Every one of those claims is qualified in the text with a phrase such as “on typical FreeBSD 14.3-amd64 hardware”, “in our lab environment”, or “order-of-magnitude”. The qualifiers exist because the absolute numbers depend on the specific machine, the specific workload, and the specific compiler that built the kernel.

This appendix exists so that those qualifiers stand on reproducible ground. For each class of claim, the companion tree under `examples/appendices/appendix-f-benchmarks/` contains a working harness that the reader can build, run, and extend. Where a harness is portable and does not require hardware access, this appendix also reports the measurement it produces on a known machine, so that readers have a concrete number to compare against. Where a harness requires a specific kernel configuration that cannot be assumed to exist on any given reader’s machine, only the harness itself is provided, together with clear instructions for reproducing it.

The aim is not to replace the Chapter 15 or Chapter 34 claims with authoritative figures. It is to let readers see how the claims were arrived at, to let them verify the claims on their own hardware, and to make the results honest about what varies with environment and what does not.

#### 44.1.1 How this appendix is organised

The appendix has five benchmark sections, each with the same internal structure.

- **What is being measured.** One paragraph describing the claim from the chapter and the quantity the harness measures.
- **The harness.** The filesystem location of the companion files, the programming language used, and a short description of the approach.
- **How to reproduce.** The exact command or command sequence the reader runs.
- **Representative result.** A measured value, or “harness only, no result captured” when the harness has not been run by the author.
- **Hardware envelope.** The range of machines over which the result is expected to generalise, and the range over which it is known not to.

The five sections in order are timecounter read cost, synchronization primitive latency, `iflib` driver code-size reduction, and DTrace-with-INVARIANTS-and-WITNESS overhead. A final section on scheduler wakeup

latency points at the existing Chapter 33 script rather than introducing a new one, since the script there is already the harness.

## 44.2 Hardware and Software Setup

Before presenting the benchmarks, a word on the envelope. The numbers in this appendix and the representative results quoted inside it come from two kinds of measurement.

The first kind is **portable measurement**: anything that counts lines of source code, reads the output of a deterministic tool, or otherwise depends only on the FreeBSD source tree and a working compiler. Those measurements produce the same result on any host that has the same source checkout. The iflib code-size comparison in Section 4 is the only portable measurement in the appendix, and its result can be reproduced exactly on any machine with `/usr/src` synchronised to a FreeBSD 14.3-RELEASE source tag.

The second kind is **hardware-dependent measurement**: anything that times a kernel path, a syscall, or a hardware register read. Those measurements depend on the CPU, the memory hierarchy, and the kernel configuration. For every hardware-dependent benchmark in this appendix, the harness is provided, the reproduction steps are precise, and a representative result is quoted only when the author has actually run the harness on a known machine. Where the author has not, the appendix says so explicitly and leaves the results table blank for the reader to fill in.

The fairer phrasing is that this appendix is a **runnable field guide**. The chapters quote qualified figures; the appendix shows you how to measure the same quantities on the hardware in front of you, and what to expect if your hardware belongs to the same broad family as the hardware the chapters had in mind (“modern amd64”, “Intel and AMD generations currently in service”).

### 44.2.1 Caveats that apply to every section

A few caveats apply throughout, and it is simpler to name them once than to repeat them in each section.

All the hardware-dependent harnesses measure averages over large loops. Averages hide tail behaviour. A P99 latency can be an order of magnitude higher than the mean on the same path, especially for anything that involves a scheduler wakeup. Any serious performance claim in production will need a distributional measurement, not a single number; this appendix is about the mean because that is what the chapter claims refer to.

Readers running these harnesses under virtualisation should expect significantly noisier results than on bare metal. A virtualised TSC, for example, may be synthesised by the hypervisor in a way that adds hundreds of nanoseconds to every read. The Chapter 33 cost hierarchy still holds qualitatively under virtualisation, but the absolute numbers will move.

Finally, none of these harnesses are intended for use in production kernels. The sync-primitive `kmod` in particular spawns kernel threads that do tight no-op loops; it is safe to load for a few seconds on a development machine and unload, but it should not be loaded on a busy server.

## 44.3 Timecounter Read Cost

### 44.3.1 What is being measured

Chapter 33 describes a three-way cost hierarchy for timecounter sources in FreeBSD: TSC is cheap to read, ACPI-fast is moderately expensive, and HPET is expensive. The claim is qualified with “on the Intel and AMD generations currently in service”, and separately with “on typical FreeBSD 14.3-amd64 hardware”. The harness in this section measures the average cost of one `clock_gettime(CLOCK_MONOTONIC)` call, which the kernel resolves through whichever source `kern.timecounter.hardware` currently selects, and separately the cost of a bare `rdtsc` instruction as a floor.

The quantity measured is nanoseconds per call, averaged over ten million iterations. The underlying kernel path is `sbinoptime()` in `/usr/src/sys/kern/kern_tc.c`, which reads the current timecounter’s `tc_get_timecount` method, scales it, and returns the result as an `sbintime_t`.

### 44.3.2 The harness

The harness lives under `examples/appendices/appendix-f-benchmarks/timecounter/` and is composed of three pieces.

`tc_bench.c` is a small userland program that calls `clock_gettime(CLOCK_MONOTONIC)` in a tight loop and reports the average nanoseconds per call. It reads `kern.timecounter.hardware` at startup and prints the current source name, so that each run is self-documenting.

`rdtsc_bench.c` is a companion userland program that reads the `rdtsc` instruction directly, using the inline assembly pattern that the kernel uses in its own `rdtsc()` wrapper in `/usr/src/sys/amd64/include/cpufunc.h`. Its output is the cost of the instruction itself, without any kernel overhead.

`run_tc_bench.sh` is a root-only shell wrapper that reads `kern.timecounter.choice` (the list of available sources for the current kernel), iterates over each entry, sets `kern.timecounter.hardware` to that source, runs `tc_bench`, and restores the original setting on exit. The result is a table with one row per timecounter source, ready to compare.

### 44.3.3 How to reproduce

Build the two userland programs:

```
$ cd examples/appendices/appendix-f-benchmarks/timecounter
$ make
```

Run the rotation (requires root to flip the `sysctl`):

```
sh run_tc_bench.sh
```

Or just the direct TSC floor:

```
$./rdtsc_bench
```

#### 44.3.4 Representative result

Harness only, no result captured. The harness has been compiled and its logic reviewed, but the author has not run it on the reference machine while writing this appendix. A reader running the harness on typical FreeBSD 14.3-amd64 hardware should expect the TSC column to report values in the low tens of nanoseconds, the ACPI-fast column to report values several times higher, and the HPET column (if available and not disabled in firmware) to report values an order of magnitude higher still. The absolute numbers will vary with CPU generation, power state, and whether `clock_gettime` is served by the fast-gettime path or falls through to the full syscall.

#### 44.3.5 Hardware envelope

The ordering of the three timecounter sources by cost has been stable across amd64 generations since invariant TSC became standard in the mid-2000s. Readers on different CPU vendors or different microarchitectural generations will see different absolute numbers but the same ordering. On ARM64, there is no HPET or ACPI-fast in the usual sense, and the relevant comparison is between the Generic Timer counter register and the software paths that wrap it; the harness will still run, but only one entry will appear in the table. If `kern.timecounter.choice` on the reader's machine shows a single source, that is itself a useful data point: the system's firmware has restricted the choice, and no rotation is possible.

See also Chapter 33 for the surrounding context, particularly the section on `sbinuptime()` and the discussion of why driver code should avoid reading `rdtsc()` directly.

### 44.4 Synchronization Primitive Latencies

#### 44.4.1 What is being measured

Chapter 15 presents a table of approximate per-operation costs for FreeBSD's synchronization primitives: atomics at a nanosecond or two, uncontended `mtx_lock` at tens of nanoseconds, uncontended `sx_slock` and `sx_xlock` slightly higher, and `cv_wait/sem_wait` at microseconds because they always involve a full scheduler wakeup. The numbers in the table are described as “order-of-magnitude estimates on typical FreeBSD 14.3 amd64 hardware”, with the caveat that they “can move by a factor of two or more across CPU generations”. The harness in this section measures each row of that table directly.

The quantities measured are:

- Nanoseconds per `mtx_lock / mtx_unlock` pair on an uncontended mutex.
- Nanoseconds per `sx_slock / sx_sunlock` pair on an uncontended `sx`.
- Nanoseconds per `sx_xlock / sx_xunlock` pair on an uncontended `sx`.
- Nanoseconds per one-shot `cv_signal / cv_wait` round-trip between two kernel threads.
- Nanoseconds per one-shot `sem_post / sem_wait` round-trip between two kernel threads.

### 44.4.2 The harness

The harness lives under `examples/appendices/appendix-f-benchmarks/sync/` and is a single loadable kernel module, `sync_bench.ko`. The module exposes five write-only sysctls under `debug.sync_bench.` (one per benchmark) and five read-only sysctls that report the most recent result for each benchmark.

Each benchmark times a fixed number of iterations using `sbinuptime()` in `/usr/src/sys/kern/kern_tc.c` for the timestamps. The `mutex`, `sx_slock`, and `sx_xlock` benchmarks run entirely in the calling thread and exercise only the uncontended fast path. The `cv` and `sema` benchmarks spawn a worker `kproc` that signs a ping/pong protocol with the main thread; every iteration therefore includes one wakeup and one context switch in each direction, which is precisely what Chapter 15’s “wakeup latency” column measures.

The module follows the `kmod` pattern used in other chapters of this book, declared with `DECLARE_MODULE` and initialised through `SI_SUB_KLD / SI_ORDER_ANY`. Sources are `/usr/src/sys/kern/kern_mutex.c` for `mtx_lock`, `/usr/src/sys/kern/kern_sx.c` for `sx_slock / sx_xlock`, `/usr/src/sys/kern/kern_condvar.c` for condition variables, and `/usr/src/sys/kern/kern_sema.c` for counting semaphores.

### 44.4.3 How to reproduce

Build the module:

```
$ cd examples/appendices/appendix-f-benchmarks/sync
$ make
```

Load and drive it:

```
kldload ./sync_bench.ko
sh run_sync_bench.sh
kldunload sync_bench
```

`run_sync_bench.sh` runs each benchmark in sequence and prints a small table; individual benchmarks can also be triggered directly by writing a 1 to the corresponding `debug.sync_bench.run_*` sysctl and then reading `debug.sync_bench.last_ns_*`.

### 44.4.4 Representative result

Harness only, no result captured. The `kmod` has been written against FreeBSD 14.3 headers and its logic reviewed against the Chapter 15 table, but the author has not loaded and run it on the reference machine while writing this appendix. A reader running the harness on typical FreeBSD 14.3-amd64 hardware should expect the uncontended `mutex` and `sx` numbers to land in the low tens of nanoseconds, and the `cv` and `sema` round-trip numbers to land in the low microseconds because those paths cross the scheduler twice. Any reader whose numbers are more than a factor of two higher should look at scheduler affinity, CPU frequency scaling, and whether the host is under additional load.

### 44.4.5 Hardware envelope

The Chapter 15 table’s “order-of-magnitude” qualifier is deliberate. Uncontended lock costs track the cost of one or two atomic compare-and-swap operations on the current cache line, which varies with CPU generation and cache topology. Round-trip wakeup costs track scheduler latency, which varies more: a dedicated-CPU server with `kern.sched.preempt_thresh` tuned for low latency can show sub-microsecond round-trips, while a busy multi-tenant machine can see tens of microseconds. The harness reports a single mean per benchmark; readers who need a distribution should extend the module to capture quantiles, or use DTrace `lockstat` probes on the running kernel instead.

See also Chapter 15 for the conceptual framework and the guidance on when each primitive is appropriate.

## 44.5 iflib Driver Code-Size Reduction

### 44.5.1 What is being measured

Chapter 28 claims that on the drivers that have been converted to `iflib(9)` to date, driver code typically shrinks by thirty to fifty percent compared with the equivalent plain-ifnet implementation. Unlike the other benchmarks in this appendix, this one is not a hardware measurement. It is a source-code measurement: how many lines of C source a modern NIC driver needs under `iflib(9)` versus how many it needed without it.

The quantity measured is the line count of a driver’s main source file, split into three figures: the raw `wc -l` total, the number of non-blank lines, and the number of non-blank non-comment lines (an approximation of “code lines” that is close enough to the truth for order-of-magnitude comparison).

### 44.5.2 The harness

The harness lives under `examples/appendices/appendix-f-benchmarks/iflib/` and is a set of portable shell scripts.

`count_driver_lines.sh` takes one driver source file and reports all three figures. The comment stripping is a simple `awk` pass that understands `/* ... */` (including multi-line) and `// ... EOL` forms; it is not a full C parser but is accurate enough to be useful.

`compare_iflib_corpus.sh` is the main driver. It walks two curated corpora and produces a comparison table:

- iflib corpus: `/usr/src/sys/dev/e1000/if_em.c`, `/usr/src/sys/dev/ixgbe/if_ix.c`, `/usr/src/sys/dev/igc/if_igc.c`, `/usr/src/sys/dev/vmware/vmxnet3/if_vmx.c`.
- Plain-ifnet corpus: `/usr/src/sys/dev/re/if_re.c`, `/usr/src/sys/dev/bge/if_bge.c`, `/usr/src/sys/dev/fxp/if_fxp.c`.

The iflib drivers were selected by grepping for `IFDI_` method callbacks, which are the characteristic iflib interface points; the plain-ifnet drivers were selected to span a comparable range of hardware classes. Both lists are variables at the top of the script that the reader can edit.

`git_conversion_delta.sh` is a third script for readers who have a full FreeBSD Git clone with history. It finds the commit that converted a named driver to iflib (by searching commits that touch the file and mention

“iflib” in the log) and reports the line-count delta at that commit. A before/after conversion diff is the only way to measure Chapter 28’s claim directly; the cross-driver comparison is a proxy that depends on driver complexity being roughly comparable, which is a strong assumption.

### 44.5.3 How to reproduce

On any FreeBSD 14.3 source checkout:

```
$ cd examples/appendices/appendix-f-benchmarks/iflib
$ sh compare_iflib_corpus.sh /usr/src
```

For the before/after measurement, on a full FreeBSD Git clone:

```
$ sh git_conversion_delta.sh /path/to/freebsd-src.git if_em.c
```

### 44.5.4 Representative result

Captured against the FreeBSD 14.3-RELEASE source tree, `compare_iflib_corpus.sh` produces the following summary:

```
=== iflib ===
 if_em.c raw=5694 nonblank=5044 code=4232
 if_ix.c raw=5168 nonblank=4519 code=3573
 if_igc.c raw=3305 nonblank=2835 code=2305
 if_vmx.c raw=2544 nonblank=2145 code=1832
 corpus=iflib drivers=4 avg_code=2985

=== plain-ifnet ===
 if_re.c raw=4151 nonblank=3693 code=3037
 if_bge.c raw=6839 nonblank=6055 code=4990
 if_fxp.c raw=3245 nonblank=2943 code=2228
 corpus=plain-ifnet drivers=3 avg_code=3418

=== summary ===
 iflib avg code lines: 2985
 plain-ifnet avg code lines: 3418
 delta: 433
 reduction: 12%
```

A cross-corpus reduction of roughly twelve percent is smaller than Chapter 28’s thirty-to-fifty-percent claim, which is exactly what the caveat at the bottom of the script warns about. The chapter claim is a per-driver before-and-after figure: the same hardware, converted to iflib, goes from N lines to (0.5-0.7) times N lines. A cross-driver comparison is a different thing: it compares different hardware with different feature sets and

different quirk counts. The cross-driver reduction sets a floor (there is *some* reduction in average size across the corpus), and the per-driver reduction quoted in Chapter 28 sets the ceiling (the individual conversion commits show the larger number). Readers with a Git clone can use `git_conversion_delta.sh` to verify the per-driver number directly.

#### 44.5.5 Pinned per-driver measurement

To anchor Chapter 28’s range to a concrete figure, we ran the per-commit comparison on 2026-04-21 against the `ixgbe` conversion commit `4fd3548cada3` (“`ixgbe(4)`: Convert driver to use `iflib`”, authored 2017-12-20 by `erj@FreeBSD.org`). That commit is the cleanest per-driver conversion in the tree: it neither consolidated drivers nor changed features on the same revision. The four driver-specific files that existed on both sides of the commit (`if_ix.c`, `if_ixv.c`, `ix_txrx.c`, and `ixgbe.h`) went from 10,606 raw lines (7,093 non-blank non-comment) down to 7,600 raw lines (5,074 non-blank non-comment) on the conversion commit itself, a twenty-eight percent reduction in code lines. Restricting the comparison to the core PF files (`if_ix.c` and `ix_txrx.c`) tightens the result to thirty-two percent, inside Chapter 28’s thirty-to-fifty-percent range. The twenty-eight-percent figure is the headline one to carry away, with the narrower thirty-two-percent figure showing how much of the residual is shared-header and VF-sibling code rather than framework-saved driver logic.

A larger but less representative data point is the earlier `em/e1000` conversion commit `efab05d61248` (“Migrate `e1000` to the `IFLIB` framework”, 2017-01-10), which achieves roughly a seventy percent reduction on the `e1000`-class driver code: the combined driver sources drop from 13,188 down to 3,920 non-blank non-comment lines. That commit folded `if_em.c`, `if_igb.c`, and `if_lem.c` into a single `iflib`-based `if_em.c` plus a new `em_txrx.c`, so the measured reduction mixes framework savings with the consolidation of three related drivers into one and should not be read as a typical per-driver figure. Taken together, the `ixgbe` and `e1000` data points bracket Chapter 28’s thirty-to-fifty-percent range from below and above: a clean single-driver conversion lands at or just below the lower edge, and a driver-consolidating conversion overshoots the upper edge.

#### 44.5.6 Hardware envelope

This benchmark does not depend on hardware. The result is a function of the FreeBSD source tree at a specific revision, and should be identical on any machine with the same checkout. Readers using a different FreeBSD branch (15-CURRENT, an older release) will see different absolute numbers because the tree evolves.

See also Chapter 28 for the surrounding discussion of `ifnet(9)` and how `iflib(9)` sits inside it.

### 44.6 DTrace, INVARIANTS, and WITNESS Overhead

#### 44.6.1 What is being measured

Chapter 34 makes two performance claims about debug kernels:

- A busy `INVARIANTS` kernel runs roughly five to twenty percent slower than a release kernel, sometimes more on allocation-heavy workloads, as a rough order-of-magnitude figure on typical FreeBSD 14.3-amd64 hardware.
- `WITNESS` adds bookkeeping to every lock acquisition and release; in our lab environment, on a busy kernel running a lock-heavy workload, the overhead can approach twenty percent.

It also mentions, in the context of DTrace, that active DTrace scripts add overhead proportional to how many probes they fire and how much work each probe does.

The quantity measured by the harness in this section is wall-clock time to complete a fixed workload. The harness does not attempt to compute percentages directly; it provides two well-defined workloads and a consistent output format, and it expects the reader to run the suite once per kernel condition and compute ratios between them.

### 44.6.2 The harness

The harness lives under `examples/appendices/appendix-f-benchmarks/dtrace/` and has four parts.

`workload_syscalls.c` is a userland program that performs one million iterations of a tight loop containing four cheap system calls (`getpid`, `getuid`, `gettimeofday`, `clock_gettime`). This workload exaggerates the cost of the syscall entry and exit path, where `INVARIANTS` assertions and `WITNESS` lock-tracking fire most often.

`workload_locks.c` is a userland program that spawns four threads and performs ten million `pthread_mutex_lock` / `pthread_mutex_unlock` pairs per thread, on a small rotating set of mutexes. Userland mutexes fall through to the kernel's `umtx(2)` path when they contend, so this workload exercises the lock-heavy contention path that `WITNESS` instruments.

`dtrace_overhead.d` is a minimal DTrace script that fires on every syscall entry and return without printing anything per probe. Attaching it during a `workload_syscalls` run measures the cost of having the DTrace probe framework actively instrumenting the syscall path.

`run_overhead_suite.sh` runs both workloads once, captures `uname` and `sysctl kern.conf.txt`, and writes a tagged report. The reader is expected to run the suite four times: on a base `GENERIC` kernel, on an `INVARIANTS` kernel, on a `WITNESS` kernel, and on any of those with `dtrace_overhead.d` attached in another terminal. Comparing the four reports gives the percentages Chapter 34 claims.

The surrounding kernel sources are `/usr/src/sys/kern/subr_witness.c` for `WITNESS`, `/usr/src/sys/sys/proc.h` and its siblings for the assertion macros enabled by `INVARIANTS`, and the DTrace provider sources under `/usr/src/sys/cddl/dev/` for the probe framework.

### 44.6.3 How to reproduce

On each kernel condition:

1. Boot into the kernel under test.
2. Build the workloads:

```
$ cd examples/appendices/appendix-f-benchmarks/dtrace
$ make
```

3. Run the suite:

```
sh run_overhead_suite.sh > result-<label>.txt
```

4. For the DTrace condition, launch the script in another terminal before running the suite:

```
dtrace -q -s dtrace_overhead.d
```

After all four runs, compare the `result-*.txt` files side by side. The ratios `INVARIANTS_ns / base_ns`, `WITNESS_ns / base_ns`, and `dtrace_ns / base_ns` are the overhead figures Chapter 34 refers to.

#### 44.6.4 Representative result

Harness only, no result captured. The workloads have been compiled on the reference system and their logic reviewed against the Chapter 34 claims, but the author has not built the three comparison kernels to capture end-to-end numbers while writing this appendix. Readers who run the four-kernel comparison on typical FreeBSD 14.3-amd64 hardware should expect `INVARIANTS` to land in the five-to-twenty-percent range on `workload_syscalls`, somewhat higher on `workload_locks` because lock paths are the hottest code under `INVARIANTS`. `WITNESS` should land lower than `INVARIANTS` on pure-syscall workloads (where few new lock orders are visited) and higher on `workload_locks`, approaching the twenty-percent figure the chapter names. The `DTrace` column should be small on `workload_locks` (no relevant probes fire in the hot path) and non-trivial on `workload_syscalls` (every iteration fires two probes).

#### 44.6.5 Hardware envelope

The ratios are more stable across hardware than the absolute numbers. Readers on different CPUs will see different wall times for the baseline workload, but the per-kernel percentage overhead should stay within a tight band because it is determined by how much extra work the debug kernel does per operation, not by how fast each operation is. The most common sources of surprise are virtualisation (where the syscall path has additional per-call hypervisor overhead that dilutes the percentage), aggressive power management (where CPU frequency varies across runs), and SMT (where per-core numbers differ from per-logical-CPU numbers). The harness does not try to control for any of these; a reader wanting production-quality numbers will need to pin the test to a single CPU, disable frequency scaling, and run the suite several times.

See also Chapter 34 for the surrounding treatment of debugging kernels and for the discussion of when each of `INVARIANTS`, `WITNESS`, and `DTrace` is worth enabling.

### 44.7 Scheduler Wakeup Latency

Chapter 33 contains a `DTrace` snippet that measures scheduler wakeup latency using `sched::wakeup` and `sched::on-cpu`. That snippet is already the harness; this section would only duplicate it. Readers interested in the sub-microsecond idle-system figure and the low-tens-of-microseconds contended-system figure that Chapter 33 names should use the script exactly as printed there, on the reader's hardware. The `DTrace` provider sources are under `/usr/src/sys/cddl/dev/dtrace/`.

If the reader wants to compare wakeup latency with and without `WITNESS`, the same script applies; just boot the two kernels and run it on each.

## 44.8 Wrapping Up: Using the Harness Without Being Misled

The harness in this appendix exists because every number in Chapters 15, 28, 33, and 34 is an order-of-magnitude claim, and order-of-magnitude claims deserve reproducibility. A few habits make the harness actually useful rather than a source of false confidence.

First, run each benchmark more than once. Single-run results are dominated by startup noise, warm-up effects, and interference from whatever else is running on the machine. The harness scripts report a single number; run them three to five times and take the median, or extend them to aggregate runs automatically before trusting the result.

Second, keep the conditions honest. If you want to compare `INVARIANTS` to a base kernel, build both kernels with the same compiler, the same `CFLAGS`, and the same `GENERIC` or `GENERIC-NODEBUG` baseline. If you want to compare two timecounter sources, run both comparisons on the same boot of the same kernel; a reboot between runs changes too many variables.

Third, resist the temptation to treat the numbers as universal. A measurement on one 4-core laptop in a quiet office is not a measurement on a 64-core production server in a noisy rack. The harness measures the machine in front of you; Chapter 15 through 34's qualified phrases ("on typical 14.3-amd64 hardware", "in our lab environment") are honest about the same limitation. The harness makes the qualified phrase testable without pretending it becomes universal.

Fourth, prefer ratios to absolutes. A claim that `WITNESS` costs twenty percent is much more stable than a claim that `WITNESS` costs four hundred nanoseconds per lock. The former survives CPU changes, compiler changes, and kernel-version changes that would wipe out the latter. When you run the harness on your hardware, the percentage overhead is what you should keep; the absolute number is just the arithmetic that produced it.

And finally, extend the harness rather than trusting it blindly. Every script here is small enough to read end to end; every `kmod` is under three hundred lines. If a chapter claim matters to you, open the harness, verify that it measures what you expect it to measure, modify it if your workload needs something different, and run the modified version. The harness is a starting point, not a finish line.

The qualified phrases in Chapters 15, 28, 33, and 34 and the runnable harness in this appendix are two halves of the same discipline. The chapters are honest about what is variable; the appendix shows you how to measure the variation yourself.
