% git commit -m "Chapter 7 complete: minimal driver with lifecycle discipline"
```

5. **Take a break.** You've earned it. Kernel programming is intense, and consolidation time matters.

When you're ready for Chapter 8:

- You'll extend this same driver (no restart from scratch).
- The structure you built here will carry forward.
- Concepts will build incrementally, not reset.

7.15.6 A Final Word

Building a driver from scratch can feel overwhelming at first. But look at what you've accomplished:

- You started with nothing but a Makefile and a blank `.c` file.
- You built a driver that compiles, loads, attaches, operates, detaches, and unloads cleanly.
- You tested error paths and verified cleanup.
- You exposed state via `sysctls` and created a user-accessible device node.

This is not beginner's luck. This is competence. Most general-purpose software developers never touch a kernel module, let alone build one with disciplined attach and detach paths. You just did.

The journey from “hello module” to “production driver” is long, but you've taken the hardest step: **starting**. Every chapter from here adds one more layer of capability, one more tool in your kit.

Keep your lab logbook updated. Keep experimenting. Keep asking “why?” when something doesn't make sense. And most importantly, **keep building**.

Welcome to the world of FreeBSD driver development. You've earned your place here.

7.15.7 See You in Chapter 8

In the next chapter, we'll breathe life into your device node by implementing real file semantics: managing per-open state, handling exclusive vs shared access, and preparing the ground for actual I/O.

Until then, enjoy your success. You've built something real, and that's worth celebrating.

"The expert at anything was once a beginner." - Helen Hayes

8 Working with Device Files

8.1 Reader Guidance & Outcomes

In Chapter 7 you built `myfirst`, a real FreeBSD driver that attaches cleanly, creates `/dev/myfirst0`, opens and closes that node, and unloads without leaks. That was the first win, and it was a real one. You now have a working driver skeleton on disk, a `.ko` file that the kernel will accept and release at your command, and a `/dev` entry that user programs can reach.

This chapter zooms in on the piece of that work that is easiest to take for granted: the **device file itself**. The line of code that created `/dev/myfirst0` in Chapter 7 was compact, but it sits on top of a subsystem called **devfs**, and that subsystem is the bridge between everything your driver does inside the kernel and every tool or program a user ever points at it. Understanding that bridge well now will make Chapters 9 and 10, where real data starts to flow, much less mysterious.

8.1.1 Why This Chapter Earns Its Own Place

Chapter 6 introduced the device-file model at the level of mental pictures, and Chapter 7 used enough of it to get a driver running. Neither chapter stopped to examine the surface itself. That is not an oversight. In a book that teaches driver writing from first principles, the device file is worth a dedicated chapter because the mistakes made on that surface are also the mistakes hardest to undo later.

Consider what the surface has to carry. It carries identity (a path a user program can predict). It carries access policy (who is allowed to open, read, or write). It carries multiplexing (one driver, many instances, many simultaneous openers). It carries lifecycle (when the node appears, when it disappears, and what happens when a user program is mid-call as it goes). It carries compatibility (legacy names alongside modern ones). It carries observability (what operators can see and change from userland). A driver that gets the internals right but the surface wrong will be a driver that operators refuse to deploy, a driver that security reviewers flag, a driver that breaks subtly inside jails, a driver that deadlocks on unload under realistic load.

Chapter 7 gave you just enough of that surface to prove the path worked. This chapter gives you enough to design it on purpose.

8.1.2 Where Chapter 7 Left the Driver

It is worth a short checkpoint on the state of `myfirst` before we extend it. Your Chapter 7 driver ends up with all of the following in place:

- A `device_identify`, `device_probe`, and `device_attach` path that creates exactly one Newbus child of `nexus0` named `myfirst0`.
- A softc allocated by Newbus, reachable through `device_get_softc(dev)`.

- A mutex, a sysctl tree under `dev.myfirst.0.stats`, and three read-only counters.
- A struct `cdevsw` populated with `d_open`, `d_close`, and stubs for `d_read` and `d_write`.
- A `/dev/myfirst0` node created with `make_dev_s(9)` in `attach` and removed with `destroy_dev(9)` in `detach`.
- A single-label error unwind that leaves the kernel in a consistent state if any `attach` step fails.
- An exclusive-open policy that refuses a second `open(2)` with `EBUSY`.

Chapter 8 treats that driver as the starting point and grows it along three axes: **shape** (what the node is called and how it is grouped), **policy** (who is allowed to use it and how that policy stays in place across reboots), and **per-descriptor state** (how two simultaneous openers can own separate book keeping).

8.1.3 What You Will Learn

By the end of this chapter you will be able to:

- Explain what a device file is in FreeBSD, and why `/dev` is not an ordinary directory.
- Describe how struct `cdev`, the devfs `vnode`, and a user file descriptor relate to each other.
- Choose sensible ownership, group, and permission values for a new device node.
- Give a device node a structured name (including a subdirectory under `/dev`).
- Create an alias so a single `cdev` is reachable under more than one path.
- Attach per-open state with `devfs_set_cdevpriv()` and clean it up safely when the file descriptor closes.
- Adjust device-node permissions persistently from userland with `devfs.conf` and `devfs.rules`.
- Exercise your driver from a small userland C program, not just with `cat` and `echo`.

8.1.4 What You Will Build

You will extend the Chapter 7 `myfirst` driver in three small steps:

1. **Stage 0: tidier permissions and a structured name.** The node moves from `/dev/myfirst0` to `/dev/myfirst/0` with a group-accessible variant for lab use.
2. **Stage 1: a user-visible alias.** You add `/dev/myfirst` as an alias for `/dev/myfirst/0` so legacy paths keep working.
3. **Stage 2: per-open state.** Each `open(2)` gets its own small counter with `devfs_set_cdevpriv()`, and you verify from userland that two simultaneous opens see independent values.

You will also write a short userland program, `probe_myfirst.c`, that opens the device, reads a bit, reports what it saw, and closes cleanly. This program will come back in Chapter 9 when real `read(2)` and `write(2)` paths are implemented.

8.1.5 What This Chapter Does Not Cover

Several topics touch `/dev` but are deliberately postponed:

- **Full read and write semantics.** Chapter 7 stubbed these; Chapter 9 implements them properly with `uiomove(9)`. Here we only prepare the ground.
- **Cloning devices** (`clone_create`, the `dev_clone` event handler). These are worth a careful look later, once the basic model is solid.

- **ioctl(2) design.** Inspecting and changing device state through `ioctl` is a topic of its own and belongs later in the book.
- **GEOM and storage devices.** GEOM builds on top of `cdevs` but adds a whole stack of its own. That belongs in Part 6.
- **Network interface nodes and ifnet.** Network drivers do not live under `/dev`. They show up through a different surface, which we will meet in Part 6.

Keeping scope tight here is the point. The surface of a device is small; the discipline around it should be the first thing you master.

8.1.6 Estimated Time Investment

- **Reading only:** about 30 minutes.
- **Reading plus the code changes to myfirst:** around 90 minutes.
- **Reading plus all four labs:** two to three hours, including rebuild cycles and userland testing.

A steady session with breaks works best. The chapter is shorter than Chapter 7, but the ideas here show up in almost every driver you will ever read.

8.1.7 Prerequisites

- A working Chapter 7 `myfirst` driver that loads, attaches, and unloads cleanly.
- FreeBSD 14.3 in your lab with matching `/usr/src`.
- Basic comfort reading `/usr/src` paths such as `/usr/src/sys/dev/null/null.c`.

8.1.8 How to Get the Most Out of This Chapter

Open your Chapter 7 source next to this chapter and edit the same file. You are not starting a new project; you are growing the one you already have. When the chapter asks you to inspect a FreeBSD file, really open it in `less` and scroll around. The device-file model clicks much faster when you have seen a couple of real drivers shape their nodes.

A practical habit that pays off immediately: as you read, keep a second terminal open against a freshly booted lab system and confirm every claim about existing nodes with `ls -l` or `stat(1)`. Typing `ls -l /dev/null` and watching the output match the prose is tiny, but it anchors the abstraction in something you can see. By the time the chapter reaches the labs, you will have a quiet reflex for verifying each claim against the running kernel rather than trusting the text alone.

A second habit: when the chapter names a source file under `/usr/src`, open it side by side with the section. Real FreeBSD drivers are the textbook; this book is only the reading guide. The material inside `/usr/src/sys/dev/null/null.c` and `/usr/src/sys/dev/led/led.c` is short enough to scan in a few minutes each, and each one is shaped by the very decisions this chapter is about to explain. A short tour there is worth more than any amount of prose here.

8.1.9 Roadmap Through the Chapter

If you want a picture of the chapter as one continuous thread, here it is. The sections in order are:

1. What a device file actually is, in theory and in `ls -l` practice.
2. How `devfs`, the filesystem behind `/dev`, came to be and what it does for you.
3. The three kernel objects that line up behind a device file.
4. How ownership, group, and mode shape what `ls -l` shows and who can open the node.
5. How names get chosen, including unit numbers and subdirectories.
6. How one `cdev` can answer to several names through aliases.
7. How per-open state is registered, retrieved, and cleaned up.
8. How the destructor really works once `destroy_dev(9)` is called.
9. How `devfs.conf` and `devfs.rules` shape policy from userland.
10. How to drive the device from small userland programs you can write yourself.
11. How real FreeBSD drivers solve these same problems.
12. Which `errno` values your `d_open` should return, and when.
13. Which tools to reach for when something on this surface looks wrong.
14. Four to eight labs that walk you through every pattern hands-on.
15. Challenges that stretch the patterns into realistic scenarios.
16. A field guide to the pitfalls that waste time if you hit them cold.

Follow the chapter end to end if this is your first time. If you are revising, you can approach each section on its own; the structure is designed to read as a complete survey, not only as a linear tutorial.

8.2 What a Device File Actually Is

Long before FreeBSD existed, UNIX committed to a famous idea: **treat devices as files**. A serial line, a disk, a terminal, a stream of random bytes, each of these could be opened, read, written, and closed with the same handful of system calls. User programs did not need to know whether the bytes they consumed came from a spinning disk, a memory buffer, or an imaginary source like `/dev/null`.

That idea was not marketing. It was a design choice Ken Thompson and Dennis Ritchie made in the first versions of UNIX in the early 1970s, and it shaped the entire operating system that followed. By presenting every device through the same system-call interface as every regular file, they turned every command-line tool that dealt with files into a tool that could also deal with devices. `cat` could copy bytes out of a serial port. `dd` could read from a tape drive. `cp` could stream a stream. That alignment is still the single most useful property of a UNIX-like system, and FreeBSD inherits it in full.

FreeBSD keeps that spirit. From user space, a device file looks like any other entry in the filesystem. It has a path, an owner, a group, a mode, and a type visible to `ls -l`. You can `open(2)` it, pass the returned file descriptor to `read(2)` and `write(2)`, query it with `stat(2)`, and close it when you are done.

8.2.1 A Short History, in Pieces Worth Knowing

The device-file model you will be writing into has gone through a few serious revisions since 1971, and each revision was driven by a real limitation of the previous one. Knowing the broad strokes saves confusion later when you read old books or old manual pages.

In **V7 UNIX** and the BSDs that followed for two decades, the entries under `/dev` were real entries on a real on-disk filesystem. An administrator used `mknod(8)` to create them, passing a device type (character or block) and a pair of small integers called the *major number* and the *minor number*. The kernel used the major number to pick a row in a table of drivers (the `cdevsw` or `bdevsw` array, depending on type), and the minor number to pick which instance of that driver the call was going to. The pair was typed into `/dev` once, by hand or by a shell script called `MAKEDEV`, and then lived on the disk forever.

That model worked for a long time. It stopped working when two things happened at once: hardware started being hot-pluggable, and the space of major numbers got crowded enough that every kernel change required coordination across the tree. A disk plugged in at runtime needed a node that had not existed before boot. A driver that moved from one tree location to another needed its numbers renegotiated. Static `/dev` entries misrepresented both.

In **FreeBSD 5**, released in 2003, the answer was **devfs**, a kernel-managed virtual filesystem that replaces the on-disk `/dev` entirely. When a driver creates a device node through `make_dev(9)`, `devfs` adds an entry to its live tree and user programs can see it immediately. When the driver calls `destroy_dev(9)`, `devfs` removes the entry. Major and minor numbers still exist inside the kernel as an implementation detail, but they are not part of the contract any more. Paths and `cdev` pointers are. That is the model you are writing into today.

A third shift worth naming: **block devices have retreated from userland visibility**. Older UNIX variants exposed certain storage devices as block-special files whose type letter in `ls -l` was `b`. FreeBSD has not shipped block-special device nodes to userland for many years. Storage drivers still exist in the kernel; they just publish themselves through `GEOM` and show up in `/dev` as character devices. The only time you will see a `b` in FreeBSD is on disks mounted from other filesystem types. Your drivers will expose character devices, full stop.

8.2.2 Why the File Abstraction Earned Its Keep

The payoff of the “everything is a file” idea is that every tool in the base system is, without special knowledge, already a tool for talking to your device. That is worth a minute of reflection because it sets the tone for how you should design your driver.

`cat` reads from files. It will also read from `/dev/myfirst/0` once your driver implements `d_read`, with no special build and no awareness that it is talking to a driver. `dd` reads and writes files in arbitrarily sized blocks; it will happily stream to or from a character device, and it offers flags (`bs=`, `count=`, `iflag=nonblock`) that let operators exercise driver behavior without writing new programs. `tee`, `head`, `tail` in follow mode, `od`, `hexdump`, `strings`, all of them already work on your device the day you ship it. Shell redirection works. Pipes work. The kernel’s file-descriptor machinery does not care which side of a pipe is a device and which side is a regular file.

The design guidance that flows from this is simple and strict: **your driver should behave like a file whenever it can**. That means returning `read(2)` lengths that match reality, returning end-of-file as zero bytes read, returning `write(2)` results that count the bytes actually consumed, respecting `errno` conventions when something goes wrong, and not inventing new meanings for existing system calls unless the meaning is unavoidable. The more your device looks like an ordinary file to every tool in `/bin` and `/usr/bin`, the less your users have to learn, and the less brittle your interface becomes when new tools appear years from now.

8.2.3 What a Device File Is Not

The abstraction is generous but it is not unlimited. It is worth naming a few things a device file is explicitly not, so you do not design around the wrong mental model.

A device file is **not an IPC channel** in general. It can behave like one, the same way a named pipe can behave like one, but the classic tools for interprocess communication are `pipe(2)`, `socketpair(2)`, UNIX-domain sockets, and `kqueue(9)`. If two user programs want to exchange messages with each other, they should use those tools rather than opening a device node as a side channel. A driver that lets itself be pressed into service as an ad-hoc IPC bus will find its semantics getting more and more complicated as users invent new uses for it.

A device file is **not a registry of settings** your driver keeps across reboots. `devfs` does not persist anything. Anything you write into `/dev/yournode` is processed by your driver at the moment it is written and is gone unless your driver chose to remember it. If you need persistent configuration, the right tools are `sysctl(8)` tunables, loader environment variables set via `loader.conf(5)`, and configuration files the userland part of your stack reads from `/etc`.

A device file is **not a broadcast medium** by default. If a driver wants to deliver the same byte stream to every open file descriptor, it must implement that explicitly; the kernel does not fan writes across readers automatically, and it does not duplicate reads into multiple files. Chapter 10's discussion of `poll(2)` and `kqueue(9)` touches the edge of this, and several drivers in the tree (for example `/usr/src/sys/net/bpf.c`) solve it on purpose. It is not free.

A device file is **not a substitute for a system call**. If your driver needs a structured, typed, versioned control interface that user programs invoke with named commands, that is what `ioctl(2)` is for. We do not design `ioctl` in this chapter, but the distinction matters today: do not smuggle control commands through `write(2)` strings when `ioctl(2)` would express them more precisely. Chapter 25 revisits `ioctl` design as part of advanced driver practice.

Holding those limits in mind now will keep your design honest later. The device-file surface is a small number of well-shaped primitives. The art is choosing which of them your driver exposes, and wiring each of them carefully.

8.2.4 The Variety You Will See Under `/dev`

A short tour of a freshly booted FreeBSD 14.3 system is a good way to calibrate what this chapter is shaping. Open a terminal and run `ls /dev` on your lab machine. You will see a cross-section of the naming patterns the book will teach you to recognise:

- **Singletons:** `null`, `zero`, `random`, `urandom`, `full`, `klog`, `mem`, `kmem`.
- **Numbered instances:** `bpf0`, `bpf1`, `md0`, `ttvu0`, `ttvv0`, `ttvv1`, `cuaU0`.
- **Subdirectories per driver:** `led/`, `pts/`, `fd/`, `input/`.
- **Standard names with special meaning:** `stdin`, `stdout`, `stderr`, `console`, `tty`.
- **Aliases for conventional paths:** `log`, `sndstat`, `midistat`.

Every entry in that tour is a `cdev` that some driver or subsystem asked `devfs` to present. Some were created by drivers that loaded at boot, some by drivers that were compiled into the kernel itself, and some by the `devfs` mount's own setup. Each of them was shaped by the same decisions you are about to make for `myfirst`.

Take a quick look at the nodes already present on your lab system:

```
% ls -l /dev/null /dev/zero /dev/random
crw-rw-rw-  1 root  wheel      0x17 Apr 17 09:14 /dev/null
crw-r--r--  1 root  wheel      0x14 Apr 17 09:14 /dev/random
crw-rw-rw-  1 root  wheel      0x18 Apr 17 09:14 /dev/zero
```

The leading **c** in each mode field tells you these are **character devices**. On FreeBSD there are no block-device nodes to worry about in this context; storage is served through character devices fronted by GEOM, and the old `block special` distinction is no longer exposed to userland the way it was in older UNIXes. For the work you are doing now, and for most drivers you will write, **character device** is the shape your node will take.

The interesting part of `ls -l` is what is *not* there. There is no backing file on disk that holds the bytes of `/dev/null`. There is no regular file hiding behind `/dev/random` somewhere under `/var`. These nodes are presented by the kernel on demand, and the permissions and ownership you see are whatever the kernel has chosen to advertise. That is the key mental shift for this chapter: in FreeBSD, the entries under `/dev` are not ordinary files that your driver pokes at. They are a **view** of kernel-side objects called `struct cdev`, served by a dedicated filesystem.

8.2.5 Character Devices Are the Common Case

A character device delivers a stream of bytes through `read(2)` and accepts a stream of bytes through `write(2)`. It may or may not support seeking. It may support `ioctl(2)`, `mmap(2)`, `poll(2)`, and `kqueue(9)`, and each of those is opt-in on the driver side. The driver declares which operations it supports by filling in the relevant fields of a `struct cdevsw`, exactly as you saw in Chapter 7.

`myfirst` is a character device. So are `/dev/null`, `/dev/zero`, the terminal nodes under `/dev/tty*`, the BPF packet interfaces under `/dev/bpf*`, and many others. When you are new to driver work, “character device” is almost always the right answer.

If you are coming from a background where block-special nodes were common, the mental adjustment is small. On FreeBSD you never write a driver that exposes a block-special node directly; storage drivers produce character devices that GEOM consumes, and GEOM in turn republishes its own character devices upward. For this chapter and the next several, the phrase “device file” always means a character device.

8.2.6 Reading `ls -l` for a Device Node

It is worth spending a minute on the shape of the output, because every line you will ever inspect with `ls -l` follows the same template.

```
% ls -l /dev/null
crw-rw-rw-  1 root  wheel      0x17 Apr 17 09:14 /dev/null
```

The **c** in the leading position says this is a character device. A regular file would show `-`, a directory would show `d`, a symbolic link would show `l`. The nine permission characters after it read exactly the same way as for

a regular file: three triples of owner, group, and other permissions, in the order read, write, execute. Devices ignore the execute bit, so you will almost never see it set.

The owner is `root` and the group is `wheel`. Those are printed from the values the kernel advertises, which is a mix of whatever the driver asked for and whatever `devfs.conf` or `devfs.rules` applied on top. Change any of them and this column changes immediately; there is no file on disk to rewrite.

The field that looks odd is `0x17`. On a regular file this column holds the size in bytes. On a device file, `devfs` reports a small hexadecimal identifier instead. It is not a major or minor number in the old System V sense, and you will not normally need to interpret it. If you want to confirm two names point at the same underlying `cdev` (for instance a primary node and an alias), `stat -f '%d %i' path` is a more reliable way to compare. We will come back to it in the userland section.

Finally, `ls -l` on a directory under `/dev` works exactly as you would expect, because `devfs` really is a filesystem. `ls -l /dev/myfirst` will list the files inside the `myfirst/` subdirectory if the driver placed one there.

8.3 devfs: Where /dev Comes From

On an old-school UNIX system, `/dev` was a real directory on a real disk, and device nodes were created by a command called `mknod(8)`. If you needed a new node, you ran `mknod` with a type, a major number, and a minor number, and an entry appeared on disk. It was static. It did not care whether the hardware was present. It did not clean up after itself.

FreeBSD moved away from that model. On a modern FreeBSD system, `/dev` is a **devfs** mount, a virtual filesystem maintained entirely by the kernel. You can see it in the output of `mount(8)`:

```
% mount | grep devfs
devfs on /dev (devfs)
```

Inside a jail, you will usually see a second `devfs` mounted at the jail's own `/dev`. The same filesystem type, the same mechanism, just a different view filtered by `devfs.rules`.

The rules of `devfs` are simple, and they are worth internalizing:

1. You do not create files under `/dev` with `touch` or `mknod`. You create them from inside the kernel, by calling `make_dev_s(9)` or one of its relatives.
2. When your driver's `cdev` goes away, the corresponding entry disappears from `/dev` automatically.
3. Ownership, group, and mode on a node start out with whatever your driver asked for, and can be adjusted from userland through `devfs.conf` and `devfs.rules`.
4. Nothing about a `devfs` node is persisted between reboots. It is always a live reflection of the current state of the kernel.

That last point is the one that catches people by surprise the first time. You cannot `chmod /dev/myfirst0` and expect the change to survive the next reboot. If you need a permission to stick, you encode it either in the driver or in one of the `devfs` configuration files. We will do both in this chapter.

If you want to look at `devfs` directly, its implementation lives in `/usr/src/sys/fs/devfs/`. You do not need to read it cover to cover, but being aware of where it is will save you confusion later when someone asks why `/dev/foo` looks the way it does.

8.3.1 Why This Model Replaced `mknod`

The move away from static device nodes in on-disk `/dev` was not a stylistic choice. It was driven by three real problems:

1. **Nodes for hardware that was not present.** Before `devfs`, `/dev` carried entries for every device the system *could* have, whether the kernel currently had a driver for it or not. Users were left guessing which paths were live.
2. **Stale nodes for hardware that had been removed.** Hot-pluggable hardware (USB, FireWire, CardBus back in its day) made static `/dev` trees actively misleading.
3. **Major and minor number exhaustion.** The pair (`major`, `minor`) was a finite resource and a source of allocation politics across the kernel tree. `devfs` sidesteps that problem entirely.

Today `/dev` is a running mirror of what the kernel actually supports and what devices are currently present. A driver that loads makes a node; a driver that unloads retracts it. A disk that is removed vanishes. That is by design, and it is why the word “node” is a better mental model than “file” for the things you see under `/dev`.

8.3.2 What `devfs` Is and Is Not

`devfs` **is** a filesystem. You can `ls` inside it, change into subdirectories, redirect into nodes, and so on. What `devfs` **is not** is a general place to keep user data. Do not try to echo a log file into `/dev`. Do not expect touch to work inside it. `devfs` accepts a small, well-defined set of operations, and anything outside that set returns an error.

This narrow surface is a feature. It means `devfs` never surprises you by persisting state, never competes with a regular filesystem for space, and never misinterprets a regular file as a device. Your driver creates nodes; `devfs` presents them; everything else goes through your `cdevsw` handlers.

8.3.3 `devfs` in the Family of Synthetic Filesystems

FreeBSD has a small family of filesystems that do not store files on any disk. `devfs` is one of them. Others you may have met are `tmpfs(5)`, which serves files from RAM, `nullfs(5)`, which republishes another directory under a new name, and `fdescfs(5)`, which presents each process’s file descriptors as files under `/dev/fd`. They are all real filesystems in the eyes of `mount(8)` and the VFS layer, but each one synthesises its contents from something other than a block device.

Knowing the family helps for two reasons. The first is that `devfs` shares a few ideas with its relatives. All synthetic filesystems lay their tree on demand, they all manage their storage outside any on-disk container, and they all have strong opinions about which operations do and do not make sense inside them. The second reason is that you will see them combined in practice. A jail typically mounts its own `devfs` under its own `/dev`, and it may also mount a `nullfs` view of `/usr/ports` or a `tmpfs` for `/var/run`. Reading the output of `mount(8)` inside a running FreeBSD host or jail is the quickest way to get a feel for how these filesystems cooperate.

A quick look on a typical lab host might show:

```
% mount
/dev/ada0p2 on / (ufs, local, journaled soft-updates)
```

```
devfs on /dev (devfs)
fdescfs on /dev/fd (fdescfs)
tmpfs on /tmp (tmpfs, local)
```

Each of those is a filesystem type with its own semantics. `devfs` is the one we care about in this chapter, and its job description is unique: present the kernel's live collection of `struct cdev` objects as a tree of file-like nodes.

8.3.4 Mount Options Worth Knowing

`devfs` accepts a handful of mount options, defined in the `devfs` code and described in the manual page for `mount_devfs(8)`. You will not often change them from the defaults, but it helps to recognise them when you see them in `/etc/fstab`, in jail configurations, or in the output of `mount -v`.

- **ruleset=N**: applies `devfs` ruleset `N` to the mount. A ruleset is a named list of path patterns and actions defined in `/etc/devfs.rules`. This option is how jails limit what their `/dev` looks like.
- **noauto**: present in `fstab` to mark the filesystem as not mounted automatically at boot.
- **late**: mounts late in the boot sequence, after local filesystems and network. Relevant when combined with `ruleset=`.

The typical host configuration needs none of these; the default `devfs` mount at `/dev` is plain. Where they matter most is in jail configuration, which is why Section 10 of this chapter walks through a complete jail example.

8.3.5 devfs Inside Jails

A FreeBSD jail is a restricted execution environment with its own filesystem view, its own set of processes, and usually its own `/dev`. When `jail(8)` starts a jail with `mount.devfs=1` in its configuration, it mounts a separate `devfs` under the jail's `/dev`. That mount is an instance of the same filesystem type, with one decisive difference: it applies a ruleset that filters what appears inside the jail.

The default ruleset for a jail is `devfsrules_jail`, numbered 4 in `/etc/defaults/devfs.rules`. That is the path readers will actually edit or consult on a running system; the source home from which it is installed is `/usr/src/sbin/devfs/devfs.rules`, for readers who want to see the canonical shipped rules. It starts from `devfsrules_hide_all` (which hides everything) and then selectively unhides exactly the handful of nodes a typical jail needs: `null`, `zero`, `random`, `urandom`, `crypto`, `ptmx`, `pts`, `fd` and the `PTY` nodes. Everything else that exists on the host's `/dev` simply does not exist inside the jail. The jail cannot open it, cannot list it, cannot stat it.

This is the mechanism that keeps jails honest. It is also the mechanism you will interact with if your driver's nodes should, or should not, appear inside a jail. If a lab needs `/dev/myfirst/0` to be reachable from a jail, you write a ruleset that unhides it. If a deployment should keep the node out of jails by default, you do nothing: `devfs` will hide it for you. Chapter 8 revisits this in detail when we reach Section 10.

8.3.6 chroot and devfs

There is one related context worth a short note because it sometimes confuses people reading older documentation. A plain `chroot(8)` environment does **not** automatically get its own `devfs`. If a shell script `chroots` into `/compat/linux` and then tries to open `/dev/null`, the open succeeds only because `/dev/null` exists on the host and is visible under the `chroot`'s path through a bind mount or because a `devfs` was mounted there explicitly. If neither is true, the open fails with `ENOENT`.

Jails are different because jails explicitly build a filesystem view with `devfs` mounted inside. A `chroot` is lower-level and leaves filesystem arrangement entirely to the caller. The practical consequence, for driver authors, is that a regression test that runs under `chroot` may or may not be able to see your device, depending on how the `chroot` was set up. When in doubt, test inside a jail.

8.3.7 /dev/fd and the Standard Symlinks

A few entries under `/dev` are not `cdevs` at all; they are symbolic links maintained as part of the `devfs` mount. `/dev/stdin`, `/dev/stdout`, `/dev/stderr` each resolve through `/dev/fd/0`, `/dev/fd/1`, and `/dev/fd/2`, and those in turn are served by `fdescfs(5)` when it is mounted on `/dev/fd`. The combination gives user programs a reliable path-based way to reference the current file descriptor, which is occasionally useful in shell scripts and `awk` programs that want to read or write “whatever the current program's `stdin` is”.

These entries are worth a mention for two reasons. First, they are examples of symlinks inside `devfs`: `ls -l /dev/stdin` shows `lrwxr-xr-x` and an arrow, not `crw-...`. Second, they are a reminder that the entries under `/dev` are not all `cdevs`. Most are; a few are not. When the chapter later contrasts `make_dev_alias(9)` with the `link` directive in `devfs.conf`, this is the distinction that sits underneath.

8.3.8 Why the “Live Mirror” Property Matters to Drivers

The fact that `devfs` is a live mirror of the kernel's current state has several implications for how you design and debug drivers. Each of these points will come back in the chapter; it helps to state them plainly now.

- **A node that is missing from `/dev` is a node your driver did not create.** If you expected `/dev/my-first/0` to exist and it does not, the first thing to check is whether `attach` ran and whether `make_dev_s` returned zero. `dmesg` usually tells you.
- **A node that lingers after unload is a node your driver did not destroy.** That cannot happen if you used `destroy_dev(9)` correctly, but it is a useful frame: if the path survives the `kldunload`, you missed a call.
- **A permission change you made interactively will not survive a reboot.** `devfs` has no on-disk record of what you did. The persistent tools for expressing policy are `devfs.conf` and `devfs.rules`, and Section 10 of this chapter covers them in depth.
- **A jail sees a filtered subset.** Assume, when reasoning about security or feature exposure, that someone is eventually going to run your driver with a jail active on the same host. If your node is too loose and a ruleset lets jails see it, the loose mode has a larger blast radius.

8.4 cdev, vnode, and File Descriptor

Open a device file and three kernel-side objects quietly line up behind your file descriptor. Understanding this trio is the difference between writing a driver that just happens to work and a driver whose lifecycle you actually control.

The first object is `struct cdev`, the **kernel-side identity of the device**. There is one `struct cdev` per device node, no matter how many programs have it open. Your driver creates it with `make_dev_s(9)` and destroys it with `destroy_dev(9)`. The `cdev` carries the identifying information about the node: its name, its owner, its mode, the `struct cdevsw` that dispatches system calls, and two driver-controlled slots called `si_drv1` and `si_drv2`. Chapter 7 already used `si_drv1` to stash the `softc` pointer, and that is by far the most common use for it.

The second object is a **devfs vnode**. Vnodes are the generic FreeBSD VFS objects that represent open filesystem inodes. Each device node has a vnode underneath it, just as a regular file does, and the VFS layer uses the vnode to route operations toward the correct filesystem. For a device node, that filesystem is `devfs`, and `devfs` forwards the operation to the `cdev`.

The third object is the **file descriptor** itself, represented inside the kernel by a `struct file`. Unlike the `cdev`, there is one `struct file` per open, not one per device. This is where per-open state lives. Two processes that both open `/dev/myfirst0` share the same `cdev` but get separate file structures, and `devfs` knows how to keep those structures cleanly distinct.

Put the three together and the path of a single `read(2)` looks like this:

Every box above exists independently, and each one has a different lifetime. The `cdev` lives for as long as your driver keeps it alive. The vnode lives for as long as anyone has the node resolved on the VFS layer. The `struct file` lives for as long as the user process keeps its descriptor open. When you write a driver, you are filling in only the last row of that diagram, but it helps enormously to know the rows above.

8.4.1 Tracing a Single read(2) Through the Stack

Walk through the story once in prose, with a concrete `read(2)` call as the anchor. A user program has this line:

```
ssize_t n = read(fd, buf, 64);
```

Here is what happens. The kernel receives the `read(2)` syscall and looks up `fd` in the calling process's file-descriptor table. That yields a `struct file`. The kernel sees that the file's type is a vnode-backed file whose vnode lives in `devfs`, so it dispatches through the generic file-operation vector into `devfs`'s read handler.

`devfs` takes a reference on the underlying `struct cdev`, retrieves the pointer to `struct cdevsw` from it, and calls `cdevsw->d_read`. That is **your** function. Inside it you inspect the `struct uio` the kernel prepared, look at the device through the `struct cdev *dev` argument, and optionally recover the per-open structure with `devfs_get_cdevpriv`. When you return, `devfs` releases its reference on the `cdev` and the read call unwinds back to the user program.

A few invariants fall out of that trace and are worth remembering:

- **Your handler never runs if the cdev is gone.** Between `destroy_dev(9)` retiring the node and the last caller dropping its reference, `devfs` simply refuses new operations.
- **Two calls from two processes can reach `d_read` simultaneously.** Neither `devfs` nor the VFS layer serialises callers on your behalf. Concurrency control is your responsibility, and Part 3 of this book is dedicated to it.
- **The `struct file` you are implicitly serving is hidden from your handler.** You do not need to know which descriptor triggered the call; you only need the `cdev`, the `uio`, and (optionally) the `cdevpriv` pointer.

That last point is the one that earns its keep in practice. By hiding the descriptor from the handler, FreeBSD gives you a clean API: all the per-descriptor bookkeeping goes through `devfs_set_cdevpriv` and `devfs_get_cdevpriv`, and your handler code stays small.

8.4.2 Why This Matters for Beginners

Two practical consequences fall out of this model, and both will come back in the next chapter.

First, **pointers stored on the cdev are shared across all opens**. If you store a counter in `si_drv1`, every process that opens the node sees the same counter. That is perfect for driver-wide state such as the `softc`, and terrible for per-session state such as a read position.

Second, **the kernel does not care how many times your device is opened**. Unless you tell it otherwise, every `open(2)` just goes through. If you need exclusive access, as the Chapter 7 code does through its `is_open` flag, you have to enforce it yourself. If you need per-open bookkeeping, you attach that bookkeeping to the file descriptor, not to the `cdev`. We will do both before the end of the chapter.

8.4.3 A Closer Look at struct cdev

You have been using `struct cdev` through a pointer for the whole of Chapter 7. It is time to look inside it. The full definition is in `/usr/src/sys/sys/conf.h`, and the important fields are these:

```

struct cdev {
    void                *si_spare0;
    u_int               si_flags;
    struct timespec      si_atime, si_ctime, si_mtime;
    uid_t               si_uid;
    gid_t               si_gid;
    mode_t              si_mode;
    struct ucred         *si_cred;
    int                 si_drv0;
    int                 si_refcount;
    LIST_ENTRY(cdev)     si_list;
    LIST_ENTRY(cdev)     si_clone;
    LIST_HEAD(, cdev)     si_children;
    LIST_ENTRY(cdev)     si_siblings;
    struct cdev          *si_parent;
    struct mount          *si_mountpt;
    void                 *si_drv1, *si_drv2;
    struct cdevsw         *si_devsw;
    int                  si_iosize_max;
    u_long               si_usecount;
    u_long               si_threadcount;
    union { ... }        __si_u;
    char                 si_name[SPECNAMELEN + 1];
};

```

Not every field matters for a beginner-level driver. A few do, and knowing what they represent saves hours the first time you look at unfamiliar code.

si_name is the null-terminated name of the node as devfs sees it. When you pass "myfirst/%d" and unit 0 to `make_dev_s`, this is the field that ends up containing the string `myfirst/0`. The helper `devtoname(struct cdev *dev)` returns a pointer to this field and is the right tool for logging or debug output.

si_flags is a bit field that carries status flags about the cdev. The flags your driver will touch most often are `SI_NAMED` (set when `make_dev*` has placed the node into devfs) and `SI_ALIAS` (set on aliases created by `make_dev_alias`). The kernel manages them; your code rarely, if ever, writes to this field directly. A useful reading habit: if you see an unfamiliar `SI_*` flag in someone else's driver, look it up in `/usr/src/sys/sys/conf.h` and read the one-line comment.

si_drv1 and **si_drv2** are the two generic driver-controlled slots. Chapter 7 used `si_drv1` to stash the softc pointer, and that is the most common pattern. `si_drv2` is available for a second pointer when you need one. These fields are yours to use; the kernel never touches them.

si_devsw is the pointer to the `struct cdevsw` that dispatches operations on this cdev. It is the link between the node and your handlers.

si_uid, **si_gid**, **si_mode** hold the advertised ownership and mode. They are set from the `mda_uid`, `mda_gid`, `mda_mode` arguments you pass to `make_dev_args_init`. They are mutable in principle, but the right way to change them is through `devfs.conf` or `devfs.rules`, not by assigning into the struct.

si_refcount, **si_usecount**, **si_threadcount** are the three counters devfs uses to keep the cdev alive while anyone might still touch it. **si_refcount** counts long-lived references (the cdev is listed in devfs, other cdevs may alias it). **si_usecount** counts active open file descriptors. **si_threadcount** counts kernel threads currently executing inside a cdevsw handler for this cdev. Your driver almost never reads these directly; the routines **dev_ref**, **dev_rel**, **dev_refthread**, and **dev_relthread** manage them on your behalf. What matters conceptually is that **destroy_dev(9)** will refuse to finish tearing a cdev down while **si_threadcount** is non-zero; it waits, sleeping briefly, until every in-flight handler has returned.

si_parent and **si_children** link a cdev into a parent-child relationship. This is how **make_dev_alias(9)** wires an alias cdev to its primary and how certain clone mechanisms wire per-open nodes to their template. Most of the time you will not interact with these fields; it is enough to know they exist and that they are one of the reasons devfs can unwind an alias cleanly when the primary is destroyed.

si_flags & **SI_ETERNAL** deserves a short note. Some nodes, in particular the ones **null** creates for **/dev/null**, **/dev/zero**, and **/dev/full**, are flagged as eternal with **MAKEDEV_ETERNAL_KLD**. The kernel refuses to destroy them during normal operation. When you start writing modules that expose devices at KLD load time and want the nodes to stay alive across unload attempts, this is the knob. For a driver in active development, leave it alone.

8.4.4 struct cdevsw: The Dispatch Table

Your Chapter 7 cdevsw filled in a handful of fields. The real structure is longer, and the remaining fields are worth at least a recognition pass, because you will meet them in real drivers and sooner or later want to use some of them.

The structure is defined in **/usr/src/sys/sys/conf.h** as:

```
struct cdevsw {
    int            d_version;
    u_int          d_flags;
    const char     *d_name;
    d_open_t       *d_open;
    d_fdopen_t     *d_fdopen;
    d_close_t      *d_close;
    d_read_t       *d_read;
    d_write_t      *d_write;
    d_ioctl_t      *d_ioctl;
    d_poll_t       *d_poll;
    d_mmap_t       *d_mmap;
    d_strategy_t   *d_strategy;
    void           *d_spare0;
    d_kqfilter_t   *d_kqfilter;
    d_purge_t      *d_purge;
    d_mmap_single_t *d_mmap_single;
    /* fields managed by the kernel, not touched by drivers */
};
```

Take the fields one at a time.

d_version is an ABI stamp. It must be set to `D_VERSION`, a value defined a few lines above the structure. The kernel checks this field when registering the `cdevsw` and will refuse to proceed if the stamp does not match. Forgetting to set it is a classic beginner bug: the driver compiles, loads, and then either produces weird errors on first open or crashes the system outright. Always set `d_version = D_VERSION` as the first field in every `cdevsw` you write.

d_flags carries a set of `cdevsw`-wide flags. The flag names are defined with the rest of the structure. The ones worth recognising now are:

- `D_TAPE`, `D_DISK`, `D_TTY`, `D_MEM`: hint to the kernel about the nature of the device. For most drivers you leave this zero.
- `D_TRACKCLOSE`: if set, `devfs` calls your `d_close` for every `close(2)` on a descriptor, not only for the last close. Useful when you want to reliably run per-descriptor teardown even in the face of `dup(2)`.
- `D_MMAP_ANON`: special handling for anonymous memory mappings. `/dev/zero` sets this, which is how `mmap(..., /dev/zero, ...)` yields zero-filled pages.
- `D_NEEDGIANT`: forces dispatch of this `cdevsw`'s handlers under the Giant lock. Modern drivers should not need this; if you see it in code, treat it as a historical marker rather than a model to follow.
- `D_NEEDMINOR`: signals that the driver uses `clone_create` to allocate minor numbers for cloned `cdevs`. You will not need this in Chapter 8.

d_name is the base name string used by the kernel when logging about this `cdevsw`. It also becomes part of the pattern the `clone_create(9)` mechanism uses when it synthesises cloned devices. Set it to a short, human-readable string such as `"myfirst"`.

d_open, **d_close**: session boundaries. Called when a user program calls `open(2)` on the node or releases its last descriptor with `close(2)`. Chapter 7 introduced both, and this chapter refines how you use them.

d_fdopen: an alternative to `d_open` for drivers that want the `struct file *` passed to them directly. Rare in beginner-level drivers. Ignore unless a future chapter introduces it.

d_read, **d_write**: byte-stream operations. Chapter 7 left these stubbed. Chapter 9 implements them with `uiomove(9)`.

d_ioctl: control-path operations. Chapter 25 will treat `ioctl` design in depth. For now, recognise the field and know that it is where structured commands from `ioctl(2)` land.

d_poll: called by `poll(2)` to ask whether the device is currently readable or writable. Chapter 10 handles this as part of the I/O-efficiency story.

d_kqfilter: called by `kqueue(9)` machinery. Same chapter.

d_mmap, **d_mmap_single**: supports mapping the device into a user process's address space. Rare in beginner drivers, covered later when it matters.

d_strategy: called by some kernel layers (notably the old `physio(9)` path) to hand the driver a block of I/O as a `struct bio`. Not relevant for the pseudo-devices you will be writing in Part 2.

d_purge: called by `devfs` during destruction if the `cdev` still has threads running inside its handlers. A well-written `d_purge` wakes those threads and convinces them to return quickly so destruction can proceed. Most simple drivers do not need one; Chapter 10 revisits this in the context of blocking I/O.

When you design your own `cdevsw`, you fill in only the fields that correspond to operations your device actually supports. Every `NULL` field is a polite refusal: the kernel interprets it either as “this operation is not supported on this device” or as “use the default behavior”, depending on which operation it is. Do not reach into the spare fields.

8.4.5 The `D_VERSION` Stamp and Why It Exists

A short aside about `d_version` is useful, because it will save you time the first time your driver mysteriously fails to register.

The kernel interface for `cdevsw` structures has evolved over FreeBSD’s lifetime. Fields have been added, removed, or changed type across major releases. The `d_version` stamp is the kernel’s way of confirming that your module was built against a compatible definition of the structure. The canonical way to set it is:

```
static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    /* ...remaining fields... */
};
```

The macro `D_VERSION` is defined in `/usr/src/sys/sys/conf.h` and will be updated by the kernel team whenever the structure changes in a way that breaks ABI. Modules built against the new header get the new stamp. Modules built against an old header get an old stamp and the kernel refuses them.

This is a small detail that saves large headaches. Set it every time. If you ever see the kernel print a `cdevsw` version mismatch on load, your build environment and your running kernel have drifted; rebuild the module against the headers of the kernel you intend to run.

8.4.6 Reference Counting at the `cdev` Level

The counters you saw on `struct cdev` are the engine that keeps device destruction safe. A simple way to picture them:

- `si_refcount` is the “how many things in the kernel still hold this `cdev` by the neck” count. Aliases, clones, and certain bookkeeping paths bump it. The `cdev` cannot actually be freed while this is non-zero.
- `si_usecount` is the “how many user-space file descriptors have this `cdev` open” count. It is incremented by `devfs` on a successful `open(2)` and decremented on `close(2)`. Your driver never touches it directly.
- `si_threadcount` is the “how many kernel threads are right now executing inside one of my `cdevsw` handlers” count. It is incremented by `dev_refthread(9)` when `devfs` enters a handler on your behalf and decremented by `dev_relthread(9)` when the handler returns. Your driver never touches it directly.

The rule that makes this usable is: `destroy_dev(9)` will block until `si_threadcount` falls to zero and will not return until no more handlers can be entered for this `cdev`. That is how `destroy_dev` is able to guarantee that after it returns, your handlers will not be called again. The section later in this chapter titled “Destroying `cdevs` Safely” revisits this guarantee and the cases where you need its stronger cousin `destroy_dev_drain(9)`.

8.4.7 One More Turn on Lifetimes

With that in hand, the diagram from the previous subsection has a little more meaning than it did the first time. The `cdev` is a long-lived kernel object whose lifetime is under your driver's control. The `vnode` is a VFS-layer object that lives only as long as the filesystem layer has use for it. The `struct file` is a short-lived per-open object that lives only as long as the process keeps the descriptor. And underneath all three, the counters described above keep them honest.

You do not need to memorise any of that. You need to recognise the shape. When you later read a driver and see `dev_refthread` or `si_refcount`, you will remember what they are for. When you watch `destroy_dev` sleep in a debugger, you will recognise that it is waiting for `si_threadcount` to drop. That recognition is what turns kernel code from a puzzle into something you can reason about.

8.5 Permissions, Ownership, and Mode

When your driver calls `make_dev_s(9)`, three fields on the `struct make_dev_args` decide what `ls -l /dev/yournode` will show:

```
args.mda_uid  = UID_ROOT;
args.mda_gid  = GID_WHEEL;
args.mda_mode = 0600;
```

`UID_ROOT`, `UID_BIN`, `UID_UUCP`, `UID_NOBODY`, `GID_WHEEL`, `GID_KMEM`, `GID_TTY`, `GID_OPERATOR`, `GID_DIALER`, and a handful of related names are defined in `/usr/src/sys/sys/conf.h`. Use those constants rather than raw numbers when a well-known identity exists. It makes your driver easier to read and it protects you from silent drift if the numeric value ever changes.

The mode is a classic UNIX permission triple. The meaning of each bit is the same as for a regular file, with the caveat that devices do not care about the execute bit. A few combinations come up often:

- `0600`: owner read and write. The safest default for a driver that is still being developed.
- `0660`: owner and group read and write. Appropriate when you have a well-defined privileged group, such as operator or dialer.
- `0644`: owner read and write, everyone can read. Rare for control devices, sometimes appropriate for read-only status or random-byte style nodes.
- `0666`: everyone can read and write. Used only for intentionally harmless sources like `/dev/null` and `/dev/zero`. Do not reach for this unless you have a real reason.

The rule of thumb is simple: ask “who actually needs to touch this node?” and encode that answer, no more. Opening permissions wider later is easy. Narrowing them after users have come to depend on the wider mode is not.

8.5.1 Where the Mode Comes From

It is worth being explicit about who decides the final mode on the node. Three actors have a say:

1. **Your driver**, through the `mda_uid`, `mda_gid`, and `mda_mode` fields at `make_dev_s()` time. This is the baseline.
2. **/etc/devfs.conf**, which can apply a one-time static adjustment when a node appears. This is the standard way an operator tightens or loosens permissions on a specific path.
3. **/etc/devfs.rules**, which can apply rule-based adjustments, commonly to filter what a jail sees.

If the driver sets `0600` and nothing else is configured, you will see `0600`. If the driver sets `0600` and `devfs.conf` says `perm myfirst/0 0660`, you will see `0660` for that node. The kernel is the mechanism; the operator's configuration is the policy.

8.5.2 Named Groups You Will Meet

FreeBSD ships with a small set of well-known groups that show up repeatedly in device ownership. Each has a matching constant in `/usr/src/sys/sys/conf.h`. A brief field guide helps you choose one quickly:

- **GID_WHEEL** (`wheel`). Trusted administrators. The safest default when you are not sure who should have access beyond root.
- **GID_OPERATOR** (`operator`). Users who run operational tools but are not full administrators. Commonly used for devices that need human supervision but should not require `sudo` every time.
- **GID_DIALER** (`dialer`). Historically for serial-port dial-out access. Still used for TTY nodes that user-space dial programs need.
- **GID_KMEM** (`kmem`). Read access to kernel memory through `/dev/kmem`-style nodes. Very sensitive, rarely the right answer for a new driver.
- **GID_TTY** (`tty`). Ownership for terminal devices.

When a suitable named group exists, use it. When none fits, leave the group as `wheel` and add `devfs.conf` entries for sites that need their own grouping. Inventing a brand-new group in your driver is rarely worth the trouble.

8.5.3 A Worked Example

Suppose the driver baseline is `UID_ROOT`, `GID_WHEEL`, `0600`, and you want to let a specific lab user read and write through a controlled group. The sequence looks like this.

With the driver loaded and no `devfs.conf` entries:

```
% ls -l /dev/myfirst/0
crw----- 1 root  wheel    0x5a Apr 17 10:02 /dev/myfirst/0
```

Add a section to `/etc/devfs.conf`:

```
own    myfirst/0    root:operator
perm   myfirst/0    0660
```

Apply it and inspect again:

```
% sudo service devfs restart
% ls -l /dev/myfirst/0
crw-rw----  1 root  operator   0x5a Apr 17 10:02 /dev/myfirst/0
```

The driver was not reloaded. The cdev in the kernel is the same object. Only the advertised ownership and mode changed, and they changed because a policy file told devfs to change them. This is the layering you want: the driver ships a defensible baseline, and the operator shapes the view.

8.5.4 Case Studies from the Tree

It helps to spend a minute on the permissions that real FreeBSD devices advertise, because the choices those drivers make are not accidental. Each one is a small design decision, and each one is consistent with the threat model for that kind of node.

`/dev/null` and `/dev/zero` ship with mode `0666`, `root:wheel`. Everyone on the system, privileged or not, is allowed to open them and read or write through them. That is the correct choice because the data they carry is trivially inexhaustible (zero bytes out, bytes-disposed-of in, no hardware state, no secrets). Making them any tighter would break a long list of scripts, tools, and programming idioms that depend on their being universally available. The code that creates them is in `/usr/src/sys/dev/null/null.c`, and the arguments to `make_dev_credf(9)` there are worth a glance.

`/dev/random` is typically mode `0644`, readable by anyone, writable only by root. Read access is deliberately broad because many userland programs need entropy. Write access is narrow because feeding the entropy pool is a privileged operation.

`/dev/mem` and `/dev/kmem` are historically mode `0640`, owner `root`, group `kmem`. The group exists precisely so that privileged monitoring tools can link to them without running as root. The mode is tight because the nodes expose raw memory; a casually readable `/dev/mem` would be a disaster. If you ever see a driver default to a mode this loose for a node that carries hardware state or kernel memory, treat it as a defect.

`/dev/pf`, the control node for the packet filter, is mode `0600`, owner `root`, group `wheel`. A user that can write into `/dev/pf` can change firewall rules. There is no acceptable broader mode; the whole point of the interface is to centralise privileged network configuration, and anything looser would turn the firewall into a free-for-all.

`/dev/bpf*`, the Berkeley Packet Filter nodes, are mode `0600`, owner `root`, group `wheel`. A reader of `/dev/bpf*` sees every packet on an attached interface. That is unambiguous privilege, and the permission reflects it.

TTY nodes under `/dev/ttyu*` and similar hardware-serial surfaces are usually mode `0660`, owner `uucp`, group `dialer`. The `dialer` group exists to let a set of trusted users run dial-out programs without `sudo`. The permission set is the narrowest that still lets the intended workflow function.

The pattern is easy to name: **FreeBSD's base system never chooses wide device permissions unless the data on the other side is harmless**. When you design a node of your own, use that pattern as a mental check. If your node carries data that could hurt someone, narrow the mode. If it carries data that is trivially regenerable and trivially discardable, widening is defensible; do it anyway only when there is a reason.

8.5.5 Least Privilege Applied to Device Files

“Least privilege” is an overused phrase, but it is precisely right when it applies to device files. You, the driver author, are choosing who can talk to your code from userland, and you get to set the lower bound. Every choice you make wider than necessary is a choice that invites mistakes later.

A practical checklist for each new node you design:

1. **Name the primary consumer in a sentence.** “The monitor daemon reads status every second.” “The control tool invokes `ioctl` to push configuration.” “Users of the operator group can read raw packet counters.” If you cannot name the consumer, you cannot set permissions; you are guessing.
2. **Derive the mode from the sentence.** A monitor daemon that runs as `root:wheel` and reads once a second wants `0600`. A control tool that a subset of privileged admins run wants `0660` with a dedicated group. A read-only status node consumed by unprivileged dashboards wants `0644`.
3. **Put the reasoning in a comment next to the `mda_mode` line.** Future maintainers will thank you. Future auditors will thank you more.
4. **Default to `UID_ROOT`.** There is almost never a reason for the owner of a node created by a driver to be anything else, unless the driver explicitly models a non-root daemon identity.

The opposite habit, which the book wants to inoculate against, is the “open it up and tighten later” impulse. Permissions on a shipped driver are very hard to tighten, because by the time someone notices, some user’s workflow depends on the loose mode and the tightening breaks their day. Start tight. Widen when you have reviewed a real request.

8.5.6 Transitioning a Loose Mode to a Tight One

Occasionally you will inherit a driver that was wide open and needs to be narrowed. The right approach is three-stage:

Stage 1: Announce. Put the planned change in a release note, in the driver’s kernel log on first attach, and in whatever operator-facing channel your project uses. Invite feedback for at least one release cycle.

Stage 2: Offer a transition path. Either a `devfs.conf` entry that reopens the old mode for people who need it, or a `sysctl` that the driver reads at attach to pick its default mode. The important property is that a site with a legitimate need to keep the old mode can do so without forking the driver.

Stage 3: Flip the default. In the next release after the transition window ends, change the driver’s own `mda_mode` to the narrower value. The `devfs.conf` escape hatch remains for sites that need it; everyone else gets the narrower default.

None of that is specific to FreeBSD; it is how any well-run project handles backward-incompatible interface changes. It is worth naming here because device-file permissions have exactly this property: they are part of your driver’s public interface.

8.5.7 What the `uid` and `gid` Constants Actually Are

The `UID_*` and `GID_*` constants defined in `/usr/src/sys/sys/conf.h` are **not** guaranteed to match the user and group database on every system. The names chosen in the header correspond to identities that the FreeBSD base system reserves in `/etc/passwd` and `/etc/group`, but a locally modified system could in theory renumber

them, or a product built on FreeBSD could add its own. In practice, on every FreeBSD system you will touch, the constants match.

The discipline to hold is simple: use the symbolic name when one exists, and look it up in the header before you invent a new identity. The header currently defines at least these:

- User IDs: `UID_ROOT` (0), `UID_BIN` (3), `UID_UUCP` (66), `UID_NOBODY` (65534).
- Group IDs: `GID_WHEEL` (0), `GID_KMEM` (2), `GID_TTY` (4), `GID_OPERATOR` (5), `GID_BIN` (7), `GID_GAMES` (13), `GID_VIDEO` (44), `GID_RT_PRI0` (47), `GID_ID_PRI0` (48), `GID_DIALER` (68), `GID_NOGROUP` (65533), `GID_NOBODY` (65534).

If you need an identity that is not in the list, the base system probably does not have one reserved. In that case, leave ownership as `UID_ROOT/GID_WHEEL` and let operators map your node to their own local group through `devfs.conf`. Inventing a new group inside your driver is almost always the wrong move.

8.5.8 Three-Layer Policy: Driver, `devfs.conf`, `devfs.rules`

When you combine the driver's baseline with `devfs.conf` and `devfs.rules`, you get a layered policy model that is worth seeing once end-to-end. Consider a device that the driver creates with `root:wheel 0600`. Three layers act on it:

- **Layer 1, the driver itself:** sets the baseline. Every `/dev/myfirst/0` on every `devfs` mount starts at `root:wheel 0600`.
- **Layer 2, `/etc/devfs.conf`:** applied once per host `devfs` mount, typically at boot. Can change ownership, mode, or add a symlink. On the running host, after `service devfs restart`, the node might appear as `root:operator 0660`.
- **Layer 3, `/etc/devfs.rules`:** applied at mount time based on the ruleset attached to the mount. A jail whose `devfs` mount uses ruleset `10` sees the filtered, possibly-modified subset. The same node might be hidden inside the jail, or it might be unhidden with further mode and group adjustments.

The practical consequence of this layering is that **the same cdev can look different in different places at the same time**. On the host it might be `0660` owned by `operator`. In a jail it might be `0640` owned by a jailed user identity. In another jail it might not exist at all.

That is a feature, not a bug. It lets you ship a driver with a strict baseline and lets operators widen per-environment without editing your code. Chapter 8 Section 10 walks through all three layers with a worked example.

8.6 Naming, Unit Numbers, and Subdirectories

The `printf`-style argument to `make_dev_s(9)` chooses where in `/dev` the node appears. In Chapter 7 you used:

```
error = make_dev_s(&args, &sc->cdev, "myfirst%d", sc->unit);
```

That produced `/dev/myfirst0`. Two details hide in there.

The first detail is `sc->unit`. It is the Newbus unit number that FreeBSD assigns to your device instance. With one instance attached, you get 0. If your driver supported multiple instances, you might see `myfirst0`, `myfirst1`, and so on.

The second detail is the format string itself. Device names are paths relative to `/dev`, and they may contain slashes. A name such as `"myfirst/%d"` does not produce a weird filename with a slash in it; `devfs` interprets the slash the way a filesystem does, creates the intermediate directory if needed, and places the node inside. So:

- `"myfirst%d"` with unit 0 gives `/dev/myfirst0`.
- `"myfirst/%d"` with unit 0 gives `/dev/myfirst/0`.
- `"myfirst/control"` gives `/dev/myfirst/control`, with no unit number at all.

Grouping related nodes into a subdirectory is a common pattern for drivers that expose more than one surface. Think of `/dev/led/*` from `/usr/src/sys/dev/led/led.c`, or `/dev/pf`, `/dev/pflog*`, and friends from the packet-filter subsystem. The subdirectory makes the relationship obvious at a glance, keeps the top level of `/dev` tidy, and lets an operator grant or deny access to the whole set with a single `devfs.conf` line.

You will adopt this pattern for `myfirst` in this chapter. The main data path moves from `/dev/myfirst0` to `/dev/myfirst/0`. Then you will add an alias so the old path keeps working for any lab scripts that remember the previous layout.

8.6.1 Names in the Real FreeBSD Tree

Browsing the `/dev` of a running FreeBSD system is educational in its own right, because the naming conventions you see there were shaped by the same pressures your driver will face. A short tour, grouped by theme:

- **Direct device names.** `/dev/null`, `/dev/zero`, `/dev/random`, `/dev/urandom`. One cdev per node, top-level, short stable names. Good for singletons with no hierarchy.
- **Unit-numbered names.** `/dev/bpf0`, `/dev/bpf1`, `/dev/ttyu0`, `/dev/md0`. One cdev per instance, numbered from zero. The format string looks like `"bpf%d"` and the driver manages the unit numbers.
- **Subdirectories per driver.** `/dev/led/*`, `/dev/pts/*`, `/dev/ipmi*` in some configurations. Used when a single driver exposes many related nodes. Makes operator policy simple: one `devfs.conf` or `devfs.rules` entry can cover the whole set.
- **Split data and control nodes.** `/dev/bpf` (the cloning entry point) plus per-open clones, `/dev/fido/*` for FIDO devices, and so on. Used when a driver needs different semantics for discovery versus data.
- **Aliased names for convenience.** `/dev/stdin`, `/dev/stdout`, `/dev/stderr` are symlinks that `devfs` provides for the current process's file descriptors. `/dev/random` and `/dev/urandom` were once aliased; in modern FreeBSD they are separate nodes served by the same random driver but the history is still visible.

You do not need to memorise these patterns. You do need to recognise them, because when you read existing drivers they will all make more sense once the naming convention is named.

8.6.2 Multiple Nodes Per Device

Some drivers expose one node and that is enough. Other drivers expose several, each with different semantics. A common split is:

- A **data node** that carries the bulk payload (reads, writes, mmaps) and is meant for high-throughput use.
- A **control node** that carries management traffic (configuration, status, reset) and is typically group-readable for monitoring tools.

When a driver does this, it calls `make_dev_s(9)` twice in `attach()` and keeps both `cdev` pointers in the softc. In Chapter 8 you will stop at one data node plus one alias, but the pattern is worth knowing now so you recognise it when you see it.

Lab 8.5 builds out a minimal two-node variant of `myfirst` with a data node at `/dev/myfirst/0` and a control node at `/dev/myfirst/0ctl`. Each node has its own `cdevsw` and its own permission mode. The lab is there to show how the pattern looks in code; most of your drivers in later chapters will use it.

8.6.3 The `make_dev` Family in Depth

You have used `make_dev_s(9)` for every node you have created so far. FreeBSD actually provides a small family of `make_dev*` functions, each with slightly different ergonomics. Reading existing drivers will expose you to all of them, and knowing when to use which saves grief later.

The full declarations live in `/usr/src/sys/sys/conf.h`. In order of increasing modernity:

```
struct cdev *make_dev(struct cdevsw *_devsw, int _unit, uid_t _uid, gid_t _gid,
                     int _perms, const char *_fmt, ...);

struct cdev *make_dev_cred(struct cdevsw *_devsw, int _unit,
                           struct ucred *_cr, uid_t _uid, gid_t _gid, int _perms,
                           const char *_fmt, ...);

struct cdev *make_dev_credf(int _flags, struct cdevsw *_devsw, int _unit,
                             struct ucred *_cr, uid_t _uid, gid_t _gid, int _mode,
                             const char *_fmt, ...);

int make_dev_p(int _flags, struct cdev **_cdev, struct cdevsw *_devsw,
               struct ucred *_cr, uid_t _uid, gid_t _gid, int _mode,
               const char *_fmt, ...);

int make_dev_s(struct make_dev_args *_args, struct cdev **_cdev,
               const char *_fmt, ...);
```

Take them one at a time.

make_dev is the original positional-argument form. It returns the new `cdev` pointer directly, or panics on any error. Panicking on error is a strong hint that it is intended for code paths that cannot recover, such as the very early initialization of truly-eternal devices. Avoid it in new drivers. It is still in the tree only because older drivers use it, and because some of those drivers are places where an early panic is genuinely acceptable.

make_dev_cred adds a credential (`struct ucred *`) argument. The credential is used by devfs when applying rules; it tells the system “this `cdev` was created by this credential” for rule-matching purposes. Most drivers

pass `NULL` for the credential and get the default behavior. You will see this form in drivers that clone devices on demand in response to user requests; it is not common elsewhere.

`make_dev_credf` extends `make_dev_cred` with a flags word. This is the first member of the family that lets you say “do not panic if this fails; return `NULL` so I can handle it”.

`make_dev_p` is a functional equivalent to `make_dev_credf` with a cleaner return-value convention: it returns an `errno` value (zero on success) and writes the new `cdev` pointer through an output parameter. This is the form most widely used in modern code bases that were written before `make_dev_s` existed.

`make_dev_s` is the modern recommended form. It accepts a pre-populated `struct make_dev_args` (initialised with `make_dev_args_init_impl` and described below) and writes the `cdev` pointer through an output parameter. It returns an `errno` value, zero on success. The reason the book uses it is simple: it is the easiest form to read, the easiest form to extend (adding a new field to the argument struct is ABI-friendly), and the easiest form to error-check.

The argument structure, also from `/usr/src/sys/sys/conf.h`:

```
struct make_dev_args {
    size_t      mda_size;
    int         mda_flags;
    struct cdevsw *mda_devsw;
    struct ucred *mda_cr;
    uid_t       mda_uid;
    gid_t       mda_gid;
    int         mda_mode;
    int         mda_unit;
    void        *mda_si_drv1;
    void        *mda_si_drv2;
};
```

`mda_size` is set automatically by `make_dev_args_init(a)`; you never touch it. `mda_flags` carries the `MAKEDEV_*` flags described below. `mda_devsw`, `mda_cr`, `mda_uid`, `mda_gid`, `mda_mode`, and `mda_unit` correspond to the positional arguments of the older forms. `mda_si_drv1` and `mda_si_drv2` let you pre-populate the driver pointer slots on the resulting `cdev`, which is how you avoid the window where `si_drv1` could briefly be `NULL` after `make_dev_s` returns but before you assign it. Always populate `mda_si_drv1` before the call.

8.6.4 Which Form Should You Use?

For new drivers, **use `make_dev_s`**. Every example in this book uses it, and every driver you write for yourself should do the same unless a very specific reason forces otherwise.

For reading existing code, recognise all of them. If you find a driver that calls `make_dev(...)` and ignores its return value, you are looking at either a driver that predates the modern APIs or a driver whose authors decided a panic on failure is acceptable. Both are defensible in context; neither is the right default for new code.

8.6.5 The MAKEDEV_* Flags

The flags that can be OR-ed into `mda_flags` (or passed as the first argument to `make_dev_p` and `make_dev_credf`) are defined in `/usr/src/sys/sys/conf.h`. Each one carries a specific meaning:

- **MAKEDEV_REF**: increments the reference count on the resulting `cdev` by one, in addition to the usual reference. Used when the caller plans to hold the `cdev` pointer long-term across events that would ordinarily drop the reference. Rare in beginner-level drivers.
- **MAKEDEV_NOWAIT**: tells the allocator not to wait if memory is tight. On an out-of-memory condition the function returns `ENOMEM` (for `make_dev_s`) or `NULL` (for older forms) instead of blocking. Use this only if your caller cannot afford to sleep.
- **MAKEDEV_WAITOK**: the inverse. Tells the allocator it is safe to sleep for memory. This is the default for `make_dev` and `make_dev_s`, so you rarely spell it out.
- **MAKEDEV_ETERNAL**: marks the `cdev` as never-to-be-destroyed. `devfs` will refuse to honor `destroy_dev(9)` on it during normal operation. Used by the eternal in-kernel devices such as `null`, `zero`, and `full`. Do not set this in a driver you plan to unload.
- **MAKEDEV_CHECKNAME**: asks the function to validate the node name against `devfs`'s rules before creating it. On failure it returns an error rather than creating a badly-named `cdev`. Useful in code paths that synthesise names from user input.
- **MAKEDEV_WHTOUT**: creates a “whiteout” entry, used in conjunction with stacked filesystems to mask an underlying entry. Not something you will encounter in driver work.
- **MAKEDEV_ETERNAL_KLD**: a macro that expands to `MAKEDEV_ETERNAL` when the code is built outside a loadable module and to zero when it is built as a KLD. This lets shared source for a device (like `null`) set the flag when statically compiled and clear it when loaded as a module, so that the module remains unloadable.

For a typical beginner-level driver, the flag field is zero, which is what the `myfirst` examples in the companion tree use. `MAKEDEV_CHECKNAME` is worth reaching for when the node name is built from user input or from a string whose provenance you do not fully control; for a driver that passes a constant format string such as `"myfirst/%d"`, the flag adds nothing useful.

8.6.6 The `cdevsw d_flags`

Separate from the `MAKEDEV_*` flags, the `cdevsw` itself carries a `d_flags` field that shapes how `devfs` and other kernel machinery treat the `cdev`. These flags were listed in the `cdevsw` tour a few sections back; this section is the place to understand when to set them.

D_TRACKCLOSE is the flag you are most likely to want in Chapter 8. By default, `devfs` calls your `d_close` only when the last file descriptor referring to the `cdev` is released. If a process has called `dup(2)` or `fork(2)` and two descriptors share the open, `d_close` fires once, at the very end. That is often what you want. It is not what you want if you need a reliable per-descriptor close hook. Setting `D_TRACKCLOSE` makes `devfs` call `d_close` for every `close(2)` on every descriptor. For a driver that uses `devfs_set_cdevpriv(9)` for per-open state, the destructor is usually the better hook; `D_TRACKCLOSE` remains useful when the semantics of your device genuinely require each close to be observable.

D_MEM tags the `cdev` as a memory-style device; `/dev/mem` itself sets this. It changes how certain kernel paths treat I/O to the node.

D_DISK, **D_TAPE**, **D_TTY** are hints for the category of device. Modern drivers mostly do not set them, because GEOM owns disks, the TTY subsystem owns TTYs, and tape devices route through their own layer. You will see them on legacy drivers.

D_MMAP_ANON alters how mapping the device yields pages. The zero device sets it; mapping `/dev/zero` yields anonymous, zero-filled pages. Useful to recognise; you will not need to set it until you write a driver that wants the same semantics.

D_NEEDGIANT requests that all `cdevsw` handlers for this `cdev` be dispatched under the Giant lock. It exists as a safety blanket for drivers that have not been audited for SMP. A new driver should not set this flag. If you see it in code written after 2010 or so, treat it with suspicion.

D_NEEDMINOR tells `devfs` that the driver uses `clone_create(9)` to allocate minor numbers on demand. You will not encounter this until you write a cloning driver, which is out of scope for this chapter.

The flags you will set in `myfirst` are, in most versions, none. Once Chapter 8 adds per-open state, the driver still does not need **D_TRACKCLOSE** because the `cdevpriv` destructor covers the per-descriptor cleanup need.

8.6.7 Name Length and Name Characters

`make_dev_s` accepts a `printf`-style format and produces a name that `devfs` stores in the `cdev`'s `si_name` field. The size of that field is `SPECNAMELEN + 1`, and `SPECNAMELEN` is currently 255. A name longer than that is an error.

In addition to length, a name must be acceptable as a filesystem path under `devfs`. That means it must not contain null bytes, it must not use `.` or `..` as components, and it should not use characters that shells or scripts interpret specially. The safest set is lowercase ASCII letters, digits, and the three separators `/`, `-`, and `..`. Other characters will sometimes work and sometimes not; if you are ever tempted to use spaces, colons, or non-ASCII characters in a device name, stop and pick a simpler name instead.

8.6.8 Unit Numbers: Where They Come From

Unit numbers are small integers that distinguish instances of the same driver. They appear in the device name (`myfirst0`, `myfirst1`), in `sysctl` branches (`dev.myfirst.0`, `dev.myfirst.1`), and in the `cdev`'s `si_drv0` field.

Two ways are common for assigning them:

Newbus assignment. When your driver attaches to a bus and Newbus instantiates a device, the bus assigns a unit number. You retrieve it with `device_get_unit(9)` and use it as `sc->unit`, exactly as Chapter 7 does. Newbus guarantees the number is unique within the driver's namespace.

Explicit allocation with `unrhdr`. For drivers that create nodes outside the Newbus flow, the `unrhdr(9)` allocator assigns unit numbers from a pool. `/usr/src/sys/dev/led/led.c` uses this: `sc->unit = alloc_unr(led_unit);`. The LED framework does not attach through Newbus for each LED, so it cannot ask Newbus for a unit number; it maintains its own unit pool.

For a beginner driver built on Newbus, the first approach is the one to use. The second becomes relevant once you write a pseudo-device that can be instantiated many times on demand, which is a later-chapter topic.

8.6.9 Naming Conventions in the Tree

Since you are likely to read real FreeBSD drivers as part of learning, it helps to recognise the shapes their names take. A short tour:

- **bpf%d**: one node per BPF instance. Seen in `/usr/src/sys/net/bpf.c`.
- **md%d**: memory disks. `/usr/src/sys/dev/md/md.c`.
- **led/%s**: subdirectory per driver, one node per LED. `/usr/src/sys/dev/led/led.c` uses the name argument as a free-form string, chosen by the caller, e.g. `led/ehci0`.
- **ttyu%d**, **cuaU%d**: hardware serial ports, paired “in” and “out” nodes.
- **ptyp%d**, **ttyp%d**: pseudo-terminal pairs.
- **pts/%d**: modern PTY allocation in a subdirectory.
- **fuse**: singleton entry point for the FUSE subsystem.
- **mem**, **kmem**: singletons for memory inspection.
- **pci**, **pciconf**: PCI bus inspection interfaces.
- **io**: I/O-port access, singleton.
- **audit**: audit subsystem control device.

Notice that in most of these the name encodes the driver’s identity. That is deliberate. When an operator later needs to write a `devfs.conf` rule or a firewall rule or a backup script, they match on paths, and predictable paths make their life easier.

8.6.10 Handling Multiple Units

Your Chapter 7 driver registered exactly one Newbus child in its `device_identify` callback, so there is only one instance and the only unit number is 0. Some drivers want more than one instance, either at boot or on demand.

For a driver instantiated at boot with a fixed count, the pattern is to add more children in `device_identify`:

```
static void
myfirst_identify(driver_t *driver, device_t parent)
{
    int i;

    for (i = 0; i < MYFIRST_INSTANCES; i++) {
        if (device_find_child(parent, driver->name, i) != NULL)
            continue;
        if (BUS_ADD_CHILD(parent, 0, driver->name, i) == NULL)
            device_printf(parent,
                "myfirst%d: BUS_ADD_CHILD failed\n", i);
    }
}
```

Newbus calls `attach` for each child, and each call gets its own `softc` and its own unit number. Your `make_dev_s` format string `"myfirst/%d"` with `sc->unit` then produces `/dev/myfirst/0`, `/dev/myfirst/1`, and so on.

For a driver instantiated on demand, the architecture is very different. You typically expose a single “control” cdev, and when a user performs an operation on it the driver allocates a new instance and a new cdev. The memory disk driver in `/usr/src/sys/dev/md/md.c` is a clear example: `/dev/mdctl` accepts a `MDIOCATTACh` ioctl, and each successful attach produces a new `/dev/mdN` cdev through the GEOM layer. The pseudo-terminal subsystem takes a similar approach: a user opening `/dev/ptmx` is handed a freshly allocated `/dev/pts/N` on the other side. Chapter 8 does not walk you through those machineries; it is enough to know that when you see a driver create cdevs from inside an event handler rather than from `attach`, dynamic instantiation is the pattern you are looking at.

8.6.11 A Small Detour: devtoname and Friends

Three small helpers come up often in driver code and in the book from here on. They are worth collecting:

- **devtoname(cdev)**: returns a pointer to the node’s name. Read-only. Used for logging: `device_printf(dev, "created /dev/%s\n", devtoname(sc->cdev))`.
- **dev2unit(cdev)**: returns the `si_drv0` field, which is conventionally the unit number. Defined as a macro in `conf.h`.
- **device_get_nameunit(dev)**: used on a `device_t`, returns the Newbus-scoped name such as `"my-first0"`. Useful for mutex names.

All three are safe to use in contexts where the cdev or device is known to be alive, which for a driver handler is always.

8.7 Aliases: One cdev, More Than One Name

Sometimes a device needs to be reachable under more than one name. Maybe you renamed a node and want the old name to keep working during a deprecation window. Maybe you want a stable short name that always points at unit 0 without the user having to know which unit is current. Maybe the rest of the system already has a strong convention and you want to play nicely with it.

FreeBSD offers `make_dev_alias(9)` for this. An alias is itself a `struct cdev`, but one that carries the `SI_ALIAS` flag and shares the same underlying dispatch machinery as the primary node. A user program opening the alias lands in the same `cdevsw` handlers as a user program opening the primary name.

Signatures, from `/usr/src/sys/sys/conf.h`:

```
struct cdev *make_dev_alias(struct cdev *_pdev, const char *_fmt, ...);
int         make_dev_alias_p(int _flags, struct cdev **_cdev,
                             struct cdev *_pdev, const char *_fmt, ...);
```

You pass in the primary cdev, a format string, and optional arguments. You get back a new cdev that represents the alias. When you are done, you destroy the alias with `destroy_dev(9)`, the same way you destroy any other cdev.

Here is the shape of the code you will add to `myfirst_attach()`:

```

sc->cdev_alias = make_dev_alias(sc->cdev, "myfirst");
if (sc->cdev_alias == NULL) {
    device_printf(dev, "failed to create /dev/myfirst alias\n");
    /* fall through; the primary node is still usable */
}

```

Two observations about that snippet. First, failing to create an alias is not fatal. The primary path still works, so we log and continue. Second, you only need to keep a pointer to the alias cdev if you plan to destroy it on detach. In most drivers you do, so stash it in the softc right next to cdev.

8.7.1 Aliases vs link in devfs.conf

Readers familiar with UNIX symbolic links sometimes ask why FreeBSD offers two different ways to give a device a second name. The distinction is real and worth stating clearly.

A `make_dev_alias(9)` alias is a **second cdev that shares its dispatch machinery with the primary**. When the user opens it, devfs walks directly to your cdevsw handlers. There is no symlink in the filesystem. `ls -l` on the alias shows another character-special node with its own mode and ownership. The kernel knows the alias is bound to the primary cdev (the `SI_ALIAS` flag and `si_parent` pointer record that relationship) and cleans it up automatically if the primary goes away, provided your driver remembers to call `destroy_dev(9)` on it.

A `link` directive in `/etc/devfs.conf` creates a **symbolic link inside devfs**. `ls -l` shows an `l` in the type field and an arrow pointing at the target. Open it and the kernel first resolves the symlink, then opens the target. The target and the link have independent permission and ownership; the symlink itself carries no access policy beyond its existence.

Which to choose?

- Use `make_dev_alias` when the driver itself has a reason to expose the extra name, for instance a short well-known form or a legacy path that must look identical to the new one at the permission level.
- Use `link` in `devfs.conf` when the operator wants a convenience shortcut and the driver has no opinion. Nothing about that sort of link belongs in kernel code.

Both approaches work. The wrong choice is not dangerous; it is usually just clumsy. Keep driver code lean and let operator policy stay where policy lives.

8.7.2 Comparison Table: Three Ways to Give a Node Two Names

A short comparison pulls the distinctions into one place:

Property	<code>make_dev_alias</code>	<code>devfs.conf link</code>	Symbolic link via <code>ln -s</code>
Lives in kernel code	yes	no	no
Lives in devfs	yes	yes	no (lives in underlying FS)
<code>ls -l</code> shows as c	yes	no (shows as l)	no (shows as l)

Property	make_dev_alias	devfs.conf link	Symbolic link via ln -s
Carries its own mode and owner	yes	inherits target	inherits target
Auto-cleaned on driver unload	yes	yes (next service devfs restart)	no
Survives a reboot	only while driver is loaded	yes, if in devfs.conf	yes, if under /etc or similar
Appropriate for driver-owned name	yes	no	no
Appropriate for operator shortcut	no	yes	sometimes

The pattern is: drivers own their primary names and any aliases that carry policy; operators own convenience links that do not carry policy. Crossing that line is where future maintenance pain comes from.

8.7.3 The make_dev_alias_p Variant

make_dev_alias has a sibling that accepts a flags word and returns an errno, for the same reasons the main make_dev family does. Its declaration in /usr/src/sys/sys/conf.h:

```
int make_dev_alias_p(int _flags, struct cdev **_cdev, struct cdev *_pdev,
                    const char *_fmt, ...);
```

The valid flags are MAKEDEV_WAITOK, MAKEDEV_NOWAIT, and MAKEDEV_CHECKNAME. Behavior is analogous to make_dev_p: zero on success, the new cdev written through the output pointer, a non-zero errno value on failure.

If your alias creation is in a path that cannot sleep, use make_dev_alias_p(MAKEDEV_NOWAIT, ...) and be prepared for ENOMEM. In the ordinary case where your alias is created during attach under regular conditions, make_dev_alias(9) is fine; it uses MAKEDEV_WAITOK internally.

8.7.4 The make_dev_physpath_alias Variant

There is a third alias function, make_dev_physpath_alias, used by drivers that want to publish physical-path aliases in addition to their logical names. It exists to support the hardware-topology paths under /dev/something/by-path/... that certain storage drivers expose. Most beginner drivers never need it.

8.7.5 Reading Uses of make_dev_alias in the Tree

A useful exercise: grep for make_dev_alias across /usr/src/sys and look at the contexts where it is used. You will find it in storage drivers that want to publish a stable name alongside a dynamically-numbered one, in certain pseudo-devices that want a legacy compatibility name, and in a small number of specialised drivers that model a hardware topology.

Most drivers do not use it, and that is fine. When a driver does, the reason is almost always one of three:

1. **Legacy path compatibility.** A driver that was renamed but must keep the old name working.
2. **A well-known shortcut.** A short name that always resolves to instance zero or to the current default, so shell scripts can write one path instead of negotiating the unit number.
3. **Topology exposure.** A name that reflects where the hardware sits, in addition to what the hardware is.

Your `myfirst` driver is using case 1: `/dev/myfirst` as a shortcut for `/dev/myfirst/0` so the Chapter 7 prose still resolves. That is the shape of a typical beginner use.

8.7.6 Alias Lifetimes and Destruction Order

A cdev that is registered as an alias has the `SI_ALIAS` flag set and is linked into the primary cdev's `si_children` list with the `si_parent` back-pointer. This means the kernel knows the relationship and will do the right thing even if you tear the cdev down in a slightly wrong order. It does not mean you can ignore the order; it means destruction is more forgiving than teardown of general kernel objects.

In practice, the rule you should follow in your detach path is: **destroy the alias first, then the primary**. The example drivers in the companion tree do this, and the reason is simple readability. Any other order makes your code harder to reason about, and reviewers will flag it.

If a driver omits the `destroy_dev` call on the alias entirely, the primary's destruction will unwind the alias automatically when the primary goes away; that is what `destroy_dev1` does when it walks `si_children`. But leaving that work to the destructor is wasteful because the primary is holding a reference that keeps it alive longer than needed, and because the operator sees the alias disappear "later" rather than cleanly at unload time. Just destroy both.

8.7.7 When Aliases Start to Smell

A few patterns with aliases are mild code smells worth naming:

- **Chains of aliases.** Aliases of aliases are legal but almost always mean the driver is trying to paper over a naming decision that should have been revisited. If you find yourself wanting to alias an alias, stop and rename the primary.
- **Too many aliases.** One or two is routine. Five or more suggests the driver is not sure what it wants to be called. Revisit the naming.
- **Aliases with wildly different modes.** Two cdevs that point at the same handler set but expose radically different permission modes are indistinguishable from a trap. Make the permissions consistent, or use two separate primaries with two separate `cdevsw` values that enforce different policies in code.

None of these are errors. They are signals that the design is drifting. Notice them early and the driver stays readable; ignore them and the driver becomes a thing reviewers dread.

8.8 Per-Open State with `devfs_set_cdevpriv`

Now we come to the piece of the chapter that prepares the ground for Chapter 9. Your Chapter 7 driver enforced **exclusive open** by setting a flag in the `softc`. That works, but it is the coarsest possible policy. Many real devices

allow several openers and want to keep a small amount of bookkeeping **per file descriptor**, not per device. Think of a log stream, a status feed, or any node where different consumers want their own read positions.

FreeBSD offers three related routines for this, declared in `/usr/src/sys/sys/conf.h` and implemented in `/usr/src/sys/fs/devfs/devfs_vnops.c`:

```
int  devfs_set_cdevpriv(void *priv, d_priv_dtor_t *dtr);
int  devfs_get_cdevpriv(void **datap);
void devfs_clear_cdevpriv(void);
```

The model is simple and pleasant to use:

1. Inside your `d_open` handler, allocate a small per-open structure and call `devfs_set_cdevpriv(priv, dtor)`. The kernel attaches `priv` to the current file descriptor and remembers `dtor` as the function to call when that descriptor eventually closes.
2. In `d_read`, `d_write`, or any other handler, call `devfs_get_cdevpriv(&priv)` to retrieve the pointer.
3. When the process calls `close(2)`, or exits, or otherwise drops its last reference to the descriptor, `devfs` calls your destructor with `priv`. You free whatever you allocated.

You do not need to worry about the order of cleanup with respect to your own `d_close` handler. `Devfs` handles it. The important invariant is that your destructor will be called exactly once per successful `devfs_set_cdevpriv`.

A real example from `/usr/src/sys/net/bpf.c` looks like this:

```
d = malloc(sizeof(*d), M_BPF, M_WAITOK | M_ZERO);
error = devfs_set_cdevpriv(d, bpf_dtor);
if (error != 0) {
    free(d, M_BPF);
    return (error);
}
```

That is essentially the whole pattern. `BPF` allocates a per-open descriptor, registers it, and if the registration fails, frees the allocation and returns the error. The destructor `bpf_dtor` cleans up when the descriptor dies. You will do the same thing for `myfirst`, with a much smaller per-open structure.

8.8.1 A Minimal Per-Open Counter for `myfirst`

You will add one small structure and one destructor. Nothing else in the driver changes shape.

```
struct myfirst_fh {
    struct myfirst_softc *sc;    /* back-pointer to the owning softc */
    uint64_t             reads; /* bytes this descriptor has read */
    uint64_t             writes; /* bytes this descriptor has written */
};
```

```
static void
myfirst_fh_dtor(void *data)
{
    struct myfirst_fh *fh = data;
    struct myfirst_softc *sc = fh->sc;

    mtx_lock(&sc->mtx);
    sc->active_fhs--;
    mtx_unlock(&sc->mtx);

    device_printf(sc->dev, "per-open dtor fh=%p reads=%lu writes=%lu\n",
        fh, (unsigned long)fh->reads, (unsigned long)fh->writes);

    free(fh, M_DEVBUF);
}
```

The destructor does three things worth noticing. It decrements `active_fhs` under the same mutex that guards the other `softc` counters, so the count stays consistent with what `d_open` saw when it opened the descriptor. It logs a line that matches the shape of the `open via ...` message, so every `open` in `dmesg` has a visibly paired destructor. And it frees the allocation last, after everything that might need to read from `fh` has already run.

In your `d_open`, allocate one of these and register it:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc;
    struct myfirst_fh *fh;
    int error;

    sc = dev->si_drv1;
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    fh = malloc(sizeof(*fh), M_DEVBUF, M_WAITOK | M_ZERO);
    fh->sc = sc;

    error = devfs_set_cdevpriv(fh, myfirst_fh_dtor);
    if (error != 0) {
        free(fh, M_DEVBUF);
        return (error);
    }

    mtx_lock(&sc->mtx);
    sc->open_count++;
}
```

```
    sc->active_fhs++;
    mtx_unlock(&sc->mtx);

    device_printf(sc->dev, "open via %s fh=%p (active=%d)\n",
        devtoname(dev), fh, sc->active_fhs);
    return (0);
}
```

Notice two things. First, the exclusive-open check from Chapter 7 is gone. With per-open state in place, there is no reason to refuse a second opener. If you do want exclusivity later, you can still add it back in; it is a separate decision. Second, the destructor will take care of the free. Your `d_close` does not need to touch `fh` at all.

In a handler that runs later, such as `d_read`, you retrieve the per-open structure:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_fh *fh;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);

    /* Real read logic arrives in Chapter 9. For now, report EOF
     * and leave the counter untouched so userland tests can observe
     * that the descriptor owns its own state.
     */
    (void)fh;
    return (0);
}
```

The `(void)fh` silences the “unused variable” warning until Chapter 9 gives it work to do. That is fine. What matters for now is that your driver has a clean, working, cleanly destroyed per-file structure. From userland you can confirm the wiring by opening the device from two processes and watching the device-printf messages come through with two different `fh=` pointers.

8.8.2 What the Destructor Guarantees

Because the destructor does most of the work, it is worth being precise about when it runs and what state the world is in at that moment. Reading `devfs_destroy_cdevpriv` in `/usr/src/sys/fs/devfs/devfs_vnops.c` confirms the details.

- The destructor runs **exactly once per successful `devfs_set_cdevpriv` call**. If the function returned

EBUSY because the descriptor already had private data, the destructor for *your* data is never invoked; you must free the allocation yourself, as the example code does.

- The destructor runs **when the file descriptor is released**, not when your `d_close` is called. For an ordinary `close(2)`, the two moments are close together. For a process that exits while holding the descriptor, the descriptor is released as part of exit teardown; the destructor still runs. For a descriptor shared through `fork(2)` or passed through a UNIX-domain socket, the destructor runs only when the last reference drops.
- The destructor runs with no kernel lock held on your behalf. If your destructor touches softc state, take whatever lock the softc uses, just as the stage 2 example does when decrementing `active_fhs`.
- The destructor must not block for long. It is not a sleep-forever context, but it is also not an interrupt handler. Treat it like an ordinary kernel function and keep it short.

8.8.3 When `devfs_set_cdevpriv` Returns EBUSY

`devfs_set_cdevpriv` can fail in exactly one interesting way: the descriptor already has private data associated with it. That happens when something, typically your own code in a previous call, has already set a `cdevpriv` and you are trying to set another. The clean fix is to do the set once, early, and then read it back with `devfs_get_cdevpriv` wherever you need it.

Two cautions follow from this. The first is: do not call `devfs_set_cdevpriv` twice from the same open. The second is: when the call fails, free whatever you allocated before trying to set it. The example `myfirst_open` in this chapter follows both rules. When you port the pattern to your own driver, keep them in view.

8.8.4 When Not to Use `devfs_set_cdevpriv`

Per-open state is not the right home for everything. Keep device-wide state in the softc, reachable through `si_drv1`. Keep per-open state in the `cdevpriv` structure, reachable through `devfs_get_cdevpriv`. Mixing the two is the quickest way to write a driver that works in single-opener tests and falls apart when two processes show up at once.

`devfs_clear_cdevpriv(9)` exists, and you may see it in third-party code, but for most drivers the automatic cleanup through the destructor is sufficient. Reach for `devfs_clear_cdevpriv` only when you have a concrete reason, for instance a driver that can cleanly detach per-open state early in response to an `ioctl(2)`. If you are not sure you need it, you do not.

8.8.5 Inside `devfs_set_cdevpriv`: How the Machinery Works

The two functions you call look almost trivial from the outside. The machinery they drive is worth looking at once, because knowing the shape of it makes every edge case easier to reason about.

From `/usr/src/sys/fs/devfs/devfs_vnops.c`:

```
int
devfs_set_cdevpriv(void *priv, d_priv_dtor_t *priv_dtr)
{
    struct file *fp;
    struct cdev_priv *cdp;
```

```

    struct cdev_privdata *p;
    int error;

    fp = curthread->td_fpop;
    if (fp == NULL)
        return (ENOENT);
    cdp = cdev2priv((struct cdev *)fp->f_data);
    p = malloc(sizeof(struct cdev_privdata), M_CDEVpdata, M_WAITOK);
    p->cdpd_data = priv;
    p->cdpd_dtr = priv_dtr;
    p->cdpd_fp = fp;
    mtx_lock(&cdevpriv_mtx);
    if (fp->f_cdevpriv == NULL) {
        LIST_INSERT_HEAD(&cdp->cdp_fdpriv, p, cdpd_list);
        fp->f_cdevpriv = p;
        mtx_unlock(&cdevpriv_mtx);
        error = 0;
    } else {
        mtx_unlock(&cdevpriv_mtx);
        free(p, M_CDEVpdata);
        error = EBUSY;
    }
    return (error);
}

```

A short walk through the important bits:

- `curthread->td_fpop` is the file pointer for the current dispatch. `devfs` sets this up before it calls into your `d_open` and unsets it afterward. If you called `devfs_set_cdevpriv` from a context where no dispatch is active, `fp` would be `NULL` and the function would return `ENOENT`. In practice this only happens if you try to call it from the wrong context, for instance from a timer callback that is not bound to a file.
- A small record, `struct cdev_privdata`, is allocated from a dedicated malloc bucket `M_CDEVpdata`. It carries three fields: your pointer, your destructor, and a back-pointer to the `struct file`.
- Two threads entering this function at the same time for the same descriptor would be a disaster, so a single mutex `cdevpriv_mtx` guards the critical section. The check for `fp->f_cdevpriv == NULL` is what prevents double-registration: if a record is already attached, the new record is freed and `EBUSY` comes back.
- On success the record is inserted onto two lists: the descriptor's own pointer `fp->f_cdevpriv`, and the `cdev`'s list of all its descriptor-private records `cdp->cdp_fdpriv`. The first makes `devfs_get_cdevpriv` a one-pointer lookup. The second makes it possible for `devfs` to iterate every live record when the `cdev` is destroyed.

The destructor path is equally small:

```
void
devfs_destroy_cdevpriv(struct cdev_privdata *p)
{
    mtx_assert(&cdevpriv_mtx, MA_OWNED);
    KASSERT(p->cdpd_fp->f_cdevpriv == p,
        ("devfs_destroy_cdevpriv %p != %p",
            p->cdpd_fp->f_cdevpriv, p));
    p->cdpd_fp->f_cdevpriv = NULL;
    LIST_REMOVE(p, cdpd_list);
    mtx_unlock(&cdevpriv_mtx);
    (p->cdpd_dtr)(p->cdpd_data);
    free(p, M_CDEVPDATA);
}
```

Two things to notice. First, the destructor is called **with the mutex dropped**, so your destructor can take locks of its own without a risk of a deadlock against `cdevpriv_mtx`. Second, the record itself is freed immediately after your destructor returns, so a stale pointer into it would be a use-after-free. If your destructor stashes the pointer somewhere else, stash a copy of the data, not the record.

8.8.6 Interaction with fork, dup, and SCM_RIGHTS

File descriptors in UNIX have three common ways of multiplying: `dup(2)`, `fork(2)`, and passing through a UNIX-domain socket with `SCM_RIGHTS`. Each produces additional references to the same `struct file`. `devfs`'s `cdevpriv` machinery behaves consistently across all three.

After `dup(2)` or `fork(2)`, the new file descriptor refers to the **same** `struct file` as the original. The `cdevpriv` record is keyed on the `struct file`, not the descriptor number, so both descriptors share the record. Your destructor fires exactly once, when the last descriptor pointing at that file is released. That last-release can be an explicit `close(2)`, an implicit `exit(3)` that closes everything, or even a crash that terminates the process.

Passing the descriptor through `SCM_RIGHTS` is the same story from the `cdevpriv`'s point of view. The receiving process gets a new descriptor that points at the same `struct file`. The record stays attached; the destructor still fires only when the last reference drops, which may now be in the process on the other end of the socket.

This is usually exactly what you want, because it matches the user's mental model. One per-open state per conceptual open. If you ever need a different model, for instance a model where every `dup(2)`'d descriptor should have its own state, the solution is to set `D_TRACKCLOSE` on your `cdevsw` and allocate per-descriptor state inside `d_open` itself without using `devfs_set_cdevpriv`. That is unusual; ordinary drivers do not need it.

8.8.7 A Tour of Real Uses in the Tree

To cement the pattern, a short tour of three drivers that use `cdevpriv` in recognisable ways. You do not need to understand what each driver does as a whole; focus only on the device-file shape.

`/usr/src/sys/net/bpf.c` is the canonical example. Its `bpfopen` allocates a per-open descriptor, calls `devfs_set_cdevpriv(d, bpf_dtor)`, and sets up a small pile of counters and state. The destructor `bpf_dtor` tears down all of it: it detaches the descriptor from its BPF interface, frees counters, drains a select list, and drops a reference. The pattern is exactly the one this chapter has described, plus a lot of BPF-specific machinery that Part 6 will revisit.

`/usr/src/sys/fs/fuse/fuse_device.c` takes the same pattern and layers FUSE-specific state on top. The open allocates a struct `fuse_data`, registers it with `devfs_set_cdevpriv`, and every subsequent handler retrieves it with `devfs_get_cdevpriv`. The destructor tears down the FUSE session.

`/usr/src/sys/opencrypto/crypto_dev.c` uses `cdevpriv` for per-open crypto session state. Each open gets its own bookkeeping, and the destructor cleans it up.

These three drivers have almost nothing in common at the subsystem level: one is about packet capture, one about userland filesystems, one about hardware crypto offload. What they share is the device-file shape. The same three steps, in the same order, for the same reasons.

8.8.8 Patterns for What to Put in the Per-Open Structure

Now that you know the mechanics, the design question is what fields your per-open structure should hold. A few patterns recur across real drivers.

Counters. Bytes read, bytes written, calls made, errors reported. Each descriptor owns its own counter. `myfirst` in stage 2 already does this with `reads` and `writes`.

Read positions. If your driver exposes a seekable stream of bytes, the current offset belongs in the per-open structure, not in the `softc`. Two readers at different offsets are the reason.

Subscription handles. If the descriptor is reading events and a `poll` or `kqueue` needs to know whether there are more events pending for this specific descriptor, the subscription record belongs here. Chapter 10 uses this pattern.

Filter state. Drivers like BPF let each descriptor install a filter program. That program's compiled form is per-descriptor. Again, belongs in the per-open structure.

Reservations or tickets. If the driver hands out scarce resources (a hardware slot, a DMA channel, a shared buffer range) and ties them to an open, the record goes into per-open state. When the descriptor closes, the destructor frees the reservation automatically.

Credentials snapshots. Some drivers want to remember who opened the descriptor at the time of open, separately from whoever is currently doing a read or write on it. Capturing a snapshot of `td->td_ucred` at open time is a common pattern. Credentials are reference-counted (`crhold/crfree`), and the destructor is the right place to drop the reference.

Not every driver needs all of these. The list is a menu, not a checklist. When you design a driver, walk through it and ask “what information belongs to this specific open of the node?” The answers go into the per-open structure.

8.8.9 A Warning Against Cross-Referencing From the softc to Per-Open Records

A temptation that crops up with per-open state is for the softc to carry pointers back to per-open records, so that broadcasting an event to every descriptor becomes a simple list walk. The temptation is understandable; the implementation is full of edge cases. Two threads racing to close the last descriptor while a third is trying to broadcast is the scenario that breaks the straightforward code, and fixing it tends to require more locks than you want to add.

FreeBSD's answer is `devfs_foreach_cdevpriv(9)`, a callback-based iterator that walks the per-open records attached to a given cdev under the right lock. If you ever need the pattern, use that function and give it a callback. Do not maintain your own lists.

We will not use `devfs_foreach_cdevpriv` in Chapter 8. It is named here because if you scan the FreeBSD tree for `cdevpriv` you will find it, and you should recognise it as the safe alternative to reinventing the iteration yourself.

8.9 Destroying cdevs Safely

The act of putting a cdev into `devfs` is routine. Taking it out again is the part that needs thought. Chapter 7 taught you `destroy_dev(9)`, and for the simple path of a well-behaved driver it is all you need. Real drivers sometimes need more. This section walks through the family of destruction helpers, explains what they guarantee, and shows where each one is the right tool.

8.9.1 The Draining Model

Let us start from the question destruction has to answer: “when is it safe to free the softc and unload the module?” The naive answer, “after `destroy_dev` returns”, is almost right. The careful answer is, “after `destroy_dev` returns **and** no more kernel threads can be in any of my handlers for this cdev.”

The struct `cdev` counters you met earlier are how the kernel tracks this. `si_threadcount` increments every time `devfs` enters one of your handlers on behalf of a user syscall, and decrements every time the handler returns. `destroy_dev1`, which is the internal function that `destroy_dev` calls, watches that counter. Here is the relevant excerpt from `/usr/src/sys/kern/kern_conf.c`:

```
while (csw != NULL && csw->d_purge != NULL && dev->si_threadcount) {
    csw->d_purge(dev);
    mtx_unlock(&cdp->cdp_threadlock);
    msleep(csw, &devmtx, PRIBIO, "devprg", hz/10);
    mtx_lock(&cdp->cdp_threadlock);
    if (dev->si_threadcount)
        printf("Still %lu threads in %s\n",
            dev->si_threadcount, devtoname(dev));
}
while (dev->si_threadcount != 0) {
    /* Use unique dummy wait ident */
    mtx_unlock(&cdp->cdp_threadlock);
```

```
msleep(&csw, &devmtx, PRIBIO, "devdrn", hz / 10);  
mtx_lock(&cdp->cdp_threadlock);  
}
```

Two loops. The first loop calls `d_purge` if the driver provides one; the second simply waits. In both cases the result is the same: `destroy_dev` does not return until `si_threadcount` is zero. This is the **draining** behavior that makes destruction safe. When the call returns, no thread is inside any handler, and no new thread can enter one, because `si_devsw` has been cleared.

What this means for your code: **after `destroy_dev(sc->cdev)` returns, nothing in user space can trigger a call into your handlers with this `cdev`.** You are free to destroy softc members that those handlers depend on.

8.9.2 The Four Destruction Functions

FreeBSD exposes four related functions for `cdev` destruction. Each handles a slightly different case.

`destroy_dev(struct cdev *dev)`

The ordinary case. Synchronous: waits for in-flight handlers to finish, then unlinks the `cdev` from `devfs` and releases the kernel's primary reference. Used in Chapter 7 and in every single-threaded destruction path in this book. Requires the caller to be sleepable and to not hold any lock that the in-flight handlers might need.

`destroy_dev_sched(struct cdev *dev)`

A deferred form. Schedules the destruction on a taskqueue and returns immediately. Useful when the calling context cannot sleep, for instance from inside a callback that runs under a lock. The actual destruction happens asynchronously, and the caller must not assume it has completed when the function returns.

`destroy_dev_sched_cb(struct cdev *dev, void (*cb)(void *), void *arg)`

The same deferred form, but with a callback that runs after destruction completes. Use when you need to do follow-up work (free the softc, for example) once you know the `cdev` is truly gone.

`destroy_dev_drain(struct cdevsw *csw)`

The sweep. Waits for **every** `cdev` registered against the given `cdevsw` to be fully destroyed, including those scheduled through the deferred forms. Used when you are about to unregister or free the `cdevsw` itself, for instance inside the `MOD_UNLOAD` handler of a module that ships multiple drivers.

8.9.3 The Race That `destroy_dev_drain` Exists to Prevent

Draining is a subtle point, and the best way to explain it is with the scenario it fixes.

Suppose your module exports a `cdevsw`. In `MOD_UNLOAD`, your code calls `destroy_dev(sc->cdev)` and then returns success. The kernel proceeds to tear the module down. Everything looks fine, until a moment later when a deferred task scheduled earlier through `destroy_dev_sched` finally runs. That task dereferences the `struct cdevsw` as part of its cleanup. The `cdevsw` has been unmapped along with the module. The kernel panics.

The race is narrow but real. `destroy_dev_drain` is the fix: call it on your `cdevsw` after you are confident no new `cdevs` will be created, and it will not return until every `cdev` registered against that `cdevsw` has completed its destruction. Only then is it safe to let the module go.

If your driver creates one `cdev` from `attach`, destroys it from `detach`, and never uses the deferred forms, you do not need `destroy_dev_drain`. `myfirst` does not need it. Real drivers that manage cloning `cdevs` or that destroy `cdevs` from event handlers usually do.

8.9.4 The Order of Operations in detach

Given all this, the right order of operations in a `detach` handler for a driver with a primary `cdev`, an alias, and per-open state is:

1. Refuse to detach if any descriptors are still open. Return `EBUSY`. Your `active_fhs` counter is the right thing to check.
2. Destroy the alias `cdev` with `destroy_dev(sc->cdev_alias)`. This unlinks the alias from `devfs` and drains any in-flight calls against it.
3. Destroy the primary `cdev` with `destroy_dev(sc->cdev)`. Same as above for the primary.
4. Tear down the `sysctl` tree with `sysctl_ctx_free(9)`.
5. Destroy the mutex with `mtx_destroy(9)`.
6. Clear the `is_attached` flag in case anything still reads it.
7. Return zero.

Notice that steps 2 and 3 serve two purposes each. They remove the nodes from `devfs` so no new opens can arrive, and they drain in-flight calls so no handler is still running when step 4 tries to free state that a handler would read.

The pattern is simple. The only way to get it wrong is to free something before the draining `destroy_dev` has finished with it. Stick to this order and you will be safe.

8.9.5 Unload Under Load

A healthy intuition-building exercise is to reason about what happens when `kldunload` arrives while a userland program is inside a `read(2)` on your device.

Walk through the timeline:

- The kernel begins unloading the module. It calls your `MOD_UNLOAD` handler, which ultimately calls `device_delete_child` on your Newbus device, which invokes your `detach`.
- Your `detach` reaches `destroy_dev(sc->cdev)`. This call is synchronous and will wait for in-flight handlers to finish.
- The userland `read(2)` is currently executing your `d_read`. `si_threadcount` is 1.
- `destroy_dev` sleeps, watching `si_threadcount`.
- Your `d_read` returns. `si_threadcount` drops to 0.
- `destroy_dev` returns. Your `detach` continues with `sysctl` and mutex teardown.
- The userland `read(2)` has already returned its bytes to user space. The descriptor is still open.
- A subsequent `read(2)` on the same descriptor from the same process now fails cleanly, because the `cdev` is gone.

This is what “destroy the node first, then tear down its dependencies” buys you. The window where userland could observe inconsistent state is made vanishingly small by the kernel’s draining behavior.

8.9.6 When `destroy_dev` Refuses to Proceed Quickly

Sometimes `destroy_dev` will sit in its drain loop for longer than you expect. There are a few common reasons.

- A handler is blocked in a sleep that no wakeup is going to release. For instance, a `d_read` that calls `msleep(9)` on a condition variable that nobody ever signals. In that case your driver has a logic bug. Destruction is doing exactly the right thing by refusing to proceed; your job is to wake the blocked thread, either by writing a `d_purge` handler that nudges it or by ensuring the control flow that eventually wakes it is still functional during unload.
- A userland program is stuck in a `ioctl` that is waiting on hardware. The fix is usually the same: a `d_purge` handler that tells the blocked thread to abandon the wait.
- Two destructions racing, each draining the other. That is the case `destroy_dev_drain` exists for.

If you watch `dmesg` during a stuck unload, you will see the “Still N threads in foo” message printed by the loop above. That is your cue: find out what those threads are doing and convince them to return.

8.9.7 A Minimal `d_purge` Example

For completeness, here is what a simple `d_purge` looks like. Not every driver needs one; it is worth showing so you recognise the shape when you read real code:

```
static void
myfirst_purge(struct cdev *dev)
{
    struct myfirst_softc *sc = dev->si_drv1;

    mtx_lock(&sc->mtx);
    sc->shutting_down = 1;
    wakeup(&sc->rx_queue);    /* nudge any thread waiting on us */
    mtx_unlock(&sc->mtx);
}

static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_purge   = myfirst_purge,
    /* ... */
};
```

The function is called from inside `destroy_dev1` while `si_threadcount` is still non-zero. Its job is to poke any blocked kernel thread inside your handlers so that the thread observes the shutdown and returns. For drivers that do only blocking reads, setting a shutdown flag and issuing a `wakeup(9)` is usually all that is needed. Chapter 10 revisits this when blocking I/O becomes a first-class topic.

8.9.8 Summary

Destruction of a cdev is a rehearsed dance between three participants: your driver, devfs, and any userland threads currently mid-call. The guarantees are strong if you use the right tools:

- Use `destroy_dev` in ordinary paths. Let it drain.
- Use the deferred forms when you cannot sleep or when you need a callback after destruction.
- Use `destroy_dev_drain` when you are about to free or unregister a cdevsw.
- Destroy the node before anything the node's handlers depend on.
- Provide a `d_purge` if your handlers can block indefinitely.

Beyond that, the detail is the kind of thing you look up when you need it. The shape is the part that matters, and the shape is simple.

8.10 Persistent Policy: `devfs.conf` and `devfs.rules`

Your driver fixes the **baseline** mode, owner, and group of each node. Persistent operator-side adjustments belong in `/etc/devfs.conf` and `/etc/devfs.rules`. Both files are standard parts of the FreeBSD base system, and both apply to every devfs mount on the host.

8.10.1 `devfs.conf`: one-time, per-path adjustments

`devfs.conf` is the simplest tool. Each line applies a one-shot adjustment when a matching device node appears. The format is documented in `devfs.conf(5)`. The common directives are `own`, `perm`, and `link`:

```
# /etc/devfs.conf
#
# Adjustments applied once when each node appears.

own      myfirst/0      root:operator
perm     myfirst/0      0660
link     myfirst/0      myfirst-primary
```

Those three lines say: every time `/dev/myfirst/0` shows up, chown it to `root:operator`, set its mode to `0660`, and create a symlink named `/dev/myfirst-primary` that points at it. Restart the devfs service to apply changes on a running system:

```
% sudo service devfs restart
```

`devfs.conf` is fine for small, stable lab setups. It is not a policy engine. If you need conditional rules or jail-specific filtering, reach for `devfs.rules`.

8.10.2 devfs.rules: rule-based, used by jails

`devfs.rules` describes named rulesets; each ruleset is a list of patterns and actions. A jail references a ruleset by name in its `jail.conf(5)`, and when the jail's own `devfs` mount comes up, the kernel walks the matching ruleset and filters the node set accordingly. The format is documented in `devfs(8)` and `devfs.rules(5)`.

A tiny example:

```
# /etc/devfs.rules

[myfirst_lab=10]
add path 'myfirst/*' unhide
add path 'myfirst/*' mode 0660 group operator
```

This defines a ruleset numbered 10, named `myfirst_lab`. It unhides any node under `myfirst/` (jails hide nodes by default), and then sets them group-readable and group-writable by operator. To use the ruleset, name it in `jail.conf`:

```
devfs_ruleset = 10;
```

We are not going to set up a jail in this chapter. The point here is recognition: when you see `devfs_ruleset` in a jail configuration or `service devfs restart` in operator documentation, you are looking at policy that sits on top of whatever your driver exposed, not inside it. Keep your driver honest at the baseline, and let these files shape what the operator allows.

8.10.3 The Full devfs.conf Syntax

`devfs.conf` has a small, stable grammar. Each line is a directive. Blank lines and lines that begin with `#` are ignored. A `#` anywhere on a line starts a comment to end-of-line. Only three directive keywords exist:

- **own path user[:group]**: change the ownership of `path` to `user`, and, if `:group` is given, to that group as well. The user and group can be names that exist in the password database or numeric ids.
- **perm path mode**: change the mode of `path` to the given octal mode. Leading zero is optional but conventional.
- **link path linkname**: create a symbolic link at `/dev/linkname` pointing at `/dev/path`.

Each directive operates on the node whose path is given relative to `/dev`. The path can name a device directly, or it can name a glob that matches a family of devices. Glob characters are `*`, `?`, and character classes in brackets.

The action is applied when the node first appears under `/dev`. For nodes that exist at boot, that means during the early `service devfs start` phase. For nodes that appear later, as when a driver module loads, the action is applied when the matching `cdev` is added to `devfs`.

The effect of `service devfs restart` on a running system is to re-run every directive in `/etc/devfs.conf` against whatever is currently under `/dev`. This is how you apply a newly-added directive to devices that already exist.

8.10.4 Reading the Example devfs.conf

The FreeBSD base system ships a commented-out example at `/etc/defaults/devfs.conf` (or equivalent path; the file is installed by the base system). The upstream source at `/usr/src/sbin/devfs/devfs.conf` is instructive:

```
# Commonly used by many ports
#link    cd0      cdrom
#link    cd0      dvd

# Allow a user in the wheel group to query the smb0 device
#perm    smb0     0660

# Allow members of group operator to cat things to the speaker
#own     speaker  root:operator
#perm    speaker  0660
```

The file is mostly comments, which is the expected state: FreeBSD installs with no `devfs.conf` directives active. Operators who need host-specific changes add them to `/etc/devfs.conf`. This chapter's Lab 8.4 adds entries for `myfirst/0`.

8.10.5 Worked Examples That Recur in Practice

Three `devfs.conf` patterns come up often. Each is worth showing once.

Granting a monitoring tool access to a status node. Suppose a driver exposes `/dev/something/status` as `root:wheel 0600`, and you want a local monitoring tool that runs as a non-root user to read it. The simplest answer is a dedicated group:

```
# /etc/devfs.conf
own     something/status      root:monitor
perm    something/status      0640
```

After service `devfs` restart, the node is readable by members of the `monitor` group. Create the group with `pw groupadd monitor` and add the relevant users.

Providing a stable, convenient name for a renumbered device. Suppose the driver used to create `/dev/old_name` and now creates `/dev/new_name/0`, and you have scripts that still reference the old path. A `link` directive preserves compatibility:

```
link    new_name/0          old_name
```

`/dev/old_name` becomes a symbolic link to `/dev/new_name/0`. The link carries no policy of its own; ownership and mode come from the target.

Widening a narrow default for a lab system. Suppose a driver defaults to `root:wheel 0600` and you want a lab machine where the local admin user can interact with the node without `sudo`. Rather than modifying the driver, give the local admin the operator group and widen the mode in `devfs.conf`:

```
own      myfirst/0      root:operator
perm     myfirst/0      0660
```

This is exactly the Lab 8.4 setup. It stays contained to the lab machine and leaves the driver's shipping default intact.

8.10.6 devfs.rules in Depth

`devfs.rules` is a different beast. Rather than applying one-shot directives to a path, it defines **named rulesets** that a `devfs` mount can reference. Each ruleset is a list of rules; each rule matches paths by pattern and applies actions.

The file lives at `/etc/devfs.rules` and the base system ships defaults at `/etc/defaults/devfs.rules`. The format is documented in `devfs.rules(5)` and `devfs(8)`.

A ruleset is introduced by a bracketed header:

```
[rulesetname=number]
```

`number` is a small integer, the way `devfs` identifies the ruleset internally. `rulesetname` is a human-readable tag for use in jail configuration. Rules following a header belong to that ruleset until the next header.

A rule begins with the `add` keyword and names a path pattern and an action. The common actions are:

- **unhide**: make matching nodes visible. Rulesets that derive from `devfsrules_hide_all` use this to whitelist a specific set of nodes.
- **hide**: make matching nodes invisible. Used to remove something from the default set.
- **group name**: change the group of matching nodes.
- **user name**: change the owner.
- **mode N**: change the mode to octal `N`.
- **include \$name**: include the rules from another ruleset named `$name`.

Include directives are how FreeBSD's shipping rulesets compose. The `devfsrules_jail` ruleset begins with `add include $devfsrules_hide_all` to establish a clean slate, then includes `devfsrules_unhide_basic` for the handful of nodes every reasonable program expects, then `devfsrules_unhide_login` for the PTYs and standard descriptors, then adds a few jail-specific paths on top.

8.10.7 Reading the Default Rulesets

The FreeBSD source ships `/etc/defaults/devfs.rules` (installed from `/usr/src/sbin/devfs/devfs.rules`). Reading it once gives you a model of how rules are layered.

```
[devfsrules_hide_all=1]
add hide
```

Ruleset 1 hides every node in devfs. It is the starting point for jail rulesets that need to whitelist.

```
[devfsrules_unhide_basic=2]
add path null unhide
add path zero unhide
add path crypto unhide
add path random unhide
add path urandom unhide
```

Ruleset 2 unhides the basic pseudo-devices every reasonable process expects.

```
[devfsrules_unhide_login=3]
add path 'ptyp*' unhide
add path 'ptyq*' unhide
/* ... many more PTY paths ... */
add path ptmx unhide
add path pts unhide
add path 'pts/*' unhide
add path fd unhide
add path 'fd/*' unhide
add path stdin unhide
add path stdout unhide
add path stderr unhide
```

Ruleset 3 unhides the TTY and file-descriptor infrastructure that logged-in users depend on.

```
[devfsrules_jail=4]
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
add include $devfsrules_unhide_login
add path fuse unhide
add path zfs unhide
```

Ruleset 4 composes the three previous rulesets and adds fuse and zfs. This is the default ruleset most jails use.

```
[devfsrules_jail_vnet=5]
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
```

```
add include $devfsrules_unhide_login
add include $devfsrules_jail
add path pf unhide
```

Ruleset 5 is ruleset 4 plus the packet-filter control node. Used by jails that need pf to be reachable.

Reading these carefully is a good investment. Every pattern you will need for your own rulesets is in one of them.

8.10.8 A Complete Jail Example End to End

To ground the theory, here is a complete example that a reader can apply on a lab system. It assumes you have built and loaded the Chapter 8 stage 2 driver and that `/dev/myfirst/0` exists on the host.

Step 1: define a ruleset in `/etc/devfs.rules`. Add to the end of the file:

```
[myfirst_jail=100]
add include $devfsrules_jail
add path 'myfirst' unhide
add path 'myfirst/*' unhide
add path 'myfirst/*' mode 0660 group operator
```

The ruleset is numbered 100 (any unused small integer works; 100 is safely above the shipped numbers). It includes the default jail ruleset so the jail still has `/dev/null`, `/dev/zero`, the PTYs, and everything else a normal jail needs. Then it unhides the `myfirst/` directory and the nodes inside it, and sets their mode and group.

Step 2: create a jail. A minimal `/etc/jail.conf` entry:

```
myfirstjail {
    path = "/jails/myfirstjail";
    host.hostname = "myfirstjail.example.com";
    mount.devfs;
    devfs_ruleset = 100;
    exec.start = "/bin/sh";
    exec.stop = "/bin/sh -c 'exit'";
    persist;
}
```

Create the jail root:

```
% sudo mkdir -p /jails/myfirstjail
% sudo bsdinstall jail /jails/myfirstjail
```

Replace `bsdinstall` with whatever jail-creation method fits your lab if you already have one.

Step 3: start the jail and inspect.

```
% sudo service devfs restart
% sudo service jail start myfirstjail
% sudo jexec myfirstjail ls -l /dev/myfirst
total 0
crw-rw----  1 root  operator  0x5a Apr 17 10:00 0
```

The node appears inside the jail with the ruleset-specified ownership and mode. If the ruleset did not unhide it, the jail would see no `myfirst` directory at all.

Step 4: prove it. Comment out the `add path 'myfirst/*' unhide` line in `/etc/devfs.rules`, run `sudo service devfs restart`, and re-enter the jail:

```
% sudo jexec myfirstjail ls -l /dev/myfirst
ls: /dev/myfirst: No such file or directory
```

The node is invisible to the jail. The host still sees it. The driver has not been reloaded. Policy in the file completely determines what the jail sees.

This end-to-end exercise is what Lab 8.7 walks through. The point of showing it once in prose is to establish the pattern: **rulesets shape what the jail sees, and the driver does nothing different regardless**. Your driver's job is to expose a sound baseline; the rulesets' job is to filter and adjust per environment.

8.10.9 Debugging Rule Mismatches

When `devfs` does not present a node the way you expect, there are a few tools for diagnosing why.

- **devfs rule show** displays the rulesets currently loaded into the kernel. You can compare them against the file.
- **devfs rule showsets** lists the ruleset numbers currently active.
- **devfs rule ruleset NUM** followed by **devfs rule show** displays rules inside a specific ruleset.
- **service devfs restart** reapplies `/etc/devfs.conf` and reloads all rulesets from `/etc/devfs.rules`. Use this any time you change either file.

Common failure modes:

- A rule uses a path pattern that does not match. Single-quote your glob patterns and remember that `my-first/*` is different from `myfirst` (the directory itself is not covered by the `/*` pattern; you need both rules).
- A ruleset is referenced by a jail but not present in `/etc/devfs.rules`. The jail's `/dev` ends up with no matching rules applied, which often means a hidden-by-default filesystem.
- A ruleset is present but never restarted. After you add a rule, run `service devfs restart` to actually push it into the kernel.

8.10.10 Runtime Manipulation With `devfs(8)`

`devfs(8)` is the low-level administrative tool that `service devfs restart` uses under the hood. You can invoke it directly to apply changes without rebooting or restarting the whole `devfs` subsystem.

```
% sudo devfs rule -s 100 add path 'myfirst/*' unhide
```

This adds a rule to ruleset 100 in the running kernel, without touching the file. Useful for experimentation. Rules added this way do not persist across reboots.

```
% sudo devfs rule showsets
0 1 2 3 4 5 100
```

Shows which ruleset numbers are currently loaded.

```
% sudo devfs rule -s 100 del 1
```

Deletes rule number 1 in ruleset 100.

You will rarely need to touch `devfs(8)` directly in production; the file-based workflow and `service devfs restart` are enough for most needs. During the debugging of a stubborn ruleset, the interactive command is invaluable.

8.10.11 A Caveat About `devfs.conf` Timing

One pattern that bites newcomers is this: you add a `devfs.conf` line, reboot, and discover the line did not take effect. Usually the reason is ordering. `service devfs start` runs early in the boot sequence, before some modules load. Nodes created later by modules loaded later will not be matched by the already-run directives unless you restart the `devfs` service after the module loads.

In practice this means:

1. If your driver is compiled into the kernel, its nodes exist at the time `devfs.conf` is applied. The directives take effect on first boot.
2. If your driver is loaded from `/boot/loader.conf`, its nodes exist before userland starts, so directives are applied normally.
3. If your driver is loaded later (from `rc.d` or by hand), you must run `service devfs restart` after the load so the directives apply to the newly-appeared nodes.

For labs, the last case is the common one. Load the driver, run `service devfs restart`, then verify.

8.11 Exercising Your Device From Userland

Shell tools will get you surprisingly far. You already know these from Chapter 7:

```
% ls -l /dev/myfirst/0
% sudo cat </dev/myfirst/0
% echo "hello" | sudo tee /dev/myfirst/0 >/dev/null
```

They remain useful, especially `ls -l` for confirming that a permission change took effect. But at some point you will want to open the device from a program you wrote yourself, so you can control timing, measure behavior, and simulate realistic user code. The companion files under `examples/part-02/ch08-working-with-device-files/userland/` contain a small probe program that does exactly that. The relevant pieces look like this:

```
#include <err.h>
#include <fcntl.h>
#include <stdio.h>
#include <unistd.h>

int
main(int argc, char **argv)
{
    const char *path = (argc > 1) ? argv[1] : "/dev/myfirst/0";
    char buf[64];
    ssize_t n;
    int fd;

    fd = open(path, O_RDWR);
    if (fd < 0)
        err(1, "open %s", path);

    n = read(fd, buf, sizeof(buf));
    if (n < 0)
        err(1, "read %s", path);

    printf("read %zd bytes from %s\n", n, path);

    if (close(fd) != 0)
        err(1, "close %s", path);

    return (0);
}
```

Two things to notice. First, there is nothing device-specific in the code. It is the same `open`, `read`, `close` you would write against a regular file. That is the UNIX tradition paying off. Second, compiling and running this program gives you a repeatable way to drive your driver without shell quoting to worry about. In Chapter 9 you will extend it to write data, measure byte counts, and compare per-open state across descriptors.

Running it once against your Stage 2 driver should produce something like:

```
% cc -Wall -Werror -o probe_myfirst probe_myfirst.c
% sudo ./probe_myfirst
read 0 bytes from /dev/myfirst/0
```

Zero bytes, because `d_read` still returns EOF. The number is boring; the fact that the whole path worked is not.

8.11.1 A Second Probe: Inspecting With `stat(2)`

Reading the metadata of a device node is just as instructive as opening it. FreeBSD's `stat(1)` command and the `stat(2)` system call both report what devfs is advertising. A tiny program built around `stat(2)` makes it easy to compare a primary node and an alias and confirm that they resolve to the same cdev.

The companion source `examples/part-02/ch08-working-with-device-files/userland/stat_myfirst.c` looks like this:

```
#include <err.h>
#include <stdio.h>
#include <sys/stat.h>
#include <sys/types.h>

int
main(int argc, char **argv)
{
    struct stat sb;
    int i;

    if (argc < 2) {
        fprintf(stderr, "usage: %s path [path ...]\n", argv[0]);
        return (1);
    }

    for (i = 1; i < argc; i++) {
        if (stat(argv[i], &sb) != 0)
            err(1, "stat %s", argv[i]);
        printf("%s: mode=%06o uid=%u gid=%u rdev=%#jx\n",
            argv[i],
            (unsigned)(sb.st_mode & 07777),
            (unsigned)sb.st_uid,
            (unsigned)sb.st_gid,
            (uintmax_t)sb.st_rdev);
    }
    return (0);
}
```

Running it against both the primary node and the alias should show the same rdev on both paths:

```
% sudo ./stat_myfirst /dev/myfirst/0 /dev/myfirst
/dev/myfirst/0: mode=020660 uid=0 gid=5 rdev=0x5a
/dev/myfirst:   mode=020660 uid=0 gid=5 rdev=0x5a
```

rdev is the identifier devfs uses to tag the node, and it is the simplest proof that two names really refer to the same underlying cdev. The 020000 high bits in the mode say “character special file”; the low bits are the familiar 0660.

8.11.2 A Third Probe: Parallel Opens

The stage 2 driver lets multiple processes hold the device open simultaneously, and each gets its own per-open structure. A good way to confirm the wiring is to run a program that opens the node several times from within the same process, holds every descriptor for a moment, and reports what happened.

The companion source `examples/part-02/ch08-working-with-device-files/userland/parallel_probe.c` does exactly that:

```
#include <err.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

#define MAX_FDS 8

int
main(int argc, char **argv)
{
    const char *path = (argc > 1) ? argv[1] : "/dev/myfirst/0";
    int fds[MAX_FDS];
    int i, n;

    n = (argc > 2) ? atoi(argv[2]) : 4;
    if (n < 1 || n > MAX_FDS)
        errx(1, "count must be 1..%d", MAX_FDS);

    for (i = 0; i < n; i++) {
        fds[i] = open(path, O_RDWR);
        if (fds[i] < 0)
            err(1, "open %s (fd %d of %d)", path, i + 1, n);
        printf("opened %s as fd %d\n", path, fds[i]);
    }
}
```

```

    printf("holding %d descriptors; press enter to close\n", n);
    (void) getchar();

    for (i = 0; i < n; i++) {
        if (close(fds[i]) != 0)
            warn("close fd %d", fds[i]);
    }
    return (0);
}

```

Run it and watch dmesg at the same time:

```

% sudo ./parallel_probe /dev/myfirst/0 4
opened /dev/myfirst/0 as fd 3
opened /dev/myfirst/0 as fd 4
opened /dev/myfirst/0 as fd 5
opened /dev/myfirst/0 as fd 6
holding 4 descriptors; press enter to close

```

You should see four open via `myfirst/0 fh=<ptr> (active=N)` lines in dmesg, each with a different pointer. When you press Enter, four per-open dtor `fh=<ptr>` lines follow as each descriptor closes. This is your strongest evidence that per-open state really is per-descriptor.

8.11.3 A Fourth Probe: Stress Testing

A short stress test exercises the destructor path repeatedly and catches leaks that a single-open test would miss. `examples/part-02/ch08-working-with-device-files/userland/stress_probe.c` loops open-and-close:

```

#include <err.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char **argv)
{
    const char *path = (argc > 1) ? argv[1] : "/dev/myfirst/0";
    int iters = (argc > 2) ? atoi(argv[2]) : 1000;
    int i, fd;

    for (i = 0; i < iters; i++) {

```

```

        fd = open(path, O_RDWR);
        if (fd < 0)
            err(1, "open (iter %d)", i);
        if (close(fd) != 0)
            err(1, "close (iter %d)", i);
    }
    printf("%d iterations completed\n", iters);
    return (0);
}

```

Run it against the loaded driver and then verify that the active-open counter returns to zero:

```

% sudo ./stress_probe /dev/myfirst/0 10000
10000 iterations completed
% sysctl dev.myfirst.0.stats.active_fhs
dev.myfirst.0.stats.active_fhs: 0
% sysctl dev.myfirst.0.stats.open_count
dev.myfirst.0.stats.open_count: 10000

```

If `active_fhs` settles above zero after the program exits, your destructor is failing to run on some path and you have a real leak to investigate. If `open_count` matches the iteration count, every open was seen. The stress probe is a blunt instrument but it is fast and catches most common mistakes.

8.11.4 Observing devd Events

`devd(8)` is the userland daemon that reacts to device events. Each time a `cdev` appears or disappears, `devd` receives a notification and can run a configured action. You do not need to configure `devd` to see its events; you can subscribe to the event stream directly through the `/var/run/devd.pipe` socket.

A short helper, `examples/part-02/ch08-working-with-device-files/userland/devd_watch.sh`, wires this up:

```

#!/bin/sh
# Print devd events related to the myfirst driver.
nc -U /var/run/devd.segpacket.pipe | grep -i 'myfirst'

```

Run this in one terminal, then load and unload the driver in another:

```

% sudo sh ./devd_watch.sh &
% sudo kldload ./myfirst.ko
!system=DEVFS subsystem=CDEV type=CREATE cdev=myfirst/0
% sudo kldunload myfirst
!system=DEVFS subsystem=CDEV type=DESTROY cdev=myfirst/0

```

You should see CREATE and DESTROY notifications with the cdev name. This is how operators build automatic reactions: a devd rule in `/etc/devd.conf` can match on these events and run a script in response. Challenge 5 at the end of this chapter asks you to write a minimal `devd.conf` rule that logs `myfirst` events.

8.11.5 Handling errno From Device Operations

A good userland probe does more than just call `open` and `exit`. It distinguishes between the different `errno` values the kernel returns and takes sensible action on each. The probes in this chapter all use `err(3)` to print a readable message and `exit`, which is right for a small experimental tool. Production userland code over device nodes usually looks more like this:

```
fd = open(path, O_RDWR);
if (fd < 0) {
    switch (errno) {
        case ENXIO:
            /* Driver not ready yet. Retry or report. */
            warnx("%s: driver not ready", path);
            break;
        case EBUSY:
            /* Node is exclusive and already open. */
            warnx("%s: in use by another process", path);
            break;
        case EACCES:
            /* Permission denied. */
            warnx("%s: permission denied", path);
            break;
        case ENOENT:
            /* Node does not exist. Is the driver loaded? */
            warnx("%s: not present", path);
            break;
        default:
            warn("%s", path);
            break;
    }
    return (1);
}
```

That table of `errno` values is worth internalising. Chapter 8 Section 13 treats it as a first-class topic, because the same values appear on the driver side and deciding which one to return is a design choice.

8.11.6 Driving Devices From Shell Scripts

Before you reach for a userland C program, remember that shell tools cover many cases adequately. For `myfirst`, a handful of one-liners are useful:

```
# Verify the node exists and report its ownership and mode.
ls -l /dev/myfirst/0

# Open and immediately close the device, for probe purposes.
sudo sh -c ': </dev/myfirst/0'

# Read once from the device and pipe the result into hexdump.
sudo cat /dev/myfirst/0 | hexdump -C | head

# Hold the device open for a few seconds with a background shell.
sudo sh -c 'exec 3</dev/myfirst/0; sleep 5; exec 3<&-'

# Show what processes currently have the device open.
sudo fstat /dev/myfirst/0
```

Each of these is a separate debugging move, and together they make up a useful shell toolkit. When you can express your test in shell, shell is often the fastest path.

8.12 Reading Real FreeBSD Drivers Through a Device-File Lens

Nothing cements the device-file model like reading drivers that have had to solve the same problems you are now solving. This section is a guided tour of three drivers in `/usr/src/sys`. The goal is not to understand each driver end to end. The goal is to see how each of them shapes its device file, so you build a library of patterns in your head.

Each walkthrough follows the same shape: open the file, find the `cdevsw`, find the `make_dev` call, find the `destroy_dev` call, notice what is idiomatic and what is unusual.

8.12.1 Walkthrough 1: `/usr/src/sys/dev/null/null.c`

The `null` module is the smallest good example in the tree. Open it in an editor. It is short enough to read in a single pass.

What to notice first: there are **three** `cdevsw` structures in one file.

```
static struct cdevsw full_cdevsw = {
    .d_version =    D_VERSION,
    .d_read =      zero_read,
    .d_write =     full_write,
    .d_ioctl =     zero_ioctl,
    .d_name =      "full",
};

static struct cdevsw null_cdevsw = {
```

```

        .d_version =    D_VERSION,
        .d_read =      (d_read_t *)nullop,
        .d_write =     null_write,
        .d_ioctl =     null_ioctl,
        .d_name =      "null",
};

static struct cdevsw zero_cdevsw = {
        .d_version =    D_VERSION,
        .d_read =      zero_read,
        .d_write =     null_write,
        .d_ioctl =     zero_ioctl,
        .d_name =      "zero",
        .d_flags =     D_MMAP_ANON,
};

```

Three distinct nodes, three distinct cdevsw values, no softc. The module registers three cdevs in its MOD_LOAD handler:

```

full_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &full_cdevsw, 0,
        NULL, UID_ROOT, GID_WHEEL, 0666, "full");
null_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &null_cdevsw, 0,
        NULL, UID_ROOT, GID_WHEEL, 0666, "null");
zero_dev = make_dev_credf(MAKEDEV_ETERNAL_KLD, &zero_cdevsw, 0,
        NULL, UID_ROOT, GID_WHEEL, 0666, "zero");

```

Notice MAKEDEV_ETERNAL_KLD. When this code is statically compiled into the kernel, the macro expands to MAKEDEV_ETERNAL and marks the cdevs as never-to-be-destroyed. When the same code is built as a loadable module, the macro expands to zero, and the cdevs can be destroyed during unload.

Also notice that mode 0666 and root:wheel. Everything the null module serves is intentionally accessible to everyone.

Unload reads as simply as load:

```

destroy_dev(full_dev);
destroy_dev(null_dev);
destroy_dev(zero_dev);

```

One destroy_dev per cdev. No softc to tear down. No per-open state. No locking beyond what the kernel provides. This is what minimal looks like.

What to copy from null: the habit of setting d_version, the habit of giving each cdevsw its own d_name, the symmetry between load and unload, the willingness to use simple named handlers instead of inventing abstractions.

What to leave alone: `MAKEDEV_ETERNAL_KLD`. Your driver should be unloadable, so you do not want the eternal flag. The `null` module is special because the nodes it creates predate almost every other kernel subsystem and are expected to remain live for the life of the kernel.

8.12.2 Walkthrough 2: `/usr/src/sys/dev/led/led.c`

The LED framework is a step up in structural complexity. It is still small enough to read in a sitting. Where `null` has no softc, `led` has a full per-LED softc. Where `null` creates three singletons, `led` creates one cdev per LED on demand.

Look first at the single cdevsw:

```
static struct cdevsw led_cdevsw = {
    .d_version =    D_VERSION,
    .d_write =      led_write,
    .d_name =       "LED",
};
```

One cdevsw for all LEDs. The framework uses it for every cdev it creates, relying on `si_drv1` to distinguish between them. The minimalism of this definition is itself a lesson: `led` does not implement `d_open`, `d_close`, or `d_read`, because every interaction an operator has with a LED is a pattern string written with `echo`. Reading from the node is not meaningful, and no session state needs to be tracked on open, so the driver simply leaves those fields unset. `devfs` interprets each `NULL` slot as “use the default behaviour”, which for `d_read` is returning zero bytes and for `d_open` and `d_close` is doing nothing. Keep that in mind when you design your own cdevsw values: populate what your device truly needs, and leave the rest alone.

The per-LED softc lives in a `struct ledsc` defined near the top of the file:

```
struct ledsc {
    LIST_ENTRY(ledsc)    list;
    char                 *name;
    void                 *private;
    int                  unit;
    led_t                *func;
    struct cdev           *dev;
    /* ... more state ... */
};
```

It carries a back-pointer to its cdev in the `dev` field, and a unit number allocated from an `unrhdr(9)` pool rather than from `Newbus`:

```
sc->unit = alloc_unr(led_unit);
```

The actual `make_dev` call is right below:

```
sc->dev = make_dev(&led_cdevsw, sc->unit,
    UID_ROOT, GID_WHEEL, 0600, "led/%s", name);
```

Notice the path: "led/%s". Every LED created by the framework lands in the /dev/led/ subdirectory with a free-form name chosen by the calling driver (for instance led/ehci0). This is how the framework keeps its nodes grouped.

Immediately after the make_dev, the framework stashes the_softc pointer:

```
sc->dev->si_drv1 = sc;
```

This is the pre-mda_si_drv1 way of doing it, and it predates make_dev_s. Newer drivers should pass mda_si_drv1 through the args struct instead, so the pointer is set before the cdev becomes reachable.

Destruction is a single call:

```
destroy_dev(dev);
```

Simple. Synchronous. No deferred destruction, no drain loop at the caller level. The framework relies on the kernel's draining behavior in destroy_dev to finish any in-flight handlers.

What to copy from led: the naming convention (subdirectory per framework), the_softc layout (back-pointer plus identity fields plus callback pointer), the clean alloc_unr / free_unr pattern for unit numbers that do not come from Newbus.

What to leave alone: the sc->dev->si_drv1 = sc assignment after make_dev. Use mda_si_drv1 in make_dev_s instead.

8.12.3 Walkthrough 3: /usr/src/sys/dev/md/md.c

The memory disk driver is larger than the previous two, and most of its bulk is not about device files at all. It is about GEOM, about backing store, about swap-backed and vnode-backed instances. For our purposes, we look at one specific thing: the control node /dev/mdctl.

Find the cdevsw declaration near the top of md.c:

```
static struct cdevsw mdctl_cdevsw = {
    .d_version =    D_VERSION,
    .d_ioctl =      mdctl_ioctl,
    .d_name =       MD_NAME,
};
```

Only two fields set. d_version and d_ioctl and a name. No d_open, d_close, d_read, or d_write. The control node is used exclusively through ioctl(2): create an md, attach a backing store, destroy an md. That is the shape of many control interfaces in the tree.

The cdev is created near the bottom of the file:

```
status_dev = make_dev(&mdctl_cdevsw, INT_MAX, UID_ROOT, GID_WHEEL,  
0600, MDCTL_NAME);
```

INT_MAX is a common pattern for singletons when the unit number does not matter: it places the cdev outside any plausible range of driver-instance unit numbers. 0600 and root:wheel are the narrow baseline you would expect for a privileged control node.

Destruction happens in the module unload path:

```
destroy_dev(status_dev);
```

Again, a single call.

What to copy from md: the pattern of exposing a single control cdev for a subsystem whose data path lives elsewhere (in md's case, in GEOM), and the very narrow permissions for a node that has genuine privilege.

What to leave alone: md is a large subsystem; do not try to copy its structure as a template. Copy the control-node idea; leave the GEOM layering for Chapter 27.

8.12.4 A Brief Word About Cloning

The LED framework creates one cdev per LED in response to an API call from other drivers. The md module creates one cdev per memory disk in response to an ioctl on its control node. Both are examples of **drivers that create cdevs dynamically in response to events**.

FreeBSD also has a dedicated cloning mechanism: clone_create(9) and the dev_clone event handler. When a user opens a name that matches a pattern registered by a cloning driver, the kernel synthesises a new cdev, opens it, and returns the descriptor. This was historically a common pattern for subsystems that wanted a new per-session cdev on every open. Modern FreeBSD leans on devfs_set_cdevpriv(9) instead whenever the only reason to clone a cdev was to give each descriptor independent state, because per-open state is simpler, lighter, and does not need a pool of minor numbers. True cloning is still in the tree (the PTY subsystem under /dev/pts/* is the clearest living example), and the API surface that supports it is worth recognising.

Cloning is flexible and we will not cover it in Chapter 8. Several of the API elements we have already met (the D_NEEDMINOR flag, dev_stdclone, the CLONE_* constants) exist to support it. Mentioning them here gives you a vocabulary for the day you encounter a driver that uses them. For now, the takeaway is that FreeBSD has a spectrum of mechanisms for creating cdevs, and make_dev_s from attach is the simplest end of it.

8.12.5 Walkthrough 4: /usr/src/sys/net/bpf.c (Device-File Surface Only)

BPF, the Berkeley Packet Filter, is a large subsystem. We will not try to understand what it does at the network level; Part 6 of this book has a chapter dedicated to network drivers. Here we look at one specific thing: how BPF shapes its device-file surface.

The relevant declarations are near the top of /usr/src/sys/net/bpf.c. The cdevsw is populated with the full set of data-path operations plus poll and kqueue:

```
static struct cdevsw bpf_cdevsw = {
    .d_version =    D_VERSION,
    .d_open =      bpfopen,
    .d_read =      bpfread,
    .d_write =     bpfwrite,
    .d_ioctl =     bpfioctl,
    .d_poll =      bpfpoll,
    .d_name =      "bpf",
    .d_kqfilter =  bpfkqfilter,
};
```

No `d_close`. BPF does everything on close through the `cdevpriv` destructor, which is the pattern this chapter recommends. The dispatch table says “for these operations, call these handlers, and do nothing special on close because the destructor has it”.

The open handler, already quoted in the per-open state section, fits the pattern exactly:

```
d = malloc(sizeof(*d), M_BPF, M_WAITOK | M_ZERO);
error = devfs_set_cdevpriv(d, bpf_dtor);
if (error != 0) {
    free(d, M_BPF);
    return (error);
}
```

Allocate, register with `devfs`, free on registration failure. Nothing else in the open path matters for our purposes here.

The destructor is the interesting part. BPF’s `bpf_dtor` has to unwind a fair amount of state: it stops a callout, disconnects from its BPF interface, drains a select set, and drops references. It does all of that **without ever calling `d_close`** from the `cdevsw`. Destructor-based cleanup is cleaner than close-based cleanup for a driver that supports multiple openers, because the destructor fires exactly once per open, whereas `d_close` without `D_TRACKCLOSE` fires only on the last close of the final shared file.

The `cdev` layout on the BPF side is simpler than a first reading of the subsystem suggests. BPF creates exactly one primary node and one alias:

```
dev = make_dev(&bpf_cdevsw, 0, UID_ROOT, GID_WHEEL, 0600, "bpf");
make_dev_alias(dev, "bpf0");
```

That is the full register-a-device surface. There is no per-instance `/dev/bpfN` `cdev`; the names you may see on a running system such as `/dev/bpf0` and `/dev/bpf` both resolve to the same `cdev`, and every distinct user of BPF is distinguished entirely by its per-open structure, attached through `devfs_set_cdevpriv` at open time. That is exactly the shape you adopt for `myfirst` at the end of this chapter: one `cdev`, an alias, per-descriptor state, and a destructor that handles teardown. BPF is a large subsystem, but its device-file surface is one you now know how to write.

What to copy from BPF: the practice of doing open-time cleanup in the destructor rather than in `d_close`. The practice of allocating per-open state immediately and registering it before any other work. The discipline of freeing the allocation on registration failure. The willingness to keep the `cdev` count small and let the descriptor carry the session.

What to leave alone: the BPF-specific machinery that surrounds the open and close paths, including the interface attach logic, the select-set bookkeeping, and the counter-based statistics. Those belong to the network side of BPF, and Part 6 will revisit them when the book introduces network drivers.

8.12.6 A Synthesis Across All Four Drivers

With four walkthroughs under your belt, it helps to line up the commonalities and the differences in one table. Every row is a driver property; every column is a driver.

Property	<code>null</code>	<code>led</code>	<code>md</code>	<code>bpf</code>
How many <code>cdevsw</code> values	3	1	1 (plus GEOM)	1
<code>cdevs</code> per attach	3 total	1 per LED	1 control + many	1 plus 1 alias
Softc?	no	yes	yes	yes (per-open)
Subdirectory in <code>/dev</code> ?	no	yes (<code>led/*</code>)	no	no
Permission mode	<code>0666</code>	<code>0600</code>	<code>0600</code>	<code>0600</code>
Uses <code>devfs_set_cdevpriv</code> ?	no	no	no	yes
Uses cloning?	no	no	no	no
Uses <code>make_dev_alias</code> ?	no	no	no	yes
<code>d_close</code> populated?	no	no	no	no
Uses <code>destroy_dev_drain</code> ?	no	no	no	no
Primary use-case	pseudo-data	hardware ctl	subsystem ctl	packet capture

Every column is defensible. Each driver has chosen the simplest set of features that fits its job. Your `myfirst` driver by the end of Chapter 8 has a profile closer to `led` than to the others: one `cdevsw`, per-instance `softc`, subdirectory naming, narrow permissions, plus `devfs_set_cdevpriv` for per-open state (which `led` does not need) and an alias (which `led` does not use).

That profile is a good place to be. It is large enough to show that you have engaged with the real mechanisms, and small enough that every line of the driver is there for a reason.

8.12.7 What Four Drivers Taught Us

Four drivers, four different shapes, all of them good examples:

- `null` is minimalism: three `cdevsw` values, three singletons, no `softc`, no per-open state, mode `0666` because the data is harmless.

- `led` is a framework: one `cdevsw`, many `cdevs`, each with its own `softc` and unit number, subdirectory naming, narrow permissions, only `d_write` populated because the device is written-to rather than read-from.
- `md` is a control interface: one `cdevsw` with only `d_ioctl`, a singleton `cdev`, `INT_MAX` as unit number, narrow permissions for privileged operations.
- `bpf` is a per-session driver: one `cdevsw` with the full data-path set, a single primary `cdev` plus an alias, and the whole of per-descriptor state carried through `devfs_set_cdevpriv(9)`.

Your `myfirst` is closest to `bpf` in shape by the end of this chapter: one `cdevsw`, one primary `cdev` with an alias, a `softc` for device-wide state, and per-open state for per-descriptor book keeping. Where it differs is scope. `bpf` implements the full data path, and it does so to serve real packets. `myfirst` stops at the surface. That is fine for now. You are in good company, and the rooms behind the door open in Chapter 9.

Reading other drivers becomes a skill you build over time. The device-file lens is just one of several lenses you will apply. Keep the four walkthroughs above in mind as a starting library.

8.13 Common Scenarios and Recipes

This section is a cookbook. Each entry is a situation you will run into sooner or later, a short recipe for handling it, and a pointer to which part of the chapter explains the underlying machinery. Read them now or bookmark them for when they come up.

8.13.1 Recipe 1: A Driver That Must Never Be Opened Twice

Situation. Your hardware has state that is only sane with a single concurrent user. A second `open(2)` would corrupt the state.

Recipe.

1. In the `softc`, keep a single `int is_open` flag and a mutex.
2. In `d_open`, take the mutex, check the flag, return `EBUSY` if set, set it, drop the mutex.
3. In `d_close`, take the mutex, clear the flag, drop the mutex.
4. In `detach`, check the flag under the mutex and return `EBUSY` if set.
5. Do **not** also use `devfs_set_cdevpriv` for per-open state; there is no “per-open” because there is only one open at a time.

This is the Chapter 7 pattern. `myfirst` used it to force attention on the lifecycle; Chapter 8 stage 2 moves away from it because most drivers want multiple openers. Use the exclusive pattern only when hardware constraints force it.

8.13.2 Recipe 2: A Driver With Per-User Read Offsets

Situation. Your device exposes a seekable stream. Two different user processes should each get their own offset into the stream; neither should see the other’s position change their own view.

Recipe.

1. Define struct `myfirst_fh` with an `off_t read_offset` field.
2. In `d_open`, allocate the struct and call `devfs_set_cdevpriv` with a destructor that frees it.
3. In `d_read`, call `devfs_get_cdevpriv` to retrieve the struct. Use `fh->read_offset` as the starting point. Advance it by the number of bytes actually transferred.
4. In `d_close`, do nothing; the destructor runs automatically when the descriptor releases.

Chapter 9 will fill in the `d_read` body. The skeleton is already in stage 2.

8.13.3 Recipe 3: A Device With a Privileged Control Node

Situation. Your driver has a data surface anyone should be able to read, and a control surface only privileged users should touch.

Recipe.

1. Define two `cdevsw` structures, `something_cdevsw` and `something_ctl_cdevsw`.
2. Create two `cdevs` in `attach`: one for the data node (`0644 root:wheel` or similar), one for the control node (`0600 root:wheel`).
3. Keep both pointers in the `softc`. Destroy the control `cdev` before the data `cdev` in `detach`.
4. Use `priv_check(9)` inside the control node's `d_ioctl` handler if you want enforcement beyond file permissions.

Lab 8.5 walks through this. The `md` walkthrough in the Reading Real Drivers section is a real-world variant.

8.13.4 Recipe 4: A Node That Appears Only When a Condition Is Met

Situation. You want `/dev/myfirst/status` to appear only when the driver's hardware is in a specific state, and disappear otherwise.

Recipe.

1. Keep `sc->cdev_status` as a struct `cdev *` in the `softc`, initialised to `NULL`.
2. In the handler where the condition becomes true, call `make_dev_s` and store the pointer.
3. In the handler where the condition becomes false, call `destroy_dev` on the pointer and set it to `NULL`.
4. Guard both with the `softc` mutex so concurrent transitions do not race.
5. In `detach`, if the pointer is non-`NULL`, destroy it before tearing down the other `cdevs`.

This is the same pattern as the primary data node, just triggered by a different event. Watch for the case where the condition changes repeatedly in quick succession: you will hit the `devfs` allocator harder than expected, and you may want to debounce.

8.13.5 Recipe 5: A Node Whose Ownership Should Change Based on a Runtime Knob

Situation. A lab system sometimes wants the node owned by `operator`, sometimes by `wheel`. You do not want to reload the driver to switch.

Recipe.

1. Leave the driver's `mda_uid` and `mda_gid` at a narrow baseline (`UID_ROOT`, `GID_WHEEL`).

2. Use `devfs.conf` to widen when wanted:

```
own      myfirst/0      root:operator
perm     myfirst/0      0660
```

3. Apply with `service devfs restart`.
4. To switch back, comment out the lines and re-run `service devfs restart`.

Policy lives in userland; the driver stays pristine. Lab 8.4 practices this.

8.13.6 Recipe 6: A Node That Should Be Visible Only Inside a Jail

Situation. A node should appear inside a specific jail but not on the host.

Recipe.

1. In the driver, default to creating the node as usual on the host.
2. In `/etc/devfs.rules`, create a ruleset for the jail that explicitly hides the node:

```
[special_jail=120]
add include $devfsrules_hide_all
add include $devfsrules_unhide_basic
add path myfirst hide
```

3. Apply the ruleset number in the jail's `jail.conf`.

This is a blunter variant of Lab 8.7. For a node that should be visible in the jail and not on the host, the logic inverts: create the node on the host (where it is always created), and use a host-side `devfs.conf` rule to tighten permissions so nothing on the host touches it.

8.13.7 Recipe 7: A Node That Can Survive Unexpected Process Deaths

Situation. Your driver holds resources per open. If a process crashes, you must not leak the resource.

Recipe.

1. Allocate the resource in `d_open`.
2. Register a destructor with `devfs_set_cdevpriv`. The destructor frees the resource.
3. Rely on the kernel to run the destructor when the last reference to the `struct file` drops, regardless of why. `close(2)`, `exit(3)`, or `SIGKILL` all reach the same cleanup path.

The destructor guarantee is the primary reason `devfs_set_cdevpriv` exists. No matter how badly userland misbehaves, your resource gets freed.

8.13.8 Recipe 8: A Device That Must Support Polling

Situation. Your driver produces events, and user programs want to `select(2)` or `poll(2)` on the device to learn when an event is pending.

Recipe. Out of scope for Chapter 8; this is Chapter 10 territory. The short form for recognition: set `.d_poll = myfirst_poll` in your `cdevsw`, implement the handler to return the appropriate mask of `POLLIN`, `POLLOUT`, `POLLERR` bits, and use `selrecord(9)` to register interest for deferred wake-up. Chapter 10 walks through each of these in detail.

8.13.9 Recipe 9: A Device That Needs to Be Mapped Into User Memory

Situation. Your driver has a shared memory region (DMA buffer, hardware register window) that a user process should access directly through `mmap(2)`.

Recipe. Out of scope for Chapter 8; covered in Part 4 when hardware access is introduced. For recognition only: set `.d_mmap = myfirst_mmap` in your `cdevsw`, implement the handler to return the physical page address for each offset and protection mask, and think carefully about what happens when the user-mapped memory is backed by hardware that can vanish. This is one of the more nuanced areas of driver work.

8.13.10 Recipe 10: A Device That Exposes a Log

Situation. Your driver produces log messages that are more voluminous than `device_printf` should handle, and user programs should be able to `read(2)` them in order.

Recipe.

1. Allocate a ring buffer in the softc.
2. In the code paths that produce log events, format them into the ring buffer under a lock.
3. In `d_read`, copy bytes from the ring buffer to userland via `uiomove(9)` (Chapter 9).
4. Use per-open state (a `read_offset` in the `fh`) so each reader drains the buffer at its own pace.
5. Consider setting `D_TRACKCLOSE` if a single reader should be allowed to empty the buffer on close.

This is the shape of several kernel log devices. It is worth knowing the pattern exists; the full implementation is a later-chapter exercise.

8.13.11 When a Recipe Does Not Fit

The cookbook is not exhaustive. When you face a situation that does not match any of the recipes above, a useful habit is to ask three questions in order:

- **Is it about identity?** Then it is a `cdev` question: naming, subdirectories, aliases, creation, destruction.
- **Is it about policy?** Then it is a permissions and policy question: ownership, mode, `devfs.conf`, `devfs.rules`.
- **Is it about state?** Then it is a per-open versus per-device question: `softc` or `devfs_set_cdevpriv`.

Most real-world driver design questions resolve into one of these three. When you have classified the question, the rest of the chapter tells you which tool to reach for.

8.14 Practical Workflows for the Device-File Surface

Knowing the APIs is half the job. Knowing when to reach for which one, and how to spot problems quickly, is the other half. This section collects the workflows that will make the next several chapters go smoothly: the inner loop for editing a driver, the habits that catch bugs early, and the checklists worth running through before a serious change.

8.14.1 The Inner Loop

The “inner loop” is the cycle of edit, build, load, test, unload, edit again. Your Chapter 7 scripts already have a version of this. For Chapter 8 the inner loop gets a little richer because there are more user-visible surfaces to verify.

A useful sequence when you are working on a stage of `myfirst`:

```
% cd ~/drivers/myfirst
% sudo kldunload myfirst 2>/dev/null || true
% make clean && make
% sudo kldload ./myfirst.ko
% dmesg | tail -5
% ls -l /dev/myfirst /dev/myfirst/0 2>/dev/null
% sysctl dev.myfirst.0.stats
% sudo ./probe_myfirst /dev/myfirst/0
% sudo kldunload myfirst
% dmesg | tail -3
```

Each line has a purpose. The first unload is defensive: the previous test left the module loaded, and this clears the slate. The `make clean && make` rebuilds from scratch to avoid a stale object file. The first `dmesg | tail -5` shows the attach messages. The `ls -l` and `sysctl` confirm that the user-visible surface is present and the internal counters are initialised. The probe exercises the data path. The final unload and `dmesg` confirm the detach messages.

If any step produces an unexpected result, you know which step. That is the value of scripting the loop: not to save typing, but to make the failure signal unambiguous.

The `rebuild.sh` helper shipped with Chapter 7’s examples wraps most of this for you. Lab 8 reuses it unchanged.

8.14.2 Reading dmesg Well

`dmesg` is the narrative of what your driver did. Reading it well is a habit worth building early.

The kernel’s default ring buffer can show tens of thousands of lines from earlier boot and runtime activity. When you are developing a specific driver, three techniques make the relevant slice visible:

Clearing before the test. `sudo dmesg -c > /dev/null` clears the buffer. The next load/unload cycle then produces a small, focused log. Use this between experiments.

Filtering by tag. `dmesg | grep myfirst` narrows the view to lines your driver produced, assuming your `device_printf` calls emit the driver name. They do, because `device_printf(9)` prefixes every line with the Newbus name of the device.

Watching in real time. Run `tail -f /var/log/messages` in a second terminal. Every driver message that makes it to `dmesg` also appears there, with timestamps. This is especially useful during long-running tests such as Lab 8.6's parallel-probe exercise.

8.14.3 Watching fstat

For detach problems, `fstat(1)` is your friend. Two idioms come up often:

```
% fstat /dev/myfirst/0
```

Plain lookup; shows all processes holding the node open. The output columns are user, command, pid, fd, mount, inum, mode, rdev, r/w, name.

```
% fstat -p $$ | grep myfirst
```

Restrict the search to the current shell. Useful when you are not sure whether your current shell has a leftover descriptor open from an earlier test.

```
% fstat -u $USER | grep myfirst
```

Restrict to your own user's processes. Similar use case, broader scope.

8.14.4 The sysctl Partner of Every Driver

From Chapter 7 your driver already exposes a `sysctl` tree under `dev.myfirst.0.stats`. Chapter 8 stage 2 adds `active_fhs` to that tree. When you are running experiments, the `sysctls` are the cheapest possible observation tool:

```
% sysctl dev.myfirst.0.stats
dev.myfirst.0.stats.attach_ticks: 123456
dev.myfirst.0.stats.open_count: 42
dev.myfirst.0.stats.active_fhs: 0
dev.myfirst.0.stats.bytes_read: 0
```

Every counter is a check on what the driver thinks is true. Discrepancies between what you expected and what `sysctl` shows are always a signal. If `active_fhs` is non-zero when no descriptor should be open, you have a leak. If `open_count` is smaller than the number of times you opened the device, your attach path is running twice or your counter is racy.

`Sysctls` are cheaper than any other observation mechanism. Prefer them over reading the device itself whenever a numeric or short-string piece of information will do.

8.14.5 A Quick Checklist for Every Code Change

Before you commit a change to the driver, walk through the following. Ten minutes spent here saves hours of debugging later.

1. Does the driver still build from a clean tree?
2. Does it still load and unload cleanly on a system with no open descriptors?
3. Does the user-visible surface (`ls -l /dev/myfirst/...`) match what your code intends?
4. Are the permissions still the narrow defaults they should be?
5. If you changed `attach`, does every error path still unwind completely?
6. If you changed `detach`, does the driver still unload cleanly when descriptors are held open (either with a clean `EBUSY` return or, if you chose a different policy, without leaking)?
7. If you changed per-open state, do all three of `stress_probe`, `parallel_probe`, and `hold_myfirst` still behave as expected?
8. Did you introduce any `device_printf` calls that should be `if (bootverbose)-gated` so they do not flood the log?
9. Did you leave any `#if 0` or debug prints in place? Pull them out now.
10. If you changed ownership or mode, does `devfs.conf` still produce the expected override?

This checklist is deliberately boring. That is the point. A boring, reliable process beats a heroic debugging session every time.

8.14.6 A Quick Checklist Before a Release

When you are preparing a stage of your driver for “done”, the checklist gets a little longer. All of the above, plus:

1. `make clean && make` from a truly clean tree builds without warnings.
2. `kldload ./myfirst.ko; sleep 0.1; kldunload myfirst` completes ten times without issue.
3. `stress_probe 10000` completes without issue and `active_fhs` returns to zero.
4. `parallel_probe 8` opens eight descriptors, holds, and cleanly closes. Kernel log shows eight distinct `fh=` pointers and eight destructors.
5. `kldunload` while a descriptor is open returns `EBUSY` cleanly, not a panic.
6. `devfs.conf` with a widening entry applies on service `devfs` restart.
7. An `ls -l` audit of `/dev/myfirst*` shows no unexpected modes or ownerships.
8. `dmesg` contains exactly the attach and detach messages you expect, with no warnings or errors.
9. Source code is free of commented-out experiments, TODO lines, and debug helpers.
10. The sysctls your driver exposes are descriptive and documented in code comments.

No commit should skip items 1 through 3. They are the cheapest high-value insurance you can buy.

8.14.7 A Workflow for Adding a New Node

Walking through the workflow end-to-end once will anchor the earlier sections. Suppose you decide `myfirst` should expose an additional read-only status node at `/dev/myfirst/status`, distinct from the numbered data nodes. Here is how you would do it.

Step 1: design. Decide on the shape of the node. Does it belong in the same `cdevsw` as the data node, or a different one? A status-only node that answers `read(2)` with a short text summary usually wants its own `cdevsw` with only `d_read` set, because the policy is different from the data node. Decide on the permission mode. Read-only by anyone suggests `0444`; read-only by operators suggests `0440` with an appropriate group.

Step 2: declare. Add the new `cdevsw`, its `d_read` handler, and a `struct cdev *cdev_status` field to the `softc`.

Step 3: implement. Write the `d_read` handler. It formats a short string based on `softc` state and returns it through `uiomove(9)`. For Chapter 8 you might stub this and fill it in after Chapter 9.

Step 4: wire. In `attach`, add the `make_dev_s` call for the status node. In `detach`, add the `destroy_dev` call, before the data node's `destroy`.

Step 5: test. Rebuild, reload, inspect, exercise, unload. Check that `ls -l` shows the status node with the expected mode. Check that `cat /dev/myfirst/status` works and produces sensible output. Check that the whole driver still unloads cleanly.

Step 6: document. Add a comment in the driver source describing the node. Add an entry in the `dev.myfirst.0.stats` `sysctl` if the status is numeric and would fit there too. Note the change in whatever change log you keep.

Six steps, each one small, each one specific. That is the level of granularity at which bugs stay visible.

8.14.8 A Workflow for Diagnosing a Missing Node

The Chapter 8 troubleshooting walkthrough in the Tools section gave you a short checklist. Here is a fuller workflow that fits on an index card.

Phase 1: is it the module?

- `kldstat | grep myfirst` shows the module.
- `dmesg | grep myfirst` shows the attach messages.

If the module is not loaded or the attach did not run, fix that first.

Phase 2: is it Newbus?

- `devinfo -v | grep myfirst` shows the Newbus device.

If Newbus shows nothing, your `device_identify` or `device_probe` is not creating the child. Look there.

Phase 3: is it devfs?

- `ls -l /dev/myfirst` lists the directory (or reports it missing).
- `dmesg | grep 'make_dev'` shows any failure from `make_dev_s`.

If Newbus is fine but devfs shows nothing, `make_dev_s` returned an error. Check your path format string, your `mda_devsw`, your argument structure.

Phase 4: is it policy?

- `devfs rule showsets` lists active rulesets.
- `devfs rule -s N show` lists rules in ruleset N.

If devfs has the cdev but your jail or your local session does not see it, the ruleset is hiding it.

Every failure maps to one of these four phases. Work through them in order and you will almost always identify the cause in under a minute.

8.14.9 A Workflow for Reviewing Someone Else's Driver

When you review a pull request that touches a driver's device-file surface, the useful questions are:

- Does every `make_dev_s` have a matching `destroy_dev`?
- Does every error path after `make_dev_s` call `destroy_dev` before returning?
- Does detach destroy every cdev it created?
- Is `si_drv1` populated through `mda_si_drv1` rather than a post-hoc assignment?
- Is the permission mode defensible for the node's purpose?
- Is the `cdevsw`'s `d_version` set to `D_VERSION`?
- Are all `d_*` handlers present for the operations the node should support, and is each of them consistent about its `errno` returns?
- If the driver uses `devfs_set_cdevpriv`, is there exactly one successful set per open and exactly one destructor?
- If the driver uses aliases, are they destroyed in detach before the primary?
- If the driver has more than one cdev, does it call `destroy_dev_drain` in its unload path?

This is a review checklist, not a tutorial. The review is faster because every question has a yes or no answer and every yes can be checked mechanically.

8.14.10 Keeping a Lab Logbook

A lab logbook is a small notebook or text file where you record what you did, what you saw, and what you learned. The book has recommended this since Chapter 2. In Chapter 8 it pays off in a specific way: you will run the same kinds of experiments many times, and a brief note lets you avoid repeating the same misstep twice.

A useful template for a logbook entry:

```
Date: 2026-04-17
Driver: myfirst stage 2
Goal: verify per-open state is isolated across two processes
Steps:
- loaded stage 2 kmod
- ran parallel_probe with count=4
- observed 4 distinct fh= pointers in dmesg
- observed active_fhs=4 in sysctl
- closed, observed 4 destructor lines, active_fhs=0
Result: as expected
Notes: first run missed destructor lines because dmesg ring buffer
      was full; dmesg -c before the test solved it
```

Two minutes per experiment, no more. The value appears months later when you are tracking down a new issue and a logbook search reveals that the same symptom appeared once before under different circumstances.

8.14.11 Common Design Questions and How to Think About Them

Some questions recur when driver authors reach the device-file stage. Each of these has come up more than once in real review discussions. The answers are short; the reasoning is worth internalising.

Q: Should I create the `cdev` in `device_identify` or in `device_attach`?

In `device_attach`. The `identify` callback runs very early, before the driver instance has a `softc`. The `cdev` wants to reference the `softc` via `mda_si_drv1`, which means the `softc` must already exist. Chapter 7 set this pattern; keep it.

Q: Should I create additional `cdevs` outside `attach` and `detach`?

If they are genuinely per-driver-instance, put them in `attach` and destroy them in `detach`. If they are dynamic, created in response to a user action, create them in whichever handler receives the user's request and destroy them either when a later handler unwinds the request or when the driver detaches. Track them carefully; lost `cdevs` are a common source of leaks.

Q: Should I set `D_TRACKCLOSE`?

Usually no. The per-open state mechanism via `devfs_set_cdevpriv` covers almost every case for which `D_TRACKCLOSE` would be tempting, and it cleans itself up automatically. Set `D_TRACKCLOSE` only when you need your `d_close` to run on every descriptor close, not just the last one. Real use cases are rare; TTY drivers and a handful of others fit.

Q: Should I allow multiple openers?

Default to yes, via per-open state. Exclusive access is sometimes necessary for hardware that can only support one session at a time, but it is a choice, not a default. Chapter 7 forced exclusivity as a teaching move; Chapter 8 stage 2 lifts that restriction precisely because it is not the common case.

Q: Should I return `ENXIO` or `EBUSY` on a failed open?

`ENXIO` when the driver is not ready. `EBUSY` when the device can be opened in principle but not right now. The user-visible messages are different, and an operator who reads your kernel log will thank you for picking the correct one.

Q: Should I `strdup` strings I get from userland?

Not on the open path. If a handler has a legitimate reason to remember a user-supplied string beyond the call, use `malloc(9)` with an explicit size and copy the string in. Never rely on a pointer into userland memory after a handler returns; it may no longer be valid, and even if it is, the kernel should never trust userland-owned memory for long.

Q: Should the `softc` remember which descriptors have it open?

Usually no. Per-open state via `devfs_set_cdevpriv` is the answer. If you need an iteration mechanism, `devfs_foreach_cdevpriv` exists and is correct. Do not maintain your own list of descriptor pointers in the `softc`; the locking is nontrivial and the kernel already provides the right answer.

Q: When should my `detach` refuse with `EBUSY`?

When the driver cannot safely tear itself down with the current state. Open descriptors are the most common reason. Some drivers also refuse if hardware is actively transferring, or if a control operation is in progress. Error out early and cleanly; do not try to coerce the system into a clean state from inside detach.

Q: Can I unload the driver while descriptors are open?

Not if detach refuses. If your detach accepts the situation, the kernel will still drain in-flight handlers, but open descriptors remain on existing file tables until the processes close them, and those descriptors will then return ENXIO (or similar) from further operations. For a teaching driver, refusing EBUSY is the cleaner choice.

These questions are the ones that will come up in your first real driver review. Having seen them once here means you are not seeing them for the first time when the reviewer asks.

8.14.12 A Decision Tree for Common Design Choices

When you sit down to design a new node or change an existing one, the questions tend to fall into a small set of branches. The tree below is a field guide, not an algorithm; real design always involves judgement, but knowing the shape of the tree helps.

Start: I want to expose something through /dev.

Branch 1: What kind of state does the node carry?

- **Session-less, trivial data source or sink** (like /dev/null, /dev/zero): no softc, no per-open state, one cdevsw per behaviour. Use make_dev or make_dev_s in a MOD_LOAD handler. Mode typically 0666.
- **Per-device hardware** (like a serial port, a sensor, an LED): one softc per instance, one cdev per instance. Use attach/detach pattern. Mode typically 0600 or 0660.
- **Subsystem control** (like /dev/pf or /dev/mdctl): one cdev exposing d_ioctl-only operations. Mode 0600.
- **Per-session state** (like BPF, like FUSE): one cdev per session or one cloning entry point. Per-open state via devfs_set_cdevpriv. Mode 0600.

Branch 2: How do users discover the node?

- **Stable fixed name** (like /dev/null): put the name in the make_dev format string and leave it.
- **Per-instance numbered name** (like /dev/myfirst0): use %d in the format string and device_get_unit(9) for the number.
- **Subdirectory grouping** (like /dev/led/foo): use / inside the format string; devfs creates the directory on demand.
- **On-demand per-open instance**: use cloning. Covered later.

Branch 3: Who can touch it?

- **Anyone**: UID_ROOT, GID_WHEEL, mode 0666. Rare; use only for harmless nodes.
- **Root only**: UID_ROOT, GID_WHEEL, mode 0600. The default for anything privileged.
- **Root plus an operator group**: UID_ROOT, GID_OPERATOR, mode 0660. Common for hands-on privileged tools.
- **Root write, anyone read**: UID_ROOT, GID_WHEEL, mode 0644. For status nodes.
- **Custom named group**: define the group in /etc/group, use devfs.conf to adjust ownership at node creation time. Do not invent a group inside your driver.

Branch 4: How many concurrent openers?

- **Exactly one at a time:** exclusive open pattern, flag in `softc`, check under mutex in `d_open`, return `EBUSY` on conflict. No `devfs_set_cdevpriv`.
- **Multiple, each with independent state:** remove the exclusive check, allocate per-open struct in `d_open`, call `devfs_set_cdevpriv`, read back with `devfs_get_cdevpriv`.
- **Multiple, all sharing driver-wide state:** allocate nothing per open; just read and write the `softc` under its mutex.

Branch 5: What happens when the driver unloads with users active?

- **Refuse the unload** with `EBUSY` from `detach` as long as any descriptor is open. This is the clean default.
- **Accept the unload** but invalidate open descriptors. In this case you need a `d_purge` handler to wake any blocked threads and convince them to return promptly. More complex; do this only when the refusal would leave the system in a worse state.

Branch 6: What kind of name adjustments do users and operators need?

- **A second name maintained by the driver itself** (legacy path, well-known shortcut): `make_dev_alias(9)` in `attach`, `destroy_dev(9)` on it in `detach`.
- **A second name maintained by the operator:** link in `/etc/devfs.conf`. Driver does nothing.
- **A permission widening or narrowing per host:** `own` and `perm` in `/etc/devfs.conf`. Driver keeps its baseline.
- **A jail-filtered view:** a ruleset in `/etc/devfs.rules`, referenced in `jail.conf`. Driver has nothing to say.

Branch 7: How do userland programs receive events from the driver?

- **Polling by reading:** drivers that only need to hand out bytes. `d_read` and `d_write`.
- **Blocking reads with signals:** drivers that should unblock on `SIGINT`. Covered in Chapter 10.
- **Poll/select:** `d_poll`. Covered in Chapter 10.
- **Kqueue:** `d_kqfilter`. Covered in Chapter 10.
- **devd notifications:** `devctl_notify(9)` from the driver; operator-side rules in `/etc/devd.conf`.
- **sysctl pulls:** for observability without file-descriptor cost. Always complementary to the `/dev` surface.

This tree does not cover every case. It covers enough that a driver author can navigate the first several design decisions without panicking. When a new question comes up that is not on the tree, write down the question and the answer you settled on; that is how the tree grows for you personally.

8.14.13 A Warning About Over-Engineering

A few design temptations are worth calling out specifically, because they tend to turn simple drivers into complicated drivers with no gain.

- **Inventing your own IPC protocol over read/write.** If the messages are structured, use `ioctl(2)` (Chapter 25).
- **Embedding a tiny language into `ioctl` commands** so users can “script” the driver. This is almost always a sign that the feature belongs in userland.

- **Multiplexing many unrelated subsystems through one cdevsw.** If two surfaces have different semantics, give them two cdevsw values; it costs nothing and reads better.
- **Adding D_NEEDGIANT to silence an SMP warning.** The warning is correct; fix the locking.
- **Handling every possible errno value from every possible userland program.** Pick the right one for your situation and stick with it. The standard err(3) family does the rest.

The discipline of “as simple as it can be, but no simpler” is especially important at this level. Every line of driver code is a line that could have a bug in it under load. A lean driver is easier to review, easier to debug, easier to port, and easier to hand off to the next maintainer.

8.15 Hands-On Labs

These labs extend the Chapter 7 driver in place. You should not need to retype anything from scratch. The companion directory mirrors the stages.

8.15.1 Lab 8.1: Structured Name and Tighter Permissions

Goal. Move the device from /dev/myfirst0 to /dev/myfirst/0, and change the group to operator with mode 0660.

Steps.

1. In myfirst_attach(), change the make_dev_s() format string to "myfirst/%d".
2. Change args.mda_gid from GID_WHEEL to GID_OPERATOR, and args.mda_mode from 0600 to 0660.
3. Rebuild and reload:

```
% make clean && make
% sudo kldload ./myfirst.ko
% ls -l /dev/myfirst
total 0
crw-rw----  1 root  operator  0x5a Apr 17 09:41 0
```

4. Confirm that a normal user in the operator group can now read from the node without sudo. On FreeBSD, you add a user to that group with pw groupmod operator -m yourname, then start a fresh shell.
5. Unload the driver and confirm the /dev/myfirst/ directory disappears along with the node.

Success criteria.

- /dev/myfirst/0 appears on load and disappears on unload.
- ls -l /dev/myfirst/0 shows crw-rw---- root operator.
- A member of the operator group can cat </dev/myfirst/0 without error.

8.15.2 Lab 8.2: Add an Alias

Goal. Expose `/dev/myfirst` as an alias for `/dev/myfirst/0`.

Steps.

1. Add a struct `cdev` `*cdev_alias` field to the softc.
2. After the successful `make_dev_s()` call in `myfirst_attach()`, call:

```
sc->cdev_alias = make_dev_alias(sc->cdev, "myfirst");
if (sc->cdev_alias == NULL)
    device_printf(dev, "failed to create alias\n");
```

3. In `myfirst_detach()`, destroy the alias before destroying the primary `cdev`:

```
if (sc->cdev_alias != NULL) {
    destroy_dev(sc->cdev_alias);
    sc->cdev_alias = NULL;
}
if (sc->cdev != NULL) {
    destroy_dev(sc->cdev);
    sc->cdev = NULL;
}
```

4. Rebuild, reload, and verify:

```
% ls -l /dev/myfirst /dev/myfirst/0
```

Both paths should respond. `sudo cat </dev/myfirst` and `sudo cat </dev/myfirst/0` should behave identically.

Success criteria.

- Both paths exist while the driver is loaded.
- Both paths disappear on unload.
- The driver does not panic or leak if the alias creation fails; comment out the `make_dev_alias` line temporarily to confirm this.

8.15.3 Lab 8.3: Per-Open State

Goal. Give each `open(2)` its own small structure, and verify from userland that two descriptors see independent data.

Steps.

1. Add the struct `myfirst_fh` type and the `myfirst_fh_dtor()` destructor as shown earlier in this chapter.
2. Rewrite `myfirst_open()` to allocate a `myfirst_fh`, call `devfs_set_cdevpriv()`, and free on registration failure. Remove the exclusive-open check.

3. Rewrite `myfirst_read()` and `myfirst_write()` so each starts with a call to `devfs_get_cdevpriv(&fh)`. Leave the body unchanged for now; Chapter 9 fills it in.
4. Rebuild, reload, then run two `probe_myfirst` processes side by side:

```
% (sudo ./probe_myfirst &) ; sudo ./probe_myfirst
```

5. In `dmesg`, confirm that the two `open (per-open fh=...)` messages show different pointers.

Success criteria.

- Two simultaneous opens succeed. No `EBUSY`.
- Two distinct `fh=` pointers appear in the kernel log.
- `kldunload myfirst` is only possible once both probes have exited.

8.15.4 Lab 8.4: devfs.conf Persistence

Goal. Make the ownership change from Lab 8.1 survive reboots, without editing the driver again.

Steps.

1. In Lab 8.1, revert `args.mda_gid` and `args.mda_mode` to the Chapter 7 defaults (`GID_WHEEL, 0600`).
2. Create or edit `/etc/devfs.conf` and add:

```
own    myfirst/0      root:operator
perm   myfirst/0      0660
```

3. Apply the change without rebooting:

```
% sudo service devfs restart
```

4. Reload the driver and confirm that `ls -l /dev/myfirst/0` again shows `root operator 0660`, even though the driver itself asked for `root wheel 0600`.

Success criteria.

- With the driver loaded and `devfs.conf` in place, the node shows the `devfs.conf` values.
- With the driver loaded and the `devfs.conf` lines commented out and `devfs` restarted, the node returns to the driver's baseline.

Notes. Lab 8.4 is an operator-side lab. The driver does not change between steps. The point is to see the two-layer policy model at work: driver sets the baseline, `devfs.conf` shapes the view.

8.15.5 Lab 8.5: Two-Node Driver (Data and Control)

Goal. Extend `myfirst` to expose two distinct nodes: a data node at `/dev/myfirst/0` and a control node at `/dev/myfirst/0ctl`, each with its own `cdevsw` and its own permission mode.

Prerequisites. Completed Lab 8.3 (stage 2 with `per-open` state).

Steps.

1. Define a second struct `cdevsw` in the driver, named `myfirst_ctl_cdevsw`, with `d_name = "my-first_ctl"` and only `d_ioctl` stubbed (you will not implement `ioctl` commands; just make the function exist and return `ENOTTY`).
2. Add a struct `cdev *cdev_ctl` field to the `softc`.
3. In `myfirst_attach`, after the data node is created, create the control node with a second `make_dev_s` call. Use `"myfirst/%d.ctl"` as the format. Set the mode to `0640` and the group to `GID_WHEEL` so the control node is narrower than the data node.
4. Pass `sc` through `mda_si_drv1` for the control `cdev` as well, so `d_ioctl` can find it.
5. In `myfirst_detach`, destroy the control `cdev` **before** the data `cdev`. Log each destruction.
6. Rebuild, reload, and verify:

```
% ls -l /dev/myfirst
total 0
crw-rw----  1 root  operator  0x5a Apr 17 10:02 0
crw-r-----  1 root  wheel    0x5b Apr 17 10:02 0.ctl
```

Success criteria.

- Both nodes appear on load.
- Both nodes disappear on unload.
- The data node is group-readable by operator; the control node is not.
- Attempting `cat </dev/myfirst/0.ctl` from a non-root non-wheel user fails with `Permission denied`.

Notes. In real drivers the control node is where `ioctl` commands for configuration live. This chapter does not implement any `ioctl` commands; that work is Chapter 25's. The point of Lab 8.5 is to show that you can have two nodes with different policies wired into one driver.

8.15.6 Lab 8.6: Parallel Probe Verification

Goal. Use the `parallel_probe` tool from the companion tree to prove that per-open state really is per-descriptor.

Prerequisites. Completed Lab 8.3. The stage 2 driver is loaded.

Steps.

1. Build the userland tools:

```
% cd examples/part-02/ch08-working-with-device-files/userland
% make
```

2. Run `parallel_probe` with four descriptors:

```
% sudo ./parallel_probe /dev/myfirst/0 4
opened /dev/myfirst/0 as fd 3
opened /dev/myfirst/0 as fd 4
opened /dev/myfirst/0 as fd 5
```

```
opened /dev/myfirst/0 as fd 6
holding 4 descriptors; press enter to close
```

3. Open a second terminal and inspect dmesg:

```
% dmesg | tail -20
```

You should see four open via myfirst/0 fh=<pointer> (active=N) lines, each with a different pointer value.

4. In the second terminal, check the active_opens sysctl:

```
% sysctl dev.myfirst.0.stats.active_fhs
dev.myfirst.0.stats.active_fhs: 4
```

5. Return to the first terminal and press Enter. The probe closes all four descriptors. Check dmesg again:

```
% dmesg | tail -10
```

You should see four per-open dtor fh=<pointer> lines, one per descriptor, with the same pointer values that appeared in the open log.

6. Verify active_fhs is back to zero:

```
% sysctl dev.myfirst.0.stats.active_fhs
dev.myfirst.0.stats.active_fhs: 0
```

Success criteria.

- Four distinct fh= pointers in the open log.
- Four matching pointers in the destructor log.
- active_fhs increments to four and decrements back to zero.
- No kernel log messages about leaked memory or unexpected state.

Notes. Lab 8.6 is the strongest evidence you can easily produce that per-open state is isolated. If any step fails, the most common culprit is a missed call to `devfs_set_cdevpriv` or a destructor that does not decrement `active_fhs`.

8.15.7 Lab 8.7: devfs.rules for a Jail

Goal. Make `/dev/myfirst/0` visible inside a jail through a devfs ruleset.

Prerequisites. A working FreeBSD jail on your lab system. If you do not have one yet, skip this lab and return after Part 7.

Steps.

1. Add a ruleset to `/etc/devfs.rules`:

```
[myfirst_jail=100]
add include $devfsrules_jail
```

```
add path 'myfirst'    unhide
add path 'myfirst/*' unhide
add path 'myfirst/*' mode 0660 group operator
```

2. Add a devfs entry to the jail's jail.conf:

```
myfirstjail {
    path = "/jails/myfirstjail";
    host.hostname = "myfirstjail.example.com";
    mount.devfs;
    devfs_ruleset = 100;
    exec.start = "/bin/sh";
    persist;
}
```

3. Reload devfs and start the jail:

```
% sudo service devfs restart
% sudo service jail start myfirstjail
```

4. Inside the jail, confirm the node:

```
% sudo jexec myfirstjail ls -l /dev/myfirst
```

5. Verify the ruleset is working by commenting out the `add path 'myfirst/*' unhide` line, restarting devfs and the jail, and observing the node disappear.

Success criteria.

- `/dev/myfirst/0` appears inside the jail with mode `0660` and group operator.
- Removing the `unhide` rule removes the node from inside the jail.
- The host continues to see the node regardless of the jail's ruleset.

Notes. Jail configuration is ordinarily covered in later chapters; this lab is a preview to demonstrate the driver-side outcome. If the lab is difficult on your system, come back to it after you have jails configured for other purposes.

8.15.8 Lab 8.8: Destroy-Dev Drain

Goal. Demonstrate the difference between `destroy_dev` and `destroy_dev_drain` when a `cdevsw` is being freed along with many `cdevs`.

Prerequisites. Completed Lab 8.3. Your driver is loaded and quiet.

Steps.

1. Review the Stage 2 detach code. The one-cdev driver does not need `destroy_dev_drain`. The lab models what goes wrong in a multi-cdev driver that does.
2. Build the `stage4-destroy-drain` variant of the driver (in the companion tree). This variant creates five `cdevs` in `attach` and uses `destroy_dev_sched` to schedule their destruction in `detach`, without draining.

3. Load the variant, then immediately unload it while a userland process is holding one of the cdevs open:

```
% sudo kldload ./stage4.ko
% sudo ./hold_myfirst 60 /dev/myfirstN/3 &
% sudo kldunload stage4
```

4. Observe the kernel log. You should see complaints or, depending on timing, a panic. The variant is deliberately unsafe.
5. Switch to the “fixed” version of the stage 4 source, which calls `destroy_dev_drain(&mycdevsw)` after the per-cdev destroy-sched calls. Repeat the load/hold/unload sequence.
6. Confirm that the fixed version unloads cleanly, waiting for the held descriptor to close before the module goes away.

Success criteria.

- The broken variant produces an observable problem (message, hang, or panic) when unloaded with a descriptor held.
- The fixed variant completes the unload cleanly.
- Reading the source makes it clear which call made the difference.

Notes. This lab deliberately triggers a bad state. Run it in a throwaway VM, not on a system you care about. The point is to build intuition for why `destroy_dev_drain` exists; once you have watched the broken path fail, you will remember to call it in multi-cdev drivers.

8.16 Challenge Exercises

These build on the labs. Take your time; none of them introduce new mechanics, they only stretch the ones you just practised.

8.16.1 Challenge 1: Use the Alias

Change `probe_myfirst.c` to open `/dev/myfirst` instead of `/dev/myfirst/0` by default. Confirm from the kernel log that your `d_open` runs, and that `devfs_set_cdevpriv` succeeds exactly once per `open(2)`. Then change the path back. You should not have to edit the driver.

8.16.2 Challenge 2: Observe Per-Open Cleanup

Add a `device_printf` inside `myfirst_fh_dtor()` that logs the `fh` pointer being freed. Run `probe_myfirst` once and confirm that exactly one destructor line appears in `dmesg` per run. Then write a tiny program that opens the device, sleeps for 30 seconds, and exits without calling `close(2)`. Confirm that the destructor still fires when the process exits. Cleanup is not a politeness; it is guaranteed.

8.16.3 Challenge 3: Experiment with devfs.rules

If you have a FreeBSD jail configured, add a `myfirst_lab` ruleset to `/etc/devfs.rules` that makes `/dev/myfirst/*` visible inside the jail. Start the jail, open the device from inside it, and confirm that the driver sees a new open. If you do not have a jail yet, skip this challenge for now and return to it after Part 7.

8.16.4 Challenge 4: Read Two More Drivers

Pick two drivers from `/usr/src/sys/dev/` that you have not read yet. Good candidates are `/usr/src/sys/dev/random/randomdev.c`, `/usr/src/sys/dev/hwpmc/hwpmc_mod.c`, `/usr/src/sys/dev/kbd/kbd.c`, or anything else short enough to skim. For each driver, find:

- The `cdevsw` definition and its `d_name`.
- The `make_dev*` call and the permission mode it sets.
- The `destroy_dev` calls, or absence of them.
- Whether the driver uses `devfs_set_cdevpriv`.
- Whether the driver creates a subdirectory under `/dev`.

Write a short paragraph for each driver classifying its device-file surface. The point is to sharpen your eye; there is no single correct taxonomy.

8.16.5 Challenge 5: devd Configuration

Write a minimal `/etc/devd.conf` rule that logs a message every time `/dev/myfirst/0` appears or disappears. The `devd` configuration format is documented in `devd.conf(5)`. A starting template:

```
notify 100 {
    match "system"      "DEVFS";
    match "subsystem"   "CDEV";
    match "cdev"        "myfirst/0";
    action              "/usr/bin/logger -t myfirst event=$type";
};
```

Install the rule, restart `devd` (`service devd restart`), load and unload the driver, then verify that `grep myfirst /var/log/messages` shows both events.

8.16.6 Challenge 6: Add a Status Node

Modify `myfirst` to expose a read-only status node alongside the data node. The status node lives at `/dev/myfirst/0.status`, mode `0444`, owner `root:wheel`. Its `d_read` returns a short plaintext string summarising the current state of the driver:

```
attached_at=12345
active_fhs=2
open_count=17
```

Hint: allocate a small fixed-size buffer in the softc, format the string under the mutex, and return it to the user with `uiomove(9)` if you have read Chapter 9, or with a manual implementation for now.

If you are not yet comfortable with `uiomove`, defer this challenge until after Chapter 9. It is a natural first use of what Chapter 9 teaches.

8.17 Error Codes for Device File Operations

Every `d_open` and `d_close` that returns a non-zero value tells devfs something specific. The `errno` values you choose are the contract between your driver and every user program that ever touches your node. Getting them right costs nothing; getting them wrong produces bug reports you will not understand at first read.

This section surveys the `errno` values that come up in practice on the device-file surface. Chapter 9 will treat the `errno` choices for `d_read` and `d_write` separately, because the data-path choices are different in character. Here we stay focused on `open`, `close`, and `ioctl`-adjacent returns.

8.17.1 The Short List

In rough order of how often you will reach for them:

- **ENXIO (No such device or address):** “The device is not in a state where it can be opened.” Use when the driver is attached but not ready, when the hardware is known to be missing, when the softc is in a transient state. The user sees `Device not configured`.
- **EBUSY (Device busy):** “The device is already open and this driver does not allow concurrent access.” Use for exclusive-open policies. The user sees `Device busy`.
- **EACCES (Permission denied):** “The credential presenting this open is not allowed.” The kernel normally catches permission failures before your handler runs, but a driver may check a secondary policy (for instance, an `ioctl`-only node that refuses opens for read) and return `EACCES` itself.
- **EPERM (Operation not permitted):** “The operation requires privilege the caller does not have.” Similar to `EACCES` in spirit but aimed at privilege distinctions (`priv_check(9)` failures) rather than UNIX file permissions.
- **EINVAL (Invalid argument):** “The call was structurally valid but the driver does not accept these arguments.” Use when `oflags` specifies a combination the driver refuses.
- **EAGAIN (Resource temporarily unavailable):** “The device could be opened in principle, but not right now.” Use this when you have a temporary shortage (a slot is full, a resource is being reconfigured) and the user should retry later. The user sees `Resource temporarily unavailable`.
- **EINTR (Interrupted system call):** Returned when a sleep inside your handler is interrupted by a signal. You will not normally return this from `d_open` because opens do not usually sleep interruptibly. It shows up more in data-path handlers.
- **ENOENT (No such file or directory):** Almost always synthesised by devfs itself when the path does not resolve. A driver rarely returns this from its own handlers.
- **ENODEV (Operation not supported by device):** “The operation itself is valid but this device does not support it.” Use when a secondary interface of the driver refuses an operation the other interface supports.
- **EOPNOTSUPP (Operation not supported):** A cousin of `ENODEV`. Used in some subsystems for similar situations.

8.17.2 Which Value for Which Situation?

Real drivers fall into patterns. Here are the patterns you will write most often.

Pattern A: Driver attached but softc not yet ready. You might hit this during a two-stage attach where the cdev is created before some initialisation completes, or during detach while the cdev still exists.

```
if (sc == NULL || !sc->is_attached)
    return (ENXIO);
```

Pattern B: Exclusive-open policy.

```
mtx_lock(&sc->mtx);
if (sc->is_open) {
    mtx_unlock(&sc->mtx);
    return (EBUSY);
}
sc->is_open = 1;
mtx_unlock(&sc->mtx);
```

This is what Chapter 7 did. Chapter 8's stage 2 removes the exclusive check because per-open state is available; the EBUSY is simply no longer needed.

Pattern C: Read-only node refusing writes.

```
if ((oflags & FWRITE) != 0)
    return (EACCES);
```

Use this when the node is conceptually read-only and opening for write is a caller mistake.

Pattern D: Privileged-only interface.

```
if (priv_check(td, PRIV_DRIVER) != 0)
    return (EPERM);
```

Returns EPERM when a non-privileged caller tries to open a node that enforces additional privilege checks beyond the filesystem mode.

Pattern E: Temporarily unavailable.

```
if (sc->resource_in_flight) {
    return (EAGAIN);
}
```

Use this when the driver can accept the open later but not now, and the user should retry.

Pattern F: Driver-specific invalid combination.

```
if ((oflags & O_NONBLOCK) != 0 && !sc->supports_nonblock) {
    return (EINVAL);
}
```

Use this when the caller's oflags specify a mode your driver does not implement.

8.17.3 Returning Errors From `d_close`

`d_close` has its own considerations. The kernel does not usually care about errors from `close`, because by the time `close(2)` returns to userland the descriptor is already gone. But `close` is still your last chance to notice a failure and log it, and some callers may check. The safest pattern is:

- Return zero from ordinary close paths.
- Return a non-zero `errno` only when something genuinely unusual happened and userland should know about it.
- When in doubt, log with `device_printf(9)` and return zero.

A driver that returns random errors from `d_close` is a driver whose tests will mysteriously fail, because most userland code ignores close errors. Save `errno` for open and for `ioctl`, where it matters.

8.17.4 Mapping Your `errno` to User Messages

The values defined in `/usr/include/errno.h` have stable textual representations through `strerror(3)` and `perror(3)`. Every `err(3)` and `warn(3)` message in a userland program will use these. A short table of the mappings:

errno	strerror text	Typical user program behavior
ENXIO	Device not configured	Wait or give up; report clearly
EBUSY	Device busy	Retry later or abort
EACCES	Permission denied	Prompt for sudo or exit
EPERM	Operation not permitted	Similar to EACCES
EINVAL	Invalid argument	Report bug in calling code
EAGAIN	Resource temporarily unavailable	Retry after a short delay
EINTR	Interrupted system call	Retry, usually in a loop
ENOENT	No such file or directory	Verify driver is loaded
ENODEV	Operation not supported by device	Report design mismatch
EOPNOTSUPP	Operation not supported	Report design mismatch

Appendix E of this book collects the full list of kernel `errno` values and their meanings. For Chapter 8 the list above covers everything you will reach for on the device-file surface.

8.17.5 A Quick Checklist Before You Pick an `errno`

When you are unsure which `errno` fits, ask three questions:

1. **Is the problem about identity?** “This device cannot be opened now” is `ENXIO`. “This device does not exist” is `ENOENT`. Rarely the driver’s call; `devfs` usually handles it.
2. **Is the problem about permission?** “You do not have permission” is `EACCES`. “You lack a specific privilege” is `EPERM`.
3. **Is the problem about arguments?** “The call was structurally fine but the driver will not accept these arguments” is `EINVAL`.

When two `errno` values could plausibly fit, pick the one whose textual representation matches what you would want a frustrated user to read. Remember that `errno` values become error messages in tools you do not control, and the clearer the mapping between kernel intent and user-facing text, the more kindly your driver will be reviewed.

8.17.6 A Short Narrative: `errno` Chosen Three Times

To make the abstract concrete, here are three small scenes drawn from real driver review conversations. Each is about the choice of a single `errno` value.

Scene 1. The too-early open.

A driver attaches an onboard sensor. The sensor takes a hundred milliseconds after power-on to produce valid data. During those hundred milliseconds, user programs that try to read will get garbage.

The first draft of the driver returns `EAGAIN` from `d_open` during the warm-up window. The reviewer flags it. `EAGAIN` means “retry later”, which is fine, but the user-facing text is “Resource temporarily unavailable”, and that does not match what the user is seeing: the device exists and can in principle be opened, but it is not producing data yet.

The revised draft returns `ENXIO` during the warm-up. The user sees “Device not configured”, which is closer to the truth. A well-written userland program can special-case that `errno` if it wants to wait for the device. A typical tool will print a clear message and exit.

Lesson: think about what the user sees, not just what you mean internally.

Scene 2. The wrong permission error.

A driver has a configurable mode: a `sysctl` can set it to “read-only”. When the `sysctl` is set, `d_write` returns an error. The first draft returns `EPERM`. The reviewer flags it. `EPERM` is about privilege; the kernel uses it when a specific `priv_check(9)` call fails. But in this driver, no privilege check is being performed; the device is simply in a read-only state.

The revised draft returns `EROFS`, “Read-only file system”. The textual mapping is almost perfect for this scenario.

Lesson: the nearer `errno` value is usually the better `errno` value. Do not default to `EPERM` for every refusal.

Scene 3. The busy file.

A driver that enforces exclusive access returns `EBUSY` from `d_open` when a second opener arrives. That is correct. In code review, one reviewer points out that the driver also returns `EBUSY` from a control-node `ioctl` that

refuses during an in-progress reconfiguration. The review argument is that those are different situations and the two uses of `EBUSY` will confuse operators who are reading logs.

The discussion lands on a compromise: `EBUSY` for the open-path exclusive check, `EAGAIN` for the reconfiguration-in-progress case. The distinction is that the open-path refusal is “will be busy until the other user closes”, while the reconfiguration refusal is “retry in a moment, it will clear on its own”.

Lesson: two situations that feel similar may map to different `errno` values if the reasoning about the user’s next action differs.

These scenes are small, but the principle is not. Every `errno` value is a hint to the user about what to do next. Choose it with the user’s perspective in view, not only yours.

8.17.7 Using `err(3)` and `warn(3)` to Exercise `errno` Values

The `err(3)` family in FreeBSD’s `libc` prints a clean “program: message: `errno`-string” when an operation fails. Your userland probes use `err(3)` because it is the shortest path to a readable error. You can verify your driver’s `errno` choices by running a probe that deliberately triggers each one:

```
fd = open("/dev/myfirst/0", O_RDWR);
if (fd < 0)
    err(1, "open /dev/myfirst/0");
```

When the driver returns `EBUSY`, the program prints:

```
probe_myfirst: open /dev/myfirst/0: Device busy
```

When the driver returns `ENXIO`, the program prints:

```
probe_myfirst: open /dev/myfirst/0: Device not configured
```

Run the probe against each of the error cases you can construct. Read the messages out loud. If any of them would confuse a user who had not read your driver’s source code, reconsider the `errno`.

8.17.8 `errno` Values Your Driver Should Almost Never Return

For balance, a list of values that rarely fit a device-file open or close:

- **ENOMEM**: let the `malloc` call report this by returning it through your function, but do not invent it.
- **EIO**: reserved for hardware I/O errors. If your device has no hardware, this value is out of place.
- **EFAULT**: used when userland hands the kernel a bad pointer. On the open path you rarely touch user pointers, so `EFAULT` does not fit.
- **ESRCH**: “No such process”. Unlikely to be right for a device-file operation.
- **ECHILD**: process-relationship `errno`. Not applicable.
- **EDOM** and **ERANGE**: math errors. Not applicable.

When in doubt, if the value does not appear in the Chapter 8 “Short List” earlier in this section, it is almost certainly wrong for an open or close. Save the unusual values for the unusual operations that genuinely produce them.

8.18 Tools for Inspecting /dev

Several small utilities are worth knowing about, because once you reach Chapter 9 you will be leaning on them to confirm behavior quickly. This section introduces each in enough depth to use it, and ends with two short troubleshooting walkthroughs.

8.18.1 ls -l for Permissions and Existence

The first stop. `ls -l /dev/yourpath` confirms existence, type, ownership, and mode. If the node is missing after a load, your `make_dev_s` likely failed; check `dmesg` for the error code.

`ls -l` on a devfs directory works the way you expect: `ls -l /dev/myfirst` lists the entries in the subdirectory. Combined with `-d`, it reports on the directory itself:

```
% ls -ld /dev/myfirst
dr-xr-xr-x  2 root  wheel  512 Apr 17 10:02 /dev/myfirst
```

The mode on a devfs subdirectory is 0555 by default, and it is not directly configurable through `devfs.conf`. The subdirectory exists only because at least one node is inside it; when the last node inside disappears, the directory disappears too.

8.18.2 stat and stat(1)

`stat(1)` prints a structured view of any node. The default output is verbose and includes timestamps. A more useful form is a custom format:

```
% stat -f '%Sp %Su %Sg %T %N' /dev/myfirst/0
crw-rw---- root operator Character Device /dev/myfirst/0
```

The placeholders are documented in `stat(1)`. The five above are permissions, user name, group name, file type description, and path. This form is useful inside scripts that need a stable text representation.

For comparing two paths to check that they resolve to the same cdev, `stat -f '%d %i %Hr,%Lr'` prints the device of the filesystem, the inode, and the major and minor components of `rdev`. On two devfs nodes that refer to the same cdev, the `rdev` component will match.

8.18.3 fstat(1): Who Has It Open?

`fstat(1)` lists every open file on the system. Filtered to a device path, it tells you which processes have the node open:

```
% fstat /dev/myfirst/0
USER      CMD          PID   FD MOUNT      INUM  MODE      SZ|DV R/W NAME
root      probe_myfir 1234   3 /dev          4 crw-rw---- 0,90 rw  /dev/myfirst/0
```

This is the tool that solves the “kldunload returns EBUSY and I do not know why” puzzle. Run it against your node, identify the offending process, and either wait for it to finish or terminate it.

`fstat -u username` filters by user, useful when you suspect a particular user’s daemons are holding the node. `fstat -p pid` inspects one process.

8.18.4 `procstat -f`: A Process-First View

`fstat(1)` lists files and tells you who holds them. `procstat -f pid` does the inverse: it lists the files held by a given process. When you have the PID of a running program and want to confirm which device nodes it currently has open, this is the tool:

```
% procstat -f 1234
  PID COMM          FD T V FLAGS      REF  OFFSET PRO NAME
1234 probe_myfirst    3 v c rw-----   1      0    /dev/myfirst/0
```

Column `T` shows the file type (`v` for vnode, which includes device files), and column `V` shows the vnode type (`c` for character-device vnode). This is the quickest way to confirm what a debugger shows you.

8.18.5 `devinfo(8)`: The Newbus Side

`devinfo(8)` does not look at devfs at all. It walks the Newbus device tree and prints the device hierarchy. Your `myfirst0` child of `nexus0` shows up there regardless of whether a `cdev` exists:

```
% devinfo -v
nexus0
  myfirst0
  pcib0
    pci0
      <...lots of PCI children...>
```

This is the tool you reach for when something is missing from `/dev` and you need to check whether the device itself attached. If `devinfo` shows `myfirst0` but `ls /dev` does not, your `make_dev_s` failed. If neither shows the device, your `device_identify` or `device_probe` did not create the child. Two different bugs, two different fixes.

The `-r` flag filters to the Newbus hierarchy rooted at a specific device, which becomes useful in complex systems with lots of PCI devices.

8.18.6 devfs(8): Rulesets and Rules

`devfs(8)` is the low-level administrative interface to `devfs` rulesets. You met it in Section 10. Three subcommands come up often:

- `devfs rule showsets` lists ruleset numbers currently loaded.
- `devfs rule -s N show` prints the rules inside ruleset `N`.
- `devfs rule -s N add path 'pattern' action args` adds a rule at runtime.

Rules added at runtime do not persist; to make them permanent, add them to `/etc/devfs.rules` and run `service devfs restart`.

8.18.7 sysctl dev.* and Other Hierarchies

`sysctl dev.myfirst` prints every `sysctl` variable under your driver's namespace. From Chapter 7 you already have a `dev.myfirst.0.stats` tree. Reading it confirms the softc is present, the attach ran, and the counters are advancing.

`Sysctls` are a complementary surface to `/dev`. They are primarily for observability; they are cheaper to read than opening a device; they have no file-descriptor cost. When a piece of information is simple enough to be a number or a short string, consider exposing it as a `sysctl` rather than as a read on the device node.

8.18.8 kldstat: Is the Module Loaded?

When a node is missing, the question “is my driver even loaded?” is worth asking first.

```
% kldstat | grep myfirst
8      1 0xfffffffff82a00000      3a50 myfirst.ko
```

If you see the module in `kldstat`, the module is in the kernel. If `devinfo` shows the device but `ls /dev` does not show the node, the issue is inside your driver. If `kldstat` does not show the module, the issue is outside: you forgot to `kldload`, or the load failed. Check `dmesg`.

8.18.9 dmesg: The Log of What Happened

Every `device_printf` and `printf` call from a driver ends up in the kernel message buffer, and `dmesg` (or `dmesg -a`) prints it. When something goes wrong on this surface, `dmesg` is the first place to look:

```
% dmesg | tail -20
```

Your attach and detach messages, any `make_dev_s` failures, and any panic messages from destruction paths land here. Get in the habit of watching `dmesg` with a second terminal open to `tail -f /var/log/messages` during development.

8.18.10 Troubleshooting Walkthrough 1: The Node Is Missing

A checklist for “I expected `/dev/myfirst/0` to exist and it does not”.

1. Is the module loaded? `kldstat | grep myfirst`.
2. Did attach run? `devinfo -v | grep myfirst`.
3. Did `make_dev_s` succeed? `dmesg | tail` should show your attach-success message.
4. Is `devfs` mounted on `/dev`? `mount | grep devfs`.
5. Are you looking at the right path? If your format string was `"myfirst%d"`, the node is `/dev/myfirst0`, not `/dev/myfirst/0`. Typos happen.
6. Is a `devfs.rules` entry hiding the node? `devfs rule showsets` and inspect.

Nine times out of ten, one of the first three questions yields the answer.

8.18.11 Troubleshooting Walkthrough 2: `kldunload` Returns `EBUSY`

A checklist for “I can load my module but cannot unload it”.

1. Is the node still open? `fstat /dev/myfirst/0` shows the holder.
2. Is your detach returning `EBUSY` itself? Check `dmesg` for a message from your driver. Stage 2’s detach returns `EBUSY` when `active_fhs > 0`.
3. Is a `devfs.conf` link pointing at your node? The link can keep a reference if the target is held open.
4. Is a kernel thread stuck inside one of your handlers? Look for a `Still N threads in foo` message in `dmesg`. If present, you need a `d_purge`.

Most `EBUSY`s are open descriptors. The other cases are rare.

8.18.12 A Note on Habits

None of these tools are unusual. They are the everyday instruments of FreeBSD administration. What matters is the habit of reaching for them in a known order when something looks wrong. The first three times you debug a missing node, you will grope for the right tool; the fourth time, the order will feel automatic. Build that reflex now, while the problems are small.

8.19 Pitfalls and Things Worth Watching

A field guide to the mistakes that catch beginners most often. Each one names the symptom, the cause, and the cure.

- **Creating the device node before the softc is ready.** *Symptom:* `open` causes a NULL dereference as soon as the driver loads. *Cause:* `si_drv1` still unset, or a `softc` field that `open()` consults has not been initialized. *Cure:* set `mda_si_drv1` in `make_dev_args` and finalize `softc` fields before the `make_dev_s` call. Think of `make_dev_s` as publishing, not preparing.
- **Destroying the softc before the device node.** *Symptom:* occasional panics during or shortly after `kldunload`. *Cause:* reversing the order of teardown in `detach()`. *Cure:* always destroy the `cdev` first, then the alias, then the lock, then the `softc`. The `cdev` is the door; close it before dismantling the rooms behind it.

- **Storing per-open state on the cdev.** *Symptom:* works fine with one user, garbled state with two. *Cause:* read positions or similar per-descriptor data stored in `si_drv1` or in the `softc`. *Cure:* move them into a struct `myfirst_fh` and register it with `devfs_set_cdevpriv`.
- **Forgetting that /dev changes are not persistent.** *Symptom:* a `chmod` you ran by hand is gone after a reboot or module reload. *Cause:* `devfs` is live, not on disk. *Cure:* put the change in `/etc/devfs.conf` and service `devfs` restart.
- **Leaking the alias on detach.** *Symptom:* `kldunload` returns `EBUSY` and the driver is wedged. *Cause:* the alias `cdev` is still live. *Cure:* call `destroy_dev(9)` on the alias before the primary in `detach()`.
- **Calling devfs_set_cdevpriv twice.** *Symptom:* the second call returns `EBUSY` and your handler returns the error to the user. *Cause:* two independent paths in `open` both tried to register private data, or the handler ran twice for the same `open`. *Cure:* audit the code path so exactly one successful `devfs_set_cdevpriv` happens per `d_open` invocation.
- **Allocating fh without freeing it on the error path.** *Symptom:* steady memory leak correlated with failed opens. *Cause:* `devfs_set_cdevpriv` returned an error and the allocation was abandoned. *Cure:* on any error after `malloc` and before a successful `devfs_set_cdevpriv`, free the allocation explicitly.
- **Confusing aliases with symlinks.** *Symptom:* permissions set through `devfs.conf` on a link do not match what the driver advertises on the primary. *Cause:* mixing both mechanisms on the same name. *Cure:* pick one tool per name; use aliases when the driver owns the name, symlinks when operator convenience is the goal.
- **Using wide-open modes for “just testing”.** *Symptom:* a driver that shipped to staging with `0666` suddenly needs to have that narrowed without breaking consumers. *Cause:* a temporary lab mode turned into a default. *Cure:* default to `0600`, widen only when a concrete consumer asks, and note the reason in a comment next to the `mda_mode` line.
- **Using make_dev in new code.** *Symptom:* the driver compiles and works, but a reviewer flags the call. *Cause:* `make_dev` is the oldest form of the family and panics on failure. *Cure:* use `make_dev_s` with a populated struct `make_dev_args`. The newer form is easier to read, easier to error-check, and friendlier to future API additions. *How you catch it earlier:* run `mandoc -Tlint` on your driver and read the `SEE ALSO` in `make_dev(9)`.
- **Forgetting D_VERSION.** *Symptom:* the driver loads but the first open returns a cryptic failure, or the kernel prints a `cdevsw` version mismatch. *Cause:* the `d_version` field of `cdevsw` was left zero. *Cure:* set `.d_version = D_VERSION` as the first field in every `cdevsw` literal. *How you catch it earlier:* a code template that includes the field keeps you from ever typing a `cdevsw` without it.
- **Shipping with D_NEEDGIANT “because it compiled”.** *Symptom:* the driver works but every operation serialises behind the Giant lock, making SMP-heavy workloads slow. *Cause:* the flag was copied from an older driver, or added to silence a warning, and never removed. *Cure:* delete the flag. If your driver actually needs Giant to hold together, it has a real locking bug that needs real fixing, not a flag.
- **Hard-coding the hex identifier in test scripts.** *Symptom:* a test fails on a slightly different machine because the `0x5a` in `ls -l` output is different there. *Cause:* `devfs`’s `rdev` identifier is not stable across reboots, kernels, or systems. *Cure:* compare `stat -f '%d %i'` across two paths to check alias equivalence rather than scraping `ls -l` for the hex identifier.
- **Assuming devfs.conf runs before your driver loads.** *Symptom:* a `devfs.conf` line for your driver’s node does not take effect after `kldload`. *Cause:* service `devfs` start runs early in boot, before modules loaded at runtime. *Cure:* service `devfs` restart after loading the driver, or statically compile the driver so its nodes exist before `devfs` starts.
- **Relying on node names with non-POSIX characters.** *Symptom:* shell scripts break with quoting errors;

`devfs.rules` patterns fail to match. *Cause:* the node name uses spaces, colons, or non-ASCII characters. *Cure:* stick to lowercase ASCII letters, digits, and the three separators `/`, `-`, `..`. Other characters will sometimes work and sometimes not, and the “sometimes not” always surfaces at the worst moment.

- **Leaking per-open state on the error path of `d_open`.** *Symptom:* subtle memory leak, detected much later by running a stress test for hours. *Cause:* `malloc` succeeded, `devfs_set_cdevpriv` failed, and the allocation was abandoned without being freed. *Cure:* every error path in `d_open` between `malloc` and the successful `devfs_set_cdevpriv` must free the allocation. Writing the error path first, before the success path, is a useful habit.
- **Registering `devfs_set_cdevpriv` twice in the same open.** *Symptom:* the second call returns `EBUSY` and the user sees `Device busy` on open, for no reason they can discern. *Cause:* two independent code paths in `d_open` both try to attach private data, or the open handler runs twice for the same file. *Cure:* audit the code path so exactly one successful `devfs_set_cdevpriv` happens per `d_open` invocation. If the driver genuinely wants to replace the data, use `devfs_clear_cdevpriv(9)` first, but this is almost always a sign the design needs a rethink.

8.19.1 Pitfalls That Are Really About Lifecycle

A separate cluster of pitfalls comes from confusion about lifecycle. They are worth calling out explicitly.

- **Freeing the `softc` before the `cdev` is destroyed.** *Symptom:* a panic shortly after `kldunload`, usually a `NULL` dereference or a use-after-free in a handler. *Cause:* the driver tore down `softc` state in `detach` before `destroy_dev` finished draining the `cdev`, and an in-flight handler then dereferenced the freed state. *Cure:* destroy the `cdev` first and rely on its draining behavior; only tear down `softc` after. *How you catch it earlier:* run any of the stress tests while watching `dmesg` for kernel panics; the race is easy to hit on an SMP system with moderate load.
- **Assuming `destroy_dev` returns immediately.** *Symptom:* a deadlock, usually in a handler that holds a lock and then calls a function that ends up needing the same lock. *Cause:* `destroy_dev` blocks until in-flight handlers return; if the caller holds a lock one of those handlers needs, the system deadlocks. *Cure:* never call `destroy_dev` while holding a lock an in-flight handler might need. For the common case in `detach`, hold nothing.
- **Forgetting to set `is_attached = 0` on an error unwind.** *Symptom:* subtle misbehavior after a failed load-unload-reload cycle; handlers believe the device is still attached and try to use freed state. *Cause:* a `goto fail_*` path that did not clear the flag. *Cure:* the single-label unwind pattern from Chapter 7; the last fail label always clears `is_attached` before returning.

8.19.2 Pitfalls in Permission and Policy

Two categories of mistakes around permission tend to surface long after the driver ships.

- **Assuming a node is “only visible to root” because you created it with `0600`.** *Symptom:* a security review flags the node as reachable from a jail that should not see it. *Cause:* mode alone does not filter jail visibility; `devfs.rules` is the filter, and the default may be inclusive enough to pass the node to the jail. *Cure:* if the node must not be visible inside jails, ensure the default jail ruleset hides it. `devfs_rules_hide_all` is the conservative starting point.

- **Relying on `devfs.conf` to keep a node secret on a shared lab machine.** *Symptom:* a collaborator changes `devfs.conf` and the node becomes readable by everyone. *Cause:* `devfs.conf` is operator policy; any operator with write access to `/etc` can change it. *Cure:* the driver's own baseline should be safe in the absence of any `devfs.conf` entry. Treat `devfs.conf` as a permission widener, never as a permission tightener relative to a fundamentally safe baseline.

8.19.3 Pitfalls in Observability

A handful of pitfalls have nothing to do with code but a lot to do with how easy your driver is to debug.

- **Logging every open and close at full volume.** *Symptom:* the kernel message buffer fills with routine driver noise; real errors are harder to find. *Cause:* the driver uses `device_printf` for every `d_open` and `d_close`. *Cure:* gate routine messages with `if (bootverbose)` or remove them entirely once the driver is stable. Leave `device_printf` for lifecycle events and for genuine errors.
- **Not exposing enough sysctls to diagnose unusual states.** *Symptom:* a user reports a bug, you cannot tell what the driver thinks is happening, and adding diagnostics to the driver requires a rebuild and a reload. *Cause:* the sysctl tree is sparse. *Cure:* expose counters generously. `active_fhs`, `open_count`, `read_count`, `write_count`, `error_count` are cheap. Add an `attach_ticks` and a `last_event_ticks` to let operators tell how long the driver has been up and how recently it was active.

8.20 A Final Study Plan

If you want to deepen your grasp of the material beyond the labs and challenges, here is a suggested plan across the week after you finish the chapter.

Day 1: Re-read a section. Pick any single section that felt shakiest on first reading and read it again with the companion tree open next to the text. Just read. Do not try to code yet.

Day 2: Rebuild stage 2 from scratch. Starting from Chapter 7's stage 2 source, make every change the Chapter 8 stages describe, one commit at a time. Diff your work against the companion tree at each stage.

Day 3: Break the driver on purpose. Introduce three different bugs, one at a time: skip the destructor, forget to destroy the alias, return the wrong `errno`. Predict what each bug does. Run the probes. See whether the failure matches your prediction.

Day 4: Read `null.c` and `led.c` end-to-end. Two small drivers, focused on the device-file surface. Write one paragraph on each summarising what you noticed.

Day 5: Add the status node from Challenge 6. Implement the read-only status node with a hand-rolled `uiomove`-equivalent for now; Chapter 9 will show the real idiom.

Day 6: Try the jail lab. If you have not done Lab 8.7 yet, do it now. Jails are worth the effort to set up because later chapters will assume familiarity.

Day 7: Move on. Do not wait to feel like you have “mastered” Chapter 8. You will return to its material naturally as later chapters build on it. The way to become fluent is to keep building; the way to become stuck is to wait for perfection.

8.21 Companion Tree Quick Reference

Because the companion source tree is part of how this chapter teaches, a quick index of what lives where may help you find things during the labs and challenges.

8.21.1 Driver Stages

- `examples/part-02/ch08-working-with-device-files/stage0-structured-name/` is the Lab 8.1 output: Chapter 7's stage 2 driver with the node moved to `/dev/myfirst/0` and ownership tightened to `root:operator 0660`.
- `examples/part-02/ch08-working-with-device-files/stage1-alias/` is the Lab 8.2 output: stage 0 plus `make_dev_alias("myfirst")`.
- `examples/part-02/ch08-working-with-device-files/stage2-perhandle/` is the Lab 8.3 output: stage 1 plus `devfs_set_cdevpriv` per-open state and removal of the exclusive-open check. This is the driver most of the chapter's other exercises use.
- `examples/part-02/ch08-working-with-device-files/stage3-two-nodes/` is the Lab 8.5 output: adds a control node at `/dev/myfirst/%d.ctl` with its own `cdevsw` and a narrower permission mode.
- `examples/part-02/ch08-working-with-device-files/stage4-destroy-drain/` is the Lab 8.8 exercise: a multi-cdev driver demonstrating the difference between `destroy_dev` alone and `destroy_dev_drain`. Build with `make CFLAGS+=-DUSE_DRAIN=1` for the correct variant.

8.21.2 Userland Probes

- `userland/probe_myfirst.c`: one-shot open, read, close.
- `userland/hold_myfirst.c`: open and sleep without closing, to exercise the `cdevpriv` destructor on process exit.
- `userland/stat_myfirst.c`: report `stat(2)` metadata for one or more paths; useful for comparing alias and primary.
- `userland/parallel_probe.c`: open `N` descriptors from one process, hold, close all.
- `userland/stress_probe.c`: loop open/close to shake leaks out.
- `userland/devd_watch.sh`: subscribe to `devd(8)` events and filter for `myfirst`.

8.21.3 Configuration Samples

- `devfs/devfs.conf.example`: Lab 8.4 persistence entries.
- `devfs/devfs.rules.example`: Lab 8.7 jail ruleset.
- `devfs/devd.conf.example`: Challenge 5 `devd` rule.
- `jail/jail.conf.example`: Lab 8.7 jail definition that references ruleset 100.

8.21.4 How the Stages Differ

Every stage is a diff against Chapter 7's stage 2. A useful first exercise after reading the chapter is to run `diff` between each pair of stages and read the result. The changes are small enough to understand line by line, and

the diff tells the progressive story of the chapter's code changes more compactly than re-reading each source file.

```
% diff -u examples/part-02/ch07-writing-your-first-driver/stage2-final/myfirst.c \  
↔ examples/part-02/ch08-working-with-device-files/stage0-structured-name/myfirst.c  
  
% diff -u  
↔ examples/part-02/ch08-working-with-device-files/stage0-structured-name/myfirst.c \  
    examples/part-02/ch08-working-with-device-files/stage1-alias/myfirst.c  
  
% diff -u examples/part-02/ch08-working-with-device-files/stage1-alias/myfirst.c \  
    examples/part-02/ch08-working-with-device-files/stage2-perhandle/myfirst.c
```

Each diff should be a handful of additions and no unexpected subtractions. If you see surprising changes, the chapter text is where the reasoning is.

8.21.5 On Re-using This Tree Later

The stages here are not meant to be the “final” driver. They are snapshots that correspond to checkpoints in the chapter. When you continue into Chapter 9, you will edit stage 2 in place, and it will keep growing. By the time you reach the end of Part 2, the driver has evolved into something much richer than any one stage captures. That is the point: each chapter adds a layer, and the companion tree is there to show each layer individually so you can see the progression.

8.22 A Closing Reflection on Interfaces

Every chapter in this book teaches something different, but a few chapters teach something that runs across the whole practice of driver writing. Chapter 8 is one of them. The specific subject is device files, but the broader subject is **interface design**: how do you shape the boundary between a piece of code you control and a world you do not?

The UNIX philosophy has an answer that has survived half a century. Make the boundary look as much like an ordinary file as you can. Let the existing vocabulary of `open`, `read`, `write`, and `close` do the heavy lifting. Choose names and permissions so operators can reason about them without reading your source. Expose only what the user needs, and no more. Clean up after yourself so aggressively that the kernel can tell when you have lost track of something. Document every choice you make with a comment, a `device_printf`, or a `sysctl`.

None of these principles are unique to device files. They show up again in network interface design, in storage layering, in the kernel's internal APIs, in the userland tools that talk to the kernel. The reason we spent a whole chapter on the small surface under `/dev` is that the same habits, practised here on something tangible and bounded, will serve you in every layer of the kernel you go on to touch.

When you read a driver in `/usr/src/sys` that feels elegant, one of the reasons is almost always that its device-file surface is narrow and honest. When you read a driver that feels tangled, one of the reasons is almost

always that its device-file surface was designed in haste, or widened in response to a short-term pressure, and never narrowed again. The goal of this chapter has been to help you notice that difference, and to give you the vocabulary and the discipline to write the first kind of driver rather than the second.

8.23 Wrapping Up

You now understand the layer between your driver and user space well enough to shape it deliberately. Specifically:

- `/dev` is not a directory on disk. It is a `devfs` view of live kernel objects.
- A `struct cdev` is the kernel-side identity of your node. A `vnode` is how the VFS reaches it. A `struct file` is how an individual `open(2)` sits in the kernel.
- `mda_uid`, `mda_gid`, and `mda_mode` set the baseline of what `ls -l` shows. `devfs.conf` and `devfs.rules` layer operator policy on top.
- The node's path is whatever your format string says, slashes included. Subdirectories under `/dev` are a normal and welcome way to group related nodes.
- `make_dev_alias(9)` lets one `cdev` answer to more than one name. Remember to destroy the alias when you tear down the primary.
- `devfs_set_cdevpriv(9)` gives each `open(2)` its own state, with automatic cleanup. This is the tool you will lean on hardest in the next chapter.

The driver you carry into Chapter 9 is the same `myfirst` you started with, but with a cleaner name, a saner set of permissions, and per-open state ready to hold the read positions, byte counters, and small book keeping that real I/O will need. Keep the file open. You will be editing it again soon.

8.23.1 A Short Self-Check

Before moving on, make sure you can answer each of the following without looking back at the chapter. If any answer is fuzzy, revisit the relevant section before starting Chapter 9.

1. What is the difference between a `struct cdev`, a `devfs vnode`, and a `struct file`?
2. Where does `make_dev_s(9)` get the ownership and mode for the node it creates?
3. Why does a `chmod` on `/dev/yournode` not survive a reboot?
4. What does `make_dev_alias(9)` do, and how does it differ from `link` in `devfs.conf`?
5. When does the destructor registered with `devfs_set_cdevpriv(9)` run, and when does it *not* run?
6. How would you confirm from userland that two paths resolve to the same `cdev`?
7. Why is `D_VERSION` required on every `cdevsw`, and what happens when it is missing?
8. When would you choose `make_dev_s` over `make_dev_p`, and why?
9. What guarantees does `destroy_dev(9)` give you about threads currently inside your handlers?
10. If a jail does not see `/dev/myfirst/0` but the host does, where is the policy that hid it, and how would you inspect it?

If you can answer all ten in your own words, the next chapter will feel like a natural continuation rather than a jump.

8.23.2 Recap Organised by Topic

The chapter covered a lot. Here is a short re-organisation of the material by topic rather than by section, so you can anchor what you learned.

On the relationship between the kernel and the filesystem:

- `devfs` is a virtual filesystem that presents the kernel's live collection of `struct cdev` objects as file-like nodes under `/dev`.
- It has no on-disk storage. Every node reflects something the kernel currently holds.
- It supports only a small, well-defined set of operations on its nodes.
- Changes made interactively (with `chmod`, for instance) do not persist. Persistent policy lives in `/etc/devfs.conf` and `/etc/devfs.rules`.

On the objects your driver interacts with:

- A `struct cdev` is the kernel-side identity of a device node. One per node, regardless of how many file descriptors point at it.
- The `struct cdevsw` is the dispatch table your driver provides. It maps each kind of operation to a handler in your code.
- `struct file` and the `devfs vnode` sit between the user's file descriptor and your `cdev`. They carry per-open state and route operations.

On creating and destroying nodes:

- `make_dev_s(9)` is the modern, recommended way to create a `cdev`. Fill in a `struct make_dev_args`, pass it in, get a `cdev` back.
- `make_dev_alias(9)` creates a second name for an existing `cdev`. Aliases are first-class `cdevs`; the kernel keeps them in step with the primary.
- `destroy_dev(9)` destroys a `cdev` synchronously, draining in-flight handlers. Its cousins `destroy_dev_sched` and `destroy_dev_drain` cover deferred and sweep cases respectively.

On per-open state:

- `devfs_set_cdevpriv(9)` attaches a driver-provided pointer to the current file descriptor, along with a destructor.
- `devfs_get_cdevpriv(9)` retrieves that pointer inside later handlers.
- The destructor fires exactly once per successful set call, when the last reference to the file descriptor drops.
- This is the primary mechanism for per-open bookkeeping in modern FreeBSD drivers.

On policy:

- The driver sets a baseline mode, uid, and gid in the call to `make_dev_s`.
- `/etc/devfs.conf` can adjust those per-node on host `devfs` mounts.
- `/etc/devfs.rules` can define named rulesets that filter and adjust per-mount, typically for jails.
- Three layers can act on the same `cdev`, and the order matters.

On userland:

- `ls -l`, `stat(1)`, `fstat(1)`, `procstat(1)`, `devinfo(8)`, `devfs(8)`, `sysctl(8)`, and `kldstat(8)` are the everyday tools for inspecting and manipulating the surface your driver exposes.
- Small userland C programs that open, read, close, and stat the device are worth writing. They give you control over timing and let you test edge cases cleanly.

On discipline:

- Default to narrow permissions and widen only when a concrete consumer asks.
- Use named constants (`UID_ROOT`, `GID_WHEEL`) rather than raw numbers.
- Destroy in the reverse order of creation.
- Free allocations on every error path before returning.
- Log lifecycle events with `device_printf(9)` so that `dmesg` tells the story of what your driver is doing.

That is a lot. You do not need to hold it all at once. The labs and challenges are where the material becomes muscle memory; the text is only the reading guide.

8.23.3 Looking Ahead to Chapter 9

In Chapter 9 we will fill in `d_read` and `d_write` properly. You will learn how the kernel moves bytes between user memory and kernel memory with `uiomove(9)`, why `struct uio` looks the way it does, and how to design a driver that is safe against short reads, short writes, misaligned buffers, and misbehaving user programs. The per-open state you just wired in will carry read offsets and write state. The alias will keep the old user interfaces working while the driver grows. And the permissions model you set up here will keep your lab scripts honest as you start sending real data through.

Specifically, Chapter 9 will need the fields you added to `struct myfirst_fh` for two things. The reads counter will grow a matching `read_offset` field so each descriptor remembers where it was in a synthesised data stream. The writes counter will be joined by a small ring buffer that `d_write` appends into and `d_read` drains from. The `fh` pointer you retrieve with `devfs_get_cdevpriv` in every handler will be the entry point for all of that state.

The alias you created in Lab 8.2 will keep working without any changes: both `/dev/myfirst` and `/dev/myfirst/0` will produce data, and per-descriptor state will be independent between them.

The permissions you set in Lab 8.1 and Lab 8.4 will remain the correct defaults for development: tight enough to force a conscious `sudo` when a raw user reaches for the device, open enough that a test harness in the operator group can run the data-path tests without escalating.

You have built a well-shaped door. In the next chapter, the rooms behind it come alive.

8.24 Reference: `make_dev_s` and `cdevsw` at a Glance

This reference collects the most useful declarations and flag values in one place, cross-referenced to the sections of the chapter that explained each one. Keep it open while you write your own drivers; most of the mistakes that cost a day are mistakes about one of these values.

8.24.1 Canonical make_dev_s Skeleton

A disciplined template for a single-node driver:

```
struct make_dev_args args;
int error;

make_dev_args_init(&args);
args.mda_devsw    = &myfirst_cdevsw;
args.mda_uid      = UID_ROOT;
args.mda_gid      = GID_OPERATOR;
args.mda_mode     = 0660;
args.mda_si_drv1  = sc;

error = make_dev_s(&args, &sc->cdev, "myfirst/%d", sc->unit);
if (error != 0) {
    device_printf(dev, "make_dev_s: %d\n", error);
    /* unwind and return */
    goto fail;
}
```

8.24.2 Canonical cdevsw Skeleton

```
static struct cdevsw myfirst_cdevsw = {
    .d_version = D_VERSION,
    .d_name    = "myfirst",
    .d_open    = myfirst_open,
    .d_close   = myfirst_close,
    .d_read    = myfirst_read,
    .d_write   = myfirst_write,
    .d_ioctl   = myfirst_ioctl,    /* add in Chapter 25 */
    .d_poll    = myfirst_poll,    /* add in Chapter 10 */
    .d_kqfilter = myfirst_kqfilter, /* add in Chapter 10 */
};
```

Fields omitted are equivalent to NULL, which the kernel interprets either as “not supported” or “use the default behavior” depending on the field.

8.24.3 The make_dev_args Structure

From `/usr/src/sys/sys/conf.h`:

```

struct make_dev_args {
    size_t      mda_size;           /* set by make_dev_args_init */
    int         mda_flags;         /* MAKEDEV_* flags */
    struct cdevsw *mda_devsw;      /* required */
    struct ucred *mda_cr;         /* usually NULL */
    uid_t       mda_uid;          /* see UID_* in conf.h */
    gid_t       mda_gid;          /* see GID_* in conf.h */
    int         mda_mode;         /* octal mode */
    int         mda_unit;         /* unit number (0..INT_MAX) */
    void        *mda_si_drv1;     /* usually the softc */
    void        *mda_si_drv2;     /* second driver pointer */
};

```

8.24.4 The MAKEDEV Flag Word

Flag	Meaning
MAKEDEV_REF	Add an extra reference at creation.
MAKEDEV_NOWAIT	Do not sleep for memory; return ENOMEM if tight.
MAKEDEV_WAITOK	Sleep for memory (default for make_dev_s).
MAKEDEV_ETERNAL	Mark the cdev as never-to-be-destroyed.
MAKEDEV_CHECKNAME	Validate the name; return error on bad names.
MAKEDEV_WHTOUT	Create a whiteout entry (stacked filesystems).
MAKEDEV_ETERNAL_KLD	MAKEDEV_ETERNAL when static, zero when built as KLD.

8.24.5 The cdevsw d_flags Field

Flag	Meaning
D_TAPE	Category hint: tape device.
D_DISK	Category hint: disk device (legacy; modern disks use GEOM).
D_TTY	Category hint: TTY device.
D_MEM	Category hint: memory device such as /dev/mem.
D_TRACKCLOSE	Call d_close for every close(2) on every descriptor.
D_MMAP_ANON	Anonymous-mmap semantics for this cdev.
D_NEEDGIANT	Force Giant-lock dispatch. Avoid in new code.
D_NEEDMINOR	Driver uses clone_create(9) for minor number allocation.

8.24.6 Common UID and GID Constants

Constant	Numeric	Purpose
UID_ROOT	0	Superuser. Default owner for most nodes.
UID_BIN	3	Daemon executables.
UID_UUCP	66	UUCP subsystem.
UID_NOBODY	65534	Unprivileged placeholder.
GID_WHEEL	0	Trusted administrators.
GID_KMEM	2	Read access to kernel memory.
GID_TTY	4	Terminal devices.
GID_OPERATOR	5	Operational tools.
GID_BIN	7	Daemon-owned files.
GID_VIDEO	44	Video framebuffer access.
GID_DIALER	68	Serial-port dial-out programs.
GID_NOGROUP	65533	No group.
GID_NOBODY	65534	Unprivileged placeholder.

8.24.7 Destruction Functions

Function	When to use
<code>destroy_dev(cdev)</code>	Ordinary, synchronous destruction with drain.
<code>destroy_dev_sched(cdev)</code>	Deferred destruction when you cannot sleep.
<code>destroy_dev_sched_cb(cdev, cb, arg)</code>	Deferred destruction with a follow-up callback.
<code>destroy_dev_drain(cdevsw)</code>	Wait for all cdevs of a cdevsw to finish, before freeing it.
<code>delist_dev(cdev)</code>	Remove a cdev from devfs without fully destroying yet.

8.24.8 Per-Open State Functions

Function	Purpose
<code>devfs_set_cdevpriv(priv, dtor)</code>	Attach private data to the current descriptor.
<code>devfs_get_cdevpriv(&priv)</code>	Retrieve the private data of the current descriptor.
<code>devfs_clear_cdevpriv()</code>	Detach and run the destructor early.
<code>devfs_foreach_cdevpriv(dev, cb, arg)</code>	Iterate all per-open records on a cdev.

8.24.9 Alias Functions

Function	Purpose
<code>make_dev_alias(pdev, fmt, ...)</code>	Create an alias for a primary cdev.
<code>make_dev_alias_p(flags, &cdev, pdev, fmt, ...)</code>	Create an alias with flags and error return.
<code>make_dev_physpath_alias(...)</code>	Create a topology-path alias.

8.24.10 Reference-Count Helpers

Usually not called directly by drivers. Listed here for recognition.

Function	Purpose
<code>dev_ref(cdev)</code>	Acquire a long-lived reference.
<code>dev_rel(cdev)</code>	Release a long-lived reference.
<code>dev_refthread(cdev, &ref)</code>	Acquire a reference for a handler call.
<code>dev_relthread(cdev, ref)</code>	Release the handler call's reference.

8.24.11 Where to Read More

- `make_dev(9)`, `destroy_dev(9)`, `cdev(9)` manual pages for the API surface.
- `devfs(5)`, `devfs.conf(5)`, `devfs.rules(5)`, `devfs(8)` for the filesystem-layer documentation.
- `/usr/src/sys/sys/conf.h` for the canonical struct and flag definitions.
- `/usr/src/sys/kern/kern_conf.c` for the implementation of the `make_dev*` family.
- `/usr/src/sys/fs/devfs/devfs_vnops.c` for the implementation of `devfs_set_cdevpriv` and friends.
- `/usr/src/sys/fs/devfs/devfs_rule.c` for the rules subsystem.

This reference is kept short on purpose. The chapter is where the reasoning lives; this section is just the lookup table.

8.24.12 A Condensed Pattern Catalogue

The table below summarises the main patterns the chapter has shown, each paired with the section that explains it in detail. When you are partway through building a driver and need a quick orientation, scan this list first.

Pattern	Section in the chapter
Create one data node in <code>attach</code> , destroy in <code>detach</code>	Chapter 7, referenced in Chapter 8 Lab 8.1
Move the node into a subdirectory under <code>/dev</code>	Naming, Unit Numbers, and Subdirectories

Pattern	Section in the chapter
Expose both a data node and a control node	Multiple Nodes Per Device; Lab 8.5
Add an alias so the driver answers on two paths	Aliases: One cdev, More Than One Name; Lab 8.2
Widen or narrow permissions at the operator level	Persistent Policy; Lab 8.4
Hide or expose a node inside a jail	Persistent Policy; Lab 8.7
Give each open its own state and counters	Per-Open State with <code>devfs_set_cdevpriv</code> ; Lab 8.3
Run pre-open allocation that is safe against crashes	Per-Open State; Challenge 2
Enforce exclusive open with <code>EBUSY</code>	Error Codes; Recipe 1
Tear down many cdevs in one detach	Destroying cdevs Safely; Lab 8.8
React to node creation in userland via <code>devd</code>	Exercising Your Device From Userland; Challenge 5
Compare two paths to verify they share a cdev	Exercising Your Device From Userland
Expose driver state through <code>sysctl</code>	Practical Workflows; Chapter 7 reference

Each row names a pattern. Each pattern has a short recipe somewhere in the chapter. When you face a design problem, find the row that fits and follow the link back.

8.24.13 Common errno Values by Operation

A compact cross-reference of which `errno` values are conventional for which operations. Pair with Section 13.

Operation	Common <code>errno</code> returns
<code>d_open</code>	<code>0</code> , <code>ENXIO</code> , <code>EBUSY</code> , <code>EACCES</code> , <code>EPERM</code> , <code>EINVAL</code> , <code>EAGAIN</code>
<code>d_close</code>	<code>0</code> almost always; log unusual conditions, do not return them
<code>d_read</code>	<code>0</code> on success, <code>ENXIO</code> if device gone, <code>EFAULT</code> for bad buffers, <code>EINTR</code> on signal, <code>EAGAIN</code> for non-blocking retry
<code>d_write</code>	Same family as <code>d_read</code> , plus <code>ENOSPC</code> for out-of-space
<code>d_ioctl</code> (Chapter 25)	<code>0</code> on success, <code>ENOTTY</code> for unknown commands, <code>EINVAL</code> for bad arguments
<code>d_poll</code> (Chapter 10)	Returns a revents mask, not an <code>errno</code>

Your Chapter 8 driver is concerned mostly with the first two rows. Chapter 9 will extend into the third and fourth.

8.24.14 A Short Glossary of Terms Used in the Chapter

For readers who have not seen every term before, or who want a quick reminder.

- **cdev**: the kernel-side identity of a device file, one per node.

- **cdevsw**: the dispatch table that maps operations to driver handlers.
- **cdevpriv**: per-open state attached to a file descriptor via `devfs_set_cdevpriv(9)`.
- **devfs**: the virtual filesystem that presents cdevs as nodes under `/dev`.
- **mda_***: members of the `make_dev_args` structure passed to `make_dev_s(9)`.
- **softc**: per-device private data allocated by Newbus and reachable through `device_get_softc(9)`.
- **SI_***: flags stored on a `struct cdev` in its `si_flags` field.
- **D_***: flags stored on a `struct cdevsw` in its `d_flags` field.
- **MAKEDEV_***: flags passed to `make_dev_s(9)` and its relatives through `mda_flags`.
- **UID_*** and **GID_***: symbolic constants for standard user and group identities.
- **destroy_dev_drain**: the cdevsw-level drain function used when unloading a module that has created many cdevs.
- **devfs.conf**: the host-level policy file for persistent node ownership and mode.
- **devfs.rules**: the ruleset file that shapes per-mount views of devfs, primarily for jails.

The glossary will grow as the book progresses. Chapter 8 introduced most of the terms it will need; later chapters will add their own and reference back to this list.

8.25 Consolidation and Review

Before you put the chapter down, one more pass through the material is worthwhile. This section ties the pieces together in a way that the section-by-section structure could not quite do.

8.25.1 The Three Ideas That Matter Most

If you could only remember three things from Chapter 8, let them be these:

First, `/dev` is a live filesystem maintained by the kernel. Every node is backed by a `struct cdev` your driver owns. Nothing you see in `/dev` is persistent; it is a window into the current state of the kernel. When you write a driver, you are adding to and removing from that window, and the kernel is honest about reflecting your changes.

Second, the device-file surface is part of your driver's public interface. The name, the permissions, the ownership, the existence of aliases, the set of operations you implement, the `errno` values you return, the order of destruction, all of these are decisions a user depends on. Treat them as contractual from day one. Widening or tightening after the fact is always more disruptive than picking the right baseline the first time.

Third, per-open state is the right home for per-descriptor information. `devfs_set_cdevpriv(9)` exists because UNIX's descriptor model is more expressive than a single `softc` can represent. When two processes open the same node, they each deserve their own view of it. Giving them per-open state costs a small allocation and a destructor; the alternative is a maze of shared-state races that you will not want to debug.

Everything else in Chapter 8 elaborates one of these three ideas.

8.25.2 The Shape of the Driver You End the Chapter With

By the end of Lab 8.8, your `myfirst` driver has grown into something that looks much more like a real FreeBSD driver than it did at the end of Chapter 7. Specifically:

- It has a softc, a mutex, and a sysctl tree.
- It creates its node in a subdirectory under /dev, with ownership and mode chosen on purpose.
- It offers an alias for the legacy name so existing users keep working.
- It allocates per-open state on every open(2) and cleans it up through a destructor that fires reliably in all cases.
- It counts active opens and refuses to detach while any are still alive.
- It destroys its cdevs in a sensible order during detach.

That is the shape of almost every small driver in /usr/src/sys/dev. You do not need to build every driver you ever write from scratch; most of the time, you will start from a template that looks exactly like this, and add the subsystem-specific logic on top.

8.25.3 What to Practice Before Starting Chapter 9

A short list of exercises that cement the chapter's material, in rough order of increasing stretch:

1. **Rebuild myfirst stage by stage without looking at the companion tree.** Open Chapter 7's stage 2 source. Make the changes for Lab 8.1 from scratch. Then the changes for Lab 8.2. Then Lab 8.3. Compare your result to the companion tree's stage 2 source. Differences are things worth understanding.
2. **Break a stage on purpose.** Introduce a deliberate bug into Lab 8.3 (for instance, skip the `devfs_set_cdevpriv` call). Predict what will happen when you load and run the parallel probe. Run it. See whether the failure matches your prediction.
3. **Add a third cdev.** Extend Lab 8.5's stage-3 driver with a second control node serving a different namespace. Watch the node appear and disappear in lockstep with the driver.
4. **Write a userland service.** Write a small daemon that opens /dev/myfirst/0 at startup, holds the descriptor, and responds to SIGUSR1 by reading and logging. Install it. Test it across driver load and unload. Notice what happens when the driver unloads while the daemon still has its descriptor open.
5. **Read a new driver.** Pick a driver from /usr/src/sys/dev that you have not touched yet, read it through the device-file lens, and classify it using the decision tree from Section 15. Write a paragraph describing what you found.

Each exercise takes between thirty minutes and an hour. Doing two or three of them is enough to move the chapter's material from "I read this once" to "I am comfortable with it". Doing all five gives you intuition that will serve you for the rest of the book.

Chapter 9 is next. The rooms behind the door come alive.

9 Reading and Writing to Devices

9.1 Reader Guidance & Outcomes

Chapter 7 taught you to stand a driver up. Chapter 8 taught you how that driver meets userland through `/dev`. The driver you finished the previous chapter with attaches as a Newbus device, creates `/dev/myfirst/0`, carries an alias at `/dev/myfirst`, allocates per-open state, logs cleanly, and detaches without leaking. Every one of those pieces was important, but none of them actually moved a byte.

This chapter is where the bytes start to move.

When a user program calls `read(2)` or `write(2)` on one of your device nodes, the kernel has to deliver real data between the user's address space and the driver's memory. That transfer is not a simple `memcpy`. It crosses a trust boundary. The buffer pointer the user passed might be invalid. The buffer might not all be resident. The length might be zero, or enormous, or part of a scatter-gather list. The user might be in a jail, might have a signal pending, might be reading with `O_NONBLOCK`, might have redirected the result through a pipe. Your driver does not need to understand every one of those cases in isolation, but it does need to cooperate with the single kernel abstraction that solves them all. That abstraction is `struct uio`, and the primary tool for using it is `uiomove(9)`.

This chapter is where we finally implement the `d_read` and `d_write` entry points that Chapter 7 left as stubs. Along the way, we will look carefully at how the kernel describes an I/O request, why the book has been saying “do not touch user pointers directly” ever since Chapter 5, and how to shape a driver so that partial transfers, misaligned buffers, signalled reads, and short writes all behave the way a classical UNIX file would.

9.1.1 Why This Chapter Earns Its Own Place

It would be tempting to write a short chapter that just says “call `uiomove`” and moves on. That would leave a reader with a driver that passes the simplest test and then fails in twenty subtle ways. The reason this chapter has the length it does is that I/O is where beginner drivers most often go wrong, and the places they go wrong are not where the code looks risky. The mistakes are usually in the return values, in the handling of `uio_resid`, in the treatment of a zero-length transfer, in what happens when the driver wakes up from `msleep(9)` because the process was killed, in the direction in which a partial read should drain.

A driver that gets these details wrong compiles cleanly, passes a single `cat /dev/myfirst`, and then produces corrupted data when a real program starts pushing bytes through it. That is the kind of bug that eats days. The goal of this chapter is to stop that class of bug at the source.

9.1.2 Where Chapter 8 Left the Driver

At the end of Chapter 8 your `myfirst` driver had the following shape. It is worth a checkpoint because Chapter 9 builds directly on top of it:

- A single Newbus child, created in `device_identify`, registered under `nexus0`.
- A struct `myfirst_softc` allocated by Newbus and initialised in `attach`.
- A mutex named after the device, used to guard `softc` counters.
- A sysctl tree under `dev.myfirst.0.stats` exposing `attach_ticks`, `open_count`, `active_fhs`, and `bytes_read`.
- A primary cdev at `/dev/myfirst/0` with ownership `root:operator` and mode `0660`.
- An alias cdev at `/dev/myfirst` pointing at the primary.
- A struct `myfirst_fh` allocated per `open(2)`, registered through `devfs_set_cdevpriv(9)`, and freed by a destructor that fires exactly once per descriptor.
- Stub `d_read` and `d_write` handlers that retrieve the per-open state, optionally look at it, and return immediately: `d_read` returns zero bytes (EOF), `d_write` claims to have consumed every byte by setting `uio_resid = 0`.

Chapter 9 takes those stubs and makes them real. The shape of the driver does not change much at the outside. A new reader should still see `/dev/myfirst/0`, still see the alias, still see the sysctls. What changes is that a `cat /dev/myfirst/0` will now produce output, a `echo hello > /dev/myfirst/0` will now store the text into driver memory, and a second `cat` will read back exactly what the first write deposited. By the end of the chapter your driver will be a small, disciplined, in-memory buffer that you can push bytes through and pull bytes out of. It will not yet be a circular buffer with blocking reads; that is Chapter 10's job. It will be a driver that moves bytes correctly.

9.1.3 What You Will Learn

After finishing this chapter you will be able to:

- Explain how `read(2)` and `write(2)` flow from user space through `devfs` into your `cdevsw` handlers.
- Read and write the fields of `struct uio` without memorising them.
- Use `uiomove(9)` to transfer bytes between a kernel buffer and the caller's buffer in either direction.
- Use `uiomove_frombuf(9)` when the kernel buffer has a fixed size and you want automatic offset accounting.
- Decide when to reach for `copyin(9)` or `copyout(9)` instead of `uiomove(9)`.
- Return correct byte counts for short transfers, empty transfers, end-of-file, and interrupted reads.
- Choose an appropriate `errno` value for every error path a driver read or write can take.
- Design an internal buffer that the driver fills from `d_write` and drains from `d_read`.
- Identify and fix the most common `d_read` and `d_write` bugs.
- Exercise the driver from the base-system tools (`cat`, `echo`, `dd`, `od`, `hexdump`) and from a small C program.

9.1.4 What You Will Build

You will take the `myfirst` driver from the end of Chapter 8 through three incremental stages.

1. **Stage 1, a static-message reader.** `d_read` returns the contents of a fixed kernel-space string. Every open starts at offset zero and reads its way through the message. This is the “hello world” of device reads, but done with correct offset handling.

2. **Stage 2, a write-once / read-many buffer.** The driver owns a fixed-size kernel buffer. `d_write` appends into it. `d_read` returns whatever has been written so far, from a per-descriptor offset that remembers how far each reader has consumed. Two concurrent readers still see their own progress independently.
3. **Stage 3, a small echo driver.** The same buffer, now used as a first-in / first-out store. Every `write(2)` appends bytes to the tail. Every `read(2)` removes bytes from the head. A two-process test script writes in one terminal and reads the echoed data in another. This is the handoff point to Chapter 10, where we will rebuild the same driver around a true circular buffer, add partial-I/O and non-blocking support, and wire up `poll(2)` and `kqueue(9)`.

All three stages compile, load, and behave predictably. You will exercise each one from `cat`, `echo`, and a small userland program called `rw_myfirst.c` that exercises the edge cases `cat` does not reach on its own.

9.1.5 What This Chapter Does Not Cover

Several topics touch `read` and `write` but are deliberately postponed:

- **Circular buffers and wrap-around:** Chapter 10 implements a real ring buffer. Stage 3 here uses a simple linear buffer so we can keep focus on the I/O path itself.
- **Blocking reads and `poll(2)`:** Chapter 10 introduces `msleep(9)`-based blocking and the `d_poll` handler. This chapter keeps all reads non-blocking at the driver level; an empty buffer produces an immediate zero-byte read.
- **`ioctl(2)`:** Chapter 25 builds out `d_ioctl`. We touch it only where the reader needs to understand why certain control paths belong there rather than in `write`.
- **Hardware registers and DMA:** Part 4 handles bus resources, `bus_space(9)`, and DMA. The memory we read and write in this chapter is ordinary kernel heap, allocated with `malloc(9)` from `M_DEVBUF`.
- **Concurrency correctness under load:** Part 3 is dedicated to race conditions, locking, and verification. We take mutex-protected care where a race would corrupt the stage-3 buffer, but the deeper discussion is deferred.

Staying inside these lines is how we keep the chapter honest. A beginner chapter that drifts into `ioctl`, DMA, and `kqueue` is a beginner chapter that teaches none of them well.

9.1.6 Estimated Time Investment

- **Reading only:** roughly one hour.
- **Reading plus typing the three stages:** around three hours, including a couple of load / unload cycles per stage.
- **Reading plus all labs and challenges:** five to seven hours over two or three sessions.

Give yourself a fresh lab boot at the start. Do not rush. The stages are small on purpose, and the real value comes from watching `dmesg`, watching `sysctl`, and probing the device from userland after every change.

9.1.7 Prerequisites

Before starting this chapter, confirm:

- You have a working `myfirst` driver equivalent to the Chapter 8 stage 2 source under `examples/part-02/ch08-working-with-device-files/stage2-perhandle/`. If you have not yet reached the end of Chapter 8, pause here and come back.
- Your lab machine is running FreeBSD 14.3 with a matching `/usr/src`.
- You have been through Chapter 4's discussion of pointers, structures, and memory layout, and Chapter 5's discussion of kernel-space idioms and safety.
- You understand what a `struct cdev` is and how it is related to a `cdevsw`. Chapter 8 covered this in detail.

If you are uncertain about any of these, the rest of the chapter will be harder than it needs to be. Revisit the relevant sections first.

9.1.8 How to Get the Most Out of This Chapter

Three habits pay off immediately.

First, keep `/usr/src/sys/dev/null/null.c` open in a second terminal. It is the shortest, cleanest, most readable example of `d_read` and `d_write` in the tree. Every idea this chapter introduces appears somewhere in `null.c` in fifty lines or fewer. Real FreeBSD drivers are the textbook; this book is the reading guide.

Second, keep `/usr/src/sys/sys/uio.h` and `/usr/src/sys/_uio.h` open. The declarations there are short and stable. Read them once now so that when the chapter refers to `uio_iov`, `uio_iovcnt`, `uio_offset`, and `uio_resid`, you do not have to trust the prose alone.

Third, rebuild between changes and confirm behaviour from userland before the next change. This is the habit that separates writing drivers from writing prose about drivers. You will run `cat`, `echo`, `dd`, `stat`, `sysctl`, `dmesg`, and a short C program at every checkpoint. Do not skip them. The failure modes this chapter is teaching you to recognise only become visible when you run the code.

9.1.9 Roadmap Through the Chapter

The sections in order are:

1. A visual map of the full I/O path, from `read(2)` in user space to `uiomove(9)` inside your handler.
2. A short refresher on what `read` and `write` mean in UNIX, and what they mean specifically to a driver writer.
3. The anatomy of `d_read`: its signature, what it is asked to do, and what it is asked to return.
4. The anatomy of `d_write`: the mirror of `d_read`, plus a few details that only apply in the write direction.
5. A reading protocol for unfamiliar handlers, followed by a second real-driver walkthrough (`mem(4)`) to show a different shape.
6. The `ioflag` argument: where it comes from, what bits matter, and why Chapter 9 mostly ignores it.
7. A close look at `struct uio`, the kernel's I/O description object, field by field, including three snapshots of the same `uio` through a call.
8. `uiomove(9)` and its companions, the functions that actually move the bytes.
9. `copyin(9)` and `copyout(9)`: when to reach for them, and when to leave them alone in favour of `uiomove`. Plus a cautionary case study about structured data.
10. Internal buffers: static, dynamic, and fixed-size. How to choose one, how to own it safely, and the kernel helpers you should recognise.

11. Error handling: the `errno` values that matter for I/O, how to signal end of file, and how to think about partial transfers.
12. The three-stage `myfirst` implementation, driver source included.
13. A step-by-step trace of `read(2)` from user space through the kernel down to your handler, plus a mirrored write trace.
14. A practical workflow for testing: `cat`, `echo`, `dd`, `truss`, `ktrace`, and the discipline that turns them into a development rhythm.
15. Observability: `sysctl`, `dmesg`, and `vmstat -m`, with a concrete snapshot of the driver under light load.
16. Signed, unsigned, and the perils of off-by-one, a short but high-value section.
17. Troubleshooting notes for the mistakes this chapter's material is most likely to produce, and a contrast table of correct versus buggy handler patterns.
18. Hands-on labs (seven) that walk you through each stage and consolidate the observability workflow.
19. Challenge exercises (eight) that stretch the patterns.
20. Wrapping up and a bridge to Chapter 10.

If this is your first time through the chapter, read linearly and do the labs as you hit them. If you are revisiting the material to consolidate, the reference-style sections at the end stand alone.

9.2 A Visual Map of the I/O Path

Before the prose gets deep, a single picture is worth keeping in mind. The diagram below is the path a `read(2)` call takes from a user program down to your driver, and back up to the caller. Every box is a real piece of kernel code you can find under `/usr/src/sys/`. Every arrow is a real function call. None of it is metaphorical.

```

+-----+|-----+
|
|      v
+-----+|-----+
| struct file ops -> vn_read |
| /usr/src/sys/kern/vfs_vnops.c |
+-----+|-----+
|
|      v
+-----+|-----+
| devfs_read_f() |
| /usr/src/sys/fs/devfs/devfs_vnops.c |
| - devfs_fp_check -> cdev + cdevsw |
| - acquire thread-count ref |
| - compose ioflag from f_flag |
| - call cdevsw->d_read(dev, uio, ioflag) |
+-----+|-----+
|
|      v
+-----+|-----+
| YOUR HANDLER (myfirst_read) |
| - devfs_get_cdevpriv(&fh) |
| - verify is_attached |
| - call uiomove(9) to transfer bytes |
| | | |
| |      v |
| | +-----+ |
| | | uiomove_faultflag() | |
| | | /usr/src/sys/kern/subr_uio.c | |
| | | - for each iovec entry | |
| | | copyout(kaddr, uaddr, n) ===> |====|====> user's buf
| | | decrement uio_resid | |
| | | advance uio_offset | |
| | +-----+ |
| | - return 0 or an errno |
+-----+|-----+
|
|      v
+-----+|-----+
| devfs_read_f continues |
| - release thread-count ref |
| - update atime if bytes moved |
+-----+|-----+
|

```

A handful of features of the picture are worth pinning down because they recur throughout the chapter.

The trust boundary is crossed exactly twice. Once on the way down (the user enters the kernel via a syscall trap), and once on the way up (the kernel returns control to user space). Everything in between is kernel-only execution. Your handler runs entirely inside the kernel, on a kernel stack, with the user’s registers saved out of the way.

Your handler is the only place the driver’s knowledge enters the path. Everything above it is kernel machinery that works identically for every character device in the tree. Everything below it is uiomove and copyout, also kernel machinery. Your handler is the single function where the answer to “what bytes should this read produce?” is computed.

The user’s buffer is never touched by your driver directly. It is touched by copyout from inside uiomove. Your driver hands uiomove a kernel pointer, and uiomove is the only code that dereferences the user pointer on your behalf. This is the shape of the trust boundary, drawn as code: user memory is accessed only through the one API that knows how to do it safely.

Every step has a matching step on the way back up. The thread-count reference acquired by devfs is released after your handler returns; the uio’s state is inspected to compute the byte count; control unwinds through each layer and returns to user space. Understanding this symmetry is what makes reference-counting feel natural rather than arbitrary.

Print this diagram or sketch it on paper. When you read an unfamiliar driver later in the book, refer back to it. Every `d_read` or `d_write` you will ever study sits at exactly this point in the call chain. The differences between drivers are in the handler; the path around the handler is constant.

For `d_write`, the picture is the mirror image. `devfs_write_f` dispatches to `cdevsw->d_write`, your handler calls `uiomove(9)` in the other direction, `uiomove` calls `copyin` instead of `copyout`, and the kernel unwinds back to `write(2)`. Every arrow in the diagram has a twin; every property listed above applies to writes as well.

9.3 Devices in UNIX: A Quick Refresher

It is worth ten minutes of refresher before we start writing code. Chapter 6 introduced the UNIX I/O model at a conceptual level; Chapter 7 put it into practice; Chapter 8 made the device-file surface tidy. All three of those treatments had reasons not to dwell on the behaviour of `read(2)` and `write(2)` themselves, because the drivers in those chapters did not carry real data. Now we do, and a tight refresher sets the stage for everything that follows.

9.3.1 What Makes a Device Different from a File?

From the outside, they look identical. Both are opened with `open(2)`. Both are read with `read(2)` and written with `write(2)`. Both are closed with `close(2)`. A user program that works on a regular file almost always works on a device file without changes to its source, because the user-space API makes no distinction between them.

From the inside, there are real differences, and a driver author needs to internalise them.

A regular file has a backing store, usually bytes on disk managed by a filesystem. The kernel decides when to read ahead, when to cache, when to flush. The data has a persistent identity; two programs reading byte zero of a file see the same byte. Seeking is cheap and unlimited within the file's size.

A device file has no backing store in the filesystem sense. When a user program reads from it, the driver decides what bytes to produce. When a user program writes to it, the driver decides what to do with them. The data's identity is whatever your driver defines. Two programs reading from the same device do not necessarily see the same bytes; depending on the driver, they may see the same bytes, may see disjoint halves of a single stream, or may see completely independent streams. Seeking may be meaningful, or meaningless, or actively forbidden.

The practical consequence for your `d_read` and `d_write` handlers is that **the driver is the authoritative definition of what read and write mean** on this device. The kernel will deliver you an I/O request; it will not tell you what to do with it. The conventions UNIX programs expect, a byte stream, consistent return values, honest error codes, end of file as zero bytes returned, are conventions your driver has to honour on purpose. The kernel does not enforce them.

9.3.2 How UNIX Treats Devices as Streams of Data

The word “stream” is worth pinning down, because it appears in every discussion of UNIX I/O and carries at least three different meanings depending on context.

For our purposes a stream is a **sequence of bytes delivered in order**. Neither the caller nor the driver knows the total length in advance. Either side can stop at any time. The sequence may have a natural end (a file that has been fully read) or may go on indefinitely (a terminal, a network socket, a sensor). The rules are the same either way: the reader requests some number of bytes, the writer requests that some number of bytes be accepted, and the kernel reports how many bytes actually moved.

A stream has no side-effects beyond the data transfer itself. If your driver needs to expose a control surface, a way to change configuration, reset state, or negotiate parameters, that surface does not belong in read and write. The interface for control is `ioctl(2)`, covered in Chapter 25. Do not smuggle control commands through the data stream. It makes your driver harder to use, harder to test, and harder to evolve.

A stream is unidirectional per call. `read(2)` moves bytes from the driver to the user. `write(2)` moves bytes from the user to the driver. A single system call never does both. If you need duplex behaviour, for example a request-response pattern, you implement it as a write followed by a read, with whatever coordination your driver requires inside it.

9.3.3 Sequential vs. Random Access

Most drivers produce sequential streams: the bytes come out in the order they arrive, and `lseek(2)` either does nothing interesting or is refused. A terminal, a serial port, a packet-capture device, a log stream, all of these are sequential.

A few drivers are random-access: the caller can address any byte through `lseek(2)`, and the same offset always reads the same data. A memory-disk driver, `/dev/mem`, and a handful of others fit this model. They look more like regular files than like devices in most respects.

A driver author chooses where on this spectrum the driver sits. Your `myfirst` driver will sit on the sequential end for most of this chapter, with one nuance: each open descriptor carries its own read offset, so two processes reading concurrently start from different points in the stream. This is the compromise most small character devices use. It gives each reader a consistent view of what they have consumed, without imposing a true random-access contract on the driver.

The choice shows up in two places in code:

- **Your `d_read` updates `uio->uio_offset`** (which `uiomove(9)` does for you) if and only if the offset is meaningful to you. For a truly sequential device where offset has no meaning, the value is ignored.
- **Your driver either honours or ignores the incoming `uio->uio_offset`** at the start of each read. Sequential drivers ignore it and serve from wherever they are. Random-access drivers treat it as an address into a linear space.

For the three-stage `myfirst` we will treat `uio->uio_offset` as a per-call snapshot of where this descriptor is in the stream and update our internal counters to match.

9.3.4 The Role of `read()` and `write()` in Device Drivers

Inside the kernel, `read(2)` and `write(2)` on a device file eventually call into your `cdevsw->d_read` and `cdevsw->d_write` function pointers. Everything between the system call and your function is `devfs` and `VFS` machinery; everything after your function returns is the kernel delivering the result back to userland. Your handler is the single place where the driver-specific answer to “what happens on this call?” is computed.

The handler’s job is not complicated in the abstract:

1. Look at the request. How many bytes are being asked for or handed to you?
2. Move the bytes. Use `uiomove(9)` to transfer data between your kernel buffer and the user’s.
3. Return a result. A zero for success (with `uio_resid` updated accordingly), or an `errno` value for failure.

What makes the handler non-trivial is that step 2 is the trust boundary between user memory and kernel memory, and every interaction with user memory has to be safe against misbehaving or malicious user programs. That is why `uiomove(9)` exists. You do not write the safety logic; the kernel does, as long as you ask through the right API.

9.3.5 Character Devices vs. Block Devices Revisited

Chapter 8 noted that FreeBSD has not shipped block-special device nodes to userland for many years. Storage drivers live in GEOM and publish themselves up as character devices. For the purposes of this chapter, character device is the only shape we care about.

The practical consequence is that everything in this chapter applies to every driver you are likely to write in Parts 2 through 4. `d_read` and `d_write` are the entry points. `struct uio` is the carrier. `uiomove(9)` is the mover. When we get to Part 6 and look at GEOM-backed storage drivers, their data path will look different, but it will still be built out of the same primitives we are studying now.

9.3.6 Exercise: Classifying Real Devices on Your FreeBSD System

Before the rest of the chapter digs into code, take five minutes on your lab machine. Open a terminal and walk through `/dev`:

```
% ls /dev
% ls -l /dev/null /dev/zero /dev/random /dev/urandom /dev/console
```

For each node you see, ask yourself three questions:

1. Is it sequential or random access?
2. If I cat it, should it produce any bytes? What bytes?
3. If I echo something > it, should anything be visible? Where?

Try a few:

```
% head -c 16 /dev/zero | od -An -tx1
% head -c 16 /dev/random | od -An -tx1
% echo "hello" > /dev/null
% echo $?
```

Notice that `/dev/zero` is inexhaustible, `/dev/random` delivers unpredictable bytes, `/dev/null` swallows writes silently and returns success, and none of these three are seekable in a useful sense. Those behaviours are not accidents. They are the `d_read` and `d_write` handlers of those drivers, doing exactly what we are about to study.

If you open `/usr/src/sys/dev/null/null.c` and look at `null_write`, you will see the one-line implementation: `uio->uio_resid = 0; return 0;`. That is a fully functional write handler. The driver has announced “I consumed every byte; no error”. That is the smallest meaningful write implementation in FreeBSD, and by the end of this chapter you will be able to write it, and many larger ones, without hesitation.

9.4 The Anatomy of `d_read()`

Your driver’s read path begins the moment `devfs` dispatches a call to `cdevsw->d_read`. The signature is fixed, declared in `/usr/src/sys/sys/conf.h`:

```
typedef int d_read_t(struct cdev *dev, struct uio *uio, int ioflag);
```

Every `d_read` function in the FreeBSD tree has exactly this shape. The three arguments are the complete description of the call:

- `dev` is the `struct cdev *` representing the device node that was opened. In a driver that handles more than one `cdev` per instance, it tells you which one the call is on. In `myfirst`, where the primary and its alias dispatch through the same handler, both resolve to the same underlying softc via `dev->si_drv1`.
- `uio` is the `struct uio *` that describes the I/O request: what buffers the user provided, how big they are, where in the stream the read is supposed to start, and how many bytes still need to move. We will dissect it in the next section.
- `ioflag` is a bitmask of flags defined in `/usr/src/sys/sys/vnode.h`. The one that matters for non-blocking I/O is `IO_NDELAY`, which is set when the user opened the descriptor with `O_NONBLOCK` (or passed `O_NONBLOCK` later via `fcntl(F_SETFL, ...)`). There are a handful of other flags related to vnode-based filesystem I/O, but for character-device drivers you will usually inspect only `IO_NDELAY`.

The return value is an `errno`-style integer: zero on success, a positive `errno` code on failure. It is **not** a byte count. The kernel computes the byte count by looking at how much `uio_resid` decreased during the call and reports that value up to user space as the return value of `read(2)`. This inversion is one of the two or three most important things to internalise from the chapter. `d_read` returns an error code; the number of bytes transferred is implicit in the `uio`.

9.4.1 What `d_read` Is Asked to Do

Reduced to a single sentence, the job is: **produce up to `uio->uio_resid` bytes from the device, deliver them through `uiomove(9)` into whatever buffer the `uio` describes, and return zero.**

A few corollaries follow from that sentence and are worth making explicit.

The function may produce fewer bytes than were asked for. Short reads are legitimate and expected. A user program that asked for 4096 bytes and received 17 does not treat that as an error; it treats it as “the driver had 17 bytes to give right now”. The number is visible to the caller because `uiomove(9)` decremented `uio_resid` by 17 as it moved the bytes.

The function may produce zero bytes. A zero-byte read is how UNIX reports end of file. If your driver has no more data to give and is not going to have any more, return zero and leave `uio_resid` untouched. The caller sees a zero-byte `read(2)` and knows the stream is done.

The function must not produce more bytes than were asked for. `uiomove(9)` enforces this for you; it will not move more than `MIN(uio_resid, n)` bytes in a single call. If you call `uiomove` repeatedly inside a single `d_read`, make sure your loop also respects `uio_resid`.

The function must return an `errno` on failure. On success the return value is zero. Non-zero return values are interpreted by the kernel as errors; the kernel propagates them to user space through `errno`. Common values are `ENXIO`, `EFAULT`, `EIO`, `EINTR`, and `EAGAIN`. We will walk through each in the error-handling section.

The function can sleep. `d_read` runs in a process context (the context of the caller), so `msleep(9)` and friends are legal. This is how drivers implement blocking reads that wait for data. We will not use `msleep(9)` in this chapter (Chapter 10 introduces it formally), but it is worth knowing that you have the right to block.

9.4.2 What `d_read` Is Not Asked to Do

A short list of things the handler is explicitly not responsible for, because the kernel or devfs takes care of them:

- **Locating user memory.** The `uio` already describes the target buffer. Your handler does not need to look up page tables or validate addresses.
- **Checking permissions.** The user's credentials were verified by `open(2)`; by the time `d_read` runs, the caller is allowed to read from this descriptor.
- **Counting bytes for the caller.** The kernel computes the byte count from `uio_resid`. You never return a byte count.
- **Enforcing the global size limit.** The kernel has already clamped `uio_resid` to something the system can handle.

Every one of these is a temptation at some point. Resist them all. Each one is a place where a handler can introduce a subtle bug that a correct use of `uiomove` avoids by construction.

9.4.3 A First Real `d_read`

Here is the smallest useful `d_read` in the FreeBSD tree. It is the `zero_read` function from `/usr/src/sys/dev/null/null.c`, and it is how `/dev/zero` produces an infinite stream of zero bytes:

```
static int
zero_read(struct cdev *dev __unused, struct uio *uio, int flags __unused)
{
    void *zbuf;
    ssize_t len;
    int error = 0;

    zbuf = __DECONST(void *, zero_region);
    while (uio->uio_resid > 0 && error == 0) {
        len = uio->uio_resid;
        if (len > ZERO_REGION_SIZE)
            len = ZERO_REGION_SIZE;
        error = uiomove(zbuf, len, uio);
    }
    return (error);
}
```

Pause on that for a minute. The loop body is three lines. The termination condition is two: either `uio_resid` reaches zero (we transferred everything the caller asked for) or `uiomove` returns an error. Each iteration moves as much of the zero-filled region as the request has room for. The function returns the last error code, which is zero if the transfer completed cleanly.

The loop is necessary because the zero region is finite: a single `uiomove` call cannot move arbitrarily many bytes from it, so the loop chunks the transfer. For a driver whose source data fits in a single kernel buffer of modest size, the loop collapses to a single call. Stage 1 of `myfirst` will be exactly that shape.

Notice also what the function does **not** do. It does not look at `uio_offset`. It does not care where in some imaginary stream the read is starting; every read of `/dev/zero` produces zero bytes. It does not check the `cdev`. It does not check the flags. It does exactly one job, and it does that job using one API.

That is the model. Your `d_read` will usually look like some variation of that loop.

9.4.4 A Variant: `uiomove_frombuf`

When your source data is a fixed-size kernel buffer and you want the driver to behave like a file backed by that buffer, the helper function `uiomove_frombuf(9)` does the offset arithmetic for you.

Its declaration, from `/usr/src/sys/sys/uio.h`:

```
int uiomove_frombuf(void *buf, int buflen, struct uio *uio);
```

Its implementation, from `/usr/src/sys/kern/subr_uio.c`, is short enough to reproduce:

```
int
uiomove_frombuf(void *buf, int buflen, struct uio *uio)
{
    size_t offset, n;

    if (uio->uio_offset < 0 || uio->uio_resid < 0 ||
        (offset = uio->uio_offset) != uio->uio_offset)
        return (EINVAL);
    if (buflen <= 0 || offset >= buflen)
        return (0);
    if ((n = buflen - offset) > IOSIZE_MAX)
        return (EINVAL);
    return (uiomove((char *)buf + offset, n, uio));
}
```

Read that carefully, because the behaviour is precise. The function takes a pointer `buf` to a kernel buffer of size `buflen`, consults the `uio->uio_offset`, and:

- If the offset is negative or otherwise nonsensical, returns `EINVAL`.
- If the offset is past the end of the buffer, returns zero without moving any bytes. This is end of file: the caller will see a zero-byte read.
- Otherwise, calls `uiomove(9)` with a pointer into `buf` at the current offset and a length equal to the remaining tail of the buffer.

The function does not loop; `uiomove` will move as many bytes as `uio_resid` has room for, and will decrement `uio_resid` accordingly. The driver never has to touch `uio_offset` after the fact, because `uiomove` does.

If your driver exposes a fixed buffer as a readable file, a one-line `d_read` suffices:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    return (uiomove_frombuf(sc->buf, sc->buflen, uio));
}
```

Stage 1 of this chapter uses exactly that pattern, with a small adjustment to track the per-descriptor read offset so two concurrent readers see their own progress.

9.4.5 The Signature in Use: myfirst_read Stage 1

Here is what our Stage 1 `d_read` will look like. Do not type it in yet; we will walk through the full source in the implementation section. Seeing it here and now is mostly to anchor the discussion.

Before you read the code, pause on one detail that will recur in almost every handler for the rest of this chapter. The first four lines of any per-open-aware handler follow a fixed **boilerplate pattern**:

```
struct myfirst_fh *fh;
int error;

error = devfs_get_cdevpriv((void **)&fh);
if (error != 0)
    return (error);
```

This pattern retrieves the per-descriptor `fh` that `d_open` registered through `devfs_set_cdevpriv(9)`, and it propagates any failure back to the kernel unchanged. You will see it at the top of `myfirst_read`, `myfirst_write`, `myfirst_ioctl`, `myfirst_poll`, and the `kqfilter` helpers. When a later lab says “retrieve the per-open state with the usual `devfs_get_cdevpriv` boilerplate”, this is the block it refers to, and the rest of the chapter will not re-explain it. If a handler ever re-orders these lines, treat that as a red flag: running any logic before this call means the handler does not yet know which open it is serving. The one subtlety worth remembering is that the `sc == NULL` liveness check comes *after* this boilerplate, not before, because you need the per-open state retrieved safely even on a device that is being torn down.

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    off_t before;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
```

```
        return (error);

    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    before = uio->uio_offset;
    error = uiomove_frombuf(__DECONST(void *, sc->message),
        sc->message_len, uio);
    if (error == 0)
        fh->reads += (uio->uio_offset - before);
    fh->read_off = uio->uio_offset;
    return (error);
}
```

A few points worth noticing before we continue. The function retrieves the per-open structure through `devfs_get_cdevpriv(9)`, checks that the softc is live, and then hands the real work to `uiomove_frombuf`. We snapshot `uio->uio_offset` into a local `before` at entry so that after the call we can compute the number of bytes the kernel just moved as `uio->uio_offset - before`. That increment is recorded into the per-descriptor counter. The closing assignment to `fh->read_off` remembers the stream position so the rest of the driver can report it later.

If the driver has no data to deliver, `uiomove_frombuf` returns zero and `uio_resid` is unchanged, which is how end of file is reported. If an error occurs inside `uiomove`, we propagate it back up by returning the error code. Nothing about this handler needs copyin or copyout directly. The safety of the transfer is handled by `uiomove` on our behalf.

9.4.6 Reading `d_read` in the Tree

A good reading exercise, after finishing this section, is to `grep` for `d_read` across `/usr/src/sys/dev` and look at what other drivers do inside it. You will find three recurring shapes:

- **Drivers that read from a fixed buffer.** They use `uiomove_frombuf(9)` or a hand-rolled equivalent, one call, done. `/usr/src/sys/fs/pseudofs/pseudofs_vnops.c` uses the helper extensively; the pattern is identical for character devices.
- **Drivers that read from a dynamic buffer.** They take an internal lock, snapshot how much data is available, call `uiomove(9)` with that length, release the lock, and return. We will build one of these in Stage 2.
- **Drivers that read from a blocking source.** They check whether data is available, and if not, either sleep on a condition variable (blocking mode) or return `EAGAIN` (non-blocking mode). This is Chapter 10 territory.

All three shapes share the same four-line spine: retrieve per-open state if you use it, verify liveness, call `uiomove` (or a relative), return the error code. The differences are in how they prepare the buffer, not in how they transfer it.

9.5 The Anatomy of `d_write()`

The write handler is the mirror image of the read handler, with a few small differences at the edges. The signature, from `/usr/src/sys/sys/conf.h`:

```
typedef int d_write_t(struct cdev *dev, struct uio *uio, int ioflag);
```

The shape is identical. The three arguments carry the same meaning. The return value is an `errno`, zero on success. The byte count is still computed from `uio_resid`: the kernel looks at how much `uio_resid` decreased during the call and reports that as the return value of `write(2)`.

9.5.1 What `d_write` Is Asked to Do

One sentence again: **consume up to `uio->uio_resid` bytes from the user, deliver them through `uiomove(9)` into wherever your driver keeps its data, and return zero.**

The corollaries are almost exactly the same as for reads, with two notable differences:

- A short write is legitimate but unusual. A driver that accepts fewer bytes than were offered must update `uio_resid` to reflect the truth, and the kernel will report the partial count to user space. Most well-behaved user programs will loop and retry the remainder; many will not. The rule of thumb is: accept everything you can, and if you cannot accept more, return `EAGAIN` for non-blocking callers and (eventually) sleep for blocking callers.
- A zero-byte write is not end of file. It is simply a write that moved zero bytes. `d_write` does not have an EOF concept; only reads do. A driver that wants to refuse a write returns a non-zero `errno`.

The most common return value on the error side is `ENOSPC` (no space left on device) when the driver's buffer is full, `EFAULT` when a pointer-related failure occurs inside `uiomove`, and `EIO` for catch-all hardware errors. A driver that enforces a per-write length limit can return `EINVAL` or `EMSGSIZE` for writes that exceed the limit; we will look at which to pick later in the chapter.

9.5.2 What `d_write` Is Not Asked to Do

The same list as for `d_read`: it does not locate user memory, does not check permissions, does not count bytes for the caller, and does not enforce system-wide limits. The kernel takes care of all four.

One addition specific to writes: **do not assume the incoming data is null-terminated or otherwise structured.** Users may write arbitrary bytes. If your driver expects structured input, it must parse it defensively. If your driver expects binary data, it must handle writes that are not aligned with any natural boundary. `write(2)` is a byte stream, not a message queue. Chapter 25's `ioctl` path is where structured, framed commands belong.

9.5.3 A First Real `d_write`

The simplest non-trivial `d_write` in the tree is `null_write` from `/usr/src/sys/dev/null/null.c`:

```
static int
null_write(struct cdev *dev __unused, struct uio *uio, int flags __unused)
{
    uio->uio_resid = 0;

    return (0);
}
```

Two lines. The handler tells the kernel “I consumed all the bytes” by setting `uio_resid` to zero, and returns success. The kernel reports the original request length to user space as the number of bytes written. `/dev/null` does not actually do anything with the bytes; that is the whole point of `/dev/null`. But the pattern is instructive: **setting `uio_resid = 0` is the shortest way to mark a write as fully consumed**, and it is exactly what `uiomove(9)` would have done if we had given it a destination.

A marginally more interesting case is `full_write`, also in `null.c`:

```
static int
full_write(struct cdev *dev __unused, struct uio *uio __unused, int flags __unused)
{
    return (ENOSPC);
}
```

This is the backing for `/dev/full`, a device that is full forever. Every write fails with `ENOSPC`, and the caller sees the corresponding `errno` value. The handler does not touch `uio_resid`; the kernel sees that no bytes moved and reports a return value of -1 with `errno = ENOSPC`.

Together, these two handlers illustrate the two extremes of the write side: accept everything, or reject everything. Real drivers sit somewhere in between, deciding how many of the offered bytes they can accept and storing those bytes somewhere.

9.5.4 A Write That Actually Stores Data

Here is the shape of the write handler we will implement at the end of this chapter. Again, do not type it in yet; this is a preview for orientation.

```
static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    size_t avail, towrite;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
```

```

    if (error != 0)
        return (error);

    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    mtx_lock(&sc->mtx);
    avail = sc->buflen - sc->bufused;
    if (avail == 0) {
        mtx_unlock(&sc->mtx);
        return (ENOSPC);
    }
    towrite = MIN((size_t)uio->uio_resid, avail);
    error = uiomove(sc->buf + sc->bufused, towrite, uio);
    if (error == 0) {
        sc->bufused += towrite;
        fh->writes += towrite;
    }
    mtx_unlock(&sc->mtx);
    return (error);
}

```

The handler locks the softc mutex, checks how much buffer space is left, clamps the transfer to whatever fits, calls `uiomove(9)` with that length, and accounts for the successful transfer by advancing `bufused`. If the buffer is full, it returns `ENOSPC` to signal the caller. Everything the handler does to cope with concurrency or partial writes is captured in the combination of the lock and the clamp.

Note that `uiomove` itself is called **with the mutex held**. This is fine as long as the mutex is an ordinary `MTX_DEF` mutex (as `myfirst`'s is) and the calling context is a regular kernel thread that can sleep. `uiomove` may page-fault when copying to or from user memory, and page faults may require the kernel to sleep waiting for a disk read. A sleep while holding an `MTX_DEF` mutex is legal; a sleep while holding a spin lock (`MTX_SPIN`) would be a bug. Part 3 covers the locking rules formally; for now, trust the lock type you picked in Chapter 7.

9.5.5 Symmetry With `d_read`

Reads and writes are almost identical from the driver's point of view. The data flows in opposite directions, and the `uio->uio_rw` field tells `uiomove` which direction to move the bytes. On the driver side you pass the same arguments: a pointer to kernel memory, a length, and the `uio`. On the user side, `uiomove` either copies out of the kernel buffer (for a read) or into it (for a write). You rarely have to think about the direction; `uio_rw` is already set.

What changes between the two handlers is the **intent**. A read is the driver's opportunity to produce data. A write is the driver's opportunity to consume data. Your code in each handler knows what role it is playing and does the appropriate bookkeeping: a reader tracks how much it has delivered, a writer tracks how much it has stored.

9.5.6 Reading `d_write` in the Tree

After reading this section, take a few minutes with `grep d_write /usr/src/sys/dev | head -20` and look at what other drivers do. Three shapes show up:

- **Drivers that discard writes.** Usually one line: `set uio_resid = 0` and return zero. The `null` driver's `null_write` is the prototype.
- **Drivers that store writes.** They lock, check capacity, call `uiomove(9)`, account, unlock, and return. Our Stage 3 handler is this shape.
- **Drivers that forward writes to hardware.** They pull data out of the `uio`, stage it into a DMA buffer or a hardware-owned ring, and trigger the hardware. This shape is out of scope until Part 4; the mechanics of `uiomove` are the same, but the destination is a DMA-mapped region rather than a `malloc'd` buffer.

Every real driver fits one of these three. The ones that accumulate or reshape data first, and then forward it somewhere, tend to combine shape 2 and shape 3, but the primitives are identical.

9.5.7 Reading an Unfamiliar `d_read` or `d_write` in the Wild

A chapter like this one is most useful when it helps you read other people's code, not only your own. As you explore the FreeBSD tree you will encounter handlers that look nothing like `null_write` or `zero_read`. The shape will still be there; the decoration will differ. Here is a small reading protocol that takes the guesswork out.

Step one: find the return type and argument names. Every `d_read_t` and `d_write_t` takes the same three arguments. If the handler has renamed them from `dev`, `uio`, and `ioflag`, note what the author chose (`cdev`, `u`, `flags` are all common). Keep those names in mind as you read.

Step two: find the `uiomove` call (or relative). Track backward from there to understand what kernel pointer is being handed to it and what length. That pair is the heart of the handler. Everything before the `uiomove` call is preparing the pointer and length; everything after is accounting.

Step three: find the lock acquisition and release. A handler that takes a lock before `uiomove` and releases it after is serializing with other handlers. A handler with no lock is either operating on read-only data or using some other synchronisation primitive (a condition variable, a `refcount`, a reader lock). Name which it is.

Step four: find the `errno` returns. List the `errno` values the handler can produce. If the list is short and each value has an obvious trigger, the handler is well-written. If the list is long or opaque, the author probably left loose ends.

Step five: find the state transitions. What counters does the handler increment? What per-handle fields does it touch? Those transitions are the driver's behavioural signature, and they are usually the part that differs most between one driver and the next.

Apply this protocol to `zero_read` in `/usr/src/sys/dev/null/null.c`. The argument names are the standard ones. The `uiomove` call hands the kernel pointer `zbuf` (pointing at `zero_region`) and a length clamped by `ZERO_REGION_SIZE`. There is no lock; the data is constant. The only `errno` the handler can return is whatever `uiomove` returned. There are no state transitions; `/dev/zero` is stateless.

Now apply the same protocol to `myfirst_write` at Stage 3. Argument names: standard. `uiomove` call: kernel pointer `sc->buf + bufhead + bufused`, length `MIN((size_t)uio->uio_resid, avail)`. Lock: `sc->mtx`

taken before and released after. Errno returns: ENXIO (device gone), ENOSPC (buffer full), EFAULT via uiomove, or zero. State transitions: `sc->bufused += towrite`, `sc->bytes_written += towrite`, `fh->writes += towrite`.

Two drivers, same protocol, two coherent descriptions of what the handler does. Once you apply this reading habit half a dozen times, unfamiliar handlers stop looking unfamiliar.

9.5.8 What If You Leave `d_read` or `d_write` Unset?

A detail that beginners sometimes wonder about: what happens if your `cdevsw` does not set `.d_read` or `.d_write`? The short answer is that the kernel substitutes a default that returns either `ENODEV` or acts like a no-op, depending on which specific slot is empty and which other `d_flags` are set. The long answer is worth knowing because real drivers do use the defaults, on purpose, when they want to express “this device does not do reads” or “writes are silently discarded”.

Look at how `/usr/src/sys/dev/null/null.c` wires up its three drivers:

```
static struct cdevsw null_cdevsw = {
    .d_version =    D_VERSION,
    .d_read =      (d_read_t *)nullop,
    .d_write =     null_write,
    .d_ioctl =     null_ioctl,
    .d_name =      "null",
};
```

`.d_read` is set to the kernel helper `nullop`, cast to a `d_read_t *`. `nullop` is a universal “do nothing, return zero” function declared in `/usr/src/sys/sys/system.h` and defined in `/usr/src/sys/kern/kern_conf.c`; it takes no arguments and returns zero. It is used across the kernel wherever a method slot needs a harmless default. The cast works because `d_read_t` expects a function returning `int`, and `nullop`’s `int (*)(void)` shape is close enough for the `cdevsw` dispatch to call it without surprise.

For `/dev/null`, `(d_read_t *)nullop` means “every read returns zero bytes, forever”. A user who `cat /dev/null` sees an immediate EOF. This is different from `/dev/zero`, which installs `zero_read` to produce an infinite stream of zero bytes. The contrast between the two drivers is a contrast between two default read behaviours, and both are exactly one line in the `cdevsw`.

If you omit both `.d_read` and `.d_write` entirely, the kernel fills them with defaults that return `ENODEV`. That is the right choice when the device honestly does not support data transfer; callers see a clear error rather than silent success. But for devices that should quietly accept writes or produce zero-byte reads, setting the slot to `(d_read_t *)nullop` is the idiomatic FreeBSD gesture.

Practical rule: decide deliberately. Either implement the handler (for real behaviour), or set it to `(d_read_t *)nullop` / `(d_write_t *)nullop` (for harmless defaults), or leave it entirely unset (for `ENODEV`). Every real driver in the tree picks one of these three on purpose, and the choice is visible to users.

9.5.9 A Second Real Driver: How mem(4) Uses One Handler for Both Directions

null.c is the canonical minimal example. A slightly richer example is worth a look before we move on, because it demonstrates a pattern you will meet often in the tree: **a single handler that serves both d_read and d_write**, relying on uio->uio_rw to tell the two directions apart.

The driver is mem(4), which exposes /dev/mem and /dev/kmem. The common pieces live in /usr/src/sys/dev/mem/memdev.c, and the architecture-specific read and write logic lives under /usr/src/sys/<arch>/<arch>/mem.c. On amd64, the file is /usr/src/sys/amd64/amd64/mem.c, and the function is memrw.

Look first at the cdevsw:

```
static struct cdevsw mem_cdevsw = {
    .d_version =    D_VERSION,
    .d_flags =      D_MEM,
    .d_open =       memopen,
    .d_read =       memrw,
    .d_write =      memrw,
    .d_ioctl =      memioctl,
    .d_mmap =       memmmap,
    .d_name =       "mem",
};
```

Both .d_read and .d_write point at the same function. This is legal because the d_read_t and d_write_t typedefs are identical (both are int (*)(struct cdev *, struct uio *, int)), so a single function can satisfy both. The trick is reading uio->uio_rw inside the handler to decide which direction to move.

A condensed sketch of memrw looks like this:

```
int
memrw(struct cdev *dev, struct uio *uio, int flags)
{
    struct iovec *iov;
    /* ... locals ... */
    ssize_t orig_resid;
    int error;

    error = 0;
    orig_resid = uio->uio_resid;
    while (uio->uio_resid > 0 && error == 0) {
        iov = uio->uio_iov;
        if (iov->iov_len == 0) {
            uio->uio_iov++;
            uio->uio_iovcnt--;
            continue;
        }
    }
```

```

    }
    /* compute a page-bounded chunk size into c */
    /* ... direction-independent mapping logic ... */
    error = uiomove(kernel_pointer, c, uio);
}
/*
 * Don't return error if any byte was written. Read and write
 * can return error only if no i/o was performed.
 */
if (uio->uio_resid != orig_resid)
    error = 0;
return (error);
}

```

There are three ideas in this sketch that generalise to your own drivers.

First, one handler for both directions saves code when the per-byte work is identical. The mapping logic in `memrw` resolves a user-space offset to a piece of kernel-accessible memory; whether you are reading from or writing to that memory is decided later, by `uiomove` looking at `uio->uio_rw`. You save yourself the duplication of a near-identical read-vs-write pair at the cost of a single function that has to be clear about which direction it is in. If the two directions share almost nothing, write two functions; if they share nearly everything, combine them.

Second, `memrw` walks the `iovec` itself. Unlike `myfirst`, which hands the whole transfer to `uiomove` in one or two calls, `memrw` walks `iovec` entries explicitly so that it can map each requested offset into kernel memory and then call `uiomove` on the mapped region. This is the pattern you use when the *kernel pointer* your driver hands to `uiomove` depends on the offset being serviced. It is less common than the `myfirst` style, but it is the right shape when each chunk of the transfer corresponds to a different piece of the driver's backing storage.

Third, note the `orig_resid` trick at the end. The handler saves `uio_resid` at entry, then after the loop checks whether anything at all moved. If something did, it returns zero (success) even if an error happened later, because UNIX conventions require that a read or write with a non-zero byte count return that count to the caller rather than failing the whole call. This is the “partial success” idiom: if any byte moved, report the byte count; only fail when no bytes moved at all.

Your `myfirst` handlers do not need the idiom, because they call `uiomove` exactly once. If `uiomove` succeeds, everything moved; if it fails, nothing moved (from the driver's accounting point of view). The `orig_resid` idiom matters when your handler loops and the loop can be interrupted mid-way by an error from `uiomove`. Remember the pattern; you will use it in later chapters when your driver serves data from multiple sources.

9.5.10 Why This Walkthrough Was Worth the Detour

Two drivers. Two very different backing stores. One primitive. In `null.c`, `zero_read` serves a pre-allocated zero region; in `memrw`, the handler serves physical memory mapped on demand. The code looks different in the middle, because the middle is where the driver's unique knowledge lives. The ends look the same: both functions take a `uio`, both loop on `uio_resid`, both call `uiomove(9)` to do the actual transfer, both return zero on success or an `errno`.

That uniformity is the point. Every character-device read and write in the tree obeys this shape. Once you recognise it, you can open any unfamiliar driver under `/usr/src/sys/dev` and read the handler with confidence: the part you do not yet understand is always the middle, never the ends.

9.6 Understanding the `ioflag` Argument

Both `d_read` and `d_write` receive a third argument that the rest of the chapter has barely used so far. This section is the short but useful explanation of what `ioflag` is, where it comes from, and when a character-device driver should actually look at it.

9.6.1 Where `ioflag` Comes From

Every time a process performs a `read(2)` or `write(2)` on a `devfs` node, the kernel composes an `ioflag` value from the current file-descriptor flags before calling your handler. The composition lives in `devfs` itself, in `/usr/src/sys/fs/devfs/devfs_vnops.c`. The relevant lines from `devfs_read_f` are:

```
ioflag = fp->f_flag & (O_NONBLOCK | O_DIRECT);
if (ioflag & O_DIRECT)
    ioflag |= IO_DIRECT;
```

The pattern in `devfs_write_f` is the mirror image. The kernel takes whichever bits of the file table's `f_flag` word are interesting for I/O, masks them out, and passes that subset on as `ioflag`.

This is important for two reasons. First, it means the `ioflag` your driver receives is a *snapshot*. If the user program changes its non-blocking setting (via `fcntl(F_SETFL, O_NONBLOCK)`) between two `read(2)` calls, each call will carry its own up-to-date `ioflag`. You do not need to cache the state or watch for changes; the kernel re-derives the value at every dispatch.

Second, it means most of the constants you might expect to see never reach your handler. Things like `O_APPEND`, `O_TRUNC`, `O_CLOEXEC`, and the various `O_EXLOCK`-style flags belong to the filesystem and file-table layers. They do not influence character-device I/O and are not forwarded.

9.6.2 The Flag Bits That Matter

The `IO_*` flags are declared in `/usr/src/sys/sys/vnode.h`. For character-device drivers, only a small subset is worth remembering:

```
#define IO_UNIT      0x0001    /* do I/O as atomic unit */
#define IO_APPEND    0x0002    /* append write to end */
#define IO_NDELAY    0x0004    /* FNDELAY flag set in file table */
#define IO_DIRECT    0x0010    /* attempt to bypass buffer cache */
```

Of these, **only `IO_NDELAY` and `IO_DIRECT` are composed into the `ioflag` your handler receives**. The first three bits exist for filesystem I/O. A character-device driver that inspects `IO_UNIT` or `IO_APPEND` is looking at values that will always be zero.

`IO_NDELAY` is the common case. It is set when the descriptor is in non-blocking mode. A driver that implements blocking reads (Chapter 10) uses this bit to decide between sleeping and returning `EAGAIN`. A Chapter 9 driver does not sleep on anything, so the bit is informational only, but future chapters rely on it.

`IO_DIRECT` is a hint that the user program opened the descriptor with `O_DIRECT`, asking the kernel to bypass buffer caches where possible. For a simple character driver it is almost always irrelevant. Storage-adjacent drivers may choose to honour it; most do not.

Note the numerical identity: `O_NONBLOCK` in `/usr/src/sys/sys/fcntl.h` has the value `0x0004`, and `IO_NDELAY` in `/usr/src/sys/sys/vnode.h` has the same value. That is not an accident. The header comment above the `IO_*` definitions explicitly states that `IO_NDELAY` and `IO_DIRECT` are aligned with the corresponding `fcntl(2)` bits so that devfs does not need to translate. Your driver can inspect the bit either way and get the same answer.

9.6.3 A Handler That Checks `ioflag`

Here is what a non-blocking-aware read handler looks like at the skeleton level. We will not use this shape in Chapter 9 because we never sleep, but studying it now makes Chapter 10's introduction quicker.

```
static int
myfirst_read_nb(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error;

    mtx_lock(&sc->mtx);
    while (sc->bufused == 0) {
        if (ioflag & IO_NDELAY) {
            mtx_unlock(&sc->mtx);
            return (EAGAIN);
        }
        /* ... would msleep(9) here in Chapter 10 ... */
    }
    /* ... drain buffer, uiomove, unlock, return ... */
    error = 0;
    mtx_unlock(&sc->mtx);
    return (error);
}
```

The branch on `IO_NDELAY` is the only decision the handler makes about blocking. Everything else in the function is ordinary I/O code. That narrowness is part of why `ioflag` is a single integer: a driver's response to flag bits is usually a single `if` statement near the top of the handler, not a sprawling state machine.

9.6.4 What the Chapter 9 Stages Do With `ioflag`

Stage 1, Stage 2, and Stage 3 do **not** inspect `ioflag`. They cannot block, so the non-blocking bit is moot; they do not care about `IO_DIRECT`. The argument is present in their handler signatures because the typedef demands it, and it is silently ignored.

Silently ignoring an argument is not a bug when the ignored behaviour is obviously correct. A reader who opens one of our descriptors with `O_NONBLOCK` will see identical behaviour to a reader who did not: neither call ever sleeps, so the flag has no observable effect. Chapter 10 is where we will wire the flag through.

9.6.5 A Small Debugging Aid

If you are curious what `ioflag` contains during a test, a single `device_printf` at entry will tell you:

```
device_printf(sc->dev, "d_read: ioflag=0x%x resid=%zd offset=%jd\n",
    ioflag, (ssize_t)uio->uio_resid, (intmax_t)uio->uio_offset);
```

Load the driver, run `cat /dev/myfirst/0`, and observe the hex value. Then run a small program that uses `fcntl(fd, F_SETFL, O_NONBLOCK)` before reading, and observe the difference. This is an instructive two-minute detour when you are first making the mechanism real in your head.

9.6.6 `ioflag` in the Tree

Search `/usr/src/sys/dev` for `IO_NDELAY` and you will find dozens of hits. Almost every one of them is the same pattern: check the bit, return `EAGAIN` if set and the driver has nothing to serve, otherwise sleep. The uniformity is deliberate. FreeBSD drivers treat non-blocking I/O the same way whether they are pseudo-devices, TTY lines, USB endpoints, or GEOM-backed storage, and that consistency is part of why user programs written for one kind of device port cleanly to another.

9.7 Understanding `struct uio` Deeply

`struct uio` is the kernel's representation of an I/O request. It is passed to every `d_read` and `d_write` invocation. Every successful `uiomove(9)` call mutates it. Every driver author you will ever meet has at some point stared at its fields and wondered which ones to trust. This section is where we make the structure less mysterious.

9.7.1 The Declaration

From `/usr/src/sys/sys/uio.h`:

```
struct uio {
    struct iovec *uio_iov;          /* scatter/gather list */
    int uio_iovcnt;                /* length of scatter/gather list */
```

```

    off_t    uio_offset;           /* offset in target object */
    ssize_t  uio_resid;           /* remaining bytes to process */
    enum     uio_seg uio_segflg;   /* address space */
    enum     uio_rw uio_rw;       /* operation */
    struct    thread *uio_td;      /* owner */
};

```

Seven fields. Each one has a specific purpose, and there is exactly one function, `uiomove(9)`, that uses all of them in concert. Your driver will read some of the fields directly; a few fields you will never touch.

9.7.2 `uio_iov` and `uio_iovcnt`: The Scatter-Gather List

A single `read(2)` or `write(2)` operates on one contiguous user buffer. The related `readv(2)` and `writev(2)` operate on a list of buffers (an “iovec”). The kernel represents both cases uniformly as a list of `iovec` entries, using a list of length one for the simple case.

`uio_iov` points at the first entry of that list. `uio_iovcnt` is the number of entries. Each entry is a struct `iovec`, declared in `/usr/src/sys/sys/_iovec.h`:

```

struct iovec {
    void      *iov_base;
    size_t    iov_len;
};

```

`iov_base` is a pointer into user memory (for a `UIO_USERSPACE` `uio`) or kernel memory (for a `UIO_SYSSPACE` `uio`). `iov_len` is the number of bytes remaining in that entry.

You will almost never touch these fields directly. `uiomove(9)` walks the `iovec` list for you, consuming entries as it moves bytes, and leaving the list consistent with the remaining transfer. If your driver reaches for `uio_iov` or `uio_iovcnt` by hand, you are either writing a very unusual driver or doing something wrong. The conventional pattern is: let `uiomove` manage the `iovec`, and read the other fields to understand the state of the request.

9.7.3 `uio_offset`: The Offset Into the Target

For a read or write on a regular file, `uio_offset` is the position in the file where the I/O is taking place. The kernel increments it as bytes move, so a sequential `read(2)` naturally advances through the file.

For a device file, the meaning of `uio_offset` is defined by the driver. A device that is truly sequential and has no notion of position will ignore the incoming value and leave the outgoing value to reflect whatever `uiomove` did. A device that backs itself with a fixed buffer will treat the offset as an address into that buffer and honour it.

`uiomove(9)` updates `uio_offset` in lockstep with `uio_resid`: for every byte it moves, it decrements `uio_resid` by one and increments `uio_offset` by one. If your driver calls `uiomove` once per handler, you rarely need to read `uio_offset` by hand. If your driver calls `uiomove` more than once, or if it uses the offset to index into its own buffer, `uiomove_frombuf(9)` is the helper you want.

9.7.4 `uio_resid`: The Remaining Bytes

`uio_resid` is the number of bytes that still need to move. At the start of `d_read`, it is the total length the user asked for. At the end of a successful transfer, it is whatever did not move; the kernel subtracts this from the original length to produce the return value of `read(2)`.

Two signed-arithmetic traps are worth calling out. First, `uio_resid` is an `ssize_t`, which is signed. A negative value is illegal (and `uiomove` will `KASSERT` on it in debug kernels), but beware of accidentally constructing one through sloppy arithmetic. Second, `uio_resid` can be zero at the start of the call. This happens when a user program calls `read(fd, buf, 0)` or `write(fd, buf, 0)`. Your handler must not treat zero as “no user intent” and then proceed to do I/O against what might be an uninitialised buffer. The safe pattern is to check for zero early and return zero (or accept zero and return zero, for writes). `uiomove` handles this cleanly: it returns zero immediately without touching anything. So in practice the “check early” is often redundant; what matters is that you do not *assume* it is non-zero.

9.7.5 `uio_segflg`: Where the Buffer Lives

This field says where the `iovec` pointers refer to: user space (`UIO_USERSPACE`), kernel space (`UIO_SYSSPACE`), or a direct object map (`UIO_NOCOPY`). The enumeration is in `/usr/src/sys/sys/_uio.h`:

```
enum uio_seg {
    UIO_USERSPACE,      /* from user data space */
    UIO_SYSSPACE,       /* from system space */
    UIO_NOCOPY          /* don't copy, already in object */
};
```

For a `d_read` or `d_write` called on behalf of a user syscall, `uio_segflg` is `UIO_USERSPACE`. `uiomove(9)` reads the field and picks the right transfer primitive: `copyin` / `copyout` for user-space segments, `bcopy` for kernel-space segments. Your driver does not need to branch on this; `uiomove` does it for you.

You will occasionally see code that builds a kernel-mode `uio` by hand, typically to re-use a function that takes a `uio` but serve it from a kernel buffer. That code sets `uio_segflg` to `UIO_SYSSPACE`. It is legitimate and useful, and we will meet it briefly in the labs. Do not confuse it with a user-space `uio`: the safety properties are very different.

9.7.6 `uio_rw`: The Direction

The direction of transfer. The enumeration is in the same header:

```
enum uio_rw {
    UIO_READ,
    UIO_WRITE
};
```

For a `d_read` handler, `uio_rw` is `UIO_READ`. For a `d_write` handler, `uio_rw` is `UIO_WRITE`. The field tells `uiomove` whether to copy kernel->user (read) or user->kernel (write). Some handlers assert on this as a sanity check:

```
KASSERT(uio->uio_rw == UIO_READ,
        ("Can't be in %s for write", __func__));
```

That assertion is from `zero_read` in `/usr/src/sys/dev/null/null.c`. It is a cheap way to document the invariant. Your driver does not need assertions like this to be correct, but they can be a useful safety net during development.

9.7.7 `uio_td`: The Owning Thread

The `struct thread *` of the caller. For a `uio` built on behalf of a syscall, this is the thread that made the syscall. Some kernel APIs want a thread pointer; using `uio->uio_td` rather than `curthread` keeps the association explicit when the `uio` is handed around.

In a straightforward `d_read` or `d_write`, you rarely need `uio_td`. It becomes useful if your driver wants to inspect the credentials of the caller mid-call, beyond what `open(2)` already validated. That is uncommon.

9.7.8 An Illustration: What Happens to `uio` During a `read(fd, buf, 1024)` Call

Walking through a single `read(2)` helps cement how the fields move. Suppose a user program calls:

```
ssize_t n = read(fd, buf, 1024);
```

The kernel constructs a `uio` that looks roughly like this when it reaches your `d_read`:

- `uio_iov` points to a one-entry list.
- The one entry has `iov_base = buf` (the user's buffer) and `iov_len = 1024`.
- `uio_iovcnt = 1`.
- `uio_offset = <wherever the current file pointer was>`. For a newly opened seekable device, zero.
- `uio_resid = 1024`.
- `uio_segflg = UIO_USERSPACE`.
- `uio_rw = UIO_READ`.
- `uio_td = <calling thread>`.

Your handler calls, say, `uiomove(sc->buf, 300, uio)`. Inside `uiomove`, the kernel:

- Takes the first `iovec` entry.
- Determines that 300 is less than 1024, so it will move 300 bytes.
- Calls `copyout(sc->buf, buf, 300)`.
- Decrements `iov_len` by 300, to 724.
- Advances `iov_base` by 300, to `buf + 300`.

- Decrements `uio_resid` by 300, to 724.
- Increments `uio_offset` by 300.

Your handler returns zero. The kernel computes the byte count as $1024 - 724 = 300$ and returns 300 from `read(2)`. The user sees 300 bytes in `buf[0..299]` and knows to either call `read(2)` again to get the rest, or proceed with what they have.

That is everything `uiomove` is doing, in order. There is no magic.

9.7.9 How `readv(2)` Differs

If the user called `readv(fd, iov, 3)` with three `iovec` entries, the `uio` at the start of `d_read` would have `uio_iovcnt = 3`, `uio_iov` pointing at the list of three entries, and `uio_resid` equal to the sum of their lengths. Your handler makes one `uiomove` call (or several, in a loop) and `uiomove` walks the list for you. The driver code is identical.

This is one of the quiet benefits of the `uio` abstraction: scatter-gather reads and writes are free. Your driver was written for a single buffer; it already handles multi-buffer requests.

9.7.10 Re-entering a Handler With a Partly Consumed `uio`

A convention that occasionally trips beginners: **a single `d_read` or `d_write` invocation can make multiple `uiomove` calls**. Each call shrinks `uio_resid` and advances `uio_iov`. The `uio` remains consistent between calls. If your handler's first `uiomove` moves 128 bytes and the next moves 256, the kernel just sees a single handler call that transferred 384 bytes.

What you should **not** do is save a `uio` pointer across a handler call and try to resume it later. A `uio` is valid for the duration of the dispatch that produced it. Between dispatches, the memory it points at (including the `iovec` array) may not be valid. If you need to queue a request for later processing, you copy the necessary data out of the `uio` (into your own kernel buffer) and use your own queue.

9.7.11 What Your Driver Needs to Read and What It Should Leave Alone

A short crib sheet, in decreasing order of frequency:

Field	Read it?	Write it?
<code>uio_resid</code>	Yes, often	Only to mark a transfer consumed (e.g., <code>uio_resid = 0</code>)
<code>uio_offset</code>	Yes, if you honour it	No, let <code>uiomove</code> update it
<code>uio_rw</code>	Occasionally, for KASSERTs	No
<code>uio_segflg</code>	Rarely	No, unless building a kernel-mode <code>uio</code>
<code>uio_td</code>	Rarely	No
<code>uio_iov</code>	Almost never	Never
<code>uio_iovcnt</code>	Almost never	Never

Field	Read it?	Write it?

If a beginner-level driver writes to `uio_iov` or `uio_iovcnt`, something has gone seriously off the rails. If it writes to `uio_resid` other than the `uio_resid = 0` “I consumed everything” trick, something is slightly off. If it reads from the first three rows, it is on the normal path.

9.7.12 The uio Fields in Practice

All of this is less intimidating once you have seen a handler actually use it. The myfirst stages in this chapter inspect `uio_resid` (to clamp transfers), occasionally read `uio_offset` (to know where a reader is), and hand everything else to `uiomove`. The helpers do the real work, and the driver code stays small.

9.7.13 The Life of a Single uio: Three Snapshots

To cement the field-by-field discussion, it is worth walking through a `uio`’s state at three points in its life: the moment your handler is called, the moment after a partial `uiomove`, and the moment just before your handler returns. Each snapshot captures the same `uio`, so you can see exactly how the fields evolve.

The example is a `read(fd, buf, 1024)` call on a driver whose read handler will serve 300 bytes per call.

Snapshot 1: At the entry of `d_read`.

```
uio_iov      -> [ { iov_base = buf,          iov_len = 1024 } ]
uio_iovcnt   = 1
uio_offset   = 0          (this is the first read on the descriptor)
uio_resid    = 1024
uio_segflg   = UIO_USERSPACE
uio_rw       = UIO_READ
uio_td       = <calling thread>
```

The `uio` describes a complete request. The user asked for 1024 bytes, the buffer is in user space, the direction is read, the offset is zero. This is what the kernel hands your handler.

Snapshot 2: After `uiomove(sc->buf, 300, uio)` returns success.

```
uio_iov      -> [ { iov_base = buf + 300, iov_len = 724 } ]
uio_iovcnt   = 1
uio_offset   = 300
uio_resid    = 724
uio_segflg   = UIO_USERSPACE      (unchanged)
uio_rw       = UIO_READ           (unchanged)
uio_td       = <calling thread>   (unchanged)
```

Four fields changed in lockstep. `iov_base` advanced by 300 so the next transfer will place bytes after the ones just written. `iov_len` shrunk by 300, because the `iovec` entry now describes only the remaining 724 bytes. `uio_offset` grew by 300, because 300 bytes of stream position moved. `uio_resid` shrunk by 300, because 300 bytes of work are done.

Three fields stayed fixed: `uio_segflg`, `uio_rw`, and `uio_td` describe the *shape* of the request, which does not change mid-transfer. If your handler ever needs to check one of them, it can do so before or after `uiomove` and get the same answer.

Snapshot 3: Just before `d_read` returns.

Imagine the handler, having served 300 bytes, decides it has no more data and returns zero without calling `uiomove` again.

```
uio_iov      -> [ { iov_base = buf + 300, iov_len = 724 } ]
uio_iovcnt   = 1
uio_offset   = 300
uio_resid    = 724
uio_segflg   = UIO_USERSPACE
uio_rw       = UIO_READ
uio_td       = <calling thread>
```

Identical to Snapshot 2. The handler did not touch anything; it just returned. The kernel will see `uio_resid` = 724 versus the starting `uio_resid` = 1024 and compute $1024 - 724 = 300$, which it returns to user space as the result of `read(2)`. The caller sees a return value of 300 and knows the driver produced 300 bytes.

If the handler had looped on `uiomove` until `uio_resid` reached zero, the snapshot at return would instead have `uio_resid` = 0 and the kernel would return 1024 to user space (a full transfer). If the handler had called `uiomove` and got an error, `uio_resid` would reflect whatever partial progress happened before the fault, and the handler would return the `errno`.

9.7.14 What This Mental Model Buys You

Three observations fall out of the snapshots that are worth naming explicitly.

First, `uio_resid` is the contract. Whatever value is in `uio_resid` when your handler returns, the kernel will trust. If it is smaller than at entry, some bytes moved; the difference is the byte count. If it is unchanged, nothing moved; the return value will be zero (EOF) or an `errno` (depending on what your handler returned).

Second, `uiomove` is the only thing you should rely on to decrement `uio_resid`. A driver that manually subtracts from `uio_resid` is almost certainly doing something wrong; the kernel's fault handling, `iovec` walking, and offset updates are all baked into the `uiomove` code path. Setting `uio_resid` = 0 is the one exception, used by drivers like `null.c`'s `null_write` to say "pretend all the bytes were consumed".

Third, the `uio` is scratch space. A `uio` is not a long-lived object. It is created per `syscall`, decays as `uiomove` consumes it, and is discarded when your handler returns. Saving a `uio` pointer for later use is a lifetime bug waiting to fire. If your driver needs data from the `uio` beyond the current call, it copies the bytes out into its own storage (which is what `d_write` does: it copies bytes through `uiomove` into `sc->buf`, leaving nothing in the `uio` for later).

These three facts are the foundation everything else in the chapter is built on. If you internalise them, the rest of the uio machinery stops looking mysterious.

9.8 Safe Data Transfer: `uiomove`, `copyin`, `copyout`

The previous sections described `struct uio` and named `uiomove(9)` as the function that moves bytes. This section explains why that function exists, what it does under the hood, and when a driver should reach for `copyin(9)` or `copyout(9)` directly instead.

9.8.1 Why Direct Memory Access Is Unsafe

A user process has its own virtual address space. When a process calls `read(2)` with a buffer pointer, that pointer is a virtual address in the process's address space. It may refer to a page of memory that is present in physical RAM, or to a page that has been swapped out, or to a page that is not mapped at all. It may even be a pointer the user program fabricated deliberately to try to make the kernel crash.

From the kernel's point of view, the user's address space is not directly addressable. The kernel has its own address space; a user pointer handed to the kernel is not meaningful as a kernel pointer. Even if the kernel can resolve the user pointer through page-table machinery, using it directly is dangerous: the page might fault, the memory protection might be wrong, the address might fall outside the process's mapped regions, or the pointer might have been constructed to point at kernel memory in an attempt to leak or corrupt it.

Direct memory access, in other words, is not a feature the kernel gets for free. It is a privilege that must be exercised carefully, with every access routed through functions that know how to handle faults, check protection, and keep the user and kernel address spaces distinct.

On FreeBSD those functions are `copyin(9)` (user to kernel), `copyout(9)` (kernel to user), and `uiomove(9)` (either direction, driven by the `uio`).

9.8.2 What `copyin(9)` and `copyout(9)` Do

From `/usr/src/sys/sys/systm.h`:

```
int copyin(const void * __restrict udaddr,
           void * __restrict kaddr, size_t len);

int copyout(const void * __restrict kaddr,
            void * __restrict udaddr, size_t len);
```

`copyin` takes a user-space pointer, a kernel-space pointer, and a length. It copies `len` bytes from user to kernel. `copyout` is the reverse: kernel pointer, user pointer, length. Copies kernel to user.

Both functions validate the user address, fault in the user page if necessary, perform the copy, and catch any fault that occurs. They return zero on success and `EFAULT` if the user address was invalid or the copy otherwise failed. They never silently corrupt memory; they always either complete the copy or report the error.

These two primitives are the foundation on which all user / kernel memory transfers are built. They are what `uiomove(9)` calls underneath when the `uio` is in user space. They are what `fubyte(9)`, `subyte(9)`, and a handful of other convenience functions use. They are the functions the kernel trusts to be the trust boundary.

9.8.3 What `uiomove(9)` Does

`uiomove(9)` is a wrapper around `copyin / copyout` that understands the `uio` structure. Its implementation is short and worth reading; it lives in `/usr/src/sys/kern/subr_uio.c`.

Roughly, the algorithm is:

1. Sanity-check the `uio`: the direction is valid, the `resid` is non-negative, the owning thread is the current thread if the segment is user-space.
2. Loop: while the caller has asked for more bytes (`n > 0`) and the `uio` still has room (`uio->uio_resid > 0`), consume the next `iovec` entry.
3. For each `iovec` entry, compute how many bytes to move (the minimum of the entry length, the caller's remaining count, and the `uio`'s `resid`), and call `copyin` or `copyout` (for user-space segments) or `bcopy` (for kernel-space segments), depending on `uio_rw` and `uio_segflg`.
4. Advance the `iovec`'s `iov_base` and `iov_len` as bytes move; decrement `uio_resid`, increment `uio_offset`.
5. If any copy fails, break out and return the error.

The function returns zero on success or an `errno` code on failure. The most common failure is `EFAULT` from a bad user pointer.

The critical property of `uiomove` is that it is **the only function your driver should use to move bytes through a `uio`**. Not `bcopy`, not `memcpy`, not `copyout`. The `uio` carries the information `uiomove` needs to pick the right primitive, and the driver does not need to second-guess.

9.8.4 When to Use Which

The division of labour is straightforward in practice.

Use `uiomove(9)` in `d_read` and `d_write` handlers whenever the `uio` describes the transfer. This is the overwhelmingly common case.

Use `copyin(9)` and `copyout(9)` directly when you have a user pointer from somewhere other than a `uio`. Examples:

- Inside a `d_ioctl` handler, for control commands that carry user-space pointers as arguments (Chapter 25).
- Inside a kernel thread that accepts user-supplied data through a mechanism you built yourself, not through a `uio`.
- When reading or writing a small, fixed-size piece of user memory that is not the subject of the syscall.

Do **not** use `copyin` or `copyout` inside `d_read` or `d_write` to fetch from the `uio`'s `iovec`. Always go through `uiomove`. The `iovec` is not guaranteed to be a single contiguous buffer, and even if it is, your driver has no business reaching past the `uio` abstraction to touch it directly.

9.8.5 A Table for Quick Reference

Situation	Preferred tool
Transferring bytes through a uio (read or write)	<code>uiomove(9)</code>
Transferring bytes through a uio, with a fixed kernel buffer and automatic offset	<code>uiomove_frombuf(9)</code>
Reading a known user pointer not carried by a uio	<code>copyin(9)</code>
Writing to a known user pointer not carried by a uio	<code>copyout(9)</code>
Reading a null-terminated string from user space	<code>copyinstr(9)</code>
Reading a single byte from user space	<code>fubyte(9)</code>
Writing a single byte to user space	<code>subyte(9)</code>

`fubyte` and `subyte` are niche; most drivers never use them. They are listed here for recognition. `copyinstr` is occasionally useful in control paths that take a user string; we will not reach for it in this chapter.

9.8.6 Why Not a Straight `memcpy`?

A beginner sometimes asks “can I just cast the user pointer and `memcpy` the bytes?” The answer is an unqualified no, and it is worth understanding why.

`memcpy` assumes both pointers refer to accessible memory in the current address space. A user pointer is not guaranteed to refer to accessible memory. On architectures that separate user and kernel pointers at the hardware level (SMAP on amd64, for example), the CPU will refuse the access. On architectures that share the address space, the pointer may still be invalid, or may refer to a page that has been swapped out, or may refer to a page the kernel is forbidden to touch. None of these cases are safe to handle inside a plain `memcpy`; the resulting fault would either panic the system or leak information across the trust boundary.

The kernel primitives `copyin` and `copyout` exist precisely to handle these cases correctly. They install a fault handler before the access, so a bad user pointer returns `EFAULT` instead of panicking. They respect SMAP and similar protections. They can wait for the page to be paged in. None of that is optional, and none of it is something your driver should replicate.

The practical rule: if a pointer came from user space, route it through `copyin` / `copyout` / `uiomove`. Do not dereference it directly. Do not `memcpy` through it. Do not pass it to any function that will `memcpy` through it. If you stop at the abstraction boundary, the kernel gives you a stable, safe, well-documented interface. If you cross it, you own every bug forever.

9.8.7 What Happens Under a Fault

Something concrete: what does `uiomove` actually do when the user pointer is bad?

The kernel installs a fault handler before the copy, typically through its trap-handler table. When the CPU takes a fault on the user access, the fault handler notices that the faulting instruction is inside a `copyin` or `copyout`

code path, skips ahead to the failure-return path, and returns `EFAULT`. No panic. No data corruption. The caller of `uiomove` sees a non-zero return value, propagates it to the caller of `d_read` or `d_write`, and the syscall returns to userland with `errno = EFAULT`.

The driver does not need to do anything special to cooperate with this machinery. It just needs to check the return value of `uiomove` and propagate errors. We will do that in every handler in the chapter.

9.8.8 Alignment and Type Safety

One more subtlety worth naming. The user's buffer is a stream of bytes. It carries no type information. If your driver puts a struct into the buffer and the user pulls it out, the user gets bytes; those bytes may or may not be correctly aligned for a struct access on the caller's architecture.

For `myfirst` the problem does not arise, because the bytes are arbitrary user text. For drivers that want to export structured data, the convention is either to require the user to memcpy the bytes into an aligned local structure before interpreting them, or to include an explicit alignment and version negotiation in the data format. `ioctl(2)` sidesteps the problem because its data layout is part of the `IOCTL` command number; `read` and `write` do not have that luxury.

This is one of the places where bolting structured data onto `read/write` is tempting and wrong. If your driver wants to hand typed data to userland, the `ioctl` interface or an external RPC mechanism are the right tools. `read` and `write` carry bytes. That is the promise, and the promise is what keeps them portable.

9.8.9 A Small Worked Example

Suppose a user program writes four integers to your device:

```
int buf[4] = { 1, 2, 3, 4 };
write(fd, buf, sizeof(buf));
```

In the driver's `d_write`, the `uio` looks like:

- One `iovec` entry with `iov_base = <user address of buf[0]>`, `iov_len = 16`.
- `uio_resid = 16`, `uio_offset = 0`, `uio_segflg = UIO_USERSPACE`, `uio_rw = UIO_WRITE`.

A naive handler might call `uiomove(sc->intbuf, 16, uio)`, where `sc->intbuf` is `int sc->intbuf[4]`; `uiomove` would issue a copyin that copies the 16 bytes. On success, `sc->intbuf` would hold the four integers in the byte order of the calling program.

But note: the user may have written those integers in the byte order of a completely different CPU if the driver is ever used across architectures. The user may have used `int32_t` where the driver used `int`. The user may have padded the structure differently. For `myfirst` none of this matters because we treat the data as opaque bytes. For a driver that exposes structured data over `read/write`, these issues multiply quickly, and they are the reason most real drivers either use `ioctl` for structured payloads or declare an explicit wire format (byte order, field widths, alignment) in their documentation.

The lesson: `uiomove` moves bytes. It does not know or care about types. Your driver has to decide what those bytes mean.

9.8.10 A Mini Case Study: When a Struct Round-Trip Goes Wrong

To make the “bytes are not types” point concrete, walk through a plausible but mistaken attempt to expose a kernel counter via `read(2)` as a typed structure.

Suppose your driver maintains a set of counters:

```
struct myfirst_stats {
    uint64_t reads;
    uint64_t writes;
    uint64_t errors;
    uint32_t flags;
};
```

And suppose, optimistically, you expose them via `d_read`:

```
static int
stats_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_stats snap;

    mtx_lock(&sc->mtx);
    snap.reads  = sc->stat_reads;
    snap.writes = sc->stat_writes;
    snap.errors = sc->stat_errors;
    snap.flags  = sc->stat_flags;
    mtx_unlock(&sc->mtx);

    return (uiomove(&snap, sizeof(snap), uio));
}
```

At first glance this is fine. The bytes reach user space. A reader can cast the buffer to a `struct myfirst_stats` and look at the fields. The author tests it on amd64, sees the correct values, ships the driver.

Three problems are sitting there waiting.

Problem 1: Struct padding. The layout of `struct myfirst_stats` depends on the compiler and architecture. On amd64 with the default ABI, `uint64_t` is 8-byte-aligned, so the struct is 8 bytes for `reads`, 8 for `writes`, 8 for `errors`, 4 for `flags`, plus 4 bytes of trailing padding to round the size to 32. The user program must declare a struct with the *same* padding to read the fields correctly. A user program that redeclares the struct with `#pragma pack(1)` or uses a different compiler version will parse the bytes wrong and see garbage in errors.

Problem 2: Byte order. An amd64 machine stores `uint64_t` little-endian. A user program running on the same architecture decodes correctly. A user program running remotely on a big-endian machine, reading the bytes through a network pipe, sees the integers byte-swapped. The driver did not choose an on-the-wire byte order, so the format is CPU-dependent by accident.

Problem 3: Atomicity of the snapshot. The reader may pull the bytes out through `uiomove` after `mtx_unlock` releases the mutex and before the kernel returns control to the caller. Between those two moments, the fields `snap.reads`, `snap.writes`, etc. are already captured in the stack-local `snap`, so *that* bit is fine. But the example is small enough that the bug does not appear; a larger snapshot might be captured across several mutex acquisitions and exhibit torn reads.

The fix is not to “try harder” with struct layout. The fix is to stop using `read(2)` for structured data. Two better options exist:

- **`sysctl`:** the chapter has been using this throughout. Individual counters are exposed as named nodes of known type. `sysctl(3)` on the user side returns integers directly; no struct layout, no padding, no byte order.
- **`d_ioctl`:** Chapter 25 builds out `ioctl` properly. For this use case, an `ioctl` with a well-defined request structure would be appropriate, and the `_IOR / _IOW` macros document the size and direction.

The `read(2)` interface promises “a byte stream the driver defines”; nothing more. If you respect the promise, your driver is portable, testable, and resistant to silent layout drift. If you break the promise by exposing typed structures, you inherit every ABI trap that network protocols spent decades learning to work around.

For `myfirst` in this chapter we never hit the problem, because we only ever push and pull opaque byte streams. The point of the case study is to help you recognise the shape of the mistake before someone hands you a driver that is already making it.

9.8.11 Summary of This Section

- Use `uiomove(9)` inside `d_read` and `d_write`. It reads the `uio`, picks the right primitive, and handles user / kernel faults for you.
- Use `uiomove_frombuf(9)` when you want automatic offset-into-buffer arithmetic.
- Use `copyin(9)` and `copyout(9)` only when you have a user pointer outside the `uio` context, typically in `d_ioctl`.
- Do not dereference user pointers directly. Ever.
- Check return values. Any copy can fail with `EFAULT`, and your handler must propagate the error.

These rules are short, but they cover nearly every I/O safety mistake that beginner drivers make.

9.9 Managing Internal Buffers in Your Driver

The read and write handlers are the visible surface of your driver’s I/O path. Behind them, the driver has to store data somewhere. This section is about how that storage is designed, allocated, protected, and cleaned up, at the beginner-friendly level that this chapter needs. Chapter 10 will extend the buffer into a true ring and make it concurrent-safe under load; we are staying short of that here on purpose.

9.9.1 Why You Need Buffers

A buffer is temporary storage between I/O calls. A driver uses one for at least three reasons:

1. **Rate matching.** Producers and consumers do not arrive at the same time. A write can deposit bytes that a later read will pick up.
2. **Request reshaping.** A user may read in units that do not line up with how the driver produces data. A buffer absorbs the mismatch.
3. **Isolation.** The bytes inside the driver's buffer are kernel data. They are not user pointers, not DMA addresses, not in a scatter-gather list. Everything in a kernel buffer is addressable by the driver safely and uniformly.

For `myfirst`, the buffer is a small piece of in-RAM storage. `d_write` writes into it; `d_read` reads from it. The buffer is the driver's state. The uio machinery is the plumbing that moves bytes in and out.

9.9.2 Static vs Dynamic Allocation

Two reasonable designs exist for where the buffer lives.

Static allocation puts the buffer inside the `softc` structure or as a module-level array:

```
struct myfirst_softc {  
    ...  
    char buf[4096];  
    size_t bufused;  
    ...  
};
```

Pros: allocation never fails, sizing is explicit, lifetime is trivially tied to the `softc`. Cons: the size is baked in at compile time; if you later want to make it tunable, you will refactor.

Dynamic allocation uses `malloc(9)` from an `M_*` bucket:

```
sc->buf = malloc(sc->buflen, M_DEVBUF, M_WAITOK | M_ZERO);
```

Pros: size can be chosen at attach time from a `sysctl` or tunable; can be resized if you are careful. Cons: allocation can fail (less relevant with `M_WAITOK`, more so with `M_NOWAIT`); the driver owns another free path.

For small buffers, static allocation inside the `softc` is the simplest choice, and the one Chapter 7 used implicitly by relying on Newbus to allocate the whole `softc`. Chapter 9 will use dynamic allocation because the buffer is large enough that putting it in the `softc` is slightly wasteful, and because the dynamic path is the pattern you will use repeatedly later in the book.

9.9.3 The `malloc(9)` Call

The kernel's `malloc(9)` takes three arguments: the size, a `malloc` type (which is a tag the kernel uses for accounting and debugging), and a flag word. A common shape:

```
sc->buf = malloc(sc->buflen, M_DEVBUF, M_WAITOK | M_ZERO);
```

`M_DEVBUF` is the generic “device buffer” malloc type, defined across the tree and appropriate for driver-private data that does not deserve a dedicated type. If your driver grows large enough to warrant its own tag, you can declare one with `MALLOC_DECLARE(M_MYFIRST)` and `MALLOC_DEFINE(M_MYFIRST, "myfirst", "myfirst driver data")`, and use `M_MYFIRST` instead. For now, `M_DEVBUF` is fine.

The flag bits most relevant at this stage:

- `M_WAITOK`: it is OK for the allocation to sleep waiting for memory. In attach context this is almost always the right choice.
- `M_NOWAIT`: do not sleep; return NULL if memory is tight. Needed when you are in a context that cannot sleep (interrupt handler, inside a non-sleepable lock).
- `M_ZERO`: zero the memory before returning. Pair with `M_WAITOK` or `M_NOWAIT` as appropriate.

A call with `M_WAITOK` without `M_NOWAIT` is guaranteed to return a valid pointer on FreeBSD 14.3. The kernel will sleep and possibly trigger reclamation if needed, but it will not return NULL in practice. Still, checking for NULL is defensive and costs nothing; we will do it.

9.9.4 The Matching `free(9)` Call

Every `malloc(9)` has a matching `free(9)`. The signature is:

```
free(sc->buf, M_DEVBUF);
```

The malloc type passed to `free` must match the one passed to `malloc` for the same pointer. Passing a different type would corrupt the kernel’s accounting and is one of the bugs `INVARIANTS`-enabled kernels catch at runtime.

Where to put the `free` depends on where the `malloc` was: attach allocates, detach frees. If attach fails partway, the error-unwind path frees whatever was allocated before the failure. We saw this pattern in Chapter 7; we will reuse it here.

9.9.5 Buffer Sizing

Picking a buffer size is a design choice. For a classroom driver, any small size works. A few guidelines:

- **Small** (a few hundred bytes to a few kilobytes): fine for demonstration. Easy to reason about. User workloads larger than the buffer will observe `ENOSPC` or short reads quickly; this is a feature for teaching, not a bug.
- **Page-sized** (4096 bytes): a common, sensible default. Memory allocation is page-aligned for free, and many tools treat 4 KiB as a natural unit.
- **Larger** (many kilobytes to a megabyte): appropriate for drivers that expect to buffer a lot of data. Remember that kernel memory is not infinite; a runaway driver that allocates a megabyte per open can destabilise the system.

For `myfirst` Stage 2 we will use a 4096-byte buffer. It is large enough that a reasonable test (a paragraph of text, a few integers) fits, and small enough that `ENOSPC` behaviour is easy to trigger from a shell.

9.9.6 Buffer Overflows

The single most common bug in a driver that manages its own buffer is writing past the end of the buffer. The bug is absolutely fatal in kernel space. A user-space program that overruns a buffer might corrupt its own heap; a kernel module that does the same may corrupt another subsystem's memory, and the crash (or worse, the silent misbehaviour) can show up far from the bug.

The defence is arithmetic discipline. Every time your code is about to write N bytes starting at offset 0 into a buffer of size S , verify that $0 + N \leq S$ before the write. In the Stage 3 handler above, the expression `towrite = MIN((size_t)uio->uio_resid, avail)` is exactly that check: `towrite` is clamped to `avail`, where `avail` is `sc->buflen - sc->bufused`. No way to exceed `sc->buflen`.

A related bug is signed-vs-unsigned confusion. `uio_resid` is `ssize_t`; `sc->bufused` is `size_t`. Mixing them carelessly can produce a negative value that wraps around when cast to `size_t`, with catastrophic results. The `MIN` macro and an explicit `(size_t)` cast are worth the tiny amount of noise they add to the code.

9.9.7 Locking Considerations

If your driver can be entered from more than one user context simultaneously, the buffer needs a lock. Two simultaneous writers could race on `bufused`; two simultaneous readers could race on read offsets; a writer and a reader could interleave their state updates in a way that corrupts both.

In `myfirst`, the `struct mtx mtx` field we have carried since Chapter 7 is the lock we will use. It is an ordinary `MTX_DEF` mutex, which means it can be held across a `uiomove` call (which may sleep on a page fault). We will hold it during every update to `bufused` and during the `uiomove` that is transferring bytes into or out of the shared buffer.

Part 3 goes much deeper into locking strategy. For now, the rule is: **protect any field that more than one handler might touch at the same time**. In Stage 3, that is `sc->buf` and `sc->bufused`. Your per-open `fh` is per-descriptor; it does not need the same lock, because two handlers cannot run for the same descriptor concurrently in the cases we will exercise.

9.9.8 A Preview of Circular Buffers

Chapter 10 builds a proper ring buffer: a fixed-size buffer where head and tail pointers chase each other around. It differs from the linear buffer we are using in Chapter 9 in two ways:

1. It does not need to be reset between uses. The pointers wrap; the buffer is reused in place.
2. It can support streaming at steady state. A linear buffer fills up and then refuses writes; a ring buffer maintains a moving window of recent data.

Stage 3 of this chapter does *not* implement a ring. It implements a linear buffer that `d_write` appends into and `d_read` drains from. When the buffer is full, `d_write` returns `ENOSPC`; when it is empty, `d_read` returns zero bytes. This is enough to get the I/O path right without the extra bookkeeping of a ring. Chapter 10 adds that bookkeeping on top of the same handler shapes.

9.9.9 A Note on Thread Safety of the Per-Descriptor fh

The `struct myfirst_fh` your driver allocates in `d_open` is per-descriptor. Two handlers for the same descriptor cannot execute concurrently in the scenarios this chapter exercises (the kernel serialises per-file operations through the file-descriptor machinery for the common cases), so the fields inside `fh` do not need their own lock. Two handlers for *different* descriptors do run concurrently, but they touch different `fh` structures.

This is a comforting invariant but not an absolute one. A driver that arranges to pass the `fh` pointer to a kernel thread that runs in parallel with the syscall must add its own synchronisation. We will not do that in this chapter; for now the `fh` is safe as long as you only touch it from inside the handler that was given the descriptor.

9.9.10 Kernel Helpers You Should Recognise

Before we move on, it is worth naming the small handful of helper macros and functions the chapter has been using. They are defined in standard FreeBSD headers, and beginners sometimes copy-paste code that uses them without knowing where they come from or what constraints apply.

`MIN(a, b)` and `MAX(a, b)` are available in kernel code through `<sys/libkern.h>`, which is pulled in transitively by `<sys/system.h>`. They evaluate each argument at most twice, so a `MIN(count++, limit)` is a bug: `count` increments twice. A well-written driver avoids side effects inside `MIN/MAX` arguments.

```
towrite = MIN((size_t)uio->uio_resid, avail);
```

The explicit `(size_t)` cast is part of the pattern, not a stylistic flourish. `uio_resid` is `ssize_t`, which is signed; `avail` is `size_t`, which is unsigned. Without the cast, the compiler picks one type for the comparison, and modern compilers warn when signed and unsigned meet in the same `MIN / MAX`. The cast makes the intent explicit: we have already checked that `uio_resid` is non-negative (the kernel guarantees it), so the cast is safe.

`howmany(x, d)`, defined in `<sys/param.h>`, computes $(x + d - 1) / d$. Use it when you need ceiling division. A driver that allocates pages to hold a byte-count often writes:

```
npages = howmany(buflen, PAGE_SIZE);
```

`rounddown(x, y)` and `roundup(x, y)` align `x` down or up to the nearest multiple of `y`. `roundup2` and `rounddown2` are faster variants that only work when `y` is a power of two. These are how drivers page-align buffers or block-align offsets.

`__DECONST(type, ptr)` casts away `const` without a compiler warning. It is the polite way to tell the compiler “I know this pointer is declared `const`, but I have verified that the function I am calling will not modify the data, so please stop complaining”. Used it around `zero_region` in `null.c`’s `zero_read`; we used it in Stage 1’s `myfirst_read`. Prefer it to a plain `(void *)` cast, because it signals intent.

`curthread` is an architecture-specific macro (resolved through a per-CPU register) that points at the currently executing thread. `uio->uio_td` usually equals `curthread` when the `uio` came from a syscall; the two are interchangeable in that context but the `uio`-carried value is more self-documenting.

`bootverbose` is an integer that is set to non-zero if the kernel was booted with `-v` or if the operator toggled it via `sysctl`. Guarding chatty log lines with `if (bootverbose)` is the FreeBSD idiom for debug logging that is visible on demand but silent by default.

Recognising these helpers when you encounter them in other drivers shortens the time it takes to read unfamiliar code. None of them are exotic; all of them are part of the standard vocabulary a kernel contributor is expected to read without looking up.

9.10 Error Handling and Edge Cases

A beginner driver that “works on the happy path” is a driver that will eventually crash the kernel. The interesting part of I/O handling is the parts that are not the happy path: zero-length reads, partial writes, bad user pointers, signals delivered mid-call, exhausted buffers, and several dozen variations of those. This section walks through the common cases and the `errno` values that go with them.

9.10.1 The Errno Values That Matter for I/O

FreeBSD has a large `errno` space. Only a handful are frequent in driver I/O paths; learning them well is more useful than skimming the whole list.

`0`: success. Return this when the transfer completed cleanly. The byte count is implicit in `uio_resid`.

`ENXIO` (“Device not configured”): the operation cannot proceed because the device is not in a usable state. Return this from `d_open`, `d_read`, or `d_write` if the `softc` is missing, `is_attached` is false, or the driver has been told to shut down. It is the idiomatic “the `cdev` exists but the backing device does not” error.

`EFAULT` (“Bad address”): a user pointer was invalid. You rarely return this directly; `uiomove(9)` returns it on your behalf when a `copyin/copyout` fails. Propagate it by returning whatever error `uiomove` produced.

`EINVAL` (“Invalid argument”): some parameter is nonsensical. For a read or write, this is usually an out-of-range offset (if your driver honours offsets) or a malformed request. Avoid using it as a catch-all.

`EAGAIN` (“Resource temporarily unavailable”): the operation would block, but `O_NONBLOCK` was set. For a `d_read` that has no data, this is the right answer in non-blocking mode. For a `d_write` that has no space, same story. We will handle this in Stage 3.

`EINTR` (“Interrupted system call”): a signal was delivered while the thread was blocked inside the driver. Your `d_read` may return `EINTR` if a sleep was interrupted by a signal. The kernel will then either retry the syscall transparently (depending on the `SA_RESTART` flag) or return to userland with `errno = EINTR`. We will see `EINTR` handling in Chapter 10; Chapter 9 does not block and so does not produce `EINTR`.

`EIO` (“Input/output error”): a catch-all for hardware errors. Use when your driver talks to real hardware and the hardware reports a failure. Rare in `myfirst`, which has no hardware.

`ENOSPC` (“No space left on device”): the driver’s buffer is full and cannot accept more data. The correct response for a write when there is no room. Stage 3 returns this.

`EPIPE` (“Broken pipe”): used by pipe-like drivers when the peer has closed. Not relevant for `myfirst`.

`ERANGE`, `Eoverflow`, `EMSGSIZE`: less common in character drivers; they show up when the kernel or the driver wants to say “the number you asked for is out of range”. We will not use them in this chapter.

9.10.2 End of File in a Read

By convention, a read that returns zero bytes (because `uiomove` did not move anything and your handler returned zero) is interpreted by the caller as end of file. Shells, `cat`, `head`, `tail`, `dd`, and most other base-system tools rely on this convention.

The implication for your `d_read`: when your driver has nothing more to deliver, return zero. Do not return an `errno`. `uio_resid` should still have its original value, because no bytes were moved.

In Stage 1 and Stage 2 of `myfirst`, EOF happens when the per-descriptor read offset has reached the buffer's length. `uiomove_frombuf` returns zero in that case naturally, so we do not need a special code path.

In Stage 3, where `d_read` drains a buffer that `d_write` has appended to, EOF behaviour is subtler: “no data right now” is not the same as “no more data ever”. We will report “no data right now” as a zero-byte read. A thoughtful user program might interpret that as EOF and stop; a less thoughtful one will loop and call `read(2)` again. Chapter 10 introduces the proper blocking-read or `poll(2)` strategies that allow a user program to wait for more data without spinning.

9.10.3 Zero-Length Reads and Writes

A zero-length request (`read(fd, buf, 0)` or `write(fd, buf, 0)`) is legal. It means “do nothing, but tell me whether you could have done something”. The kernel handles most of the dispatch for you: if `uio_resid` is zero at entry, any `uiomove` call is a no-op, and your handler returns zero. The caller sees a zero-byte transfer and no error.

Two subtle points. First, do not treat `uio_resid == 0` as an error condition. It is not. It is a legitimate request. Second, do not assume `uio_resid == 0` means end of file; it just means the caller asked for zero bytes. EOF is about the driver running out of data, not about the caller asking for none.

9.10.4 Short Transfers

A short read is a read that returns fewer bytes than were requested. A short write is a write that consumed fewer bytes than were offered. Both are legal and expected in UNIX I/O; well-written user programs handle them by looping.

Your driver is the authoritative decider of how much to transfer. The `uiomove` family of functions transfers at most `MIN(user_request, driver_offer)` bytes in a call. If your code calls `uiomove(buf, 128, uio)` and the user asked for 1024, the kernel transfers 128 and leaves 896 in `uio_resid`. The caller sees a 128-byte return from `read(2)`.

A badly-behaved user program that does not loop on short I/O will miss bytes. That is not your driver's problem; UNIX has been like this since 1971. A well-behaved driver is one that returns honest byte counts (through `uio_resid`) and predictable `errno` values, even when partial transfers happen.

9.10.5 Handling EFAULT From uiomove

When `uiomove(9)` returns a non-zero error, the most common value is `EFAULT`. By the time you see it, the kernel has already:

- Installed a fault handler around the copy.
- Observed the fault.
- Unwound the partial copy.
- Returned EFAULT to uiomove's caller.

Your handler has two options for how to respond:

1. **Propagate the error.** Return EFAULT (or whatever errno was returned) from `d_read / d_write`. This is the simplest and almost always correct.
2. **Adjust driver state and return success.** If some bytes moved before the fault, `uio_resid` may have already decreased. The kernel will report that partial success to user space. You may want to update any driver-side counter that reflects how far the transfer got.

In practice, option 1 is the universal answer unless you have a specific reason to do more. Option 2 adds complexity that is rarely worth it.

9.10.6 Defensive Programming for User Input

Every byte a user writes into your device is untrusted. That sounds dramatic; it is also literally true. A kernel module that parses a user write as a structure and dereferences a pointer from that structure is a kernel module with a trivial arbitrary-memory-write vulnerability.

The rule of thumb: **treat the bytes in your buffer as arbitrary data, not as a typed structure, unless you have deliberately chosen a wire format that you validate at every boundary.** For `myfirst` this is easy, because we never interpret the bytes; they are payload. For drivers that expose a structured write interface (for example, a driver that lets users configure behaviour through writes), the defensive path is to:

- Validate the length of the write against the expected message size.
- Copy the bytes into a kernel-space structure (not a user pointer).
- Validate every field of that structure before acting on it.
- Never store a user pointer inside your driver for later use.

These rules are easier to follow than they sound, but they are easy to break without noticing. Chapter 25 revisits them when we look at `ioctl` design. For now, the bar is low: your `myfirst` driver should copy bytes through `uiomove`, not interpret them.

9.10.7 Logging Errors vs Silent Failures

When a handler returns an `errno`, the error propagates to user space as the `errno` value of the failed syscall. Most user programs will see it there and report it. Some will swallow it.

For driver development, it helps to also log significant errors to `dmesg`. `device_printf(9)` is the right tool, because it tags each line with the Newbus device name so you can tell which instance produced the message. An example from Stage 3:

```
if (avail == 0) {
    mtx_unlock(&sc->mtx);
    if (bootverbose)
```

```

        device_printf(sc->dev, "write rejected: buffer full\n");
    return (ENOSPC);
}

```

The `if (bootverbose)` guard is a common FreeBSD idiom for chatty logging: it only prints if the kernel was booted with the `-v` flag or if the `bootverbose` sysctl was set, which keeps production logs quiet while still giving developers a way to see detail.

Do not log every error on every call; that produces log spam, which makes real problems harder to find. Log the first occurrence of a condition, or log periodically, or log only under `bootverbose`. The choice depends on the driver. For `myfirst`, a single log per transition (buffer-empty, buffer-full) is plenty.

9.10.8 Predictability and User-Friendliness

A beginner writing a driver often focuses on making the good path fast. A more experienced driver author focuses on making the error paths predictable. The difference is this: when an operator runs your driver and something breaks, the `errno` value, the log message, and the user-space reaction need to add up to a clear story. If `read(2)` returns `-1` with `errno = EIO` and the logs are silent, the operator has nowhere to start. If the logs say “`myfirst0: read failed, device detached`” and the user gets `ENXIO`, the story tells itself.

Aim for that. Return the right `errno`. Log the underlying reason once. Make partial transfers honest. Never silently discard data.

9.10.9 A Short Table of Conventions

Situation in <code>d_read</code>	Return
No data to deliver, more might arrive later	0 with <code>uio_resid</code> unchanged
No data, never will be any more (EOF)	0 with <code>uio_resid</code> unchanged
Some data delivered, some not	0 with <code>uio_resid</code> reflecting remainder
Full delivery	0 with <code>uio_resid = 0</code>
User pointer invalid	<code>EFAULT</code> (from <code>uiomove</code>)
Device not ready / detaching	<code>ENXIO</code>
Non-blocking, would block	<code>EAGAIN</code>
Hardware error	<code>EIO</code>

Situation in <code>d_write</code>	Return
Full acceptance	0 with <code>uio_resid = 0</code>
Partial acceptance	0 with <code>uio_resid</code> reflecting remainder
No room, would block	EAGAIN (non-blocking) or sleep (blocking)
No room, permanent	ENOSPC
Invalid pointer	EFAULT (from <code>uiomove</code>)
Device not ready	ENXIO
Hardware error	EIO

Both tables are short on purpose. Most drivers use only four or five `errno` values in total. The cleaner your error story, the better your driver is to work with.

9.11 Evolving Your Driver: The Three Stages

With the theory in place, we turn to code. This section walks through three stages of `myfirst`, each one small, each one a complete driver that loads, runs, and exercises a specific I/O pattern.

The stages are designed to build on one another:

- **Stage 1** adds a read path that serves a fixed kernel-space message. This is `myfirst_read` at its simplest.
- **Stage 2** adds a write path that deposits user data into a kernel buffer, and a read path that reads from the same buffer. The buffer is sized at attach time and does not wrap.
- **Stage 3** turns Stage 2 into a first-in / first-out buffer, so that writes append and reads drain, and the driver can serve a continuous (if finite) stream.

All three stages start from the Chapter 8 stage 2 source. The build system (`Makefile`) does not change. The attach and detach handlers grow slightly at each stage. The shape of `cdevsw`, the Newbus methods, the per-open `fh` plumbing, and the `sysctl` tree stay the same. You will spend most of your time looking at `d_read` and `d_write`.

9.11.1 Stage 1: A Static-Message Reader

The Stage 1 driver holds a fixed message in kernel memory and serves it to readers. `d_read` uses `uiomove_frombuf(9)` to deliver the message. `d_write` stays a stub: it returns success without consuming any bytes. This stage is the bridge from the Chapter 8 stub to a real reader; it introduces `uiomove_frombuf` in the smallest possible context.

Add a pair of fields to the `softc` to hold the message and its length, and a per-descriptor offset to the `fh`:

```
struct myfirst_softc {
    /* ...existing Chapter 8 fields... */

    const char *message;
    size_t      message_len;
};

struct myfirst_fh {
    struct myfirst_softc *sc;
    uint64_t      reads;
    uint64_t      writes;
    off_t         read_off;
};
```

In `myfirst_attach`, initialise the message:

```
static const char myfirst_message[] =
    "Hello from myfirst.\n"
    "This is your first real read path.\n"
    "Chapter 9, Stage 1.\n";

sc->message = myfirst_message;
sc->message_len = sizeof(myfirst_message) - 1;
```

Note the `- 1`: we do not want to serve the terminating NUL byte to user space. Text files do not carry a NUL at the end, and neither should a device that behaves like one.

The new `myfirst_read`:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    off_t before;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);

    if (sc == NULL || !sc->is_attached)
        return (ENXIO);
```

```

    before = uio->uio_offset;
    error = uiomove_frombuf(__DECONST(void *, sc->message),
        sc->message_len, uio);
    if (error == 0)
        fh->reads += (uio->uio_offset - before);
    fh->read_off = uio->uio_offset;
    return (error);
}

```

Two details are worth stopping on.

First, `uio->uio_offset` is the per-descriptor position in the stream. The kernel maintains it across calls, advancing it as `uiomove_frombuf` moves bytes. The first `read(2)` on a freshly opened descriptor starts at offset zero; each subsequent `read(2)` starts where the previous one ended. When the offset reaches `sc->message_len`, `uiomove_frombuf` returns zero without moving any bytes, and the caller sees EOF.

Second, `before` captures `uio->uio_offset` at entry so we can compute how many bytes moved. After `uiomove_frombuf` returns, the difference is the transfer size, and we add it to the per-descriptor `reads` counter. This is where the `fh->reads` field from Chapter 8 finally earns its keep.

The `__DECONST` cast is a FreeBSD idiom for casting away `const`. `uiomove_frombuf` takes a non-`const` `void *` because it is prepared to move in either direction, but in this context we know the direction is kernel-to-user (a read), so we know the kernel buffer will not be modified. Stripping the `const` here is safe; using a plain `(void *)` cast would work as well but is less self-documenting.

`myfirst_write` stays as Chapter 8 left it for Stage 1:

```

static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_fh *fh;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);

    (void)fh;
    uio->uio_resid = 0;
    return (0);
}

```

Writes are accepted and discarded, the `/dev/null` shape. Stage 2 will change this.

Build and load. A quick smoke test from userland:

```
% cat /dev/myfirst/0
Hello from myfirst.
This is your first real read path.
Chapter 9, Stage 1.
%
```

A second read from the same descriptor returns EOF, because the offset is already past the end of the message:

```
% cat /dev/myfirst/0 /dev/myfirst/0
Hello from myfirst.
This is your first real read path.
Chapter 9, Stage 1.
Hello from myfirst.
This is your first real read path.
Chapter 9, Stage 1.
```

Wait: `cat` reads the message twice. That is because `cat` opens the file twice (once per argument) and each open gets a fresh descriptor with its own `uio_offset`. If you want to verify that two opens really do see independent offsets, open the device from a small C program and read more than once from the same descriptor:

```
#include <fcntl.h>
#include <unistd.h>
#include <stdio.h>

int
main(void)
{
    int fd = open("/dev/myfirst/0", O_RDONLY);
    if (fd < 0) { perror("open"); return 1; }
    char buf[64];
    ssize_t n;
    while ((n = read(fd, buf, sizeof(buf))) > 0) {
        fwrite(buf, 1, n, stdout);
    }
    close(fd);
    return 0;
}
```

The first `read(2)` returns the message; the second returns zero (EOF); the program exits. This confirms that `uio_offset` is being maintained per descriptor.

Stage 1 is intentionally short. It introduces three ideas (the `uiomove_frombuf` helper, per-descriptor offsets, the `__DECONST` idiom) without overloading the reader. The rest of the chapter builds on this.

9.11.2 Stage 2: A Write-Once / Read-Many Buffer

Stage 2 extends the driver to accept writes. The driver allocates a kernel buffer at attach, writes deposit into it, reads deliver from it. There is no wraparound: once the buffer fills, further writes return ENOSPC. Reads see whatever has been written so far, starting from their own per-descriptor offset.

The shape of `myfirst_softc` grows by a few fields:

```
struct myfirst_softc {
    /* ...existing Chapter 8 fields... */

    char    *buf;
    size_t   buflen;
    size_t   bufused;

    uint64_t bytes_read;
    uint64_t bytes_written;
};
```

`buf` is the pointer returned by `malloc(9)`. `buflen` is its size, a compile-time constant for simplicity; you can make it tunable later. `bufused` is the high-water mark: the number of bytes that have been written so far.

Two new sysctl nodes for observability:

```
SYSCALL_ADD_U64(&sc->sysctl_ctx, SYSCALL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "bytes_written", CTLFLAG_RD,
    &sc->bytes_written, 0, "Total bytes written into the buffer");

SYSCALL_ADD_UINT(&sc->sysctl_ctx, SYSCALL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "bufused", CTLFLAG_RD,
    &sc->bufused, 0, "Current byte count in the buffer");
```

`bufused` is a `size_t`, and the sysctl macro for unsigned integer is `SYSCALL_ADD_UINT` on 32-bit platforms or `SYSCALL_ADD_U64` on 64-bit platforms. Since this driver targets FreeBSD 14.3 on amd64 in the typical lab, `SYSCALL_ADD_UINT` is fine; the field will be presented as an unsigned `int` even though the internal type is `size_t`. If you target arm64 or another 64-bit platform, use `SYSCALL_ADD_U64` and cast accordingly.

Allocate the buffer in `attach`:

```
#define MYFIRST_BUFSIZE 4096

sc->buflen = MYFIRST_BUFSIZE;
sc->buf = malloc(sc->buflen, M_DEVBUF, M_WAITOK | M_ZERO);
if (sc->buf == NULL) {
    error = ENOMEM;
    goto fail_mtx;
```

```
}  
sc->bufused = 0;
```

Free it in detach:

```
if (sc->buf != NULL) {  
    free(sc->buf, M_DEVBUF);  
    sc->buf = NULL;  
}
```

Adjust the error-unwind in attach to include the buffer free:

```
fail_dev:  
    if (sc->cdev_alias != NULL) {  
        destroy_dev(sc->cdev_alias);  
        sc->cdev_alias = NULL;  
    }  
    destroy_dev(sc->cdev);  
    sysctl_ctx_free(&sc->sysctl_ctx);  
    free(sc->buf, M_DEVBUF);  
    sc->buf = NULL;  
fail_mtx:  
    mtx_destroy(&sc->mtx);  
    sc->is_attached = 0;  
    return (error);
```

Now the read handler:

```
static int  
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)  
{  
    struct myfirst_softc *sc = dev->si_drv1;  
    struct myfirst_fh *fh;  
    off_t before;  
    size_t have;  
    int error;  
  
    error = devfs_get_cdevpriv((void **)&fh);  
    if (error != 0)  
        return (error);  
    if (sc == NULL || !sc->is_attached)  
        return (ENXIO);
```

```

    mtx_lock(&sc->mtx);
    have = sc->bufused;
    before = uio->uio_offset;
    error = uiomove_frombuf(sc->buf, have, uio);
    if (error == 0) {
        sc->bytes_read += (uio->uio_offset - before);
        fh->reads += (uio->uio_offset - before);
    }
    fh->read_off = uio->uio_offset;
    mtx_unlock(&sc->mtx);
    return (error);
}

```

The read handler takes the mutex to read `bufused` consistently, then calls `uiomove_frombuf` with the current high-water mark as the effective buffer size. A reader that runs before any writes happen will see `have = 0` and `uiomove_frombuf` will return zero, which the caller interprets as EOF. A reader that runs after some writes will see the current `bufused` and receive up to that many bytes.

The write handler:

```

static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    size_t avail, towrite;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    mtx_lock(&sc->mtx);
    avail = sc->buflen - sc->bufused;
    if (avail == 0) {
        mtx_unlock(&sc->mtx);
        return (ENOSPC);
    }
    towrite = MIN((size_t)uio->uio_resid, avail);
    error = uiomove(sc->buf + sc->bufused, towrite, uio);
    if (error == 0) {
        sc->bufused += towrite;
        sc->bytes_written += towrite;
    }
}

```

```

        fh->writes += towrite;
    }
    mtx_unlock(&sc->mtx);
    return (error);
}

```

Notice the clamp: `towrite = MIN(uio->uio_resid, avail)`. If the user asked to write 8 KiB and we have 512 bytes of room, we accept 512 bytes and let the kernel report a short write of 512 back to user space. A well-behaved caller will loop with the remaining bytes; a less well-behaved caller will lose the surplus. That is the caller's responsibility; the driver has done its part honestly.

Smoke-test from userland:

```

% sudo kldload ./myfirst.ko
% echo "hello" | sudo tee /dev/myfirst/0 > /dev/null
% cat /dev/myfirst/0
hello
% echo "more" | sudo tee -a /dev/myfirst/0 > /dev/null
% cat /dev/myfirst/0
hello
more
% sysctl dev.myfirst.0.stats.bufused
dev.myfirst.0.stats.bufused: 11
%

```

The buffer grew by 6 bytes for "hello\n", then by 5 more for "more\n", yielding 11 bytes. `cat` reads all 11 bytes back. A second `cat` from a fresh open starts at offset zero and reads them again.

What happens if we write more than the buffer can hold?

```

% dd if=/dev/zero bs=1024 count=8 | sudo tee /dev/myfirst/0 > /dev/null
dd: stdout: No space left on device
tee: /dev/myfirst/0: No space left on device
8+0 records in
7+0 records out

```

`dd` wrote 7 blocks of 1024 bytes before the 8th one failed. `tee` reports the error. The driver accepted up to its limit and then returned `ENOSPC` cleanly. The kernel carried the `errno` value back to user space.

9.11.3 Stage 3: A First-In / First-Out Echo Driver

Stage 3 turns the buffer into a FIFO. Writes append to the tail. Reads drain from the head. When the buffer is empty, reads return zero bytes (EOF-on-empty). When the buffer is full, writes return `ENOSPC`.

The buffer remains linear: no wrap-around. After a read that drains all the data, bufused is zero, and the next write starts again at offset zero in `sc->buf`. This keeps the bookkeeping minimal and focuses the stage on the I/O direction change rather than ring-buffer mechanics.

The `softc` gains one more field:

```
struct myfirst_softc {
    /* ...existing fields... */

    size_t  bufhead;  /* index of next byte to read */
    size_t  bufused;  /* bytes in the buffer, from bufhead onward */

    /* ...remaining fields... */
};
```

`bufhead` is the offset of the first byte still to be read. `bufused` is the number of valid bytes starting at `bufhead`. The invariant `bufhead + bufused <= buflen` always holds.

Reset both in `attach`:

```
sc->bufhead = 0;
sc->bufused = 0;
```

New read handler:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    size_t toread;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    mtx_lock(&sc->mtx);
    if (sc->bufused == 0) {
        mtx_unlock(&sc->mtx);
        return (0); /* EOF-on-empty */
    }
    toread = MIN((size_t)uio->uio_resid, sc->bufused);
```

```

    error = uiomove(sc->buf + sc->bufhead, toread, uio);
    if (error == 0) {
        sc->bufhead += toread;
        sc->bufused -= toread;
        sc->bytes_read += toread;
        fh->reads += toread;
        if (sc->bufused == 0)
            sc->bufhead = 0;
    }
    mtx_unlock(&sc->mtx);
    return (error);
}

```

A few details differ from Stage 2. The read no longer honours `uio->uio_offset`; the per-descriptor offset is meaningless for a FIFO where every descriptor sees the same stream and the stream disappears as it is consumed. When `bufused` reaches zero, we reset `bufhead` to zero, which keeps the next write aligned at the beginning of the buffer and avoids pushing data toward the end.

This “collapse on empty” trick is not a ring buffer, but it is close enough for a pedagogical FIFO. The extra re-align step is $O(1)$; it costs almost nothing.

New write handler (mostly unchanged from Stage 2, but note where it appends):

```

static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    size_t avail, tail, towrite;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    mtx_lock(&sc->mtx);
    tail = sc->bufhead + sc->bufused;
    avail = sc->buflen - tail;
    if (avail == 0) {
        mtx_unlock(&sc->mtx);
        return (ENOSPC);
    }
    towrite = MIN((size_t)uio->uio_resid, avail);
}

```

```
error = uiomove(sc->buf + tail, towrite, uio);
if (error == 0) {
    sc->bufused += towrite;
    sc->bytes_written += towrite;
    fh->writes += towrite;
}
mtx_unlock(&sc->mtx);
return (error);
}
```

The write appends at `sc->bufhead + sc->bufused`, not at `sc->bufused` alone, because the valid data slice has moved as reads drained it.

Smoke-test:

```
% echo "one" | sudo tee /dev/myfirst/0 > /dev/null
% echo "two" | sudo tee -a /dev/myfirst/0 > /dev/null
% cat /dev/myfirst/0
one
two
% cat /dev/myfirst/0
%
```

After the first cat, the buffer is empty. The second cat sees no data and exits immediately.

This is the Stage 3 shape. The driver is a small, honest, in-memory FIFO. Users can push bytes in, pull them out, and observe the counters from `sysctl`. That is real I/O, and it is the waypoint Chapter 10 builds from.

9.12 Tracing a read(2) From User Space to Your Handler

Before you start working through the labs, take a step-by-step look at exactly what happens when a user program calls `read(2)` on one of your nodes. Understanding this path is one of those things that changes how you read driver code. Every handler you see in the tree is sitting at the bottom of the call chain described below; once you recognise the chain, every handler starts to look familiar.

9.12.1 Step 1: The User Program Calls read(2)

The C library's `read` wrapper is a thin translation of the call into a system-call trap: it places the file descriptor, the buffer pointer, and the count into the appropriate registers and executes the trap instruction for the current architecture. Control transfers to the kernel.

This part has nothing to do with drivers. It is the same for every syscall. What matters is that the kernel is now executing on behalf of the user process, in the kernel's address space, with the user's registers saved and the process's credentials visible through `curthread->td_ucred`.

9.12.2 Step 2: The Kernel Looks Up the File Descriptor

The kernel calls `sys_read(2)` (in `/usr/src/sys/kern/sys_generic.c`), which validates the arguments, looks up the file descriptor in the calling process's file table, and acquires a reference on the resulting `struct file`.

If the descriptor is not open, the call fails here with `EBADF`. If the descriptor is open but is not readable (for instance, the user opened the device with `O_WRONLY`), the call fails with `EBADF` as well. The driver is not involved; `sys_read` enforces the access mode.

9.12.3 Step 3: The Generic File-Operation Vector Dispatches

The `struct file` has a file-type tag (`f_type`) and a file-operations vector (`f_ops`). For a regular file the vector dispatches to the VFS layer; for a socket it dispatches to sockets; for a device opened through `devfs`, it dispatches to `vn_read`, which in turn calls the vnode operation `VOP_READ` on the vnode behind the file.

This may sound like indirection for its own sake. It is actually how the kernel keeps the rest of the syscall path identical for every kind of file. Drivers do not need to know about this layer; `devfs` and VFS hand the call to your handler eventually.

9.12.4 Step 4: VFS Calls Into `devfs`

The vnode's filesystem ops point to `devfs`'s implementation of the vnode interface (`devfs_vnops`). `VOP_READ` on a `devfs` vnode calls `devfs_read_f`, which looks at the `cdev` behind the vnode, acquires a thread-count reference on it (incrementing `si_threadcount`), and calls `cdevsw->d_read`. That is your function.

Two details from this step carry implications for your driver.

First, **the `si_threadcount` increment is what `destroy_dev(9)` uses to know your handler is active**. When a module unloads and `destroy_dev` runs, it waits until every current invocation of every handler returns. The reference is incremented before your `d_read` is called and released after it returns. The mechanism is why your driver can be safely unloaded while a user is in the middle of `read(2)`.

Second, **the call is synchronous from the VFS layer's point of view**. VFS calls your handler, waits for it to return, and then propagates the result. You do not need to do anything special to participate in this synchronisation; just return from your handler when you are done.

9.12.5 Step 5: Your `d_read` Handler Runs

This is where we have been all chapter. The handler:

- Receives a `struct cdev *dev` (the node being read), a `struct uio *uio` (the I/O description), and an `int ioflag` (flags from the file-table entry).
- Retrieves per-open state via `devfs_get_cdevpriv(9)`.
- Verifies liveness.
- Transfers bytes through `uiomove(9)`.
- Returns zero or an `errno`.

Nothing about this step should be mysterious by now.

9.12.6 Step 6: The Kernel Unwinds and Reports

`devfs_read_f` sees your return value. If zero, it computes the byte count from the decrease in `uio->uio_resid` and returns that count. If non-zero, it converts the `errno` into the syscall's error return. VFS's `vn_read` passes the result upward to `sys_read`. `sys_read` writes the result into the return-value register.

Control transfers back to user space. The C library's `read` wrapper examines the result: a positive value is returned as the return value of `read(2)`; a negative value sets `errno` and returns `-1`.

The user program sees the integer it expected, and its control flow continues.

9.12.7 Step 7: The Reference Counts Unwind

On the way out, `devfs_read_f` releases the thread-count reference on the `cdev`. If `destroy_dev(9)` had been waiting for `si_threadcount` to reach zero, it may now proceed with the tear-down.

This is why the whole chain is structured as carefully as it is. Every reference is paired; every increment has a matching decrement; every piece of state the handler touches is either owned by the handler, owned by the `softc`, or owned by the per-open `fh`. If any of those invariants breaks, unload becomes unsafe.

9.12.8 Why This Trace Matters to You

Three takeaways.

The first: the mechanism above is why your handler does not need to do anything exotic to coexist with module unload. Provided you return from `d_read` in finite time, the kernel will let your driver unload cleanly. This is part of why Chapter 9 keeps all reads non-blocking at the driver level.

The second: every layer between `read(2)` and your handler is set up by the kernel before your code runs. The user's buffer is valid (or `uiomove` will report `EFAULT`), the `cdev` is alive (or `devfs` would have refused the call), the access mode is compatible with the descriptor (or `sys_read` would have refused), and the process's credentials are the current thread's. You can focus on your driver's job and trust the layers.

The third: when you read an unfamiliar driver in the tree and its `d_read` looks weird, you can walk the chain in reverse. Who called this handler? What state did they prepare? What invariants does my handler promise on return? The chain tells you. The answers are usually the same as they are for `myfirst`.

9.12.9 The Mirror: Tracing a `write(2)`

A write follows the same kind of chain, mirrored. A full seven-step breakdown would be mostly a restatement of the read trace with words substituted, so the paragraph below is deliberately compressed.

The user calls `write(fd, buf, 1024)`. The C library traps into the kernel. `sys_write(2)` in `/usr/src/sys/kern/sys_generic.c` validates arguments, looks up the descriptor, and acquires a reference on its `struct file`. The file-ops vector dispatches to `vn_write`, which calls `VOP_WRITE` on the `devfs` vnode. `devfs_write_f` in `/usr/src/sys/fs/devfs/devfs_vnops.c` acquires the thread-count reference on the `cdev`, composes the `ioflag` from `fp->f_flag`, and calls `cdevsw->d_write` with the `uio` describing the caller's buffer.

Your `d_write` handler runs. It retrieves per-open state via `devfs_get_cdevpriv(9)`, checks liveness, takes whatever lock the driver needs around the buffer, clamps the transfer length to whatever space is available, and calls `uiomove(9)` to copy bytes from user space into the kernel buffer. On success, the handler updates its bookkeeping and returns zero. `devfs_write_f` releases the thread-count reference. `vn_write` unwinds through `sys_write`, which computes the byte count from the decrease in `uio_resid` and returns it. The user sees the return value of `write(2)`.

Three things differ from the read chain in substantive ways.

First, the kernel runs copyin inside uiomove instead of copyout. Same mechanism, opposite direction. The fault handling is identical: a bad user pointer returns `EFAULT`, a short copy leaves `uio_resid` consistent with whatever did transfer, and the handler just propagates the error code.

Second, `ioflag` carries `IO_NDELAY` in the same way, but the driver's interpretation is different. On a read, non-blocking means “return `EAGAIN` if there is no data”. On a write, non-blocking means “return `EAGAIN` if there is no space”. Symmetric conditions, symmetric `errno` values.

Third, the `atime` / `mtime` updates are direction-specific. `devfs_read_f` stamps `si_atime` if bytes moved; `devfs_write_f` stamps `si_mtime` (and `si_ctime` in some paths) if bytes moved. These are what `stat(2)` on the node reports, and why `ls -lu /dev/myfirst/0` shows different timestamps for reads versus writes. Your driver does not manage these fields; `devfs` does.

Once you recognise the read and write traces as mirror images, you have internalised most of the character-device dispatch path. Every chapter from here on will add hooks (a `d_poll`, a `d_kqfilter`, a `d_ioctl`, an `mmap` path) that sit on the same chain at slightly different slots. The chain itself stays constant.

9.13 Practical Workflow: Testing Your Driver From the Shell

The base-system tools are your first and best test harness. This section is a short field guide to using them well on a driver you are developing. None of the commands below are new to you, but using them for driver work has a rhythm worth learning explicitly.

9.13.1 `cat(1)`: the first check

`cat` reads from its arguments and writes to standard output. For a driver that serves a static message or a drained buffer, `cat` is the fastest way to see what the read path produces:

```
% cat /dev/myfirst/0
```

If the output is what you expect, the read path is alive. If it is empty, either your driver has nothing to deliver (check `sysctl dev.myfirst.0.stats.bufused`) or your handler is returning EOF on the first call. If the output is garbled, either your buffer is uninitialised or you are handing out bytes past `bufused`.

`cat` opens its argument once and reads from it until EOF. Every `read(2)` is a separate call into your `d_read`. Use `truss(1)` to see how many calls `cat` makes:

```
% truss cat /dev/myfirst/0 2>&1 | grep read
```

The output shows each `read(2)` with its arguments and return value. If you expected one read and see three, that tells you about your buffer sizing; if you expected three reads and see one, your handler delivered all the data in a single call.

9.13.2 `echo(1)` and `printf(1)`: simple writes

`echo` is the quickest way to get a known string into your driver's write path:

```
% echo "hello" | sudo tee /dev/myfirst/0 > /dev/null
```

Two things to notice. First, `echo` appends a newline by default; the string you sent is six bytes, not five. Use `echo -n` to suppress the newline when that matters. Second, the `tee` invocation is there to solve a permission problem: shell redirection (`>`) runs with the user's privileges, so a `sudo echo > /dev/myfirst/0` fails to open the node. Piping through `tee`, which runs under `sudo`, sidesteps that.

`printf` gives you more control:

```
% printf 'abc' | sudo tee /dev/myfirst/0 > /dev/null
```

Three bytes, no newline. Use `printf '\x41\x42\x43'` for binary patterns.

9.13.3 `dd(1)`: the precision tool

For any test that needs a specific byte count or a specific block size, `dd` is the right tool. `dd` is also one of the only base-system tools that reports short reads and short writes in its summary, which makes it uniquely useful for testing driver behaviour:

```
% sudo dd if=/dev/urandom of=/dev/myfirst/0 bs=128 count=4
4+0 records in
4+0 records out
512 bytes transferred in 0.001234 secs (415000 bytes/sec)
```

The `X+Y records in / X+Y records out` counters have a precise meaning: `X` is the number of full-block transfers, `Y` is the number of short transfers. A line reading `0+4 records out` means every block was accepted only partially. That is a driver telling you something.

`dd` also lets you read with a known block size:

```
% sudo dd if=/dev/myfirst/0 of=/tmp/dump bs=64 count=1
```

This issues exactly one `read(2)` for 64 bytes. Your handler sees `uio_resid = 64`; you respond with whatever you have; the result is what `dd` writes to `/tmp/dump`.

The `iflag=fullblock` flag tells `dd` to loop on short reads until it has filled the requested block. Useful when you want to soak all of the driver's output without losing bytes to the short-read default.

9.13.4 `od(1)` and `hexdump(1)`: byte-level inspection

For driver testing, `od` and `hexdump` let you see the exact bytes your driver emitted:

```
% sudo dd if=/dev/myfirst/0 bs=32 count=1 | od -An -tx1z
    68 65 6c 6c 6f 0a                >hello.<
```

The `-An` flag suppresses address printing. `-tx1z` shows bytes in hex and ASCII. If the expected output is text, you see it on the right; if it is binary, you see the hex on the left.

These tools become essential when a read produces unexpected bytes. “It looks weird” and “I can see every byte in hex” are very different debugging states.

9.13.5 `sysctl(8)` and `dmesg(8)`: the kernel’s voice

Your driver publishes counters through `sysctl` and lifecycle events through `dmesg`. Both are worth checking during every test:

```
% sysctl dev.myfirst.0
% dmesg | tail -20
```

The `sysctl` output is your view into the driver’s state right now. `dmesg` is your view into the driver’s history since boot (or since the ring buffer wrapped).

A useful habit: after every test, run both. If the numbers do not match your expectation, you have narrowed down the bug quickly.

9.13.6 `fstat(1)`: who has the descriptor open?

When your driver refuses to unload (“module busy”), the question is “who has `/dev/myfirst/0` open right now?”. `fstat(1)` answers it:

```
% fstat -p $(pgrep cat) /dev/myfirst/0
```

USER	CMD	PID	FD	MOUNT	INUM	MODE	SZ DV	R/W	NAME
ebrandi	cat	1234	3	/dev	0	crw-rw----	myfirst/0	r	/dev/myfirst/0

Alternatively, `fuser(8)`:

```
% sudo fuser /dev/myfirst/0
/dev/myfirst/0:      1234
```

Either tool names the processes holding the descriptor. Kill the culprit (carefully; do not kill anything you did not start) and the module will unload.

9.13.7 truss(1) and ktrace(1): watching the syscalls

For a user program whose interaction with your driver you want to inspect, `truss` shows every syscall and its return value:

```
% truss ./rw_myfirst
open("/dev/myfirst/0",O_WRONLY,0666)      = 3 (0x3)
write(3,"round-trip test payload\n",24)    = 24 (0x18)
close(3)                                   = 0 (0x0)
...
```

`ktrace` records to a file that `kdump` prints later; it is the right tool when you want to capture a trace of a long-running program.

These two tools are not driver-specific, but they are how you confirm from the outside that your driver is producing the results a user program will see.

9.13.8 A Suggested Test Rhythm

For each stage of the chapter, try this loop:

1. Build and load.
2. `cat` to produce initial output, confirm by eye.
3. `sysctl dev.myfirst.0` to see counters match.
4. `dmesg | tail` to see lifecycle events.
5. Write something with `echo` or `dd`.
6. Read it back.
7. Repeat with a larger size, a boundary size, and a pathological size.
8. Unload.

After a couple of iterations this becomes automatic and fast. It is the kind of rhythm that turns driver development from a slog into a routine.

9.13.9 A Concrete truss Walkthrough

Running a userland program under `truss(1)` is one of the fastest ways to see exactly what syscalls it makes to your driver and what return values the kernel produces. Here is a typical session with the Stage 3 driver loaded and empty:

```
% truss ./rw_myfirst rt 2>&1
open("/dev/myfirst/0",O_WRONLY,00)        = 3 (0x3)
write(3,"round-trip test payload, 24b\n",29) = 29 (0x1d)
close(3)                                   = 0 (0x0)
open("/dev/myfirst/0",O_RDONLY,00)         = 3 (0x3)
read(3,"round-trip test payload, 24b\n",255) = 29 (0x1d)
```

```
close(3)                = 0 (0x0)
exit(0x0)
```

A few things are worth pausing on. Each line shows a single syscall, its arguments, and its return value in both decimal and hex. The `write` call received 29 bytes and the driver accepted all 29 (the return value matches the request length). The `read` call received a buffer of 255 bytes of room and the driver produced 29 bytes of content; a short read, which the user program explicitly accepts. Both open calls returned 3, because file descriptors 0, 1, and 2 are standard streams and the first free descriptor is 3.

If you force a short write by limiting the driver, `truss` will show it plainly:

```
% truss ./write_big 2>&1 | head
open("/dev/myfirst/0", O_WRONLY, 00)      = 3 (0x3)
write(3, "<8192 bytes of data>", 8192)     = 4096 (0x1000)
write(3, "<4096 bytes of data>", 4096)     ERR#28 'No space left on device'
close(3)                                  = 0 (0x0)
```

The first write requested 8192 bytes and was accepted for 4096. The second write had nothing to say because the buffer is full; the driver returned `ENOSPC`, which `truss` rendered as `ERR#28 'No space left on device'`. This is the view from the user side; your driver side was returning zero (with `uio_resid` decremented to 4096) for the first call and `ENOSPC` for the second. Comparing what `truss` sees against what your `device_printf` says is an excellent way to catch mismatches between the driver's intent and the kernel's reporting.

`truss -f` follows forks, which is useful when your test harness spawns worker processes. `truss -d` prefixes each line with a relative timestamp; useful for reasoning about latency between calls. Both flags are small investments; the rewards add up quickly when you start running multi-process stress tests.

9.13.10 A Quick Note on `ktrace`

`ktrace(1)` is `truss`'s bigger sibling. It records a binary trace to a file (`ktrace.out` by default) which you then format with `kdump(1)`. It is the right tool when:

- The test run is long and you do not want to watch output live.
- You want to capture detail that is too fine-grained for `truss` (syscall timing, signal delivery, namei lookups).
- You want to replay a trace later, perhaps on a different machine.

A typical session:

```
% sudo ktrace -i ./stress_rw -s 5
% sudo kdump | head -40
2345 stress_rw CALL  open(0x800123456, 0x1<O_WRONLY>)
2345 stress_rw NAMI  "/dev/myfirst/0"
2345 stress_rw RET   open 3
2345 stress_rw CALL  write(0x3, 0x800123500, 0x40)
```

```

2345 stress_rw RET    write 64
2345 stress_rw CALL  write(0x3,0x800123500,0x40)
2345 stress_rw RET    write 64
...

```

For Chapter 9 the difference between `truss` and `ktrace` is small. Use `truss` as the default; reach for `ktrace` when you need more detail or a recorded trace.

9.13.11 Watching Kernel Memory With `vmstat -m`

Your driver allocates kernel memory through `malloc(9)` with the `M_DEVBUF` type. FreeBSD's `vmstat -m` reveals how many allocations are active in each type bucket. Run it while your driver is loaded and idle, then again while it has a buffer allocated, and the increase will be visible in the `devbuf` row:

```

% vmstat -m | head -1
      Type InUse MemUse HighUse Requests  Size(s)
% vmstat -m | grep devbuf
      devbuf   415   4120K          -    39852  16, 32, 64, 128, 256, 512, 1024, 2048, ...

```

The `InUse` column is the current count of live allocations of this type. `MemUse` is the total size currently in use. `HighUse` is the all-time high-water mark since boot. `Requests` is the lifetime count of `malloc` calls that selected this type.

Load the Stage 2 driver. `InUse` goes up by one (the 4096-byte buffer), `MemUse` goes up by approximately 4 KiB, and `Requests` increments. Unload. `InUse` goes down by one; `MemUse` goes down by the 4 KiB. If it does not, you have a memory leak, and `vmstat -m` just told you so.

This is the second observability channel worth adding to your test rhythm. `sysctl` shows driver-owned counters. `dmesg` shows driver-owned log lines. `vmstat -m` shows kernel-owned allocation counts, and it catches a class of bug (forgot to free) that the first two cannot see.

For a driver that declares its own `malloc` type via `MALLOC_DEFINE(M_MYFIRST, "myfirst", ...)`, `vmstat -m | grep myfirst` is even better: it isolates your driver's allocations from the generic `devbuf` pool. `myfirst` stays with `M_DEVBUF` throughout this chapter for simplicity, but upgrading to a dedicated type is a small change you may want to make before shipping a driver outside the book's lab environment.

9.14 Observability: Making Your Driver Legible

A driver that does the right thing is worth more if you can confirm, from outside the kernel, that it is doing the right thing. This section is a short meditation on the observability choices this chapter has been making, and why.

9.14.1 Three Surfaces: `sysctl`, `dmesg`, `userland`

Your driver presents three surfaces to the operator:

- **`sysctl`** for live counters: point-in-time values the operator can poll.
- **`dmesg` (`device_printf`)** for lifecycle events: open, close, errors, transitions.
- **`/dev`** nodes for the data path: the actual bytes.

Each has a distinct role. `sysctl` tells the operator *what is true right now*. `dmesg` tells the operator *what changed recently*. `/dev` is the thing the operator is actually using.

A well-observed driver uses all three, deliberately. A minimally-observed driver uses only the third, and debugging it requires either a debugger or a lot of guessing.

9.14.2 `Sysctl`: Counters vs State

`myfirst` exposes counters through the `sysctl` tree under `dev.myfirst.0.stats`:

- `attach_ticks`: a point-in-time value (when the driver attached).
- `open_count`: a monotonically-increasing counter (lifetime opens).
- `active_fhs`: a live count (current descriptors).
- `bytes_read`, `bytes_written`: monotonically-increasing counters.
- `bufused`: a live value (current buffer occupancy).

Monotonically-increasing counters are easier to reason about than live values, because their rate of change is informative even when the absolute value is not. An operator who sees `bytes_read` increasing at 1 MB/s has learned something even if 1 MB/s is meaningless out of context.

Live values are essential when the state matters for decisions (`active_fhs > 0` means unload will fail). Choose monotonically-increasing counters first, live values when you need them.

9.14.3 `dmesg`: Events Worth Seeing

`device_printf(9)` writes to the kernel message buffer, which `dmesg` shows. Every line is worth seeing exactly once: use `dmesg` for events, not for continuous status.

The events `myfirst` logs:

- Attach (once per instance).
- Open (once per open).
- Destructor (once per descriptor close).
- Detach (once per instance).

That is four lines per instance per load/unload cycle, plus two lines per open/close pair. Comfortable.

What we do not log:

- Every read or write call. That would flood `dmesg` in any real workload.
- Every `sysctl` read. Those are passive.
- Every successful transfer. The `sysctl` counters carry that information, and they carry it more compactly.

If a driver needs to log something that happens many times a second, the usual answer is to guard the logging with `if (bootverbose)`, so it is silent on production systems but available to developers who boot with `boot -v`. For `myfirst` we do not need even that.

9.14.4 The Trap of Over-Logging

A driver that logs every operation is a driver that hides its important events in a sea of noise. If your `dmesg` shows ten thousand lines of `read returned 0 bytes`, the line that says `buffer full, returning ENOSPC` is invisible.

Keep logs sparse. Log transitions, not states. Log once per instance, not once per call. When in doubt, silence.

9.14.5 Counters You Will Add Later

Chapters 10 and beyond will extend the counter tree with:

- `reads_blocked, writes_blocked`: count of calls that had to sleep (Chapter 10).
- `poll_waiters`: count of active `poll(2)` subscribers (Chapter 10).
- `drain_waits, overrun_events`: ring-buffer diagnostics (Chapter 10).

Each one is one more thing an operator can look at to understand what the driver is doing. The pattern is the same: expose the counters, keep the mechanism silent, let the operator decide when to inspect.

9.14.6 What Your Driver Looks Like Under Light Load

A concrete example is more useful than abstract advice. Load Stage 3, run the companion `stress_rw` program for a few seconds with `sysctl dev.myfirst.0.stats` watching from another terminal, and you see something like this:

Before `stress_rw` starts:

```
dev.myfirst.0.stats.attach_ticks: 12345678
dev.myfirst.0.stats.open_count: 0
dev.myfirst.0.stats.active_fhs: 0
dev.myfirst.0.stats.bytes_read: 0
dev.myfirst.0.stats.bytes_written: 0
dev.myfirst.0.stats.bufused: 0
```

Zero activity, one attach, buffer empty.

During `stress_rw`, with `watch -n 0.5 sysctl dev.myfirst.0.stats`:

```
dev.myfirst.0.stats.attach_ticks: 12345678
dev.myfirst.0.stats.open_count: 2
dev.myfirst.0.stats.active_fhs: 2
dev.myfirst.0.stats.bytes_read: 1358976
```

```
dev.myfirst.0.stats.bytes_written: 1359040
dev.myfirst.0.stats.bufused: 64
```

Two active descriptors (writer + reader), counters climbing, buffer holding 64 bytes of in-flight data. `bytes_written` is slightly ahead of `bytes_read`, which is exactly what you would expect: the writer produced a chunk the reader has not quite consumed yet. The difference equals `bufused`.

After `stress_rw` exits:

```
dev.myfirst.0.stats.attach_ticks: 12345678
dev.myfirst.0.stats.open_count: 2
dev.myfirst.0.stats.active_fhs: 0
dev.myfirst.0.stats.bytes_read: 4800000
dev.myfirst.0.stats.bytes_written: 4800000
dev.myfirst.0.stats.bufused: 0
```

Both descriptors closed. Lifetime opens is 2 (cumulative). Active is 0. `bytes_read` equals `bytes_written`; the reader caught up fully. Buffer is empty.

Three signatures to notice. First, `active_fhs` always tracks live descriptors; it is a live value, not a cumulative counter. Second, `bytes_read == bytes_written` at steady state when the reader is keeping up, plus whatever is sitting in `bufused`. Third, the `open_count` is a lifetime value that never decreases; a quick way to spot churn is to watch it grow while `active_fhs` stays stable.

A driver that behaves predictably under load is a driver you can operate with confidence. Once the counters line up the way this paragraph describes, you have your first real driver, not a toy.

9.15 Signed, Unsigned, and the Perils of Off-by-One

A short section on a class of bug that has caused more kernel panics than almost any other. It shows up especially often in I/O handlers.

9.15.1 `ssize_t` vs `size_t`

Two types dominate I/O code:

- `size_t`: unsigned, used for sizes and counts. `sizeof(x)` returns `size_t`. `malloc(9)` takes `size_t`. `memcpy` takes `size_t`.
- `ssize_t`: signed, used when a value could be negative (usually -1 for error). `read(2)` and `write(2)` return `ssize_t`. `uio_resid` is `ssize_t`.

The two types have the same width on every platform FreeBSD supports, but they do not silently convert between each other without warnings, and they behave very differently when arithmetic underflows.

A subtraction of `size_t` values that would produce a negative result instead wraps around to a huge positive value, because `size_t` is unsigned. For example:

```
size_t avail = sc->buflen - sc->bufused;
```

If `sc->bufused` is larger than `sc->buflen`, `avail` is an enormous number, and the next `uiomove` attempts a transfer that blows past the end of the buffer.

The defence is the invariant. In every buffer-management section of the chapter, we maintain `sc->bufhead + sc->bufused <= sc->buflen`. As long as that invariant holds, `sc->buflen - (sc->bufhead + sc->bufused)` cannot underflow.

The risk is in code paths that violate the invariant accidentally. A double-free that restores an already-consumed value; a write that updates `bufused` twice; a race between writers. Those are the bugs to hunt for when `avail` ever looks wrong.

9.15.2 `uio_resid` Can Be Compared Against Unsigned

`uio_resid` is `ssize_t`. Your buffer sizes are `size_t`. Code like this:

```
if (uio->uio_resid > sc->buflen) ...
```

Will be compiled with a signed-vs-unsigned comparison. Modern compilers warn about this; the warning should be taken seriously.

The safer pattern is to cast explicitly:

```
if ((size_t)uio->uio_resid > sc->buflen) ...
```

Or to use `MIN`, which we have been using:

```
towrite = MIN((size_t)uio->uio_resid, avail);
```

The cast is defensible because `uio_resid` is documented to be non-negative in valid `uios` (and `uiomove` KASSERTs on it). The cast makes the compiler happy and makes the intent explicit.

9.15.3 Off-by-One in Counters

A counter updated on the wrong side of an error check is a classic bug:

```
sc->bytes_read += towrite;          /* BAD: happens even on error */
error = uiomove(sc->buf, towrite, uio);
```

The correct shape is to increment after success:

```
error = uiomove(sc->buf, towrite, uio);  
if (error == 0)  
    sc->bytes_read += towrite;
```

This is why we have `if (error == 0)` guarding every counter update in the chapter. The cost is one line of code. The benefit is that your counters match reality.

9.15.4 The `uio_offset` - before Idiom

When you want to know “how many bytes did `uiomove` actually move?”, the cleanest way is to compare `uio_offset` before and after:

```
off_t before = uio->uio_offset;  
error = uiomove_frombuf(sc->buf, sc->buflen, uio);  
size_t moved = uio->uio_offset - before;
```

This works for both full and short transfers. `moved` is the actual byte count, regardless of what the caller asked for or how much was available.

The idiom is free at runtime (two subtractions) and unambiguous in code. Use it when your driver wants to count bytes; the alternative, inferring the count from `uio_resid`, requires knowing the original request size, which is more bookkeeping.

9.16 Additional Troubleshooting: The Edge Cases

Expanding on the earlier troubleshooting section, here are a few more scenarios you are likely to hit the first time you write a real driver.

9.16.1 “The second read on the same descriptor returns zero”

Expected for a static-message driver (Stage 1): once `uio_offset` reaches the end of the message, `uiomove_frombuf` returns zero.

Unexpected for a FIFO driver (Stage 3): the first read drained the buffer, and no writer has refilled it. The caller should not be issuing a second read back-to-back without a write happening in between.

To distinguish the two cases, check `sysctl dev.myfirst.0.stats.bufused`. If it is zero, the buffer is empty. If it is non-zero and you still see zero bytes, you have a bug.

9.16.2 “The driver returns zero bytes immediately when the buffer has data”

The read handler is taking the wrong branch. Common causes:

- A `bufused == 0` check placed in the wrong spot. If the check runs before the per-open state retrieval, it might short-circuit the read before the real work.

- An accidental `return 0`; earlier in the handler (for example, in a debug branch left from a previous experiment).
- A missing `mtx_unlock` on an error path, making every subsequent call block on the mutex forever. Symptom: the second call hangs, not a zero-byte return; but it is worth checking.

9.16.3 “My `uiomove_frombuf` always returns zero regardless of the buffer”

Two common causes:

- The `buflen` argument is zero. `uiomove_frombuf` returns zero immediately if `buflen <= 0`.
- `uio_offset` is already at or past `buflen`. `uiomove_frombuf` returns zero to signal EOF in that case.

Add a `device_printf` logging the arguments at entry to confirm which case you are in.

9.16.4 “The buffer overflows into adjacent memory”

Your arithmetic is wrong. Somewhere you are calling `uiomove(sc->buf + X, N, uio)` where $X + N > sc->buflen$. The write proceeds silently and corrupts kernel memory.

Your kernel will usually panic shortly thereafter, possibly in a completely unrelated subsystem. The panic message will not mention your driver; it will mention whichever heap neighbour got clobbered.

If you suspect this, rebuild with `INVARIANTS` and `WITNESS` (and on many targets, `KASAN` on amd64). These kernel features catch buffer overruns much earlier than the default kernel does.

9.16.5 “A process reading from the device hangs forever”

Since Chapter 9 does not implement blocking I/O, this should not happen with `myfirst` Stage 3. If it does, the most likely cause is the process holding a file descriptor while you tried to unload the driver; `destroy_dev(9)` is waiting for `si_threadcount` to reach zero, and the process is sitting inside your handler for some reason.

To diagnose: `ps auxH | grep <your-test>; gdb -p <pid> and bt`. The stack should reveal where the thread is parked.

If your Stage 3 handler accidentally sleeps (for instance, because you added a `tsleep` while experimenting with Chapter 10 material early), the fix is to remove the sleep. Chapter 9’s driver does not block.

9.16.6 “`kldunload` says `kldunload: can't unload file: Device busy`”

Classic symptom of a descriptor still open. Use `fuser /dev/myfirst/0` to find the offending process, close the descriptor or kill the process, and retry.

9.16.7 “I modified the driver and make compiles but `kldload` fails with version mismatch”

Your build environment does not match your running kernel. Check:

```
% freebsd-version -k
14.3-RELEASE
% ls /usr/obj/usr/src/amd64.amd64/sys/GENERIC
```

If `/usr/src` is for a different release, your headers produce a module that the kernel refuses. Rebuild against the matching sources. In a lab VM this usually means syncing `/usr/src` with the running release via `fetch` or `freebsd-update src-install`.

9.16.8 “I see every byte written through the device printed twice in dmesg”

You have a `device_printf` inside the hot path that prints every transfer. Remove it or guard it with `if (bootverbose)`.

A milder version of the same bug: a single-line log that prints the length of every transfer. For small test workloads that looks fine; for a real user workload it will bury `dmesg` and cause timestamp compression in the kernel buffer.

9.16.9 “My `d_read` is called but my `d_write` is not”

Either the user program never calls `write(2)` on the device, or it calls `write(2)` with the descriptor not opened for writing (`O_RDONLY`). Check both.

Also: confirm that `cdevsw.d_write` is assigned to `myfirst_write`. A copy-paste bug that assigns it to `myfirst_read` results in both directions hitting the read handler, with predictably confusing results.

9.17 Design Notes: Why Each Stage Stops Where It Does

A short meta-section on why Chapter 9’s three stages have the boundaries they have. This is the kind of chapter-design reasoning that is worth making explicit, because it is the reasoning you will apply when you design your own drivers.

9.17.1 Why Stage 1 Exists

Stage 1 is the smallest possible `d_read` that is not `/dev/null`. It introduces:

- The `uiomove_frombuf(9)` helper, the easiest way to get a fixed buffer out to user space.
- Per-descriptor offset handling.
- The pattern of using `uio_offset` as the state carrier.

Stage 1 does not do anything with writes; the Chapter 8 stub is fine.

Without Stage 1, the jump from stubs to a buffered read/write driver is too large. Stage 1 lets you confirm, with minimal code, that the read handler is wired up correctly. Everything else builds on that confirmation.

9.17.2 Why Stage 2 Exists

Stage 2 introduces:

- A dynamically-allocated kernel buffer.
- A write path that accepts user data.
- A read path that honours the caller's offset across the accumulating buffer.
- The first realistic use of the `softc` mutex in an I/O handler.

Stage 2 deliberately does not drain reads. The buffer grows until full; subsequent writes return `ENOSPC`. This lets two concurrent readers confirm that they each have their own `uio_offset`, which is the property Stage 1 couldn't demonstrate (because Stage 1 had nothing to write).

9.17.3 Why Stage 3 Exists

Stage 3 introduces:

- Reads that drain the buffer.
- The coordination between a head pointer and a used count.
- The FIFO semantics that most real drivers approximate.

Stage 3 does not wrap around. The head and used pointers walk forward through the buffer and the buffer collapses to the beginning when empty. A proper ring buffer (with head and tail wrapping around a fixed-size array) belongs in Chapter 10 because it pairs naturally with blocking reads and `poll(2)`: a ring makes steady-state operation efficient, and efficient steady-state operation is exactly what a blocking reader needs.

9.17.4 Why No Ring Buffer Here

A ring buffer is five to fifteen lines of additional bookkeeping beyond what Stage 3 does. Adding it now would not be a large amount of code. The reason it is deferred is pedagogical: the two concepts ("I/O path semantics" and "ring buffer mechanics") are independently confusing to a beginner, and splitting them into two chapters lets each chapter address one pile of confusion at a time.

By the time Chapter 10 introduces the ring, the reader is fluent in the I/O path. The new material is only the ring bookkeeping.

9.17.5 Why No Blocking

Blocking is useful, but it introduces `msleep(9)`, condition variables, the `d_purge` teardown hook, and a thicket of correctness issues around what to wake and when. Each of those is a substantial topic. Mixing them into Chapter 9 would double its length and halve its clarity.

Chapter 10's first section is "when your driver has to wait". It is a natural follow-on.

9.17.6 What the Stages Are Not Trying to Be

The stages are not a simulation of a hardware driver. They do not mimic DMA. They do not simulate interrupts. They do not pretend to be anything other than what they are: in-memory drivers that exercise the UNIX I/O path.

This matters because later in the book, when we write actual hardware drivers, the I/O path will look identical. The hardware specifics (where the bytes come from, where the bytes go to) will change, but the handler shape, the `uiomove` usage, the `errno` conventions, the counter patterns, all of these will be recognisable from Chapter 9.

A driver that moves bytes correctly across the user/kernel trust boundary is 80% of any real driver. Chapter 9 teaches that 80%.

9.18 Hands-On Labs

The labs below track the three stages above. Each lab is a checkpoint that proves your driver is doing the thing the text just described. Read the lab fully before starting, and do them in order.

9.18.1 Lab 9.1: Build and Load Stage 1

Goal: Build the Stage 1 driver, load it, read the static message, and confirm per-descriptor offset handling.

Steps:

1. Start from the companion tree: `cp -r examples/part-02/ch09-reading-and-writing/stage1-static-message ~/drivers/ch09-stage1`. Alternatively, modify your Chapter 8 stage 2 driver according to the Stage 1 walkthrough above.

2. Change into the directory and build:

```
% cd ~/drivers/ch09-stage1
% make
```

3. Load the module:

```
% sudo kldload ./myfirst.ko
```

4. Confirm the device is present:

```
% ls -l /dev/myfirst/0
crw-rw----  1 root  operator ... /dev/myfirst/0
```

5. Read the message:

```
% cat /dev/myfirst/0
Hello from myfirst.
This is your first real read path.
Chapter 9, Stage 1.
```

6. Build the `rw_myfirst.c` userland tool from the companion tree and run it in “read twice” mode:

```
% cc -o rw_myfirst rw_myfirst.c
% ./rw_myfirst read
[read 1] 75 bytes:
Hello from myfirst.
This is your first real read path.
Chapter 9, Stage 1.
[read 2] 0 bytes (EOF)
```

7. Confirm the per-descriptor counter:

```
% dmesg | tail -5
```

You should see the `open via /dev/myfirst/0 fh=...` and `per-open dtor fh=...` lines from Chapter 8, plus the message body was read.

8. Unload:

```
% sudo kldunload myfirst
```

Success criteria:

- `cat` prints the message.
- The userland tool shows 75 bytes on the first read and 0 bytes on the second.
- `dmesg` shows one open and one destructor per `./rw_myfirst read` invocation.

Common mistakes:

- Forgetting the `-1` on `sizeof(myfirst_message) - 1`. The message will include a trailing NUL byte that appears as a stray character in user output.
- Not calling `devfs_get_cdevpriv` before the `sc == NULL` check. The rest of the chapter depends on this order; run it to see why it is the right one.
- Using `(void *)sc->message` instead of `__DECONST(void *, sc->message)`. Both work on most compilers; the `__DECONST` form is the convention and suppresses a warning on some compiler configurations.

9.18.2 Lab 9.2: Exercise Stage 2 with Writes and Reads

Goal: Build Stage 2, push data in from userland, pull it back out, and observe the `sysctl` counters.

Steps:

1. From the companion tree: `cp -r examples/part-02/ch09-reading-and-writing/stage2-readwrite ~/drivers/ch09-stage2`.
2. Build and load:

```
% cd ~/drivers/ch09-stage2
% make
% sudo kldload ./myfirst.ko
```

3. Check the initial state:

```
% sysctl dev.myfirst.0.stats
dev.myfirst.0.stats.attach_ticks: ...
dev.myfirst.0.stats.open_count: 0
dev.myfirst.0.stats.active_fhs: 0
dev.myfirst.0.stats.bytes_read: 0
dev.myfirst.0.stats.bytes_written: 0
dev.myfirst.0.stats.bufused: 0
```

4. Write a line of text:

```
% echo "the quick brown fox" | sudo tee /dev/myfirst/0 > /dev/null
```

5. Read it back:

```
% cat /dev/myfirst/0
the quick brown fox
```

6. Observe the counters:

```
% sysctl dev.myfirst.0.stats.bufused
dev.myfirst.0.stats.bufused: 20
% sysctl dev.myfirst.0.stats.bytes_written
dev.myfirst.0.stats.bytes_written: 20
% sysctl dev.myfirst.0.stats.bytes_read
dev.myfirst.0.stats.bytes_read: 20
```

7. Trigger ENOSPC:

```
% dd if=/dev/zero bs=1024 count=8 | sudo tee /dev/myfirst/0 > /dev/null
```

Expect a short-write error. Inspect `sysctl dev.myfirst.0.stats.bufused`; it should be 4096 (the buffer size).

8. Confirm reads still deliver the content:

```
% sudo cat /dev/myfirst/0 | od -An -c | head -3
```

9. Unload:

```
% sudo kldunload myfirst
```

Success criteria:

- Writes deposit bytes; reads deliver them back.
- `bufused` matches the number of bytes written since the last reset.
- `dd` exhibits a short write when the buffer fills; the driver returns `ENOSPC`.
- `dmesg` shows open and destructor lines for every process that opened the device.

Common mistakes:

- Forgetting to free `sc->buf` in `detach`. The driver will unload without complaint, but a subsequent kernel memory leak check (`vmstat -m | grep devbuf`) will show drift.
- Holding the `softc` mutex while calling `uiomove`, without being sure the mutex is an `MTX_DEF` and not a spin lock. Chapter 7's `mtx_init(..., MTX_DEF)` is the right choice; do not change it.
- Omitting the `sc->bufused = 0` reset in `attach`. Newbus initialises `softc` to zero for you, but making the initialisation explicit is the convention; it also makes a later refactor less error-prone.

9.18.3 Lab 9.3: Stage 3 FIFO Behaviour

Goal: Build Stage 3, exercise FIFO behaviour from two terminals, and confirm that reads drain the buffer.

Steps:

1. From the companion tree: `cp -r examples/part-02/ch09-reading-and-writing/stage3-echo ~/drivers/ch09-stage3`.

2. Build and load:

```
% cd ~/drivers/ch09-stage3
% make
% sudo kldload ./myfirst.ko
```

3. In terminal A, write some bytes:

```
% echo "message A" | sudo tee /dev/myfirst/0 > /dev/null
```

4. In terminal B, read them:

```
% cat /dev/myfirst/0
message A
```

5. Read again in terminal B:

```
% cat /dev/myfirst/0
```

Expect no output. The buffer is empty.

6. In terminal A, write two lines in rapid succession:

```
% echo "first" | sudo tee /dev/myfirst/0 > /dev/null
% echo "second" | sudo tee /dev/myfirst/0 > /dev/null
```

7. In terminal B, read:

```
% cat /dev/myfirst/0
first
second
```

Expect the two lines concatenated. Both writes appended to the same buffer before either read happened.

8. Inspect the counters:

```
% sysctl dev.myfirst.0.stats
```

bufused should be back to zero. bytes_read and bytes_written should match.

9. Unload:

```
% sudo kldunload myfirst
```

Success criteria:

- Writes append to the buffer; reads drain it.
- A read after the buffer is drained returns immediately (EOF-on-empty).
- bytes_read always equals bytes_written once the reader has caught up.

Common mistakes:

- Not resetting bufhead = 0 when bufused reaches zero. The buffer will “drift” toward the end of sc->buf and refuse writes long before it is full.
- Forgetting to update bufhead as reads drain. The driver will read the same bytes repeatedly.
- Using uio->uio_offset as a per-descriptor offset. In a FIFO, offsets are shared; a per-descriptor offset does not make sense and will confuse testers.

9.18.4 Lab 9.4: Using dd to Measure Transfer Behaviour

Goal: Use dd(1) to generate known-size transfers, read the results back, and check that the counters agree.

dd is the tool of choice here because it lets you control the block size, the number of blocks, and the behaviour on short transfers.

1. Reload the Stage 3 driver fresh:

```
% sudo kldunload myfirst; sudo kldload ./myfirst.ko
```

2. Write 512 bytes in a single block:

```
% sudo dd if=/dev/urandom of=/dev/myfirst/0 bs=512 count=1
1+0 records in
1+0 records out
512 bytes transferred
```

3. Observe bufused = 512:

```
% sysctl dev.myfirst.0.stats.bufused
dev.myfirst.0.stats.bufused: 512
```

4. Read them back with matching block size:

```
% sudo dd if=/dev/myfirst/0 of=/tmp/out bs=512 count=1
1+0 records in
```

```
1+0 records out
512 bytes transferred
```

5. Check that the FIFO is now empty:

```
% sysctl dev.myfirst.0.stats.bufused
dev.myfirst.0.stats.bufused: 0
```

6. Write 8192 bytes in one big block:

```
% sudo dd if=/dev/urandom of=/dev/myfirst/0 bs=8192 count=1
dd: /dev/myfirst/0: No space left on device
0+0 records in
0+0 records out
0 bytes transferred
```

The driver accepted 4096 bytes (the buffer size) of the 8192 requested and returned a short write for the rest.

7. Alternatively, use bs=4096 with count=2:

```
% sudo dd if=/dev/urandom of=/dev/myfirst/0 bs=4096 count=2
dd: /dev/myfirst/0: No space left on device
1+0 records in
0+0 records out
4096 bytes transferred
```

The first block of 4096 bytes succeeded in full; the second block failed with ENOSPC.

8. Drain:

```
% sudo dd if=/dev/myfirst/0 of=/tmp/out bs=4096 count=1
% sudo kldunload myfirst
```

Success criteria:

- dd reports the expected byte counts at each step.
- The driver accepts up to 4096 bytes and refuses the rest with ENOSPC.
- bufused tracks the buffer state after every operation.

9.18.5 Lab 9.5: A Small Round-Trip C Program

Goal: Write a short userland C program that opens the device, writes known bytes, closes the descriptor, opens it again, reads the bytes back, and verifies they match.

1. Save the following as `rw_myfirst.c` in `~/drivers/ch09-stage3`:

```
#include <fcntl.h>
#include <unistd.h>
#include <string.h>
#include <stdio.h>

static const char payload[] = "round-trip test payload\n";

int
main(void)
{
    int fd;
    ssize_t n;

    fd = open("/dev/myfirst/0", O_WRONLY);
    if (fd < 0) { perror("open W"); return 1; }
    n = write(fd, payload, sizeof(payload) - 1);
    if (n != (ssize_t)(sizeof(payload) - 1)) {
        fprintf(stderr, "short write: %zd\n", n);
        return 2;
    }
    close(fd);

    char buf[128] = {0};
    fd = open("/dev/myfirst/0", O_RDONLY);
    if (fd < 0) { perror("open R"); return 3; }
    n = read(fd, buf, sizeof(buf) - 1);
    if (n < 0) { perror("read"); return 4; }
    close(fd);

    if ((size_t)n != sizeof(payload) - 1 ||
        memcmp(buf, payload, n) != 0) {
        fprintf(stderr, "mismatch: wrote %zu, read %zd\n",
            sizeof(payload) - 1, n);
        return 5;
    }

    printf("round-trip OK: %zd bytes\n", n);
    return 0;
}
```

2. Build and run:

```
% cc -o rw_myfirst rw_myfirst.c
% sudo ./rw_myfirst
round-trip OK: 24 bytes
```

3. Inspect dmesg to see the two opens and two destructors.

Success criteria:

- The program prints round-trip OK: 24 bytes.
- dmesg shows one open/destructor pair for the write and one for the read.

Common mistakes:

- Writing fewer bytes than the payload and not checking the return value. `write(2)` can return a short count; your test must handle it.
- Forgetting `O_WRONLY` vs `O_RDONLY`. `open(2)` enforces the mode against the access bits of the node; opening with the wrong mode returns `EACCES` (or similar).
- Assuming `read(2)` returns the requested count. It can return less; again, the caller loops.

9.18.6 Lab 9.6: Inspecting Binary Round-Trips

Goal: Confirm that the driver handles arbitrary binary data, not only text, by pushing random bytes through and checking that the same bytes come back.

1. With Stage 3 loaded and empty, write 256 random bytes:

```
% sudo dd if=/dev/urandom of=/tmp/sent bs=256 count=1
% sudo dd if=/tmp/sent of=/dev/myfirst/0 bs=256 count=1
```

2. Read the same number of bytes back:

```
% sudo dd if=/dev/myfirst/0 of=/tmp/received bs=256 count=1
```

3. Compare:

```
% cmp /tmp/sent /tmp/received && echo MATCH
MATCH
```

4. Inspect both files byte-for-byte:

```
% od -An -tx1 /tmp/sent | head -2
% od -An -tx1 /tmp/received | head -2
```

5. Try a pathological pattern: all zeros, all `0xff`, then a file full of a single byte. Confirm every pattern round-trips exactly.

Success criteria:

- `cmp` reports no differences.
- The driver preserves every bit of the input.
- No byte-ordering, no “helpful” interpretation, no surprise transformations.

This lab is short but important: it verifies that your driver is a transparent byte store, not a text filter that accidentally interprets some bytes specially. If you ever see differences between the sent and received files, you have a bug in the transfer path, probably a length miscount or an off-by-one in the buffer arithmetic.

9.18.7 Lab 9.7: Observing a Running Driver End-to-End

Goal: Combine `sysctl`, `dmesg`, `truss`, and `vmstat` into a single end-to-end observation of the Stage 3 driver under real load. This lab has no new code; it is the bridge from “I wrote the driver” to “I can see what it is doing”.

Steps:

1. With Stage 3 loaded fresh, open four terminals. Terminal A will run the driver load / unload cycles. Terminal B will monitor `sysctl`. Terminal C will tail `dmesg`. Terminal D will run a user workload.

2. **Terminal A:**

```
% sudo kldload ./myfirst.ko
% vmstat -m | grep devbuf
```

Note the `devbuf` row's `InUse` and `MemUse` values.

3. **Terminal B:**

```
% watch -n 1 sysctl dev.myfirst.0.stats
```

4. **Terminal C:**

```
% sudo dmesg -c > /dev/null
% sudo dmesg -w
```

The `-c` clears accumulated messages; the `-w` watches for new ones.

5. **Terminal D:**

```
% cd examples/part-02/ch09-reading-and-writing/userland
% make
% sudo truss ./rw_myfirst rt 2>&1 | tail -10
```

6. Check terminal B: you should see `open_count` increment by 2 (one for the write, one for the read), `active_fhs` return to 0, and `bytes_read == bytes_written`.
7. Check terminal C: you should see two open lines and two destructor lines from `device_printf`.
8. In terminal A, run `vmstat -m | grep devbuf` again. `InUse` and `MemUse` should have decreased back to their pre-load values plus whatever the driver itself allocated (typically just the 4 KiB buffer and the softc).
9. **Stress run:** in terminal D,

```
% sudo ./stress_rw -s 5
```

Watch terminal B. You should see `bufused` oscillate, counters climb, and `active_fhs` hit 2 while the test runs.

10. When the stress run finishes, in terminal B verify `active_fhs` is 0. In terminal A,

```
% sudo kldunload myfirst
% vmstat -m | grep devbuf
```

`InUse` should have returned to its pre-load baseline. If it has not, your driver leaked an allocation and `vmstat -m` just told you.

Success criteria:

- `Sysctl` counters match the workload you ran.
- `Dmesg` shows one open/destructor pair per descriptor open/close.
- Truss output matches your mental model of what the program did.
- `vmstat -m | grep devbuf` returns to its baseline after unload.
- No panics, no warnings, no unexplained counter drift.

Why this lab matters: this is the first lab that exercises the full observability toolchain at once. In production, the signal that something is wrong almost never comes from a crash; it comes from a counter that has drifted out of bounds, a `dmesg` line nobody expected, or a `vmstat -m` reading that does not match reality. Building the habit of looking at all four surfaces together is what separates “I wrote a driver” from “I am responsible for a driver”.

9.19 Challenge Exercises

These challenges stretch the material without introducing topics that belong to later chapters. Each one uses only the primitives we have introduced. Try them before looking at the companion tree; the learning is in the attempt, not the answer.

9.19.1 Challenge 9.1: Per-Descriptor Read Counters

Extend Stage 2 so that the per-descriptor reads counter is exposed via a `sysctl`. The counter should be available per active descriptor, which means a per-`fh` `sysctl` rather than a per-`softc` one.

This challenge is harder than it looks: `sysctls` are allocated and freed at known points in the `softc` lifecycle, and the per-descriptor structure lives only as long as its descriptor. A clean solution registers a `sysctl` node per `fh` in `d_open` and unregisters it in the destructor. Be careful about lifetimes; the `sysctl` context must be freed before the `fh` memory.

Hint: `sysctl_ctx_init` and `sysctl_ctx_free` are per-context. You can give each `fh` its own context, and free it in the destructor.

Alternative: keep a linked list of `fh` pointers in the `softc` (under the mutex) and expose it through a custom `sysctl` handler that walks the list on demand. This is the pattern `/usr/src/sys/kern/tty_info.c` uses for per-process stats.

9.19.2 Challenge 9.2: A `readv(2)`-Aware Test

Write a user program that uses `readv(2)` to read from the driver into three separate buffers of sizes 8, 16, and 32 bytes. Confirm that the driver delivers bytes into all three buffers in sequence.

The kernel and `uiomove(9)` already handle `readv(2)`; the driver does not need changes. The purpose of this challenge is to convince yourself of that fact.

Hint: `struct iovec iov[3] = {{buf1, 8}, {buf2, 16}, {buf3, 32}};`, then `readv(fd, iov, 3)`. The return value is the total bytes delivered across all three buffers; the individual `iov_len` values are not modified on the user side.

9.19.3 Challenge 9.3: Short-Write Demonstration

Modify Stage 2's `myfirst_write` to accept at most 128 bytes per call, regardless of `uio_resid`. A user program that writes 1024 bytes should see a short write of 128 every time.

Then write a short test program that writes 1024 bytes in a single `write(2)` call, observes the short-write return value, and loops until all 1024 bytes have been accepted.

Questions to think through:

- Does `cat` handle short writes correctly? (Yes.)
- Does `echo > /dev/myfirst/0 "..."` handle them correctly? (Usually, via `printf` in the shell, but sometimes not; worth testing.)
- What happens if you remove the short-write behaviour and try to exceed the buffer size? (You get `ENOSPC` after the first 4096-byte write.)

This challenge teaches you to separate “the driver does the right thing” from “user programs assume what drivers do”.

9.19.4 Challenge 9.4: An `ls -l` Sensor

Make the driver's response to a read depend on the `ls -l` output of the device itself. That is: every read produces the current timestamp of the device node.

Hint: `sc->cdev->si_ctime` and `sc->cdev->si_mtime` are `struct timespec` fields on the `cdev`. You can convert them to a string with `printf` formatting, place the string in a kernel buffer, and `uiomove_frombuf(9)` it out.

Warning: `si_ctime` / `si_mtime` may be updated by `devfs` as nodes are touched. Observe what happens when you touch `/dev/myfirst/0` and read again.

9.19.5 Challenge 9.5: A Reverse-Echo Driver

Modify Stage 3 so that every read returns the bytes in reverse order from how they were written. A write of “hello” followed by a read should produce “olleh”.

This challenge is entirely about buffer bookkeeping. The `uiomove` calls stay the same; you change the addresses you hand to them.

Hint: You can either reverse the buffer on every read (expensive) or store bytes in reverse order on the write side (cheaper). Neither is the “right” answer; each has different correctness and concurrency properties. Pick one and argue for it in a comment.

9.19.6 Challenge 9.6: Binary Round Trip

Write a user program that writes a `struct timespec` to the driver, then reads one back. Compare the two structures. Are they equal? They should be, because `myfirst` is a transparent byte store.

Extend the program to write two `struct timespec` values, then `lseek(fd, sizeof(struct timespec), SEEK_SET)` and read the second one. What happens? (Clue: the FIFO does not support seeks meaningfully.)

This challenge illustrates the “read and write carry bytes, not types” point from the safe-data-transfer section. The bytes round-trip perfectly; the type information does not.

9.19.7 Challenge 9.7: A Hex-View Test Harness

Write a short shell script that, given a byte count `N`, generates `N` random bytes with `dd if=/dev/urandom bs=$N count=1`, pipes them into your Stage 3 driver, then reads them back with `dd if=/dev/myfirst/0 bs=$N count=1`, and compares the two streams with `cmp`. The script should report success for matching streams and diff-like output for mismatching streams. Run it with `N = 1, 2, 4, ..., 4096` to sweep small, boundary, and capacity-filling sizes.

Questions to answer as you run the sweep:

- Does every size round-trip cleanly up to and including 4096?
- At 4097, what does the driver do? Does the test harness report the error meaningfully?
- Is there any size at which `cmp` reports a difference? If so, what was the underlying cause?

This challenge rewards combining the tools in the Practical Workflow section: `dd` for precise transfers, `cmp` for byte-level verification, `sysctl` for counters, and the shell for orchestration. A robust test harness like this is the kind of habit that pays for itself every time you refactor a driver and want to know quickly whether the behaviour is still right.

9.19.8 Challenge 9.8: Who Has the Descriptor Open?

Write a small C program that opens `/dev/myfirst/0`, blocks on `pause()` (so it holds the descriptor indefinitely), and runs until `SIGTERM`. In a second terminal, run `fstat | grep myfirst` and then `fuser /dev/myfirst/0`. Note the output. Now try to `kldunload myfirst`. What error do you get? Why?

Now kill the holder with `SIGTERM` or plain `kill`. Observe the destructor fire in `dmesg`. Try `kldunload` again. It should succeed.

This challenge is short, but it grounds one of the chapter’s subtler invariants: a driver cannot unload while any descriptor is open on one of its `cdevs`, and FreeBSD gives operators a standard set of tools to find the holder. The next time a real-world `kldunload` fails with `EBUSY`, you will have seen the shape of the problem before.

9.20 Troubleshooting Common Mistakes

Every `d_read` / `d_write` mistake you are likely to make falls into one of a small number of categories. This section is a short field guide.

9.20.1 “My driver returns zero bytes even though I wrote data”

This is usually one of two bugs.

Bug 1: You forgot to update `bufused` (or equivalent) after the successful `uiomove`. The write arrived, the bytes moved, but the driver’s state never reflected the arrival. The next read sees `bufused == 0` and reports EOF.

Fix: always update your tracking fields inside `if (error == 0) { ... }` after `uiomove` returns.

Bug 2: You reset `bufused` (or `bufhead`) somewhere inappropriate. A common pattern is adding a reset line inside `d_open` or `d_close` “for cleanliness”. That wipes out the data the previous caller wrote.

Fix: reset driver-wide state only in `attach` (at load) or `detach` (at unload). Per-descriptor state belongs in `fh`, reset by `malloc(M_ZERO)` and cleaned up by the destructor.

9.20.2 “My reads return garbage”

The buffer is uninitialised. `malloc(9)` without `M_ZERO` returns a block of memory whose contents are undefined. If your `d_read` reaches past `bufused`, or reads from offsets that have not been written, the bytes you see are leftovers from whatever memory the kernel recycled.

Fix: always pass `M_ZERO` to `malloc` in `attach`. Always clamp reads to the current high-water mark (`bufused`), not to the buffer’s total size (`buflen`).

There is a more serious variant of this bug. A driver that returns uninitialised kernel memory to user space has just leaked kernel state into user space. In production that is a security hole. In development it is a bug; in production it is a CVE.

9.20.3 “The kernel panics with a pagefault on a user address”

You called `memcpy` or `bcopy` directly on a user pointer instead of going through `uiomove` / `copyin` / `copyout`. The access faulted, the kernel had no fault handler installed, and the result was a panic.

Fix: never dereference a user pointer directly. Route through `uiomove(9)` (in handlers) or `copyin(9)` / `copyout(9)` (in other contexts).

9.20.4 “The driver refuses to unload”

You have at least one file descriptor still open. `detach` returns `EBUSY` when `active_fhs > 0`; the module will not unload until every `fh` has been destroyed.

Fix: close the descriptor in userland. If a background process is holding it, kill the process (after confirming it is yours; do not kill system daemons). `fstat -p <pid>` shows which files a process has open; `fuser /dev/myfirst/0` shows which processes have the node open.

Chapter 10 will introduce `destroy_dev_drain` patterns for drivers that need to coerce a blocked reader to exit. Chapter 9 does not block, so this issue does not arise in normal operation; when it arises, it is because userland is holding the descriptor somewhere unexpected.

9.20.5 “My write handler returns EFAULT”

Your `uiomove` call hit an invalid user address. The common causes:

- A user program called `write(fd, NULL, n)` or `write(fd, (void*)0xdeadbeef, n)`.
- A user program wrote a pointer it had freed.
- You accidentally passed a kernel pointer as the destination to `uiomove`. This can happen if you build a `uio` by hand for kernel-space data and then pass it to a handler expecting a user-space `uio`. The resulting copyout sees a “user” address that is actually a kernel address; depending on the architecture, you either get `EFAULT` or a subtle corruption.

Fix: check `uio->uio_segflg`. For user-driven handlers, it should be `UIO_USERSPACE`. If you are passing around a kernel-space `uio`, make sure `uio_segflg == UIO_SYSSPACE` and that your code paths know the difference.

9.20.6 “My counters are wrong under concurrent writes”

Two writers raced on `bufused`. Each read the current value, added to it, and wrote back, and the second writer overwrote the first writer’s update with a stale value.

Fix: take `sc->mtx` around every read-modify-write of shared state. Part 3 makes this a first-class topic; for Chapter 9, a single mutex around the whole critical section is enough.

9.20.7 “sysctl counters do not reflect the real state”

Two variants.

Variant A: the counter is a `size_t`, but the `sysctl` macro is `SYSCTL_ADD_U64`. On 32-bit architectures, the macro reads 8 bytes where the field is only 4 bytes wide; half the value is junk.

Fix: match the `sysctl` macro to the field type. `size_t` pairs with `SYSCTL_ADD_UINT` on 32-bit platforms and `SYSCTL_ADD_U64` on 64-bit platforms. To be portable, use `uint64_t` for counters and cast when updating.

Variant B: the counter is never updated because the update is inside the `if (error == 0)` block and `uiomove` returned a non-zero error. That is actually correct behaviour: you should not count bytes you did not move. The symptom only looks like a bug if you are trying to use the counter to debug the error.

Fix: add an `error_count` counter that ticks on every non-zero return, independently of `bytes_read` and `bytes_written`. Useful for debugging.

9.20.8 “The first read after a fresh load returns zero bytes”

Usually intentional. In Stage 3, an empty buffer returns zero bytes. If you expected the static message from Stage 1, check that you are running the Stage 1 driver, not a later one.

If it is unintentional, double-check that `attach` is setting `sc->buf`, `sc->buflen`, and `sc->message_len` as expected. A common bug is copy-pasting the `attach` code from Stage 1 into Stage 2 and leaving the `sc->message = ...` assignment in place, which then takes precedence over the `malloc` line.

9.20.9 “The build fails with unknown reference to `uiomove_frombuf`”

You forgot to include `<sys/uio.h>`. Add it to the top of `myfirst.c`.

9.20.10 “My handler is called twice for one `read(2)`”

It almost certainly is not. What is more likely: your handler is being called once with `uio_iovcnt > 1` (a `readv(2)` call), and inside `uiomove` each `iovec` entry is being drained in turn. The internal loop in `uiomove` may make multiple copyout calls in what is a single invocation of your handler.

Verify by adding a `device_printf` at entry and exit of your `d_read`. You should see one entry and one exit per user-space `read(2)` call, regardless of `iovec` count.

9.21 Contrast Patterns: Correct vs. Buggy Handlers

The troubleshooting guide above is reactive: it helps when something has already gone wrong. This section is the prescriptive companion. Each entry shows a plausible but wrong way to write part of a handler, pairs it with the correct rewrite, and explains the distinction. Studying the contrasts in advance is the fastest way to avoid the bugs in the first place.

Read each pair carefully. The correct version is the pattern you should reach for; the buggy version is the shape your own hands may produce when you are moving fast. Recognising the mistake in the wild, months from now, is worth the five minutes it takes to internalise the difference today.

9.21.1 Contrast 1: Returning a Byte Count

Buggy:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    /* ... */
    error = uiomove_frombuf(sc->message, sc->message_len, uio);
    if (error)
        return (error);
    return (sc->message_len); /* BAD: returning a count */
}
```

Correct:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    /* ... */
    return (uiomove_frombuf(sc->message, sc->message_len, uio));
}
```

Why it matters. The handler's return value is an `errno`, not a count. The kernel computes the byte count from the change in `uio->uio_resid` and reports it to user space. A non-zero positive return is interpreted as an `errno`; if you returned `sc->message_len`, the caller would receive a very strange `errno` value. For example, returning 75 would manifest as `errno = 75`, which on FreeBSD happens to be `EPROGMISMATCH`. The bug is both wrong and deeply confusing to anybody looking at it from the user side.

The rule is simple and absolute: handlers return `errno` values, never counts. If you want to know the byte count, compute it from the `uio`.

9.21.2 Contrast 2: Handling a Zero-Length Request

Buggy:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    if (uio->uio_resid == 0)
        return (EINVAL); /* BAD: zero-length is legal */
    /* ... */
}
```

Correct:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    /* No special case. uiomove handles zero-resid cleanly. */
    return (uiomove_frombuf(sc->message, sc->message_len, uio));
}
```

Why it matters. A `read(fd, buf, 0)` call is legal UNIX. A driver that rejects it with `EINVAL` breaks programs that use zero-byte reads to check descriptor state. `uiomove` returns zero immediately if the `uio` has nothing to move; your handler does not need to special-case it. Special-casing it wrong is worse than not special-casing it at all.

9.21.3 Contrast 3: Buffer Capacity Arithmetic

Buggy:

```
mtx_lock(&sc->mtx);
avail = sc->buflen - sc->bufused;
towrite = uio->uio_resid;          /* BAD: no clamp */
error = uiomove(sc->buf + sc->bufused, towrite, uio);
if (error == 0)
    sc->bufused += towrite;
mtx_unlock(&sc->mtx);
return (error);
```

Correct:

```
mtx_lock(&sc->mtx);
avail = sc->buflen - sc->bufused;
if (avail == 0) {
    mtx_unlock(&sc->mtx);
    return (ENOSPC);
}
towrite = MIN((size_t)uio->uio_resid, avail);
error = uiomove(sc->buf + sc->bufused, towrite, uio);
if (error == 0)
    sc->bufused += towrite;
mtx_unlock(&sc->mtx);
return (error);
```

Why it matters. The buggy version hands `uiomove` a length of `uio_resid`, which may exceed the buffer's remaining capacity. `uiomove` will not move more than `uio_resid` bytes, but the *destination* is `sc->buf + sc->bufused`, and the math does not know about `sc->buflen`. If the user writes 8 KiB into a 4 KiB buffer with `bufused = 0`, the handler will write 4 KiB past the end of `sc->buf`. That is a classic kernel heap overflow: the crash will not be immediate, will not implicate your driver, and may reveal itself as a panic inside a completely unrelated subsystem half a second later.

The correct version clamps the transfer to `avail`, guaranteeing that the pointer arithmetic stays inside the buffer. The clamp is one `MIN` call, and it is not optional.

9.21.4 Contrast 4: Holding a Spin Lock Across `uiomove`

Buggy:

```
mtx_lock_spin(&sc->spin);          /* BAD: spin lock, not a regular mutex */
error = uiomove(sc->buf + off, n, uio);
```

```
mtx_unlock_spin(&sc->spin);
return (error);
```

Correct:

```
mtx_lock(&sc->mtx);                /* MTX_DEF mutex */
error = uiomove(sc->buf + off, n, uio);
mtx_unlock(&sc->mtx);
return (error);
```

Why it matters. uiomove(9) may sleep. When it calls copyin or copyout, the user page may be paged out, and the kernel may need to page it in from disk, which requires waiting on I/O. A sleep while holding a spin lock (MTX_SPIN) deadlocks the system. FreeBSD's WITNESS framework panics on this the first time it happens, if WITNESS is enabled. On a non-WITNESS kernel the result is silent livelock.

The rule is straightforward: spin locks cannot be held across functions that may sleep, and uiomove may sleep. Use an MTX_DEF mutex (the default, and the one myfirst uses) for softc state that is touched by I/O handlers.

9.21.5 Contrast 5: Resetting Shared State in d_open

Buggy:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    /* ... */
    mtx_lock(&sc->mtx);
    sc->bufused = 0;                /* BAD: wipes other readers' data */
    sc->bufhead = 0;
    mtx_unlock(&sc->mtx);
    /* ... */
}
```

Correct:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    /* ... no shared-state reset ... */
    fh = malloc(sizeof(*fh), M_DEVBUF, M_WAITOK | M_ZERO);
```

```
/* fh starts zeroed, which is correct per-descriptor state */
/* ... register fh with devfs_set_cdevpriv, bump counters ... */
}
```

Why it matters. `d_open` runs once per descriptor. If two readers open the device, the second open will wipe whatever the first open left behind. Driver-wide state (`sc->bufused`, `sc->buf`, counters) belongs to the whole driver, and is reset only at attach and detach. Per-descriptor state belongs in `fh`, which `malloc(M_ZERO)` initialises to zeros automatically.

A driver that resets shared state in `d_open` looks like it works under a single opener and silently corrupts state when two openers appear. The bug is invisible until the day two users read the device at once.

9.21.6 Contrast 6: Accounting Before Knowing the Outcome

Buggy:

```
sc->bytes_written += towrite;      /* BAD: count before success */
error = uiomove(sc->buf + tail, towrite, uio);
if (error == 0)
    sc->bufused += towrite;
```

Correct:

```
error = uiomove(sc->buf + tail, towrite, uio);
if (error == 0) {
    sc->bufused += towrite;
    sc->bytes_written += towrite;
}
```

Why it matters. If `uiomove` fails part-way through, some bytes may have moved and some may not. The `sc->bytes_written` counter should reflect what actually reached the buffer, not what the driver attempted. Updating counters before the outcome is known makes the counters lie. If a user reads the `sysctl` to diagnose a problem, they see numbers that do not correspond to reality.

The rule: update counters inside the `if (error == 0)` branch, so success is the only path that increments them. This is a small cost for a large correctness benefit.

9.21.7 Contrast 7: Dereferencing a User Pointer Directly

Buggy:

```
/* Imagine the driver somehow gets a user pointer, maybe through ioctl. */
static int
handle_user_string(void *user_ptr)
```

```
{
    char buf[128];
    memcpy(buf, user_ptr, 128);    /* BAD: user pointer in memcpy */
    /* ... */
}
```

Correct:

```
static int
handle_user_string(void *user_ptr)
{
    char buf[128];
    int error;

    error = copyin(user_ptr, buf, sizeof(buf));
    if (error != 0)
        return (error);
    /* ... */
}
```

Why it matters. `memcpy` assumes both pointers refer to memory accessible in the current address space. A user pointer does not. Depending on the platform, the result of passing a user pointer to `memcpy` in kernel context ranges from an EFAULT-equivalent fault (on amd64 with SMAP enabled) to silent data corruption (on platforms without user/kernel separation) to an outright kernel panic.

`copyin` and `copyout` are the one-and-only correct way to access user memory from kernel context. They install a fault handler, validate the address, walk page tables safely, and return EFAULT on any failure. The performance cost is a few extra instructions; the correctness benefit is “the kernel does not panic when a buggy user program is running”.

9.21.8 Contrast 8: Leaking a Per-Open Structure on `d_open` Failure

Buggy:

```
static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_fh *fh;
    int error;

    fh = malloc(sizeof(*fh), M_DEVBUF, M_WAITOK | M_ZERO);
    /* ... set fields ... */
    error = devfs_set_cdevpriv(fh, myfirst_fh_dtor);
    if (error != 0)
```

```

        return (error);          /* BAD: fh is leaked */
    return (0);
}

```

Correct:

```

static int
myfirst_open(struct cdev *dev, int oflags, int devtype, struct thread *td)
{
    struct myfirst_fh *fh;
    int error;

    fh = malloc(sizeof(*fh), M_DEVBUF, M_WAITOK | M_ZERO);
    /* ... set fields ... */
    error = devfs_set_cdevpriv(fh, myfirst_fh_dtor);
    if (error != 0) {
        free(fh, M_DEVBUF);      /* free before returning */
        return (error);
    }
    return (0);
}

```

Why it matters. When `devfs_set_cdevpriv` fails, the kernel does not register the destructor, so the destructor will never run on this `fh`. If the handler returns without freeing `fh`, the memory is leaked. Under steady load, repeated `d_open` failures can leak enough memory to destabilise the kernel.

The rule: in error-unwind paths, every allocation made so far must be freed. The Chapter 8 reader has seen this pattern for `attach`; it applies equally to `d_open`.

9.21.9 How to Use This Contrast Table

These eight pairs are not an exhaustive list. They are the bugs we have seen most often in early student drivers, and the bugs the chapter's text has been trying to help you avoid. Read through them once now. Before you write your first real driver outside this book, read them again.

A useful habit while developing: whenever you finish a handler, walk it against the contrast table mentally. Does the handler return a count? Does it special-case zero-resid? Does it have a capacity clamp? Is the mutex type right? Does it reset shared state in `d_open`? Does it account for bytes on failure? Does it dereference any user pointer directly? Does it leak on `d_open` failure? Eight questions, five minutes. The price of the check is small; the cost of shipping one of these bugs into production is large.

9.22 Self-Assessment Before Chapter 10

Chapter 9 has covered a lot of ground. Before you put it down, run through the following checklist. If any item makes you hesitate, the relevant section is worth re-reading before moving on. This is not a test; it is a quick

way to identify the spots where your mental model may still be thin.

Concepts:

- ☐ I can explain in one sentence what `struct uio` is for.
- ☐ I can name the three fields of `struct uio` my driver reads most often.
- ☐ I can explain why `uiomove(9)` is preferred over `copyin / copyout` inside `d_read` and `d_write`.
- ☐ I can explain why `memcpy` across the user / kernel boundary is unsafe.
- ☐ I can explain the difference between `ENXIO`, `EAGAIN`, `ENOSPC`, and `EFAULT` in driver terms.

Mechanics:

- ☐ I can write a minimal `d_read` handler that serves a fixed buffer using `uiomove_frombuf(9)`.
- ☐ I can write a minimal `d_write` handler that appends to a kernel buffer with a correct capacity clamp.
- ☐ I know where to put the mutex acquire and release around the transfer.
- ☐ I know how to propagate an `errno` from `uiomove` back to user space.
- ☐ I know how to mark a write as fully consumed with `uio_resid = 0`.

Observability:

- ☐ I can read `sysctl dev.myfirst.0.stats` and interpret each counter.
- ☐ I can spot a memory leak with `vmstat -m | grep devbuf`.
- ☐ I can use `truss(1)` to see what syscalls my test program makes.
- ☐ I can use `fstat(1)` or `fuser(8)` to find who is holding a descriptor.

Traps:

- ☐ I would not return a byte count from `d_read / d_write`.
- ☐ I would not reject a zero-length request with `EINVAL`.
- ☐ I would not reset `sc->bufused` inside `d_open`.
- ☐ I would not hold a spin lock across a `uiomove` call.

Any “no” here is a signal, not a verdict. Re-read the relevant section; run a small experiment in your lab; come back to the checklist. By the time every box is ticked, you are solidly ready for Chapter 10.

9.23 Wrapping Up

You have just implemented the entry points that make a driver alive. At the end of Chapter 7 your driver had a skeleton. At the end of Chapter 8 it had a well-shaped door. Now, at the end of Chapter 9, data flows through the door in both directions.

The central lesson of the chapter is shorter than it looks. Every `d_read` you will ever write has the same three-line spine: get per-open state, verify liveness, call `uiomove`. Every `d_write` you will ever write has a similar spine with one extra decision (how much room do I have?) and a clamp (`MIN(uio_resid, avail)`) that prevents buffer overruns. Everything else in the chapter is context: why `struct uio` looks the way it does, why `uiomove` is the only safe mover, why `errno` values matter, why counters matter, why the buffer has to be freed on every error path.

9.23.1 The Three Ideas That Matter Most

First, `struct uio` is the contract between your driver and the kernel's I/O machinery. It carries everything your handler needs to know about a call: what the user asked for, where the user's memory is, what direction the transfer should move, and how much progress has been made. You do not need to memorise all seven fields. You need to recognise `uio_resid` (the remaining work), `uio_offset` (the position, if you care), and `uio_rw` (the direction), and you need to trust `uiomove(9)` with the rest.

Second, `uiomove(9)` is the boundary between user memory and kernel memory. Everything your driver ever moves between the two passes through it (or through one of its close relatives: `uiomove_frombuf`, `copyin`, `copyout`). This is not a suggestion. Direct pointer access across the trust boundary either corrupts memory or leaks information, and the kernel has no cheap way to catch the mistake before it becomes a CVE. If a pointer came from user space, route it through the kernel's trust-boundary functions. Always.

Third, a correct handler is usually a short one. If your `d_read` or `d_write` is longer than fifteen lines, something is probably wrong. Longer handlers either duplicate logic that belongs elsewhere (in the buffer management, in the per-open state setup, in the `sysctl`s), or they are trying to do something the driver should not be doing in a data-path handler (typically, something that belongs in `d_ioctl`). Keep the handlers short. Put the machinery they call into well-named helper functions. Your future self will thank you.

9.23.2 The Shape of the Driver You End the Chapter With

Your Stage 3 `myfirst` is a small, honest, in-memory FIFO. The salient features:

- A 4 KiB kernel buffer, allocated in `attach` and freed in `detach`.
- A per-instance mutex guarding `bufhead`, `bufused`, and the associated counters.
- A `d_read` that drains the buffer and advances `bufhead`, collapsing to zero when the buffer empties.
- A `d_write` that appends to the buffer and returns `ENOSPC` when it fills.
- Per-descriptor counters stored in `struct myfirst_fh`, allocated in `d_open`, freed in the destructor.
- A `sysctl` tree exposing the live driver state.
- Clean `attach` error unwind and clean `detach` ordering.

That shape will come back, recognisable, in half the drivers you will read in Part 4 and Part 6. It is a general pattern, not a one-off demo.

9.23.3 What You Should Practice Before Starting Chapter 10

Five exercises, in rough order of increasing challenge:

1. Rebuild all three stages from scratch, without looking at the companion tree. Compare your result to the tree afterward; the differences are what you have left to internalise.
2. Introduce an intentional bug in Stage 3: forget to reset `bufhead` when `bufused` reaches zero. Observe what happens on the second big write. Explain the symptom in terms of the code.
3. Add a `sysctl` that exposes `sc->buflen`. Make it read-only. Then convert it into a tunable that can be set at load time via `kenv` or `loader.conf` and picked up in `attach`. (Chapter 10 revisits tunables formally; this is a preview.)

4. Write a shell script that writes random data of a known length to `/dev/myfirst/0` and then reads it back through `sha256`. Compare the hashes. Do the hashes match even when the write size exceeds the buffer? (They should not; think about why.)
5. Find a driver under `/usr/src/sys/dev` that implements both `d_read` and `d_write`. Read its handlers. Map them against the patterns in this chapter. Good candidates: `/usr/src/sys/dev/null/null.c` (you already know it), `/usr/src/sys/dev/random/randomdev.c`, `/usr/src/sys/dev/speaker/spkr.c`.

9.23.4 Looking Ahead to Chapter 10

Chapter 10 takes the Stage 3 driver and makes it scale. Four new capabilities show up:

- **A circular buffer** replaces the linear buffer. Writes and reads can both happen continuously without the explicit collapse that Stage 3 uses.
- **Blocking reads** arrive. A reader that calls `read(2)` on an empty buffer can sleep until data is available, rather than returning zero bytes immediately. The kernel's `msleep(9)` is the primitive; the `d_purge` handler is the teardown safety net.
- **Non-blocking I/O** becomes a first-class feature. `O_NONBLOCK` users get `EAGAIN` where a blocking caller would sleep.
- **`poll(2)` and `kqueue(9)` integration.** A user program can wait for the device to become readable or writable without actively attempting the operation. This is the standard way to integrate a device into an event loop.

All four of these build on the same `d_read` / `d_write` shapes you just implemented. You will extend the handlers rather than rewriting them, and the per-descriptor state you have in place will carry the necessary bookkeeping. The chapter before that (this one) is the one where the I/O path itself is correct. Chapter 10 is where the I/O path becomes efficient.

Before you close the file, a last reassurance. The material in this chapter is not as difficult as it may feel on a first read. The pattern is small. The ideas are real, but they are finite, and you have just exercised every one of them against working code. When you read a real driver's `d_read` or `d_write` in the tree, you will now recognise what the function is doing and why. You are not a beginner at this any more. You are an apprentice with a real tool in your hands.

9.24 Reference: The Signatures and Helpers Used in This Chapter

A consolidated reference for the declarations, helpers, and constants the chapter leans on. Keep this page bookmarked while you write drivers; most beginner questions are a lookup in one of these tables.

9.24.1 `d_read` and `d_write` Signatures

From `/usr/src/sys/sys/conf.h`:

```
typedef int d_read_t(struct cdev *dev, struct uio *uio, int ioflag);
typedef int d_write_t(struct cdev *dev, struct uio *uio, int ioflag);
```

The return value is zero on success, a positive errno on failure. The byte count is computed from the change in `uio->uio_resid` and reported to user space as the return value of `read(2)` / `write(2)`.

9.24.2 The Canonical struct uio

From `/usr/src/sys/sys/uio.h`:

```
struct uio {
    struct iovec *uio_iov;           /* scatter/gather list */
    int uio_iovcnt;                  /* length of scatter/gather list */
    off_t uio_offset;                 /* offset in target object */
    ssize_t uio_resid;                /* remaining bytes to process */
    enum uio_seg uio_segflg;          /* address space */
    enum uio_rw uio_rw;               /* operation */
    struct thread *uio_td;            /* owner */
};
```

9.24.3 The uio_seg and uio_rw Enumerations

From `/usr/src/sys/sys/_uio.h`:

```
enum uio_rw { UIO_READ, UIO_WRITE };
enum uio_seg { UIO_USERSPACE, UIO_SYSSPACE, UIO_NOCOPY };
```

9.24.4 uiomove Family

From `/usr/src/sys/sys/uio.h`:

```
int uiomove(void *cp, int n, struct uio *uio);
int uiomove_frombuf(void *buf, int buflen, struct uio *uio);
int uiomove_fromphys(struct vm_page *ma[], vm_offset_t offset, int n,
                     struct uio *uio);
int uiomove_nofault(void *cp, int n, struct uio *uio);
int uiomove_object(struct vm_object *obj, off_t obj_size, struct uio *uio);
```

In beginner driver code, only `uiomove` and `uiomove_frombuf` are common. The others support specific kernel subsystems (physical-page I/O, page-fault-free copies, VM-backed objects) and are out of scope for this chapter.

9.24.5 copyin and copyout

From `/usr/src/sys/sys/systm.h`:

```
int copyin(const void * __restrict uaddr,
           void * __restrict kaddr, size_t len);
int copyout(const void * __restrict kaddr,
            void * __restrict uaddr, size_t len);
int copyinstr(const void * __restrict uaddr,
              void * __restrict kaddr, size_t len,
              size_t * __restrict lencopied);
```

Use these in control paths (`d_ioctl`) where a user pointer arrives outside the `uio` abstraction. Inside `d_read` and `d_write`, prefer `uiomove`.

9.24.6 `ioflag` Bits That Matter for Character Devices

From `/usr/src/sys/sys/vnode.h`:

```
#define IO_NDELAY      0x0004 /* FNDELAY flag set in file table */
```

Set when the descriptor is in non-blocking mode. Your `d_read` or `d_write` can use this to decide whether to block (missing flag) or return `EAGAIN` (flag set). Most of the other `IO_*` flags are filesystem-level and irrelevant to character devices.

9.24.7 Memory Allocation

From `/usr/src/sys/sys/malloc.h`:

```
void *malloc(size_t size, struct malloc_type *type, int flags);
void free(void *addr, struct malloc_type *type);
```

Common flags: `M_WAITOK`, `M_NOWAIT`, `M_ZERO`. Common types for drivers: `M_DEVBUF` (generic) or a driver-specific type declared via `MALLOC_DECLARE` / `MALLOC_DEFINE`.

9.24.8 Per-Open State (Chapter 8 carryover, used here)

From `/usr/src/sys/sys/conf.h`:

```
int devfs_set_cdevpriv(void *priv, d_priv_dtor_t *dtr);
int devfs_get_cdevpriv(void **datap);
void devfs_clear_cdevpriv(void);
```

The pattern is: allocate in `d_open`, register with `devfs_set_cdevpriv`, retrieve in every later handler with `devfs_get_cdevpriv`, clean up in the destructor that `devfs_set_cdevpriv` registered.

9.24.9 Errno Values Used in This Chapter

Errno	Meaning in a driver context
0	Success.
ENXIO	Device not configured (softc missing, not attached).
EFAULT	Bad user address. Usually propagated from uiomove.
EIO	Input / output error. Hardware issue.
ENOSPC	No space left on device. Buffer full.
EAGAIN	Would block; relevant in non-blocking mode (Chapter 10).
EINVAL	Invalid argument.
EACCES	Permission denied at open(2).
EPIPE	Broken pipe. Not used by myfirst.

9.24.10 Helpful device_printf(9) Patterns

```
device_printf(sc->dev, "open via %s fh=%p\n", devtoname(sc->cdev), fh);
device_printf(sc->dev, "write rejected: buffer full (used=%zu)\n",
    sc->bufused);
device_printf(sc->dev, "read delivered %zd bytes\n",
    (ssize_t)(before - uio->uio_offset));
```

These are written for readability. A line in dmesg you have to decode is a line that probably will not be read when it matters.

9.24.11 The Three Stages at a Glance

Stage	d_read	d_write
1	Serve fixed message via uiomove_frombuf	Discard writes (like /dev/null)
2	Serve buffer up to bufused	Append to buffer, ENOSPC if full
3	Drain buffer from bufhead, reset on empty	Append at bufhead + bufused, ENOSPC if full

Stage 3 is the foundation Chapter 10 builds on.

9.24.12 Consolidated File List for the Chapter

Companion files under `examples/part-02/ch09-reading-and-writing/`:

- `stage1-static-message/`: Stage 1 driver source and Makefile.
- `stage2-readwrite/`: Stage 2 driver source and Makefile.
- `stage3-echo/`: Stage 3 driver source and Makefile.
- `userland/rw_myfirst.c`: small C program to exercise read and write round-trips.
- `userland/stress_rw.c`: multi-process stress test for Lab 9.3 and beyond.
- `README.md`: a short map of the companion tree.

Each stage is independent; you can build, load, and exercise any of them without building the others. The Makefiles are identical except for the driver name (always `myfirst`) and optional tuning flags.

9.25 Appendix A: A Closer Look at `uiomove`'s Internal Loop

For readers who want to see exactly what `uiomove(9)` does, this appendix walks through the core loop of `uiomove_faultflag` as it appears in `/usr/src/sys/kern/subr_uio.c`. You do not need to read this to write a driver. It is here because one reading of the loop will clarify every later question you have about `uio` semantics.

9.25.1 The Setup

At entry, the function has:

- A kernel pointer `cp` provided by the caller (your driver).
- An integer `n` provided by the caller (the max bytes to move).
- The `uio` provided by the kernel dispatch.
- A boolean `nofault` indicating whether page faults during the copy should be handled or fatal.

It sanity-checks a few invariants: the direction is `UIO_READ` or `UIO_WRITE`, the owning thread is the current thread when the segment is user-space, and `uio_resid` is non-negative. Any violation is a `KASSERT` and will panic a kernel with `INVARIANTS` enabled.

9.25.2 The Main Loop

```
while (n > 0 && uio->uio_resid) {
    iov = uio->uio_iov;
    cnt = iov->iov_len;
    if (cnt == 0) {
        uio->uio_iov++;
        uio->uio_iovcnt--;
        continue;
    }
    if (cnt > n)
```

```
        cnt = n;

    switch (uio->uio_segflg) {
    case UIO_USERSPACE:
        switch (uio->uio_rw) {
        case UIO_READ:
            error = copyout(cp, iov->iov_base, cnt);
            break;
        case UIO_WRITE:
            error = copyin(iov->iov_base, cp, cnt);
            break;
        }
        if (error)
            goto out;
        break;

    case UIO_SYSSPACE:
        switch (uio->uio_rw) {
        case UIO_READ:
            bcopy(cp, iov->iov_base, cnt);
            break;
        case UIO_WRITE:
            bcopy(iov->iov_base, cp, cnt);
            break;
        }
        break;
    case UIO_NOCOPY:
        break;
    }
    iov->iov_base = (char *)iov->iov_base + cnt;
    iov->iov_len -= cnt;
    uio->uio_resid -= cnt;
    uio->uio_offset += cnt;
    cp = (char *)cp + cnt;
    n -= cnt;
}
```

Each iteration does one unit of work: copy up to `cnt` bytes (where `cnt` is `MIN(iov->iov_len, n)`) between the current `iovec` entry and the kernel buffer. The direction is chosen by the two nested `switch` statements. After a successful copy, all the accounting fields advance in lockstep: the `iovec` entry shrinks by `cnt`, the `uio`'s `resid` shrinks by `cnt`, the `uio`'s `offset` grows by `cnt`, the kernel pointer `cp` advances by `cnt`, and the caller's `n` shrinks by `cnt`.

When an `iovec` entry is fully drained (`cnt == 0` at loop entry), the function advances to the next entry. When the caller's `n` reaches zero or the `uio`'s `resid` reaches zero, the loop terminates.

If `copyin` or `copyout` returns non-zero, the function jumps to out without updating the fields for that iteration, so the partial-copy accounting is consistent: whatever bytes did copy are reflected in `uio_resid`, whatever did not copy is still pending.

9.25.3 What You Should Take Away

Three invariants fall out of the loop that matter for your driver code.

- **Your call to `uiomove(cp, n, uio)` moves at most `MIN(n, uio->uio_resid)` bytes.** There is no way to ask for more than the `uio` has room for; the function caps at whichever side is smaller.
- **On a partial transfer, the state is consistent.** `uio_resid` reflects exactly the bytes that did not move. You can make another call and it will pick up correctly.
- **The fault handling is inside the loop, not around it.** A fault during a `copyin` / `copyout` returns `EFAULT` for the remainder; the fields are still consistent.

These three facts are why the three-line spine we keep returning to (`uiomove`, check error, update state) is sufficient. The kernel is doing the complicated work inside the loop; your driver just has to cooperate.

9.26 Appendix B: Why `read(fd, buf, 0)` Is Allowed

A short note on a question that comes up frequently: why does UNIX allow a `read(fd, buf, 0)` or `write(fd, buf, 0)` call at all?

There are two answers, and both are worth knowing.

The practical answer: zero-length I/O is a free test. A user program that wants to check whether a descriptor is in a reasonable state can call `read(fd, NULL, 0)` without committing to a real transfer. If the descriptor is broken, the call returns an error. If it is fine, the call returns zero and costs almost nothing.

The semantic answer: the UNIX I/O interface uses byte counts consistently, and special-casing zero is more work than allowing it. A call with `count == 0` is a well-defined no-op: the kernel has to do nothing, and can return zero immediately. The alternative, returning `EINVAL` for zero-count calls, would force every user program that computed a count dynamically to guard against the case. That is the kind of change that breaks decades of code for no benefit.

The driver-side consequence, which we noted earlier: your handler must not panic or error on a zero `uio_resid`. The kernel effectively handles the case for you when you go through `uiomove`, which returns zero immediately if there is nothing to move.

If you ever find yourself writing `if (uio->uio_resid == 0) return (EINVAL);` in a driver, stop. That is the wrong answer. Zero-count I/O is valid; return zero.

9.27 Appendix C: A Short Tour of `/dev/zero`'s Read Path

As a closing piece of analysis, it is worth walking through exactly what happens when a user program calls `read(2)` on `/dev/zero`. The driver is `/usr/src/sys/dev/null/null.c` and the handler is `zero_read`. Once you understand this path, you understand everything in Chapter 9.

9.27.1 From User Space to Kernel Dispatch

The user calls:

```
ssize_t n = read(fd, buf, 1024);
```

The C library makes the `read` syscall. The kernel looks up `fd` in the calling process's file table, retrieves the `struct file`, identifies its `vnode`, dispatches the call into `devfs`.

`devfs` identifies the `cdev` associated with the `vnode`, acquires a reference on it, and calls its `d_read` function pointer (`zero_read`) with the `uio` the kernel prepared.

9.27.2 Inside `zero_read`

```
static int
zero_read(struct cdev *dev __unused, struct uio *uio, int flags __unused)
{
    void *zbuf;
    ssize_t len;
    int error = 0;

    KASSERT(uio->uio_rw == UIO_READ,
        ("Can't be in %s for write", __func__));
    zbuf = __DECONST(void *, zero_region);
    while (uio->uio_resid > 0 && error == 0) {
        len = uio->uio_resid;
        if (len > ZERO_REGION_SIZE)
            len = ZERO_REGION_SIZE;
        error = uiomove(zbuf, len, uio);
    }
    return (error);
}
```

- Assert that the direction is correct. Good practice; a `KASSERT` costs nothing in production kernels.
- Set `zbuf` to point at `zero_region`, a large pre-allocated zero-filled area.
- Loop: while the caller wants more bytes, determine the transfer size (min of `uio_resid` and the zero region's size), call `uiomove`, accumulate any error.
- Return.

9.27.3 Inside `uiomove`

For the first iteration, `uiomove` sees `uio_resid = 1024`, `len = 1024` (since `ZERO_REGION_SIZE` is much larger), `uio_segflg = UIO_USERSPACE`, `uio_rw = UIO_READ`. It selects `copyout(zbuf, buf, 1024)`. The kernel performs the copy, handling any page fault on the user buffer. On success, `uio_resid` drops to zero, `uio_offset` grows by 1024, and the `iovec` is fully consumed.

9.27.4 Back Up the Stack

uiomove returns zero. The loop in zero_read sees `uio_resid == 0` and exits. zero_read returns zero.

devfs releases its reference on the cdev. The kernel computes the byte count as $1024 - 0 = 1024$. `read(2)` returns 1024 to the user.

The user's buffer now holds 1024 zero bytes.

9.27.5 What This Tells You About Your Own Driver

Two observations.

First, every data-path decision in zero_read is one you are now making too. How large of a chunk to move per iteration; which buffer to read from; how to handle the error from uiomove. Your driver's decisions will differ in the specifics (your buffer is not a pre-allocated zero region, your chunk size is not `ZERO_REGION_SIZE`), but the shape is identical.

Second, everything above zero_read is kernel machinery you do not have to write. You implement the handler, and the kernel takes care of the syscall, the file-descriptor lookup, the VFS dispatch, the devfs routing, the reference counting, and the fault handling. That is the power of the abstraction: you add your driver's knowledge, and everything else comes for free.

The flip side is that when you write a driver, you are committing to *cooperating* with that machinery. Every invariant that uiomove and devfs rely on is now your responsibility to uphold. The chapter has been walking you through those invariants one at a time, by building three small drivers that each exercise a different subset.

By now, the pattern should be familiar.

9.28 Appendix D: Common read(2) / write(2) Return Values at the User Side

A short cheat sheet for what a user program sees when it talks to your driver. This is not driver code; it is the view from the other side of the trust boundary. Reading it occasionally is the best inoculation against the subtle bugs that arise when the driver does something other than what a well-behaved UNIX program expects.

9.28.1 read(2)

- A positive integer: that many bytes were placed into the caller's buffer. Less than the requested count means a short read; the caller loops.
- Zero: end of file. No more bytes will ever be produced on this descriptor. The caller stops.
- -1 with `errno = EAGAIN`: non-blocking mode, no data available right now. The caller waits (via `select(2)` / `poll(2)` / `kqueue(2)`) and tries again.
- -1 with `errno = EINTR`: a signal interrupted the read. The caller usually retries unless the signal handler tells it not to.
- -1 with `errno = EFAULT`: the buffer pointer was invalid. The caller has a bug.
- -1 with `errno = ENXIO`: the device is gone. The caller should close the descriptor and give up.
- -1 with `errno = EIO`: the device reported a hardware error. The caller may retry or report.

9.28.2 write(2)

- A positive integer: that many bytes were accepted. Less than the offered count means a short write; the caller loops with the remainder.
- Zero: theoretically possible, rarely seen in practice. Usually treated the same as a short write of zero bytes.
- -1 with `errno = EAGAIN`: non-blocking mode, no space right now. The caller waits and retries.
- -1 with `errno = ENOSPC`: permanently no space. The caller either stops writing or reopens the descriptor.
- -1 with `errno = EPIPE`: the reader closed. Relevant for pipe-like devices, not for `myfirst`.
- -1 with `errno = EFAULT`: the buffer pointer was invalid.
- -1 with `errno = EINTR`: interrupted by a signal. Usually retried.

9.28.3 What This Means for Your Driver

Two takeaways.

First, `EAGAIN` is how non-blocking callers expect a driver to say “no data / no room right now, come back later”. A non-blocking caller that sees `EAGAIN` does not treat it as an error; it waits for a wake-up (usually via `poll(2)`) and retries. Chapter 10 makes this mechanism work for `myfirst`.

Second, `ENOSPC` is how a driver signals a permanent out-of-room condition on a write. It differs from `EAGAIN` in that the caller does not expect retries to succeed soon. For `myfirst` Stage 3 we use `ENOSPC` when the buffer fills and there is no reader actively draining; Chapter 10 will layer `EAGAIN` on top of the same condition for non-blocking readers and writers.

A driver that returns the wrong `errno` here is almost indistinguishable from a driver that is misbehaving. The cost of getting it right is tiny. The cost of getting it wrong shows up in confused user programs months later.

9.29 Appendix E: The One-Page Cheat Sheet

If you only have five minutes before starting Chapter 10, here is the one-page version of everything above.

The signatures:

```
static int myfirst_read(struct cdev *dev, struct uio *uio, int ioflag);
static int myfirst_write(struct cdev *dev, struct uio *uio, int ioflag);
```

Return zero on success, a positive `errno` on failure. Never return a byte count.

The three-line spine for reads:

```
error = devfs_get_cdevpriv((void **)&fh);
if (error) return error;
return uiomove_frombuf(sc->buf, sc->buflen, uio);
```

Or, for a dynamic buffer:

```
mtx_lock(&sc->mtx);
toread = MIN((size_t)uio->uio_resid, sc->bufused);
error = uiomove(sc->buf + offset, toread, uio);
if (error == 0) { /* update state */ }
mtx_unlock(&sc->mtx);
return error;
```

The three-line spine for writes:

```
mtx_lock(&sc->mtx);
avail = sc->buflen - (sc->bufhead + sc->bufused);
if (avail == 0) { mtx_unlock(&sc->mtx); return ENOSPC; }
towrite = MIN((size_t)uio->uio_resid, avail);
error = uiomove(sc->buf + sc->bufhead + sc->bufused, towrite, uio);
if (error == 0) { sc->bufused += towrite; }
mtx_unlock(&sc->mtx);
return error;
```

What to remember about uio:

- `uio_resid`: bytes still pending. `uiomove` decrements this.
- `uio_offset`: position, if meaningful. `uiomove` increments this.
- `uio_rw`: direction. Trust `uiomove` to use it.
- Everything else: do not touch.

What not to do:

- Do not dereference user pointers directly.
- Do not use `memcpy` / `bcopy` between user and kernel.
- Do not return byte counts.
- Do not reset driver-wide state in `d_open` / `d_close`.
- Do not forget `M_ZERO` on `malloc(9)`.
- Do not hold a spin lock across `uiomove`.

Errno values:

- 0: success.
- `ENXIO`: device not ready.
- `ENOSPC`: buffer full (permanent).
- `EAGAIN`: would block (non-blocking).
- `EFAULT`: from `uiomove`, propagate.
- `EIO`: hardware error.

That is the chapter.

9.30 Chapter Summary

This chapter built the data path. Starting from the Chapter 8 stubs, we implemented `d_read` and `d_write` in three stages, each a complete and loadable driver.

- **Stage 1** exercised `uiomove_frombuf(9)` against a static kernel string, with per-descriptor offset handling that made two concurrent readers' progress independent.
- **Stage 2** introduced a dynamic kernel buffer, a write path that appended into it, and a read path that served out of it. The buffer was sized at attach time, and a full buffer rejected further writes with `ENOSPC`.
- **Stage 3** turned the buffer into a first-in / first-out queue. Reads drained from the head, writes appended to the tail, and the driver collapsed `bufhead` to zero when the buffer emptied.

Along the way we dissected `struct uio` field by field, explained why `uiomove(9)` is the only legitimate way to cross the user / kernel trust boundary in a read or write handler, and built a small vocabulary of `errno` values that a well-behaved driver uses: `ENXIO`, `EFAULT`, `ENOSPC`, `EAGAIN`, `EIO`. We walked through the internal loop of `uiomove` so that its guarantees feel earned rather than mysterious. And we finished with five labs, six challenges, a troubleshooting guide, and a one-page cheat sheet.

The Stage 3 driver is the waypoint into Chapter 10. It moves bytes correctly. It does not yet move them efficiently: an empty buffer returns zero bytes immediately, a full buffer returns `ENOSPC` immediately, there is no blocking, no `poll(2)` integration, no ring buffer. Chapter 10 fixes all of that, building on exactly the shapes we just drew.

The pattern you just learned repeats. Every character-device I/O handler in `/usr/src/sys/dev` builds on the same three-argument signature, the same `struct uio`, and the same `uiomove(9)` primitive. The differences between drivers are in how they prepare the data, not in how they move it. Now that you recognise the moving machinery, every handler you open becomes legible almost immediately.

You now know enough to read any `d_read` or `d_write` in the FreeBSD tree and understand what it is doing. That is a significant milestone. Take a minute to appreciate it before turning the page.

10 Handling Input and Output Efficiently

10.1 Reader Guidance & Outcomes

Chapter 9 ended with a small but honest driver. Your `myfirst` module attaches as a Newbus device, creates `/dev/myfirst/0` with an alias at `/dev/myfirst`, allocates per-open state, transfers bytes through `uiomove(9)`, and maintains a simple first-in / first-out kernel buffer. You can write data into it, read the same data back, see the byte counters rise in `sysctl dev.myfirst.0.stats`, and watch your per-open destructor run when each descriptor closes. That is a complete, loadable, source-grounded driver, and the three stages you built in Chapter 9 are the foundation Chapter 10 is about to build on.

There is still something unsatisfying about that Stage 3 FIFO, however. It moves bytes correctly, but it does not use the buffer well. Once `bufhead` walks forward, the space it leaves behind is wasted until the buffer empties and `bufhead` collapses back to zero. A steady producer and a matching consumer can exhaust the capacity long before either side has truly run out of work. A full buffer returns `ENOSPC` immediately, even if a reader is a millisecond away from draining half of it. An empty buffer returns zero bytes as a pseudo end-of-file, even if the caller is prepared to wait. None of those behaviours are wrong for a teaching checkpoint, but none of them scale.

This chapter is where we make the I/O path efficient.

Real drivers move bytes in the background of other work. A reader that reaches the end of the current data may want to block until more arrives. A writer that finds the buffer full may want to block until a reader has made room. A non-blocking caller wants a clear `EAGAIN` instead of a polite fiction. A tool like `cat` or `dd` wants to read and write in chunks that match its own buffer size, not the driver's internal constraints. And the kernel wants the driver to do all of this without losing bytes, without corrupting shared state, and without the sprawling tangle of indices and edge cases that beginner drivers so often accumulate.

The way real drivers achieve this is through a handful of disciplined patterns. A **circular buffer** replaces the linear Stage 3 buffer and keeps the whole capacity in play. **Partial I/O** lets `read(2)` and `write(2)` return whatever portion of the request is actually available, instead of all-or-nothing. **Non-blocking mode** lets a well-written caller ask “is there any data yet?” without committing to sleep. And a careful **refactor** converts the buffer from an ad hoc set of fields inside the `softc` into a small, named abstraction that Chapter 11 can then protect with real synchronization primitives.

All of this sits firmly inside character-device territory. We are still writing a pseudo-device, still reading and writing through `struct uio`, still loading and unloading our module with `kldload(8)` and `kldunload(8)`. What changes is the *shape* of the data plane between the kernel buffer and the user program, and the quality of the promises the driver makes.

10.1.1 Why This Chapter Earns Its Own Place

It would be possible to shortcut this material. Many tutorials show a circular buffer in ten lines, sprinkle a `mtx_sleep` somewhere, and declare victory. That approach produces code that passes one test and then develops mysterious bugs under load. The mistakes are usually not in the read and write handlers themselves. They are in how the circular buffer wraps, how `uiomove(9)` is called when the live bytes span the physical end of the buffer, how `IO_NDELAY` is interpreted, how `selrecord(9)` and `selwakeup(9)` compose with a non-blocking caller that never calls `poll(2)`, and how partial writes should be reported back to a user-space program that is itself looping.

This chapter works through those details one at a time. The result is a driver you can stress with `dd`, bombard with a producer-consumer pair, inspect through `sysctl`, and hand to Chapter 11 as a stable base for concurrency work.

10.1.2 Where Chapter 9 Left the Driver

Checkpoint the state you should be working from. If your source tree and lab box match this outline, everything in Chapter 10 will land cleanly. If they do not, go back and bring Stage 3 to the shape below before continuing.

- One Newbus child under `nexus0`, created by `device_identify`.
- A `struct myfirst_softc` sized for the FIFO buffer plus statistics.
- A mutex `sc->mtx` named after the device, protecting `_softc` counters and buffer indices.
- A `sysctl` tree at `dev.myfirst.0.stats` exposing `attach_ticks`, `open_count`, `active_fhs`, `bytes_read`, `bytes_written`, and the current `bufhead`, `bufused`, and `buflen`.
- A primary cdev at `/dev/myfirst/0` with ownership `root:operator` and mode `0660`.
- An alias cdev at `/dev/myfirst` pointing at the primary.
- Per-open state via `devfs_set_cdevpriv(9)` and a `myfirst_fh_dtor` destructor.
- A linear FIFO buffer of `MYFIRST_BUFSIZE` bytes, with `bufhead` collapsing to zero on empty.
- `d_read` returning zero bytes when `bufused == 0` (our approximation of EOF at this stage).
- `d_write` returning `ENOSPC` when the tail reaches `buflen`.

Chapter 10 takes that driver and replaces the linear FIFO with a true circular buffer. Then it grows the `d_read` and `d_write` handlers to honour partial I/O properly, adds an `O_NONBLOCK`-aware path with `EAGAIN`, wires in a `d_poll` handler so that `select(2)` and `poll(2)` begin to work, and finishes by pulling the buffer logic into a named abstraction ready for locking.

10.1.3 What You Will Learn

Once you have finished this chapter, you will be able to:

- Explain, in plain language, what buffering buys a driver and where it starts to hurt.
- Design and implement a fixed-size byte-oriented circular buffer in kernel space.
- Reason about wrap-around correctly: detect it, split transfers across it, and keep the `uio` accounting honest while you do so.
- Integrate that circular buffer into the evolving `myfirst` driver without regressing any earlier behaviour.
- Handle partial reads and partial writes the way classical UNIX programs expect.

- Interpret and honour `IO_NDELAY` in your read and write handlers.
- Implement `d_poll` so `select(2)` and `poll(2)` work against `myfirst`.
- Stress-test buffered I/O from user space using `dd(1)`, `cat(1)`, `hexdump(1)`, and a small producer-consumer pair.
- Recognise the read-modify-write hazards the current driver contains, and make the refactors that will let Chapter 11 introduce real locking without restructuring code.
- Read `d_mmap(9)` and understand when a character-device driver wants to let user space map buffers directly, and when it genuinely does not.
- Talk about zero-copy in a way that distinguishes real savings from slogans.
- Recognise readahead and write-coalescing patterns when you see them in a driver, and describe why they matter to throughput.

10.1.4 What You Will Build

You will take the Stage 3 driver from Chapter 9 through four main stages, plus a short optional fifth stage that adds memory-mapping support.

1. **Stage 1, a standalone circular buffer.** Before touching the kernel, you will build `cbuf.c` and `cbuf.h` in userland, write a handful of small tests against them, and confirm that wrap-around, empty, and full behave the way your mental model says they should. This is the only part of the chapter you can develop entirely in userland, and it will pay for itself when the driver starts failing in ways that would have been caught by a three-line unit test.
2. **Stage 2, a circular-buffer driver.** You will splice the circular buffer into `myfirst` so that `d_read` and `d_write` now drive the new abstraction. `bufhead` becomes `cb_head`, `bufused` becomes `cb_used`, the fields live inside a small `struct cbuf`, and the wrap-around arithmetic is visible in one place. No behaviour visible to user space changes yet, but the driver is immediately better behaved under steady load.
3. **Stage 3, partial I/O and non-blocking support.** You will grow the handlers to honour partial reads and writes correctly, interpret `IO_NDELAY` as `EAGAIN`, and introduce the blocking read path with `mtx_sleep(9)` and `wakeup(9)`. The driver now rewards polite callers with low latency and rewards patient callers with blocking semantics.
4. **Stage 4, poll-aware and refactor-ready.** You will add a `d_poll` handler, wire up a `struct selinfo`, and refactor all buffer access through a tight set of helper functions so that Chapter 11 can drop in a real locking strategy.
5. **Stage 5, memory mapping (optional).** You will add a small `d_mmap` handler so user space can read the buffer through `mmap(2)`. This stage is explored alongside the supplementary topics in Section 8 and the matching lab at the end of the chapter. You can skip it on a first pass without losing the thread; it revisits the same buffer from a different angle.

You will exercise each stage with the base-system tools, with a small `cb_test` userland program you compile in Stage 1, and with two new helpers: `rw_myfirst_nb` (a non-blocking tester) and `producer_consumer` (a fork-based load harness). Each stage lives on disk under a dedicated directory in `examples/part-02/ch10-handling-io-efficiently/`, and the README there mirrors the chapter's checkpoints.

10.1.5 What This Chapter Does Not Cover

It is worth naming explicitly what we will *not* try to do here. The deeper discussions of these topics belong in later chapters, and dragging them in now would blur the lessons of this one.

- **Real concurrency correctness.** Chapter 10 uses the mutex that already exists in the softc, and it uses `mtx_sleep(9)` with that mutex as the sleep-interlock argument. That is safe by construction. But this chapter does not explore the full space of race conditions, nor does it categorize lock classes, nor does it teach the reader how to prove a piece of shared state is correctly protected. That is Chapter 11's job, and it is the reason the last section here is called "Refactoring and Preparing for Concurrency" rather than "Concurrency in Drivers."
- **`ioctl(2)`.** The driver still does not implement `d_ioctl`. A few clean-up primitives (flush the buffer, query its fill level) would fit nicely under `ioctl`, but Chapter 25 is the right place for that.
- **`kqueue(2)`.** This chapter implements `d_poll` for `select(2)` and `poll(2)`. The companion `d_kqfilter` handler, along with `knlist` machinery and `EVFILT_READ` filters, is introduced later alongside `taskqueue`-driven drivers.
- **Hardware mmap.** We will build a minimal `d_mmap` handler that lets user space map a preallocated kernel buffer as read-only pages, and we will discuss the design decisions and the things this pattern does and does not achieve. We will not venture into `bus_space(9)`, `bus_dmamap_create(9)`, or the `dev_pager` machinery; those are Part 4 and Part 5 material.
- **Real devices with real backpressure.** The backpressure model here is "the buffer has a fixed capacity and blocks or returns `EAGAIN` when full." Storage and network drivers have richer models (watermarks, credit, BIO queues, mbuf chains). Those details belong in their own chapters.

Keeping the chapter inside those lines is how we keep it honest. The material you will learn is enough to write a respectable pseudo-device and to read most character-device drivers in the tree with confidence.

10.1.6 Estimated Time Investment

- **Reading only:** roughly ninety minutes, maybe two hours if you are pausing at the diagrams.
- **Reading plus typing the four stages:** four to six hours, split into at least two sessions with a reboot or two.
- **Reading plus all labs and challenges:** eight to twelve hours over three sessions. The challenges are genuinely richer than the main labs, and they reward patient work.

As with Chapter 9, give yourself a fresh lab boot at the start. Do not rush the four stages. The value of the sequence is in watching the driver's behaviour change, one pattern at a time, as you add each capability.

10.1.7 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches the Chapter 9 Stage 3 example under `examples/part-02/ch09-reading-and-writing/stage3-echo/`. If it does not, stop here and bring it up to that shape first. Chapter 10 assumes it.
- Your lab machine is running FreeBSD 14.3 with a matching `/usr/src`. The APIs and file layouts you will see in this chapter align with that release.

- You read Chapter 9 carefully, including Appendix E (the one-page cheat sheet). The “three-line spine” there for reads and writes is exactly what we are about to grow.
- You are comfortable loading and unloading your own module, watching `dmesg`, reading `sysctl dev.myfirst.0.stats`, and reading the output of `truss(1)` or `ktrace(1)` when a test surprises you.

If any of those are shaky, fixing them now is a better use of time than pushing through this chapter.

10.1.8 How to Get the Most Out of This Chapter

Three habits stay useful.

First, keep `/usr/src/sys/dev/evdev/cdev.c` open in a second terminal. It is one of the cleanest examples in the tree of a character device that implements a ring buffer, blocks callers when the buffer is empty, honours `O_NONBLOCK`, and wakes sleepers through both `wakeup(9)` and the `selinfo` machinery. We will point at it several times.

Second, keep `/usr/src/sys/kern/subr_uio.c` bookmarked. Chapter 9 walked through this file’s `uiomove` internals; here we will revisit it when the buffer wrap forces us to split a transfer. Reading the real code reinforces the right mental model.

Third, run your tests under `truss(1)` occasionally, not only under normal shells. Tracing the syscall return values is the fastest way to distinguish a driver that is honouring partial I/O from one that is silently throwing bytes away.

10.1.9 Roadmap Through the Chapter

The sections in order are:

1. What buffered I/O is and why it matters. Buckets and pipelines, unbuffered vs. buffered patterns, and where each fits in a driver.
2. Creating a circular buffer. The data structure, invariants, wrap-around arithmetic, and a standalone user-land implementation you will test before you put it in the kernel.
3. Integrating that circular buffer into `myfirst`. How `d_read` and `d_write` change, how to handle the split transfer around the wrap, and how to log buffer state so debugging does not require guesswork.
4. Partial reads and partial writes. What they are, why they are correct UNIX behaviour, how to report them through `uio_resid`, and the edge cases you must not trip over.
5. Non-blocking I/O. The `IO_NDELAY` flag, its relationship to `O_NONBLOCK`, the `EAGAIN` convention, and the design of a simple blocking read path using `mtx_sleep(9)` and `wakeup(9)`.
6. Testing buffered I/O from user space. A consolidated test kit: `dd`, `cat`, `hexdump`, `truss`, a small non-blocking tester, and a producer-consumer harness that fork a reader and a writer against `/dev/myfirst`.
7. Refactoring and preparing for concurrency. Where the current code is at risk, how to factor the buffer into helpers, and the shape you want to hand to Chapter 11.
8. Three supplementary topics: `d_mmap(9)` as a minimal kernel-memory mapping (the optional Stage 5), zero-copy considerations for pseudo-devices, and the patterns real high-throughput drivers use (readahead on the read side, write coalescing on the write side).
9. Hands-on labs, a set of concrete exercises you should be able to complete directly against the driver.
10. Challenge exercises that stretch the same skills without introducing brand-new foundations.

11. Troubleshooting notes for the classes of bug this chapter's patterns tend to produce.
12. Wrapping Up and a bridge to Chapter 11.

If this is your first pass, read linearly and do the labs in order. If you are revisiting the material to consolidate, each numbered supplementary topic and the troubleshooting section stand alone.

10.2 Section 1: What Buffered I/O Is and Why It Matters

Every driver that moves bytes between user space and a hardware-side or kernel-side data source has to decide *where* those bytes live in between. The Stage 3 driver from Chapter 9 already makes that decision implicitly. The buffered bytes that have been written but not yet read are sitting in a kernel buffer. The reader pulls them out from the head; the writer appends new ones at the tail. The `myfirst` driver is, in that sense, already buffered.

What changes in this chapter is not whether you have a buffer. It is *how* the buffer is shaped, *how much* of its capacity you can keep in play at once, and *what promises* the driver makes to its callers about that buffer's behaviour. Before we look at the data structure, it is worth pausing on the difference between unbuffered and buffered I/O at a conceptual level. That contrast will guide every decision the rest of the chapter asks you to make.

10.2.1 A Plain-Language Definition

In the simplest framing, **unbuffered I/O** means that every `read(2)` or `write(2)` call touches the underlying source or sink directly. There is no intermediate storage that absorbs bursts, no place where the producer can leave bytes for the consumer to pick up later, no way to decouple the rate at which bytes are produced from the rate at which they are consumed. Each call goes all the way down.

Buffered I/O, by contrast, places a small region of memory between the producer and the consumer. A writer drops bytes into the buffer; a reader picks them up. As long as the buffer has free space, writers do not need to wait. As long as the buffer has live bytes, readers do not need to wait. The buffer absorbs short-term mismatches between the two sides.

That sounds like a small distinction, but in driver code it is often the difference between something that works under load and something that does not.

It is worth pausing on a small but important wrinkle. The kernel itself buffers at several layers above and below your driver. The C library's `stdio` buffers writes before they reach the `write(2)` syscall. The VFS path buffers I/O on regular files in the buffer cache. The disk drivers down in Part 7 will buffer at the BIO and queue level. When this chapter says "buffered I/O", it means a buffer *inside the driver*, between the user-facing read and write handlers and whatever data source or sink the driver represents. We are not arguing about whether buffering exists at all; we are deciding where to put one more buffer, and what it should do.

10.2.2 Two Concrete Pictures

Picture an unbuffered pseudo-device first. Imagine a driver whose `d_write` immediately hands every byte to whatever upstream code consumes them. If the consumer is busy, the writer waits. If the consumer is fast, the writer flies through. There is no give in the system. A burst on either side translates directly into pressure on the other.

Now picture a buffered pseudo-device. The same `d_write` deposits bytes into a small buffer. The consumer pulls bytes out at its own pace. A short burst of writes can complete instantly because the buffer absorbs them. A short pause from the consumer does not stall the writer because the buffer holds the backlog. Both sides feel like they are running smoothly even though their rates do not match exactly at every instant.

The buffered case is what most useful drivers look like in practice. It is not magic; the buffer is finite, and once it fills the producer has to wait or back off. But it gives the system a place to tolerate normal variability, and that tolerance is what makes throughput predictable.

10.2.3 Buckets vs. Pipelines

A useful analogy here is the difference between carrying water in buckets and carrying water through a pipeline.

When you carry water in buckets, every transfer is a discrete event. You walk to the well, fill the bucket, walk back, empty the bucket, walk again. The producer (the well) and the consumer (the cistern) are coupled tightly through your two arms and your walking pace. If you trip, the system stops. If the cistern is busy, you wait at it. If the well is busy, you wait at it. Each handoff requires that both sides be ready at the same instant.

A pipeline replaces that coupling with a length of pipe. Water enters at the well end and exits at the cistern end. The pipe holds some quantity of water in flight at any moment. The producer can pump as long as there is room in the pipe. The consumer can drain as long as there is water in the pipe. Their schedules no longer have to match. They only have to match *on average*.

A driver buffer is exactly that pipe. It is a finite reservoir that decouples writer rate from reader rate, as long as both rates average out to something the buffer's capacity can absorb. The bucket model corresponds to unbuffered I/O. The pipeline model corresponds to buffered I/O. Both are valid in different situations, and a driver writer's job is to know which one to build.

10.2.4 Performance: System Calls and Context Switches

The performance advantages of buffering inside a driver are real but indirect. They come from three places.

The first place is **system call overhead**. Every `read(2)` or `write(2)` is a transition from user space to kernel space and back. That transition is cheap on a modern processor, but it is not free. A writer that calls `write(2)` once with a thousand bytes pays one transition. A writer that calls `write(2)` a thousand times with one byte each pays a thousand transitions. If the driver buffers internally, callers can comfortably issue larger reads and writes, and the per-syscall overhead becomes a smaller fraction of the total cost.

The second place is **context switch reduction**. A call that has to wait, because nothing is available right now, often results in the calling thread being suspended and another thread being scheduled. Each suspend and resume is more expensive than a system call. A buffer absorbs the brief mismatches that would otherwise force a sleep, and the threads on both sides keep running.

The third place is **batching opportunities**. A driver that knows it has thousands of bytes ready to ship can sometimes hand the whole batch downstream in one operation, where a driver that processes byte by byte would have to do the same setup and teardown work for each transfer. We will not see this directly with the pseudo-device in this chapter, but it is the underlying argument for the read coalescing and write coalescing patterns we will look at later in the chapter.

None of these advantages should be applied blindly. Buffering also adds latency, since a byte may sit in the buffer for some time before the consumer notices. It adds memory cost. It introduces a pair of indices that must be kept consistent under concurrent access. And it forces a set of design decisions about what to do when the buffer fills (block? drop? overwrite?) and what to do when it empties (block? short-read? signal end-of-file?). There is a reason this chapter spends real time on those decisions.

10.2.5 Buffered Data Transfers in Device Drivers

Where exactly does buffering pay off in a device driver?

The clearest case is a driver whose data source produces bursts. A serial port driver receives characters whenever the UART chip raises an interrupt; if the consumer is not currently reading, those characters need somewhere to live until it does. A keyboard driver collects key events in the interrupt handler and hands them to user space at whatever rate the application is willing to read. A network driver assembles packets in DMA buffers and feeds them to the protocol stack as soon as it can. In each case, the driver needs a place to hold incoming data between the moment it arrives and the moment it can be delivered.

The mirror case is a driver whose data sink absorbs bursts. A graphics driver may queue commands until the GPU is ready to process them. A printer driver may accept a document and dribble it out at the printer's pace. A storage driver may collect write requests and let an elevator algorithm reorder them for the disk. Again, the driver needs a place to hold outgoing data between the moment the user wrote it and the moment the device is ready.

The pseudo-device we are building in this book sits in the middle of those two patterns. There is no real hardware on either end, but the *shape* of the data path mirrors what real drivers do. When you write to `/dev/myfirst`, the bytes land in a buffer the driver owns. When you read, the bytes come out of that same buffer. Once the buffer is circular and the I/O handlers know how to honour partial transfers, you can stress the driver with `dd if=/dev/zero of=/dev/myfirst bs=1m count=10` from one terminal and `dd if=/dev/myfirst of=/dev/null bs=4k` from another, and the driver will behave the same way a real character device behaves under analogous load.

10.2.6 When to Use Buffered I/O in a Driver

Almost every driver wants some form of buffering. The interesting question is not whether to buffer, but at what *granularity* and with what *backpressure model*.

Granularity is about the size of the buffer relative to the rates on either side. A buffer that is too small fills constantly and forces the writer to wait, defeating the point. A buffer that is too large hides problems for too long, lets memory grow without bound, and increases worst-case latency. The right size depends on what the buffer is for: the buffer of an interactive keyboard driver only needs to hold a handful of recent events; the buffer of a network driver may hold thousands of packets at peak load.

Backpressure is about what to do when the buffer fills (or empties) and the calling pattern does not match what the driver wants. There are three common strategies, each appropriate in a different setting.

The first is **block**. When the buffer is full, the writer waits. When the buffer is empty, the reader waits. This is the classical UNIX semantics, and it is the right default for terminal devices, pipes, and most general-purpose pseudo-devices. We will implement blocking reads (and optional blocking writes) in Section 5.

The second is **drop**. When the buffer is full, the writer drops the byte (or marks an overflow event) and proceeds. When the buffer is empty, the reader sees zero bytes and proceeds. This is the right default for some real-time and high-rate scenarios, where waiting would do more harm than missing data. Loss must be observable, however, or the driver will silently corrupt the stream from the user's perspective.

The third is **overwrite**. When the buffer is full, the writer overwrites the oldest data with new data. When the buffer is empty, the reader sees zero bytes. This is the right default for a circular log of recent events: a `dmesg(8)`-like history where the most recent bytes are always preserved at the cost of the oldest.

The driver in this chapter uses **block** for blocking-mode callers and **EAGAIN** for non-blocking-mode callers, with no overwrite path. That is the most common pattern in the FreeBSD source tree and the easiest to reason about. The other two strategies appear in later chapters when their use cases come up naturally.

10.2.7 A First Look at the Cost of an Unbuffered Driver

It is worth being concrete about why the Stage 3 driver from Chapter 9 already starts to hurt at scale.

Suppose you are running a `dd` that writes 64-byte blocks at high rate into the driver, and a parallel `dd` that reads 64-byte blocks out of it. With the Stage 3 buffer of 4096 bytes, you have at most 64 in-flight blocks before the writer hits `ENOSPC` and stops. If the reader pauses for any reason (page faulting in its destination buffer, getting preempted by the scheduler, being moved to a different CPU), the writer parks immediately. As soon as the reader resumes and drains a single block, the writer can fit one more. The overall throughput is the *minimum* of what the two halves achieve in lockstep, plus a steady stream of `ENOSPC` errors that user-space programs are not expected to see.

A circular buffer of the same size holds the same number of in-flight blocks but never wastes the trailing capacity. A non-blocking writer that hits a full buffer cleanly receives `EAGAIN` (the conventional “try again later” signal) instead of `ENOSPC` (the conventional “this device is out of room”), so a tool like `dd` can decide whether to retry or back off. A blocking writer that hits a full buffer goes to sleep on a clear condition variable and wakes up the moment a reader frees space. Each of those changes is small. Together they make a driver feel responsive instead of brittle.

10.2.8 Where We Are Going

You now have the conceptual ground. The rest of the chapter will translate it into code. Section 2 walks through the data structure, with diagrams and a userland implementation you can test before you trust it inside the kernel. Section 3 moves the implementation into the driver, replacing the linear FIFO. Sections 4 and 5 grow the I/O path so that partial transfers and non-blocking semantics work the way users expect. Section 6 builds the test harness you will use through the rest of Part 2 and most of Part 3. Section 7 prepares the code for the locking work that defines Chapter 11.

The order matters. Each section assumes the changes from the previous one are in place. If you skip ahead, you will land in code that does not compile or behaves in surprising ways. As always, the slow path is the fast path.

10.2.9 Wrapping Up Section 1

We named the difference between unbuffered and buffered I/O, and we named the costs and benefits of each. We picked an analogy (buckets vs. pipeline) that we can keep returning to. We discussed where buffering pays off in driver code, what backpressure strategies are common, and which one we are committing to for the rest of the chapter. And we set the stage for the data structure that powers the whole thing: the circular buffer.

If you are not yet sure which backpressure strategy your driver should use, that is fine. The default we will build, “block in the kernel and EAGAIN outside it,” is the safe and conventional choice for general-purpose pseudo-devices, and you will have a clean code shape to revisit if you need a different strategy later. We are about to make that buffer real.

10.3 Section 2: Creating a Circular Buffer

A circular buffer is one of those data structures whose idea is older than the operating systems we now use. It shows up in serial chips, in audio sample queues, in network receive paths, in keyboard event queues, in trace buffers, in `dmesg(8)`, in `printf(3)` libraries, and in nearly every other place where one piece of code wants to leave bytes for another piece of code to pick up later. The structure is simple. The implementation is short. The bugs that beginners make in it are predictable. We will build it once, in userland, with care, and then carry the verified version into the driver in Section 3.

10.3.1 What a Circular Buffer Is

A linear buffer is the simplest thing that could possibly work: a region of memory plus a “next free byte” index. You write into it from the start and you stop when you reach the end. Once it fills, you either grow it, copy it, or stop accepting new data.

A circular buffer (also called a ring buffer) is the same region of memory, but with a twist in how indices behave. There are two indices: the *head*, which points at the next byte to be read, and the *tail*, which points at the next byte to be written. When either index reaches the end of the underlying memory, it wraps back to the start. The buffer is treated as if its first byte were adjacent to its last byte, forming a closed loop.

Two derived counts matter for using the structure correctly. The number of *live* bytes (how many are currently stored) is what readers care about. The number of *free* bytes (how much capacity is unused) is what writers care about. Both counts can be derived from the head and tail, plus the total capacity, with a small piece of arithmetic.

Visually, the structure looks like this when it is partly full and the live region does not wrap:

```
+---+---+---+---+---+---+---+
| _ | _ | A | B | C | D | _ | _ |
+---+---+---+---+---+---+---+
          ^               ^
        head            tail

capacity = 8, used = 4, free = 4
```

After enough writes, the tail catches up to the end of the underlying memory and wraps to the start. Now the live region itself wraps:

```

+---+---+---+---+---+---+---+---+
| F | G | _ | _ | _ | _ | D | E |
+---+---+---+---+---+---+---+
          ^           ^
        tail        head

```

```
capacity = 8, used = 4, free = 4
```

```
live region: head -> end of buffer, then start of buffer -> tail
```

The “live region wraps” case is the one that catches beginners. A naive bcopy of the live data treats the buffer as if it were linear; the bytes you copy are not the bytes you wanted. The correct way to handle this case is to perform the transfer in *two pieces*: from head to the end of the buffer, and then from the start of the buffer to tail. We will codify exactly this pattern in the helpers below.

10.3.2 Managing Read and Write Pointers

The head and tail pointers (we will call them indices, because they are integer offsets into a fixed-size array) follow simple rules.

When you read n bytes, the head advances by n , modulo the capacity. When you write n bytes, the tail advances by n , modulo the capacity. Reads remove bytes; the live count drops by n . Writes add bytes; the live count rises by n .

The interesting question is how to detect the two boundary conditions: empty and full. With only head and tail, the structure is *almost* enough on its own. If $\text{head} == \text{tail}$, the buffer could be empty (no bytes stored) or full (all capacity stored). The two states look identical from the indices alone. Implementations resolve the ambiguity in one of three ways.

The first way is to keep a separate **count** of live bytes. With used available, $\text{used} == 0$ is unambiguously empty and $\text{used} == \text{capacity}$ is unambiguously full. The structure is slightly larger but the code is short and obvious. This is the design we will use in this chapter.

The second way is to **always leave one byte unused**. With this rule, $\text{head} == \text{tail}$ always means empty, and the buffer is full when $(\text{tail} + 1) \% \text{capacity} == \text{head}$. The structure is one byte smaller and the code does not need a used field, but every transfer involves an off-by-one that is easy to get wrong. This is the design used in some classic embedded code; it is fine, but it offers no real advantage in our setting.

The third way is to use **monotonically increasing indices** that are never reduced mod capacity, and to compute the live count as $\text{tail} - \text{head}$. Wrap-around is then a function of how you index into the array ($\text{tail} \% \text{capacity}$), not how you advance the pointer. This is the design used by `buf_ring(9)` in the FreeBSD kernel, which uses a 32-bit counter and trusts the wrap to behave. It is elegant, but it complicates atomic operations and debugging. We will not use it; the explicit used field is the right tradeoff for a teaching driver.

10.3.3 Detecting Buffer Full and Buffer Empty

With the explicit used count, the boundary checks become trivial:

- **Empty:** `cb->cb_used == 0`. There are no bytes available to read.
- **Full:** `cb->cb_used == cb->cb_size`. There is no space available to write.

The arithmetic for the head and tail indices is also straightforward:

- After reading `n` bytes: `cb->cb_head = (cb->cb_head + n) % cb->cb_size; cb->cb_used -= n;`
- After writing `n` bytes: `cb->cb_used += n;` (the tail is computed when needed as `(cb->cb_head + cb->cb_used) % cb->cb_size`)

We will keep the tail implicit, derived from head and used. Some implementations track the tail explicitly. Either choice works as long as you commit to it consistently. With `tail` implicit, we never have to update two indices on a single operation, which removes one whole class of bug.

Two helper-derived quantities will appear repeatedly:

- `cb_free(cb) = cb->cb_size - cb->cb_used`: how many bytes can still be written before the buffer is full.
- `cb_tail(cb) = (cb->cb_head + cb->cb_used) % cb->cb_size`: where the next write should land.

Both are pure functions of the head and used count and the capacity. They have no side effects and are safe to call at any time.

10.3.4 Allocating a Fixed-Size Circular Buffer

The buffer needs three pieces of state and one chunk of backing memory. Here is the structure we will use:

```
struct cbuf {
    char    *cb_data;        /* backing storage, cb_size bytes */
    size_t  cb_size;         /* total capacity, in bytes */
    size_t  cb_head;         /* index of next byte to read */
    size_t  cb_used;         /* count of live bytes */
};
```

Three lifetime functions cover the basics:

```
int  cbuf_init(struct cbuf *cb, size_t size);
void cbuf_destroy(struct cbuf *cb);
void cbuf_reset(struct cbuf *cb);
```

`cbuf_init` allocates the backing storage, initialises the indices, and returns zero on success or a positive `errno` on failure. `cbuf_destroy` releases the backing storage and zeros the structure. `cbuf_reset` empties the buffer without freeing memory; both indices return to zero.

Three accessor functions give the rest of the code the boundary information it needs:

```

size_t cbuf_used(const struct cbuf *cb);
size_t cbuf_free(const struct cbuf *cb);
size_t cbuf_size(const struct cbuf *cb);

```

These are tiny inline-friendly functions. They do not lock anything; the caller is expected to hold whatever synchronization the larger system requires. (In Stage 4 of this chapter, the driver's mutex will provide that synchronization.)

The two interesting functions are the byte-moving primitives:

```

size_t cbuf_write(struct cbuf *cb, const void *src, size_t n);
size_t cbuf_read(struct cbuf *cb, void *dst, size_t n);

```

`cbuf_write` copies up to `n` bytes from `src` into the buffer and returns the number actually copied. `cbuf_read` copies up to `n` bytes from the buffer into `dst` and returns the number actually copied. Both functions handle the wrap-around case internally. The caller provides a contiguous source or destination; the buffer takes care of splitting the transfer when the live region or free region crosses the end of the underlying storage.

That signature deserves a moment of attention. Notice that the functions return `size_t`, not `int`. They report progress, not error. Returning fewer bytes than requested is *not* an error condition; it is the correct way to express that the buffer was full (for writes) or empty (for reads). This mirrors the way `read(2)` and `write(2)` themselves work: a positive return value smaller than the request is a “partial transfer”, not a failure. We will lean on this in Section 4 when we make the driver honour partial I/O properly.

10.3.5 A Walkthrough of the Wrap-Around

The wrap-around logic is short, but it is worth tracing one example carefully. Suppose the buffer has capacity 8, head is 6, and used is 4. The live bytes are stored at positions 6, 7, 0, 1.

```

+---+---+---+---+---+---+---+---+
| C | D | _ | _ | _ | _ | A | B |
+---+---+---+---+---+---+---+
      ^           ^
    tail       head

```

capacity = 8, used = 4, head = 6, tail = (6+4)%8 = 2

Now the caller asks for 3 bytes via `cbuf_read`. The function does the following:

1. Compute `n = MIN(3, used) = MIN(3, 4) = 3`. The caller will get up to 3 bytes.
2. Compute `first = MIN(n, capacity - head) = MIN(3, 8 - 6) = 2`. That is the contiguous chunk starting at the head.
3. Copy `first = 2` bytes from `cb_data + 6` into `dst`. Those are A and B.
4. Compute `second = n - first = 1`. That is the part of the transfer that has to come from the start of the buffer.
5. Copy `second = 1` byte from `cb_data + 0` into `dst + 2`. That is C.

6. Advance `cb_head = (6 + 3) % 8 = 1`. Decrement `cb_used` by 3, leaving 1.

The caller's destination now holds A, B, C. The buffer state has D as its only live byte, with `head = 1` and `used = 1`. The next read will return D from position 1.

The same logic applies to `cbuf_write`, with `tail` taking the role of `head`. The function computes `tail = (head + used) % capacity`, then `first = MIN(n, capacity - tail)`, copies first bytes from `src` to `cb_data + tail`, then copies the remainder from `src + first` to `cb_data + 0`, and advances `cb_used` by the total written.

There is exactly one step in either function that wraps. Either the destination wraps (in a write) or the source wraps (in a read), but never both. This is the key property that makes the implementation manageable: the buffer's wrap is a property of the internal data, not of the caller's data, so the caller's source and destination are always treated as ordinary contiguous memory.

10.3.6 Avoiding Overwrites and Data Loss

A common beginner mistake is to make `cbuf_write` overwrite older data when the buffer fills, on the theory that “newer data is more important.” That is sometimes the right policy, as we noted in Section 1, but it must be a *deliberate* design choice and it must be visible to the caller, not a silent mutation of state. The conventional default is that `cbuf_write` returns the number of bytes it actually wrote, and the caller is expected to look at the return value.

The same goes for `cbuf_read`: when the buffer is empty, `cbuf_read` returns zero. The caller is expected to interpret zero as “no bytes available right now”, not as an error. Coupling that signal with the driver's `EAGAIN` or with a blocking sleep is the job of the I/O handler, not the buffer itself.

If you ever want a circular buffer with overwrite semantics (a `dmesg`-style log, for instance), the cleanest approach is to write a separate `cbuf_overwrite` function and leave `cbuf_write` strict. Two separate names mean two separate intentions, and a future reader of the code does not have to guess which behaviour is in effect.

10.3.7 Implementing It in Userland

The right way to learn this structure is to type it once in userland and run it through a few small tests, before you ask the kernel to trust it. The same source can then move into the kernel module almost unchanged, except for the allocation and free calls.

Below is the userland source. It lives in `examples/part-02/ch10-handling-io-efficiently/cbuf-userland/`.

`cbuf.h`:

```
/* cbuf.h: a fixed-size byte-oriented circular buffer. */
#ifndef CBUF_H
#define CBUF_H

#include <stddef.h>
```

```
struct cbuf {
    char    *cb_data;
    size_t   cb_size;
    size_t   cb_head;
    size_t   cb_used;
};

int         cbuf_init(struct cbuf *cb, size_t size);
void        cbuf_destroy(struct cbuf *cb);
void        cbuf_reset(struct cbuf *cb);

size_t      cbuf_size(const struct cbuf *cb);
size_t      cbuf_used(const struct cbuf *cb);
size_t      cbuf_free(const struct cbuf *cb);

size_t      cbuf_write(struct cbuf *cb, const void *src, size_t n);
size_t      cbuf_read(struct cbuf *cb, void *dst, size_t n);

#endif /* CBUF_H */
```

cbuf.c:

```
/* cbuf.c: userland implementation of the byte-oriented ring buffer. */
#include "cbuf.h"

#include <errno.h>
#include <stdlib.h>
#include <string.h>

#ifndef MIN
#define MIN(a, b) (((a) < (b)) ? (a) : (b))
#endif

int
cbuf_init(struct cbuf *cb, size_t size)
{
    if (cb == NULL || size == 0)
        return (EINVAL);
    cb->cb_data = malloc(size);
    if (cb->cb_data == NULL)
        return (ENOMEM);
    cb->cb_size = size;
    cb->cb_head = 0;
    cb->cb_used = 0;
}
```

```
        return (0);
    }

void
cbuf_destroy(struct cbuf *cb)
{
    if (cb == NULL)
        return;
    free(cb->cb_data);
    cb->cb_data = NULL;
    cb->cb_size = 0;
    cb->cb_head = 0;
    cb->cb_used = 0;
}

void
cbuf_reset(struct cbuf *cb)
{
    if (cb == NULL)
        return;
    cb->cb_head = 0;
    cb->cb_used = 0;
}

size_t
cbuf_size(const struct cbuf *cb)
{
    return (cb->cb_size);
}

size_t
cbuf_used(const struct cbuf *cb)
{
    return (cb->cb_used);
}

size_t
cbuf_free(const struct cbuf *cb)
{
    return (cb->cb_size - cb->cb_used);
}

size_t
cbuf_write(struct cbuf *cb, const void *src, size_t n)
```

```
{
    size_t avail, tail, first, second;

    avail = cbuf_free(cb);
    if (n > avail)
        n = avail;
    if (n == 0)
        return (0);

    tail = (cb->cb_head + cb->cb_used) % cb->cb_size;
    first = MIN(n, cb->cb_size - tail);
    memcpy(cb->cb_data + tail, src, first);
    second = n - first;
    if (second > 0)
        memcpy(cb->cb_data, (const char *)src + first, second);

    cb->cb_used += n;
    return (n);
}

size_t
cbuf_read(struct cbuf *cb, void *dst, size_t n)
{
    size_t first, second;

    if (n > cb->cb_used)
        n = cb->cb_used;
    if (n == 0)
        return (0);

    first = MIN(n, cb->cb_size - cb->cb_head);
    memcpy(dst, cb->cb_data + cb->cb_head, first);
    second = n - first;
    if (second > 0)
        memcpy((char *)dst + first, cb->cb_data, second);

    cb->cb_head = (cb->cb_head + n) % cb->cb_size;
    cb->cb_used -= n;
    return (n);
}
```

Two things in this code are worth noticing.

First, both `cbuf_write` and `cbuf_read` clamp `n` to the available space or live data *before* doing any copying. This is the key to the partial-transfer semantics: the function is happy to do less work than asked, and it tells the

caller exactly how much it did. There is no error path for “buffer is full”, because that is not an error.

Second, the second `> 0` guard around the second `memcpy` is not strictly necessary (`memcpy(dst, src, 0)` is well-defined and does nothing), but it makes the wrap-around reasoning visible at a glance. A future reader can tell that the second copy is conditional and that the wrap case is handled.

10.3.8 A Tiny Test Program

The companion `cb_test.c` exercises the structure with a small but meaningful set of cases. It is short enough to read in full:

```
/* cb_test.c: simple sanity tests for the cbuf userland implementation. */
#include "cbuf.h"

#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define CHECK(cond, msg) \
    do { if (!(cond)) { fprintf(stderr, "FAIL: %s\n", msg); exit(1); } } while (0)

static void
test_basic(void)
{
    struct cbuf cb;
    char in[8] = "ABCDEFGH";
    char out[8] = {0};
    size_t n;

    CHECK(cbuf_init(&cb, 8) == 0, "init");
    CHECK(cbuf_used(&cb) == 0, "init used");
    CHECK(cbuf_free(&cb) == 8, "init free");

    n = cbuf_write(&cb, in, 4);
    CHECK(n == 4, "write 4");
    CHECK(cbuf_used(&cb) == 4, "used after write 4");

    n = cbuf_read(&cb, out, 2);
    CHECK(n == 2, "read 2");
    CHECK(memcmp(out, "AB", 2) == 0, "AB content");
    CHECK(cbuf_used(&cb) == 2, "used after read 2");

    cbuf_destroy(&cb);
    printf("test_basic OK\n");
}
```

```
static void
test_wrap(void)
{
    struct cbuf cb;
    char in[8] = "ABCDEFGH";
    char out[8] = {0};
    size_t n;

    CHECK(cbuf_init(&cb, 8) == 0, "init");

    /* Push head forward by writing and reading 6 bytes. */
    n = cbuf_write(&cb, in, 6);
    CHECK(n == 6, "write 6");
    n = cbuf_read(&cb, out, 6);
    CHECK(n == 6, "read 6");

    /* Now write 6 more, which should wrap. */
    n = cbuf_write(&cb, in, 6);
    CHECK(n == 6, "write 6 after wrap");
    CHECK(cbuf_used(&cb) == 6, "used after wrap write");

    /* Read all of it back; should return ABCDEF. */
    memset(out, 0, sizeof(out));
    n = cbuf_read(&cb, out, 6);
    CHECK(n == 6, "read 6 after wrap");
    CHECK(memcmp(out, "ABCDEF", 6) == 0, "content after wrap");
    CHECK(cbuf_used(&cb) == 0, "empty after drain");

    cbuf_destroy(&cb);
    printf("test_wrap OK\n");
}

static void
test_partial(void)
{
    struct cbuf cb;
    char in[8] = "12345678";
    char out[8] = {0};
    size_t n;

    CHECK(cbuf_init(&cb, 4) == 0, "init small");

    n = cbuf_write(&cb, in, 8);
```

```
    CHECK(n == 4, "write clamps to free space");
    CHECK(cbuf_used(&cb) == 4, "buffer full");

    n = cbuf_read(&cb, out, 8);
    CHECK(n == 4, "read clamps to live data");
    CHECK(memcmp(out, "1234", 4) == 0, "content of partial");
    CHECK(cbuf_used(&cb) == 0, "buffer empty after partial drain");

    cbuf_destroy(&cb);
    printf("test_partial OK\n");
}

int
main(void)
{
    test_basic();
    test_wrap();
    test_partial();
    printf("all tests OK\n");
    return (0);
}
```

Compile and run with:

```
$ cc -Wall -Wextra -o cb_test cbuf.c cb_test.c
$ ./cb_test
test_basic OK
test_wrap OK
test_partial OK
all tests OK
```

The three tests cover the cases that matter: a basic write/read cycle, a write that wraps around the end of the buffer, and a partial transfer that hits the capacity boundary. They are not exhaustive, but they are enough to catch the most common implementation mistakes. The challenge exercises at the end of the chapter ask you to extend them.

10.3.9 Why Build It in Userland First

It might feel like a detour to write the buffer in userland when you know the driver is what matters. Three reasons make the detour worth it.

First, the kernel is a hostile place to debug. A bug in the kernel buffer can lock the machine, panic the kernel, or quietly corrupt unrelated state. A bug in the same code in userland is just a failed test that prints a friendly message.

Second, the kernel-side and userland-side implementations of this buffer are virtually identical. The only differences are the allocation primitive (`malloc(9)` with `M_DEVBUF` and `M_WAITOK | M_ZERO` versus `libc malloc(3)`) and the free primitive (`free(9)` versus `libc free(3)`). Once the userland version is correct, the kernel version is almost a copy-paste with a small adjustment.

Third, building the buffer once in isolation forces you to think about its API in calm conditions. By the time you are ready to splice it into the driver, you already know what `cbuf_write` returns, what `cbuf_read` returns, what `cbuf_used` means, and how wrap-around is supposed to work. None of that has to be relearned in the middle of a kernel session.

10.3.10 Things That Can Still Go Wrong

Even with the helpers above, there are a few mistakes worth flagging now so you do not make them in Section 3.

The first is **forgetting to clamp the request to the available space**. If `cbuf_write` is called with `n = 100` on a buffer with `free = 30`, the function returns 30, not 100. Callers must check the return value and act accordingly. The driver's `d_write` will translate this into a partial write by leaving `uio_resid` at the unconsumed amount. We will be very explicit about this in Section 4.

The second is **forgetting that `cbuf_used` and `cbuf_free` can change between two checks**. In single-threaded userland tests this is impossible. In the kernel, a different thread can modify the buffer between any two function calls if no lock is held. Section 3 holds the softc mutex around all buffer access; Section 7 explains why.

The third is **mixing up indices**. Some implementations track the tail explicitly and the count implicitly. Others do the reverse. Both work. Mixing the two on a single buffer does not. Pick one and stick with it. We pick “head and used”; the tail is always derived.

The fourth is **integer wrap of the indices themselves**. With `size_t` and a buffer that is a few thousand bytes, the indices can never exceed `cb_size`, and `(cb_head + n) % cb_size` is always well-defined. If you ever extend this code to a buffer larger than `SIZE_MAX / 2`, that is no longer true; you would need 64-bit indices and explicit modular arithmetic. For our pseudo-device with a 4 KB or 64 KB buffer, the basic structure is more than sufficient.

10.3.11 Wrapping Up Section 2

You now have a clean, tested, byte-oriented circular buffer. It clamps requests to the available space, reports the actual transfer size, and handles wrap-around in the only place where wrap-around is meaningful: inside the buffer itself. The userland tests give you a small piece of evidence that the implementation behaves the way the diagrams said it should.

Section 3 takes this code into the kernel. The shape stays almost identical; the allocation and synchronization change. By the end of the next section, your driver's `d_read` and `d_write` will be calling `cbuf_read` and `cbuf_write` instead of doing their own arithmetic, and the logic that used to live inline in `myfirst.c` will have a name.

10.4 Section 3: Integrating a Circular Buffer into Your Driver

The userland implementation of `cbuf` is the same code you are about to drop into the kernel. Almost. There are three small changes: the allocator, the deallocator, and a paranoia level that the kernel demands which userland does not. After the splice, the driver's read and write handlers shrink considerably, and the wrap-around arithmetic disappears from `myfirst.c` into the helpers where it belongs.

This section walks through the splice carefully. We will start with the kernel-side variant of the buffer, then move to the integration changes inside `myfirst.c`, and finally look at how to add a few `sysctl` knobs that make the driver's internal state visible while you are debugging.

10.4.1 Moving `cbuf` Into the Kernel

The kernel-side header `cbuf.h` is identical to the userland one:

```
#ifndef CBUF_H
#define CBUF_H

#include <sys/types.h>

struct cbuf {
    char    *cb_data;
    size_t   cb_size;
    size_t   cb_head;
    size_t   cb_used;
};

int    cbuf_init(struct cbuf *cb, size_t size);
void    cbuf_destroy(struct cbuf *cb);
void    cbuf_reset(struct cbuf *cb);

size_t   cbuf_size(const struct cbuf *cb);
size_t   cbuf_used(const struct cbuf *cb);
size_t   cbuf_free(const struct cbuf *cb);

size_t   cbuf_write(struct cbuf *cb, const void *src, size_t n);
size_t   cbuf_read(struct cbuf *cb, void *dst, size_t n);

#endif /* CBUF_H */
```

The kernel-side `cbuf.c` is almost a copy of the userland file with two replacements. `malloc(3)` becomes `malloc(9)` from `M_DEVBUF` with the `M_WAITOK | M_ZERO` flags. `free(3)` becomes `free(9)` from `M_DEVBUF`. The `memcpy(3)` calls remain valid in kernel context: the kernel has its own `memcpy` and `bcopy` symbols. Here is the full kernel version:

```
#include <sys/param.h>
#include <sys/kernel.h>
#include <sys/system.h>
#include <sys/malloc.h>

#include "cbuf.h"

MALLOC_DEFINE(M_CBUF, "cbuf", "Chapter 10 circular buffer");

int
cbuf_init(struct cbuf *cb, size_t size)
{
    if (cb == NULL || size == 0)
        return (EINVAL);
    cb->cb_data = malloc(size, M_CBUF, M_WAITOK | M_ZERO);
    cb->cb_size = size;
    cb->cb_head = 0;
    cb->cb_used = 0;
    return (0);
}

void
cbuf_destroy(struct cbuf *cb)
{
    if (cb == NULL || cb->cb_data == NULL)
        return;
    free(cb->cb_data, M_CBUF);
    cb->cb_data = NULL;
    cb->cb_size = 0;
    cb->cb_head = 0;
    cb->cb_used = 0;
}

void
cbuf_reset(struct cbuf *cb)
{
    if (cb == NULL)
        return;
    cb->cb_head = 0;
    cb->cb_used = 0;
}

size_t
cbuf_size(const struct cbuf *cb)
```

```
{
    return (cb->cb_size);
}

size_t
cbuf_used(const struct cbuf *cb)
{
    return (cb->cb_used);
}

size_t
cbuf_free(const struct cbuf *cb)
{
    return (cb->cb_size - cb->cb_used);
}

size_t
cbuf_write(struct cbuf *cb, const void *src, size_t n)
{
    size_t avail, tail, first, second;

    avail = cbuf_free(cb);
    if (n > avail)
        n = avail;
    if (n == 0)
        return (0);

    tail = (cb->cb_head + cb->cb_used) % cb->cb_size;
    first = MIN(n, cb->cb_size - tail);
    memcpy(cb->cb_data + tail, src, first);
    second = n - first;
    if (second > 0)
        memcpy(cb->cb_data, (const char *)src + first, second);

    cb->cb_used += n;
    return (n);
}

size_t
cbuf_read(struct cbuf *cb, void *dst, size_t n)
{
    size_t first, second;

    if (n > cb->cb_used)
```

```

        n = cb->cb_used;
    if (n == 0)
        return (0);

    first = MIN(n, cb->cb_size - cb->cb_head);
    memcpy(dst, cb->cb_data + cb->cb_head, first);
    second = n - first;
    if (second > 0)
        memcpy((char *)dst + first, cb->cb_data, second);

    cb->cb_head = (cb->cb_head + n) % cb->cb_size;
    cb->cb_used -= n;
    return (n);
}

```

Three points are worth a short comment.

The first is `MALLOC_DEFINE(M_CBUF, "cbuf", ...)`. This declares a private memory tag for the buffer's allocations so that `vmstat -m` can show how much memory the `cbuf` code is using, separately from the rest of the driver. We declare it once, in `cbuf.c`, with internal linkage to the rest of the module. The driver's `softc` still uses `M_DEVBUF`. The two tags can coexist; they are bookkeeping labels, not pools.

The second is the `M_WAITOK` flag. Because we never call `cbuf_init` from interrupt context (we call it from `myfirst_attach`, which runs in normal kernel thread context during module load), it is safe to wait for memory if the system is briefly low. With `M_WAITOK`, `malloc(9)` will not return `NULL`; if the allocation cannot proceed it will sleep until it can. We therefore do not need to test the result for `NULL`. If we ever want to call `cbuf_init` from a context where sleep is forbidden, we would need to switch to `M_NOWAIT` and handle a possible `NULL`. For Chapter 10's purposes, `M_WAITOK` is the right choice.

The third is that **the kernel `cbuf` does not lock**. It is a pure data structure. The locking strategy is the *caller's* responsibility. Inside `myfirst.c`, we will hold `sc->mtx` across every call into `cbuf`. That keeps the abstraction small and gives Chapter 11 a clean refactor target.

10.4.2 What Changes in `myfirst.c`

Bring up the Stage 3 file from Chapter 9 in your editor. The integration involves the following changes:

1. Replace the four buffer-related `softc` fields (`buf`, `buflen`, `bufhead`, `bufused`) with a single struct `cbuf` cb member.
2. Remove the `MYFIRST_BUFSIZE` macro from `myfirst.c` (we keep it but in a single header to avoid duplication).
3. Initialise the buffer in `myfirst_attach` with `cbuf_init`.
4. Tear it down in `myfirst_detach` and on the attach failure path with `cbuf_destroy`.
5. Rewrite `myfirst_read` to call `cbuf_read` against a stack-resident bounce buffer, then `uiomove` the bounce buffer out.
6. Rewrite `myfirst_write` to `uiomove` into a stack-resident bounce buffer and then `cbuf_write` into the ring.

The last two changes deserve a short discussion before we look at the code. Why a bounce buffer? Why not call `uiomove` directly against the `cbuf` storage?

The answer is that `uiomove` does not understand wrap-around. It expects a contiguous destination (for reads) or a contiguous source (for writes). If the live region of our circular buffer wraps, calling `uiomove(cb->cb_data + cb->cb_head, n, uio)` would copy past the end of the underlying memory and into whatever is allocated next. That is a heap corruption bug waiting to happen. Two safe shapes exist; you can pick either.

The first safe shape is to call `uiomove` *twice*, once for each side of the wrap. The driver computes the contiguous chunk available at `cb->cb_data + cb->cb_head`, calls `uiomove` for that chunk, and then calls `uiomove` again for the wrapped portion at `cb->cb_data + 0`. This is efficient because there is no extra copy. It is also more complex and harder to get right; the driver has to do partial accounting of `uio_resid` between the two `uiomove` calls, and any cancellation in the middle (signal, page fault) leaves the buffer in a partially drained state.

The second safe shape is to use a kernel-side **bounce buffer**: a small temporary on the stack that lives only for the duration of the I/O call. The driver reads bytes out of the `cbuf` into the bounce buffer with `cbuf_read`, then `uiomoves` the bounce buffer into user space. On the write side, it `uiomoves` from user space into the bounce buffer, then `cbuf_writes` the bounce buffer into the `cbuf`. The cost is one extra in-kernel copy per chunk; the benefit is simplicity, locality of error handling, and the ability to do all wrap-aware logic inside the `cbuf` where it belongs.

The bounce buffer approach is what we will use in this chapter. It is the same approach that drivers like `evdev/cdev.c` use (with `bcopy` between the per-client ring and a stack-resident event structure, before `uiomove`-ing the structure to user space). The stack-resident bounce is small (256 or 512 bytes is plenty), the loop runs as many times as the user's transfer size demands, and each iteration is independently restartable if `uiomove` fails. The performance cost is negligible for everything except very-high-throughput hardware drivers, and even there the trade-off is usually worth it for the readability gain.

10.4.3 The Stage 2 Driver: Handlers Refactored

Here is what the relevant pieces of the driver look like after the splice. The full source is in `examples/part-02/ch10-handling-io-efficiently/stage2-circular/myfirst.c`. We will show the I/O handlers inline, then walk through what changed.

```
#define MYFIRST_BUFSIZE      4096
#define MYFIRST_BOUNCE      256

struct myfirst_softc {
    device_t      dev;
    int           unit;

    struct mtx     mtx;

    uint64_t      attach_ticks;
    uint64_t      open_count;
    uint64_t      bytes_read;
    uint64_t      bytes_written;
```

```
int                active_fhs;
int                is_attached;

struct cbuf        cb;

struct cdev        *cdev;
struct cdev        *cdev_alias;

struct sysctl_ctx_list sysctl_ctx;
struct sysctl_oid   *sysctl_tree;
};

static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t take, got;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    while (uio->uio_resid > 0) {
        mtx_lock(&sc->mtx);
        take = MIN((size_t)uio->uio_resid, sizeof(bounce));
        got = cbuf_read(&sc->cb, bounce, take);
        if (got == 0) {
            mtx_unlock(&sc->mtx);
            break;          /* empty: short read or EOF */
        }
        sc->bytes_read += got;
        fh->reads += got;
        mtx_unlock(&sc->mtx);

        error = uiomove(bounce, got, uio);
        if (error != 0)
            return (error);
    }
}
```

```
        return (0);
    }

static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t want, put, room;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    while (uio->uio_resid > 0) {
        mtx_lock(&sc->mtx);
        room = cbuf_free(&sc->cb);
        mtx_unlock(&sc->mtx);
        if (room == 0)
            break;          /* full: short write */

        want = MIN((size_t)uio->uio_resid, sizeof(bounce));
        want = MIN(want, room);
        error = uiomove(bounce, want, uio);
        if (error != 0)
            return (error);

        mtx_lock(&sc->mtx);
        put = cbuf_write(&sc->cb, bounce, want);
        sc->bytes_written += put;
        fh->writes += put;
        mtx_unlock(&sc->mtx);

        /*
         * cbuf_write may store less than 'want' if another
         * writer slipped in between our snapshot of 'room'
         * and our cbuf_write call and consumed some of the
         * space we had sized ourselves against. With a single
         * writer that cannot happen and put == want always.
         * We still handle it defensively: a serious driver

```

```

        * would reserve space up front to avoid losing bytes,
        * and Chapter 11 will revisit this with proper
        * multi-writer synchronization.
        */
    if (put < want) {
        /*
         * The 'want - put' bytes we copied into 'bounce'
         * with uiomove have already left the caller's
         * uio and cannot be pushed back. Record the
         * loss by breaking out of the loop; the kernel
         * will report the bytes actually stored via
         * uio_resid. This path is only reachable under
         * concurrent writers, which the design here
         * does not yet handle.
         */
        break;
    }
    return (0);
}

```

A few things changed from Stage 3 of Chapter 9.

The first change is the **loop**. Both handlers now loop until `uio_resid` reaches zero or until the buffer cannot satisfy the next iteration. Each iteration moves at most `sizeof(bounce)` bytes, which is the size of the stack bounce. For a small request, the loop runs once. For a large request, it runs as many times as needed. This is what makes partial I/O work cleanly: the handlers naturally produce a short read or write when the buffer reaches a boundary.

The second change is that **all buffer access is bracketed by `mtx_lock/mtx_unlock`**. The `cbuf` data structure is unaware of locking; the driver provides it. We hold the lock around every `cbuf_*` call and around every update of the byte counters. We do *not* hold the lock across `uiomove(9)`. Holding a mutex across `uiomove` is a real bug in FreeBSD: `uiomove` may sleep on a page fault, and sleeping with a mutex held is a sleep-with-mutex panic. The Chapter 9 walkthrough discussed this; we are now operationalising the rule by separating the `cbuf` access (under lock) from the `uiomove` (without lock).

The third change is that the **read handler returns 0** when the buffer is empty, after possibly having transferred some bytes. The old Stage 3 behaviour was identical at this layer. What changes is that the *next* section makes it possible for the read to block instead, and the section after that adds an `EAGAIN` path for non-blocking callers. The structure here is the foundation for both extensions.

The fourth change is that the **write handler honours partial writes**. When `cbuf_free(&sc->cb)` returns zero, the loop exits and the handler returns 0 with `uio_resid` reflecting the bytes that were not consumed. The user-space `write(2)` call will see a short write count, which is the conventional UNIX way to say “I accepted this many of your bytes; please call me again with the rest later.” Section 4 talks at length about why this matters and how to write user code that handles it.

10.4.4 Updating attach and detach

The lifecycle changes are small but real:

```
static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc;
    struct make_dev_args args;
    int error;

    sc = device_get_softc(dev);
    sc->dev = dev;
    sc->unit = device_get_unit(dev);

    mtx_init(&sc->mtx, device_get_nameunit(dev), "myfirst", MTX_DEF);

    sc->attach_ticks = ticks;
    sc->is_attached = 1;
    sc->active_fhs = 0;
    sc->open_count = 0;
    sc->bytes_read = 0;
    sc->bytes_written = 0;

    error = cbuf_init(&sc->cb, MYFIRST_BUFSIZE);
    if (error != 0)
        goto fail_mtx;

    make_dev_args_init(&args);
    args.mda_devsw = &myfirst_cdevsw;
    args.mda_uid = UID_ROOT;
    args.mda_gid = GID_OPERATOR;
    args.mda_mode = 0660;
    args.mda_si_drv1 = sc;

    error = make_dev_s(&args, &sc->cdev, "myfirst/%d", sc->unit);
    if (error != 0)
        goto fail_cb;

    sc->cdev_alias = make_dev_alias(sc->cdev, "myfirst");
    if (sc->cdev_alias == NULL)
        device_printf(dev, "failed to create /dev/myfirst alias\n");

    sysctl_ctx_init(&sc->sysctl_ctx);
    sc->sysctl_tree = SYSCTL_ADD_NODE(&sc->sysctl_ctx,
```

```

        SYSCTL_CHILDREN(device_get_sysctl_tree(dev)),
        OID_AUTO, "stats", CTLFLAG_RD | CTLFLAG_MPSAFE, 0,
        "Driver statistics");

SYSCTL_ADD_U64(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "attach_ticks", CTLFLAG_RD,
        &sc->attach_ticks, 0, "Tick count when driver attached");
SYSCTL_ADD_U64(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "open_count", CTLFLAG_RD,
        &sc->open_count, 0, "Lifetime number of opens");
SYSCTL_ADD_INT(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "active_fhs", CTLFLAG_RD,
        &sc->active_fhs, 0, "Currently open descriptors");
SYSCTL_ADD_U64(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "bytes_read", CTLFLAG_RD,
        &sc->bytes_read, 0, "Total bytes drained from the FIFO");
SYSCTL_ADD_U64(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "bytes_written", CTLFLAG_RD,
        &sc->bytes_written, 0, "Total bytes appended to the FIFO");
SYSCTL_ADD_PROC(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "cb_used",
        CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE,
        sc, 0, myfirst_sysctl_cb_used, "IU",
        "Live bytes currently held in the circular buffer");
SYSCTL_ADD_PROC(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "cb_free",
        CTLTYPE_UINT | CTLFLAG_RD | CTLFLAG_MPSAFE,
        sc, 0, myfirst_sysctl_cb_free, "IU",
        "Free bytes available in the circular buffer");
SYSCTL_ADD_UINT(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
        OID_AUTO, "cb_size", CTLFLAG_RD,
        (unsigned int *)&sc->cb.cb_size, 0,
        "Capacity of the circular buffer");

device_printf(dev,
        "Attached; node /dev/%s (alias /dev/myfirst), cbuf=%zu bytes\n",
        devtoname(sc->cdev), cbuf_size(&sc->cb));
return (0);

fail_cb:
    cbuf_destroy(&sc->cb);
fail_mtx:
    mtx_destroy(&sc->mtx);
    sc->is_attached = 0;

```

```
        return (error);
    }

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc;

    sc = device_get_softc(dev);

    mtx_lock(&sc->mtx);
    if (sc->active_fhs > 0) {
        mtx_unlock(&sc->mtx);
        device_printf(dev,
            "Cannot detach: %d open descriptor(s)\n",
            sc->active_fhs);
        return (EBUSY);
    }
    mtx_unlock(&sc->mtx);

    if (sc->cdev_alias != NULL) {
        destroy_dev(sc->cdev_alias);
        sc->cdev_alias = NULL;
    }
    if (sc->cdev != NULL) {
        destroy_dev(sc->cdev);
        sc->cdev = NULL;
    }
    sysctl_ctx_free(&sc->sysctl_ctx);
    cbuf_destroy(&sc->cb);
    mtx_destroy(&sc->mtx);
    sc->is_attached = 0;
    return (0);
}
```

The two new sysctl handlers are short:

```
static int
myfirst_sysctl_cb_used(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int val;

    mtx_lock(&sc->mtx);
```

```

        val = (unsigned int)cbuf_used(&sc->cb);
        mtx_unlock(&sc->mtx);
        return (sysctl_handle_int(oidp, &val, 0, req));
    }

static int
myfirst_sysctl_cb_free(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    unsigned int val;

    mtx_lock(&sc->mtx);
    val = (unsigned int)cbuf_free(&sc->cb);
    mtx_unlock(&sc->mtx);
    return (sysctl_handle_int(oidp, &val, 0, req));
}

```

The handlers exist because we want a *consistent* snapshot of the buffer state when the user reads `sysctl dev.myfirst.0.stats.cb_used`. Reading the field directly (the way Stage 3 did with `bufused`) is racy: a concurrent write could be modifying it as `sysctl(8)` reads it, producing a torn value. The handler holds the mutex around the read, so the value the user sees is at least *self-consistent* (it represents the buffer state at one moment in time, not a half-update). The buffer can change immediately after the handler releases the lock, of course; that is fine, because by the time `sysctl(8)` formats and prints the number, the buffer has often changed anyway. What we are preventing is a read of a partially modified field, not a stale read.

10.4.5 Logging Buffer State for Debugging

When the driver misbehaves, the first question is almost always “what was the buffer doing?” Adding a small amount of `device_printf` traffic to the I/O handlers, behind a `sysctl`-controlled debug flag, makes this question easy to answer. Here is the pattern:

```

static int myfirst_debug = 0;
SYSCTL_INT(_dev_myfirst, OID_AUTO, debug, CTLFLAG_RW,
    &myfirst_debug, 0, "Verbose I/O tracing for the myfirst driver");

#define MYFIRST_DBG(sc, fmt, ...) do { \
    if (myfirst_debug) \
        device_printf((sc)->dev, fmt, ##__VA_ARGS__); \
} while (0)

```

Then in the I/O handlers, call `MYFIRST_DBG(sc, "read got=%zu used=%zu free=%zu\n", got, cbuf_used(&sc->cb), cbuf_free(&sc->cb))`; after a successful `cbuf_read`. With `myfirst_debug` set to 0, the macro reduces to a no-op and the production path is untouched. With `sysctl dev.myfirst.debug=1`,

every transfer prints a one-line trace into `dmesg`, which is invaluable when the driver is doing something you do not understand.

Be polite about how much trace you emit. A single log line per transfer is fine. A log line per byte transferred would melt `dmesg`'s ring buffer in seconds and would change the timing of the driver enough to hide some bugs. The pattern above logs once per `cbuf_read` or `cbuf_write` call, which is once per loop iteration, which is once per chunk of up to 256 bytes. That is roughly the right granularity.

Finally, remember to set `myfirst_debug = 0` before you load the driver in production. The line is there as a development aid, not as a permanent feature.

10.4.6 Why the `cbuf` Has Its Own Memory Tag

When you run `vmstat -m` on a FreeBSD system, you see a long list of memory tags and how much memory each one currently holds. Tags are an essential observability tool: if memory is leaking somewhere in the kernel, the tag whose count keeps growing tells you where to look. We gave `cbuf` its own tag (`M_CBUF`) so that its allocations are visible separately from the rest of the driver's allocations.

To see the effect, load the Stage 2 driver and run:

```
$ vmstat -m | head -1
      Type InUse MemUse Requests  Size(s)
$ vmstat -m | grep -E '(\s+Type|cbuf|myfirst)'
      Type InUse MemUse Requests  Size(s)
      cbuf      1      4K          1  4096
```

The four kilobytes correspond to the single 4 KB allocation `cbuf_init` made for `sc->cb.cb_data`. Unload the driver and the count drops back to zero. If at any point the count ever rises *without* a corresponding driver attach, you have a leak in `cbuf_init` or `cbuf_destroy`. This is the kind of regression that would otherwise be invisible until the system ran out of memory hours later.

10.4.7 A Quick Trace of an Aligned and a Wrapped Transfer

To make the wrap-around behaviour real, let us trace two writes through the Stage 2 driver. Assume the buffer is empty at the start, capacity is 4096, and a user calls `write(fd, buf, 100)` followed later by `write(fd, buf2, 100)`.

The first write goes through `myfirst_write`:

1. `uio_resid = 100, cbuf_free = 4096, room = 4096`.
2. Loop iteration 1: `want = MIN(100, 256, 4096) = 100`. `uiomove` copies 100 bytes from user space into bounce. `cbuf_write(&sc->cb, bounce, 100)` returns 100, advances `cb_used` to 100, leaves `cb_head = 0`. The implicit tail is now 100.
3. `uio_resid = 0`. The loop exits. The handler returns 0. The user sees a write count of 100.

The buffer state is: `cb_data[0..99]` holds the data, `cb_head = 0, cb_used = 100, cb_size = 4096`.

Now the second write arrives. Before it does, suppose a reader has consumed 80 bytes, leaving `cb_head = 80, cb_used = 20`. The implicit tail is at position 100. `myfirst_write` runs:

1. `uio_resid = 100, cbuf_free = 4076, room = 4076.`
2. Loop iteration 1: `want = MIN(100, 256, 4076) = 100.` `uiomove` copies 100 bytes from user space into bounce. `cbuf_write(&sc->cb, bounce, 100)` advances the implicit tail from 100 to 200, sets `cb_used = 120`, returns 100.
3. `uio_resid = 0.` The handler returns 0. The user sees a write count of 100.

Both transfers were “aligned” in the sense that neither crossed the end of the underlying buffer. Now imagine a much later state where `cb_head = 4000` and `cb_used = 80`. The live bytes occupy positions 4000..4079, and the implicit tail is 4080. Capacity is 4096. The free space is 4016 bytes, but it splits across the wrap: 16 bytes contiguous after position 4080, then 4000 contiguous from position 0.

A user calls `write(fd, buf, 64)`:

1. `uio_resid = 64, cbuf_free = 4016, room = 4016.`
2. Loop iteration 1: `want = MIN(64, 256, 4016) = 64.` `uiomove` copies 64 bytes into bounce. `cbuf_write(&sc->cb, bounce, 64)` runs:
 - `tail = (4000 + 80) % 4096 = 4080.`
 - `first = MIN(64, 4096 - 4080) = 16.` Copies 16 bytes from bounce + 0 to `cb_data + 4080`.
 - `second = 64 - 16 = 48.` Copies 48 bytes from bounce + 16 to `cb_data + 0`.
 - `cb_used += 64`, becoming 144.
3. `uio_resid = 0.` Handler returns 0.

The wrap was handled inside `cbuf_write` and was invisible to the driver. That is the whole point of putting the abstraction in its own file. The `myfirst.c` source has no wrap-around arithmetic; the wrap-around lives in `cbuf.c` where it can be tested in isolation.

10.4.8 What the User Sees

After the splice, a user-space program cannot tell what shape the buffer is. `cat /dev/myfirst` still prints whatever has been written, in order. `echo hello > /dev/myfirst` still stores `hello` for later reading. The byte counters in `sysctl dev.myfirst.0.stats` still tick up by one for each byte. The new `cb_used` and `cb_free` `sysctls` expose the buffer’s state, but the data path is byte-for-byte identical to Stage 3 of Chapter 9.

What differs is what happens *under load*. With the linear FIFO, a sustained writer eventually saw `ENOSPC` even when a reader was actively consuming bytes, because `bufhead` only collapsed back to zero when `bufused` reached zero. With the circular buffer, the writer keeps going indefinitely as long as the reader keeps up, because the free space and live bytes can occupy any combination of positions inside the underlying memory. The buffer’s full capacity is now actually usable.

You will be able to see this difference clearly in Section 6 when we run `dd` against the new driver and compare the throughput numbers to Stage 3 of Chapter 9. For now, take it on faith and finish the splice.

10.4.9 Handling Detach with Live Data

There is one detach-time subtlety worth addressing. With the circular buffer integrated, the buffer may hold data when the user runs `kldunload myfirst`. The Chapter 9 detach refused to unload while any descriptor was

open; that check still applies. It does not, however, refuse to unload if the buffer is non-empty but no descriptor is open. Should it?

The conventional answer is no. A buffer is a transient resource. If no one is currently reading the device, the bytes in the buffer are not going to be read; the user has implicitly accepted their loss by closing all descriptors. The detach path simply frees the buffer along with everything else. If you wanted to preserve the bytes across an unload (to a file, for instance), that would be a feature, not a bug fix, and it would belong in user space, not in the driver.

We therefore make no change to the detach lifecycle. `cbuf_destroy` is called unconditionally; the bytes are released along with the backing memory.

10.4.10 Wrapping Up Section 3

The driver now uses a real circular buffer. The wrap-around logic lives in a small abstraction that has its own header, its own source file, its own memory tag, and its own userland test program. The I/O handlers in `myfirst.c` are simpler than they were in Stage 3 of Chapter 9, and the tricky arithmetic is no longer scattered across them.

What you have at this point still does not handle partial reads and writes elegantly. If a user calls `read(fd, buf, 4096)` and the buffer holds 100 bytes, the loop will execute exactly once, transfer 100 bytes, and return zero with `uio_resid` reflecting the unconsumed portion. That is the correct behaviour, but the *prose* around what the user should expect, what `read(2)` returns, and how a well-written caller loops is what Section 4 is about. We will also resolve the question of what `d_read` should do when the buffer is empty and the caller is willing to wait, which is the door into non-blocking I/O in Section 5.

10.5 Section 4: Improving the Driver's Behaviour with Partial Reads and Writes

The Stage 2 driver from the previous section already implements partial reads and writes correctly, almost by accident. The loops in `myfirst_read` and `myfirst_write` exit when the circular buffer can no longer satisfy the next iteration, leaving `uio->uio_resid` at whatever portion of the request remains unconsumed. The kernel computes the user-visible byte count as the original request size minus that residual. Both `read(2)` and `write(2)` then return that number to user space.

What we have not done is *think clearly* about what those partial transfers mean from both sides of the trust boundary. This section does that thinking. By the end of it, you will know which user-space programs handle short reads and writes correctly, which ones do not, what your driver should report when nothing at all is available, and what the rare zero-byte transfer means.

10.5.1 What “Partial” Means in UNIX

A `read(2)` returns one of three things:

- A *positive integer* less than or equal to the requested count: that many bytes were placed in the caller's buffer.

- *Zero*: end of file. No more bytes will ever be produced on this descriptor; the caller should close.
- *-1*: an error occurred; the caller examines `errno` to decide what to do.

The first case is where partial transfers live. A “full” read returns exactly the requested count. A “partial” read returns fewer bytes. UNIX has always allowed partial reads, and any program that calls `read(2)` and assumes it got the full requested count is wrong. Robust programs always look at the return value and either loop until they have what they need, or accept the partial result and move on.

`write(2)` follows the same shape:

- A *positive integer* less than or equal to the requested count: that many bytes were accepted by the kernel.
- Sometimes *zero* (rarely seen in practice; usually treated as a short write of zero bytes).
- *-1*: an error occurred.

A short write means “I took this many of your bytes; please call me again with the remaining tail.” Robust producers always loop until they have offered the entire payload.

10.5.2 Why Drivers Should Embrace Partial Transfers

It would be tempting to make a driver always satisfy the entire request, even if it has to internally loop or wait. Some drivers do this in special cases (consider the `null` driver’s read, which loops internally to deliver `ZERO_REGION_SIZE`-byte chunks until the caller’s request is exhausted). For most drivers, however, embracing partial transfers is the right design choice for several reasons.

The first reason is **responsiveness**. A reader that asks for 4096 bytes and gets back 100 bytes has 100 bytes of work it can begin doing right now, instead of waiting for another 3996 bytes that may never arrive. The kernel does not have to guess how long the caller is willing to wait.

The second reason is **fairness**. If `myfirst_read` loops internally until it satisfies the entire request, a single greedy reader can hold the buffer’s mutex for an indefinite time, starving every other thread that wants to access the driver. A handler that returns as soon as it cannot make progress lets the kernel scheduler preserve fairness across competing threads.

The third reason is **correctness in the face of signals**. A reader that has been waiting may receive a signal (e.g. `SIGINT` from the user pressing Ctrl-C). The kernel needs the chance to deliver that signal, which usually means returning from the current syscall. A handler that loops indefinitely never gives the kernel that chance, and the user’s `kill -INT` is delayed or lost.

The fourth reason is **composition with `select(2)` / `poll(2)`**. Programs that use these readiness primitives are explicitly assuming partial-transfer semantics. They expect to be told “data is ready” and then to loop on `read(2)` until the descriptor returns zero or `EAGAIN`. A driver that always returns the full requested count breaks the polling model.

For all of these reasons, the `myfirst` driver’s loops in Section 3 are designed to make a single pass through the buffer’s available data, transfer what they can, and return. The next time the caller wants more, it calls `read(2)` again. This is the conventional UNIX shape.

10.5.3 Reporting Accurate Byte Counts

The mechanism by which the driver reports a partial transfer is `uio->uio_resid`. The kernel sets it to the requested count before calling `d_read` or `d_write`. The handler is responsible for decrementing it as it transfers bytes. `uiomove(9)` decrements it automatically. When the handler returns, the kernel calculates the byte count as `original_resid - uio->uio_resid` and returns that to user space.

This means the handler must do exactly two things consistently:

1. Use `uiomove(9)` (or one of its companions, `uiomove_frombuf(9)`, `uiomove_nofault(9)`) to do every byte movement that crosses the trust boundary. This is what keeps `uio_resid` honest.
2. Return zero when it has done as much as it can, regardless of whether `uio_resid` is now zero or some positive number.

A handler that returns a *positive* byte count is wrong. The kernel ignores positive returns; the byte count is computed from `uio_resid`. Returning a positive integer would be silently wasteful. A handler that returns a *negative* number, or any value that is not in `errno.h`, is undefined behaviour.

A common and dangerous variant of this mistake is returning `EAGAIN` when the buffer is empty *and* having transferred some bytes earlier in the same call. The user-space `read(2)` would see `-1/EAGAIN`, and the bytes that were in the user buffer would silently be considered uninvolved. The right pattern is: if the handler has transferred any bytes at all, it returns 0 and lets the partial count speak for itself; only if it has transferred *zero* bytes can it return `EAGAIN`. Section 5 will codify this rule when we add non-blocking support.

10.5.4 End-of-Data: When Should `d_read` Return Zero?

UNIX's "zero means EOF" rule has an interesting consequence for pseudo-devices. A regular file has a definite end: when `read(2)` reaches it, the kernel returns zero. A character device usually does not have a definite end. A serial line, a keyboard, a network device, a tape rewinding past the end of the medium: each of these *might* return zero in special cases, but in normal operation, "no data available right now" is not the same as "no data ever again."

Yet a naive `myfirst_read` that returns zero whenever the buffer is empty looks indistinguishable, from the caller's point of view, from a regular file at end-of-file. A `cat /dev/myfirst` will see zero bytes, treat it as EOF, and exit. That is not what we want. We want the reader to wait until more bytes arrive, or to be told "there are no bytes right now, but try again later" depending on the file descriptor's mode.

Two strategies are common.

The first strategy is **block by default**. `myfirst_read` waits on a sleep queue when the buffer is empty, and the writer wakes the queue when it adds bytes. Reading returns zero only if some condition signals true end-of-file (the device has been removed, the writer has explicitly closed). This is what most pseudo-devices and most TTY-style devices do. It matches `cat`'s expectation that a terminal will deliver lines as the user types them.

The second strategy is **immediate return with `EAGAIN` for non-blocking callers**. If the descriptor was opened with `O_NONBLOCK` (or the user later set the flag with `fcntl(2)`), `myfirst_read` returns `-1/EAGAIN` instead of blocking. This lets event-loop programs use `select(2)`, `poll(2)`, or `kqueue(2)` to multiplex many descriptors without committing to wait on any single one.

Section 5 will implement both strategies. The blocking path is the default; the non-blocking path activates when `IO_NDELAY` is set in `ioflag`. For now, in Stage 2, the driver still returns zero on empty, the same as Chapter 9 did. That is a temporary state; nothing in user space stays stable when the data path can vanish at any moment.

10.5.5 Backpressure on the Write Side

The mirror of “no data right now” is “no room right now.” When the buffer is full and a writer asks to add more bytes, the driver has to choose what to say.

The Stage 3 driver of Chapter 9 returned `ENOSPC`, which is the conventional signal for “the device has run out of space, permanently.” That was a defensible choice in Chapter 9 because the linear FIFO genuinely could not accept more data until the buffer fully drained. With the circular buffer, however, “full” is a transient state: the writer just needs to wait until a reader has consumed something. The right return is therefore *not* `ENOSPC` in the steady state; it is either a blocking sleep until space appears, or `EAGAIN` for non-blocking callers.

The Stage 2 implementation already handles the partial-write case correctly: when the buffer fills mid-transfer, the loop exits and the user sees a write count smaller than the request. What it does *not* do yet is the right thing when the buffer is full *at the start* of the call: it returns 0 with no bytes transferred, which the kernel turns into a `write(2)` return of zero. A return of zero from `write(2)` is technically legal but is an odd thing to see, and most user programs will treat it as an error or loop forever waiting for it to become non-zero.

The conventional fix, again, is mode-dependent. A blocking writer should sleep until space is available; a non-blocking writer should receive `EAGAIN`. We will implement both in Section 5. The structure of the Stage 2 loop is already correct for both cases; what is missing is the choice about what to do when *no* progress was made on the first iteration.

10.5.6 Zero-Length Reads and Writes

A zero-length read or write is a perfectly legal call. `read(fd, buf, 0)` and `write(fd, buf, 0)` are valid syscalls; they exist explicitly so that programs can validate a file descriptor without committing to a transfer. The kernel passes them down to the driver with `uio->uio_resid == 0`.

Your handler must not panic, error, or loop in this case. The Stage 2 driver naturally does the right thing: the `while (uio->uio_resid > 0)` loop never executes, and the handler returns 0 with `uio_resid` still 0. The user sees `read(2)` or `write(2)` return zero. Programs that call zero-length I/O for descriptor validation get the result they expect.

Be cautious about adding “is the request empty?” early returns at the start of your handler. They look like a small optimization but they introduce branching that is easy to get wrong. The Chapter 9 cheat sheet’s rule applies: `if (uio->uio_resid == 0) return (EINVAL);` is a bug.

10.5.7 A User-Space Walk Through the Loop

Watching what a user program does with a partial transfer is the best way to internalise the contract. Here is a small reader written in idiomatic UNIX style:

```
static int
read_all(int fd, void *buf, size_t want)
{
    char *p = buf;
    size_t left = want;
    ssize_t n;

    while (left > 0) {
        n = read(fd, p, left);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            return (-1);
        }
        if (n == 0)
            break;          /* EOF */
        p += n;
        left -= n;
    }
    return (int)(want - left);
}
```

read_all keeps calling read(2) until either it has all want bytes, or it sees end-of-file, or it sees a real error. Short reads are absorbed transparently. A EINTR from a signal causes a retry. The function returns the actual number of bytes obtained.

A correctly written write_all is the mirror image:

```
static int
write_all(int fd, const void *buf, size_t have)
{
    const char *p = buf;
    size_t left = have;
    ssize_t n;

    while (left > 0) {
        n = write(fd, p, left);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            return (-1);
        }
        if (n == 0)
            break;          /* unexpected; treat as error */
        p += n;
    }
}
```

```
        left -= n;
    }
    return (int)(have - left);
}
```

`write_all` calls `write(2)` repeatedly until the whole payload has been accepted by the kernel. Short writes are absorbed transparently. A `EINTR` causes a retry. The function returns the number of bytes accepted.

Both helpers belong in the same file (or a shared utility header) because they are nearly always used together. They are short, robust, and they make user-space code that talks to your driver behave correctly even when the driver is doing partial transfers. We will use both in the test programs you build in Section 6.

10.5.8 What `cat`, `dd`, and Friends Actually Do

The base-system tools you have been using to test the driver each handle short reads and writes differently. It is worth knowing what each does, so that you can interpret what you see.

`cat(1)` reads with a buffer of `MAXBSIZE` (16 KB on FreeBSD 14.3) and writes whatever it gets in a loop. Short reads from the source descriptor are absorbed; `cat` simply makes another `read(2)` call. Short writes to the destination descriptor are also absorbed; `cat` writes the unconsumed tail in a follow-up call. As far as `cat` is concerned, the size of the transfers does not matter; it just keeps moving bytes until it sees end-of-file on the source.

`dd(1)` is more rigid. It reads in blocks of `bs=` bytes (default 512) and writes whatever it received in the same block size. Crucially, `dd` *does not* loop on a short read by default. If `read(2)` returns 100 bytes when `bs=4096`, `dd` writes a 100-byte block and increments its short-read counter. The output you see at the end (`X+Y records in / X+Y records out`) is split between full records (`X`) and short records (`Y`). The total byte count is what matters; the split tells you whether the source was producing short reads.

There is a `dd` flag, `iflag=fullblock`, that makes it loop on the source the way `cat` does. Use it when you want to test throughput without short-read noise: `dd if=/dev/myfirst of=/dev/null bs=4k iflag=fullblock`. Without that flag, you will see records split by every short read.

`hexdump(1)` reads one byte at a time by default but can be told to read larger blocks. It does not care about short reads from the source.

`truss(1)` traces every syscall, including the byte counts returned by each. Running a producer or consumer under `truss` is the most direct way to see what byte counts your driver is returning. If you run `truss -f -t read,write cat /dev/myfirst`, the output will tell you exactly how many bytes each `read(2)` returned, and you can correlate that with `cb_used` in `sysctl`.

10.5.9 Common Mistakes in Partial-Transfer Code

The following mistakes are the ones that show up most often in beginner driver code. Each one has the same shape: the handler does something that looks reasonable in a single test case and silently misbehaves under load.

Mistake 1: returning the byte count from `d_read` or `d_write`. A handler that does return `((int)nbytes);` instead of `return (0);` is wrong. The kernel ignores the positive value (because positive returns are not valid `errno` values) and computes the byte count from `uio_resid`. The handler that returns `nbytes` and *also* does the right thing with `uiomove` accidentally works; the handler that returns `nbytes` and skips the `uiomove` step silently corrupts data. Do not invent your own return convention.

Mistake 2: returning `EAGAIN` after a partial transfer. A handler that has already consumed some bytes from `uio` and then returns `EAGAIN` because no more are available silently throws away the bytes the user already got. The correct rule is: if you transferred any bytes, return 0; only if you transferred zero bytes can you return an `errno` like `EAGAIN`.

Mistake 3: refusing zero-length transfers. As noted above, `read(fd, buf, 0)` and `write(fd, buf, 0)` are legal. A handler that returns `EINVAL` on zero `uio_resid` breaks programs that use zero-length I/O for descriptor validation.

Mistake 4: looping inside the handler when the buffer is empty. A handler that spins inside the kernel waiting for data to appear blocks the calling thread *and* every thread that wants to acquire the same lock. The right mechanism for waiting is `mtx_sleep(9)` or `cv_wait(9)`, not a busy loop. Section 5 covers this.

Mistake 5: holding the buffer mutex across `uiomove`. This is the single most common bug in beginner driver code. `uiomove` may sleep on a page fault. Sleeping while holding a non-sleepable mutex is a `KASSERT` panic on `INVAARIANTS`-enabled kernels and a `WITNESS` warning on kernels with `WITNESS` enabled; on a production kernel built without either, the same pattern can still deadlock the machine or silently corrupt state when the page fault tries to page in a user page. Either way, the behaviour is wrong, and the testing kernel should catch it before production ever does. The Stage 2 handlers carefully release the mutex before calling `uiomove`. Repeat the pattern in every new handler you write.

Mistake 6: not honouring the user's signal. A blocking handler that does not pass `PCATCH` to `mtx_sleep(9)` or `tsleep(9)` cannot be interrupted by a signal. The user's `Ctrl-C` is silently ignored, and only `kill -9` will free the thread. Always allow signals to interrupt a wait, and always handle the resulting `EINTR` cleanly.

Mistake 7: trusting `uio->uio_resid` after a failure. When `uiomove` returns a non-zero error (for instance, `EFAULT` because the user-space buffer is invalid), `uio_resid` may be partially decremented or fully decremented depending on where in the transfer the fault occurred. The convention is: propagate the error, do not retry, and accept that the byte count seen by the user may include some bytes that arrived before the fault. This is rare in practice, and the user gets `EFAULT` plus a byte count that lets them recover.

10.5.10 A Concrete Example: Watching Partial Reads

To make this real, load the Stage 2 driver, write a few hundred bytes into it, and watch a small reader collect them in chunks. With the driver loaded:

```
$ printf 'aaaaaaaaaaaaaaaaaaaaa' > /dev/myfirst          # 20 bytes
$ printf 'bbbbbbbbbbbbbbbbbbbbbb' > /dev/myfirst        # 20 more
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 40
```

The buffer holds 40 bytes. Now run a small reader, traced by `truss`:

```

/* shortreader.c */
#include <fcntl.h>
#include <stdio.h>
#include <unistd.h>

int
main(void)
{
    int fd = open("/dev/myfirst", O_RDONLY);
    char buf[1024];
    ssize_t n;

    n = read(fd, buf, sizeof(buf));
    printf("read 1: %zd\n", n);
    n = read(fd, buf, sizeof(buf));
    printf("read 2: %zd\n", n);
    close(fd);
    return (0);
}

```

```

$ cc -o shortreader shortreader.c
$ truss -t read,write ./shortreader
... read(3, ...) = 40 (0x28)
read 1: 40
... read(3, ...) = 0 (0x0)
read 2: 0

```

The first `read(2)` returned 40 even though the user asked for 1024. That is a partial read, and it is correct. The second `read(2)` returned 0 because the buffer was empty. With Stage 2 the zero is a stand-in for “no data right now”; with Stage 3 (after we add blocking) the second read will sleep until more data arrives.

Now do the same with a tighter buffer to see partial reads on a larger transfer:

```

$ dd if=/dev/zero bs=1m count=8 | dd of=/dev/myfirst bs=4096 2>/tmp/dd-w &
$ dd if=/dev/myfirst of=/dev/null bs=512 2>/tmp/dd-r

```

When the writer is producing 4096-byte blocks faster than the reader is consuming 512-byte blocks, the buffer fills up. The writer’s `write(2)` calls start returning short counts, and `dd` records each short call as a partial record. The reader keeps reading 512 at a time. When you stop both processes, look at the `records out` line in `/tmp/dd-w` and the `records in` line in `/tmp/dd-r`; the second number on each line is the count of short records.

This is healthy behaviour. The driver is doing exactly what a UNIX device should do: let each side proceed at its own pace, report partial transfers honestly, and never block when there is nothing to wait for. Without partial-transfer semantics, the writer would have hit `ENOSPC` (the Chapter 9 behaviour) and `dd` would have stopped.

10.5.11 Wrapping Up Section 4

The driver's read and write handlers are now correctly partial-transfer-aware. We have not changed the code from Section 3; we have only made the behaviour explicit and built up the vocabulary needed to talk about it. You know what `read(2)` and `write(2)` return when only some of the bytes are available, you know how to write user-space loops that handle those returns, and you know which base-system tools handle partial transfers gracefully and which need a flag.

What is still missing is the right behaviour when the buffer is *completely* empty (for reads) or *completely* full (for writes). The Stage 2 driver still returns zero or stops with no progress; that is a stand-in for the more correct behaviour we are about to add. Section 5 introduces non-blocking I/O, the blocking sleep path, and `EAGAIN`. After that, the driver will behave correctly under all combinations of fill state and caller mode.

10.6 Section 5: Implementing Non-Blocking I/O

Up to this point in the chapter, the driver has been doing one of two things when a caller asks for a transfer that cannot be satisfied right now. It returns zero (on read, mimicking end-of-file) or it stops mid-loop with no bytes transferred (on write, telling the user “zero bytes accepted”). Neither behaviour is what a real character device should do. This section replaces both with the two correct behaviours: a blocking wait for the default case, and a clean `EAGAIN` for callers that opened the descriptor non-blocking.

Before we touch the driver, let us make sure we understand what “non-blocking” means from each side of the trust boundary. That vocabulary is what ties the implementation together.

10.6.1 What Non-Blocking I/O Is

A **blocking** descriptor is one for which `read(2)` and `write(2)` are allowed to sleep. If the driver has no data available, `read(2)` waits; if the driver has no room available, `write(2)` waits. The calling thread is suspended, possibly for a long time, until progress can be made. This is the default behaviour of every file descriptor in UNIX.

A **non-blocking** descriptor is one for which `read(2)` and `write(2)` must *never* sleep. If the driver has no data right now, `read(2)` returns `-1` with `errno = EAGAIN`. If the driver has no room right now, `write(2)` returns `-1` with `errno = EAGAIN`. The caller is expected to do something else (typically call `select(2)`, `poll(2)`, or `kqueue(2)` to find out when the descriptor becomes ready) and then try again.

The per-descriptor flag that turns non-blocking mode on or off is `O_NONBLOCK`. A program sets it either at `open(2)` time (`open(path, O_RDONLY | O_NONBLOCK)`) or later with `fcntl(2)` (`fcntl(fd, F_SETFL, O_NONBLOCK)`). The flag lives in the descriptor's `f_flag` field, which is private to the file structure; the driver does not see the flag directly.

What the driver *does* see is the `ioflag` argument to `d_read` and `d_write`. The devfs layer translates the descriptor's flags into bits of the `ioflag` that the handler can check. Specifically:

- `IO_NDELAY` is set when the descriptor has `O_NONBLOCK`.
- `IO_DIRECT` is set when the descriptor has `O_DIRECT`.
- `IO_SYNC` is set on `d_write` when the descriptor has `O_FSYNC`.

The translation is even simpler than it looks. A `CTASSERT` in `/usr/src/sys/fs/devfs/devfs_vnops.c` declares that `O_NONBLOCK == IO_NDELAY`. The bit values are chosen so the two names are interchangeable, and you can write `(ioflag & IO_NDELAY)` or `(ioflag & O_NONBLOCK)` depending on which convention feels clearer. Both work. The FreeBSD source tree uses `IO_NDELAY` more often, so we will follow that.

10.6.2 When Non-Blocking Behaviour Is Useful

Non-blocking mode is the underlying mechanism that makes event-driven programs possible. Without it, a single thread that wants to read from several descriptors has to pick one, block on it, and ignore the others until it wakes up. With it, a single thread can test several descriptors for readiness, process whichever is ready, and loop back without ever committing to sleep on any single one.

Three common programs rely on this mode heavily. A classical event loop (`libevent`, `libev`, or the now-standard `kqueue`-based pattern in FreeBSD) does nothing but wait in `kevent(2)` for an event, dispatch it, and loop. A networking daemon (`nginx`, `haproxy`) uses the same shape to juggle thousands of connections per thread. A real-time application (audio processing, industrial control) needs bounded worst-case latency and cannot afford a long block.

A driver that wants to play nicely with these programs must implement non-blocking mode correctly. Returning the wrong `errno`, sleeping when `IO_NDELAY` is set, or forgetting to notify `poll(2)` when state changes each produce bugs that are hard to diagnose.

10.6.3 The `IO_NDELAY` Flag: How It Flows to the Driver

Trace the flow once so you know where the flag comes from. The user calls `read(fd, buf, n)` on a descriptor that has `O_NONBLOCK` set. Inside the kernel:

1. `sys_read` looks up the file descriptor and finds a `struct file` with `fp->f_flag` containing `O_NONBLOCK`.
2. `vn_read` or (for character devices) `devfs_read_f` assembles an `ioflag` by masking `fp->f_flag` for the bits that drivers care about. In particular, it computes `ioflag = fp->f_flag & (O_NONBLOCK | O_DIRECT);`.
3. The computed `ioflag` is passed to the driver's `d_read`.

From the driver's point of view, the translation is complete: `ioflag & IO_NDELAY` is true if and only if the caller wants non-blocking semantics. A missing bit means block-if-needed. An extra bit means non-block-and-return-EAGAIN-if-needed.

On the write side the same pattern applies. `devfs_write_f` computes `ioflag = fp->f_flag & (O_NONBLOCK | O_DIRECT | O_FSYNC);` and passes it in. The write handler's check is symmetric: `ioflag & IO_NDELAY` is "do not block."

10.6.4 The `EAGAIN` Convention

When the driver's handler decides that it cannot make progress and the caller is non-blocking, it returns `EAGAIN`. The kernel's generic layer passes this through as `-1 / errno = EAGAIN` at the user level. The user is expected to treat `EAGAIN` as "this descriptor is not ready; wait or try later," not as an error in the traditional sense.

Two details about EAGAIN are worth committing to memory.

First, EAGAIN and EWOULDBLOCK are the same value in FreeBSD. They are two names for a single errno. Some older man pages use EWOULDBLOCK for socket-related contexts and EAGAIN for file-related contexts; the compatibility is tight, and either name is acceptable in driver code. The FreeBSD source tree uses EAGAIN almost exclusively for drivers.

Second, EAGAIN must only be returned when the handler has transferred *zero* bytes. If the handler has already moved some bytes via uiomove and then wants to stop because no more can move right now, it must return 0 (not EAGAIN). The kernel will compute the partial byte count from uio_resid and deliver that to the user. A subsequent call from the user will then see EAGAIN because the buffer is still empty. The rule is: EAGAIN means “no progress at all on this call”; a partial transfer means “progress, but less than requested, and now you need to retry for the rest.”

This is exactly the rule Section 4 introduced. Here we operationalise it in code.

10.6.5 The Blocking Path: `mtx_sleep(9)` and `wakeup(9)`

The blocking path is the default behaviour for a descriptor without `O_NONBLOCK`. When the buffer is empty, the reader sleeps; when a writer adds bytes, it wakes the reader. FreeBSD provides this with a pair of primitives that compose with mutexes.

`mtx_sleep(void *chan, struct mtx *mtx, int priority, const char *wmesg, sbintime_t tmo)` puts the calling thread to sleep on the “channel” `chan` (an arbitrary address used as a key), atomically releasing `mtx`. When the thread wakes, it reacquires `mtx` before returning. The `priority` argument may include `PCATCH` to allow signal delivery to interrupt the sleep, and `wmesg` is a short human-readable name that shows up in `ps -AxH` and similar tools. The `tmo` argument specifies a maximum sleep time; zero means no timeout.

`wakeup(void *chan)` wakes *every* thread sleeping on `chan`. `wakeup_one(void *chan)` wakes only one. For a single-reader driver, `wakeup` is fine; for a multi-reader driver where we want to hand off one chunk of work to one reader, `wakeup_one` is often right. For `myfirst` we will use `wakeup` because we may have both a producer and a consumer waiting, and we want to make sure neither is starved.

The contract between the two is that the sleeper must hold the mutex, check the condition, and call `mtx_sleep` *without* releasing the mutex in between. `mtx_sleep` atomically drops the lock and sleeps; when it returns, the lock is reacquired and the sleeper must re-check the condition (spurious wake-ups are possible; a concurrent thread may have taken the byte we were waiting for). The pattern is the classic `while (condition) mtx_sleep(...)` loop.

A minimal blocking read in our driver looks like this:

```
mtx_lock(&sc->mtx);
while (cbuf_used(&sc->cb) == 0) {
    if (ioflag & IO_NDELAY) {
        mtx_unlock(&sc->mtx);
        return (EAGAIN);
    }
    error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH,
        "myfrd", 0);
}
```

```

    if (error != 0) {
        mtx_unlock(&sc->mtx);
        return (error);
    }
    if (!sc->is_attached) {
        mtx_unlock(&sc->mtx);
        return (ENXIO);
    }
}
/* ... now proceed to read from the cbuf ... */

```

Four points deserve comment.

The first is the **condition in the while loop**. We check `cbuf_used(&sc->cb) == 0`. As long as that is true, we sleep. The while-check is essential: `mtx_sleep` can return for reasons other than “data appeared” (signals, timeouts, spurious wake-ups, or a different thread having consumed the data before we could). After every return from `mtx_sleep`, we must re-check.

The second is the **EAGAIN path**. If the caller is non-blocking and the buffer is empty, we release the lock and return `EAGAIN` without sleeping. The check has to happen *before* `mtx_sleep`, not after; otherwise we would sleep, wake up, then discover the caller was non-blocking all along.

The third is the **PCATCH**. With `PCATCH`, `mtx_sleep` can return `EINTR` or `ERESTART` if a signal is delivered. Propagating that return to the user is the whole purpose of `PCATCH`: we want the user’s Ctrl-C to actually interrupt the read. Without `PCATCH`, `SIGINT` is held until the sleep completes for some other reason, and the user gets a long, unexplained hang.

The fourth is the **detach check**. After `mtx_sleep` returns, it is possible that `myfirst_detach` has begun and that `sc->is_attached` is now zero. We check and return `ENXIO` if so. This prevents a read from proceeding against a partially torn-down driver. The detach code path has to call `wakeup(&sc->cb)` to release any sleepers before tearing the mutex down; we will add that call below.

10.6.6 The Writer Side

The write path is the mirror image:

```

mtx_lock(&sc->mtx);
while (cbuf_free(&sc->cb) == 0) {
    if (ioflag & IO_NDELAY) {
        mtx_unlock(&sc->mtx);
        return (EAGAIN);
    }
    error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH,
        "myfwr", 0);
    if (error != 0) {
        mtx_unlock(&sc->mtx);
    }
}

```

```

        return (error);
    }
    if (!sc->is_attached) {
        mtx_unlock(&sc->mtx);
        return (ENXIO);
    }
}
/* ... now proceed to write into the cbuf ... */

```

The same four points apply: check the condition in a while loop, handle `IO_NDELAY` before sleeping, pass `PCATCH`, re-check `is_attached` after the sleep. Notice that both sleepers use the same “channel” (`&sc->cb`). That is deliberate. When a reader transfers bytes out of the buffer, it calls `wakeup(&sc->cb)` to unblock any writer waiting for space. When a writer transfers bytes into the buffer, it calls `wakeup(&sc->cb)` to unblock any reader waiting for data. A single channel that wakes “everything on this buffer” is simple and correct.

Some drivers use two separate channels (one for readers, one for writers) so that a reader’s wakeup only disturbs writers and vice versa. That is a valid optimisation when you have many readers or many writers. For a pseudo-device whose expected use is one producer and one consumer, a single channel is both simpler and sufficient.

10.6.7 The Full Stage 3 Handlers

Putting the non-blocking checks into the Stage 2 handlers gives us Stage 3. Here is the full shape:

```

static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t take, got;
    ssize_t nbefore;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    nbefore = uio->uio_resid;

    while (uio->uio_resid > 0) {
        mtx_lock(&sc->mtx);
        while (cbuf_used(&sc->cb) == 0) {

```

```

        if (uio->uio_resid != nbefore) {
            /*
             * We already transferred some bytes
             * in an earlier iteration; report
             * success now rather than block further.
             */
            mtx_unlock(&sc->mtx);
            return (0);
        }
        if (ioflag & IO_NDELAY) {
            mtx_unlock(&sc->mtx);
            return (EAGAIN);
        }
        error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH,
            "myfrd", 0);
        if (error != 0) {
            mtx_unlock(&sc->mtx);
            return (error);
        }
        if (!sc->is_attached) {
            mtx_unlock(&sc->mtx);
            return (ENXIO);
        }
    }
    take = MIN((size_t)uio->uio_resid, sizeof(bounce));
    got = cbuf_read(&sc->cb, bounce, take);
    sc->bytes_read += got;
    fh->reads += got;
    mtx_unlock(&sc->mtx);

    wakeup(&sc->cb);          /* space may have freed for writers */

    error = uiomove(bounce, got, uio);
    if (error != 0)
        return (error);
}
return (0);
}

static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;

```

```
char bounce[MYFIRST_BOUNCE];
size_t want, put, room;
ssize_t nbefore;
int error;

error = devfs_get_cdevpriv((void **)&fh);
if (error != 0)
    return (error);
if (sc == NULL || !sc->is_attached)
    return (ENXIO);

nbefore = uio->uio_resid;

while (uio->uio_resid > 0) {
    mtx_lock(&sc->mtx);
    while ((room = cbuf_free(&sc->cb)) == 0) {
        if (uio->uio_resid != nbefore) {
            mtx_unlock(&sc->mtx);
            return (0);
        }
        if (ioflag & IO_NDELAY) {
            mtx_unlock(&sc->mtx);
            return (EAGAIN);
        }
        error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH,
            "myfwr", 0);
        if (error != 0) {
            mtx_unlock(&sc->mtx);
            return (error);
        }
        if (!sc->is_attached) {
            mtx_unlock(&sc->mtx);
            return (ENXIO);
        }
    }
    mtx_unlock(&sc->mtx);

    want = MIN((size_t)uio->uio_resid, sizeof(bounce));
    want = MIN(want, room);
    error = uiomove(bounce, want, uio);
    if (error != 0)
        return (error);

    mtx_lock(&sc->mtx);
```

```

        put = cbuf_write(&sc->cb, bounce, want);
        sc->bytes_written += put;
        fh->writes += put;
        mtx_unlock(&sc->mtx);

        wakeup(&sc->cb);          /* data may have appeared for readers */
    }
    return (0);
}

```

Three patterns in this code are worth studying carefully.

The first is the “**transferred any bytes?**” test at the top of the inner loop. `uio->uio_resid != nbefore` is true if any previous iteration transferred data. When that condition holds and the buffer is now empty (read) or full (write), we return 0 immediately instead of blocking. The kernel will report the partial transfer to user space, and the next call will decide whether to block or to return `EAGAIN`. This is the rule from Section 4 in code form: a handler that has already made progress must return 0, not `EAGAIN`, and not a deeper block.

The second is the **wakeup after progress**. When the reader drains bytes, space has freed; the writer may be waiting for space, and we wake it. When the writer adds bytes, data has appeared; the reader may be waiting for data, and we wake it. Every state change is paired with a wakeup. Missing a wakeup causes threads to sleep forever (or until a timer fires, if one exists); spurious wakeup calls are harmless because the while-loops re-check the condition.

The third is the **order of `mtx_unlock` and `uiomove`**. The handler holds the lock while it manipulates the `cbuf`, then releases the lock *before* calling `uiomove`. `uiomove` may sleep; sleeping under a mutex is a bug. Notice also that on the write side, the handler takes a snapshot of room while holding the lock, uses that snapshot to size the bounce, and releases the lock before `uiomove`. If a concurrent thread has modified the buffer while the handler was copying out of user space, the subsequent `cbuf_write` may store less than `want` bytes (the clamp in `cbuf_write` ensures it is safe). In our current single-writer design this race is never triggered, but the code handles it for free.

10.6.8 Waking Sleepers on Detach

We also need to teach `myfirst_detach` to release any sleepers. The pattern is:

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    mtx_lock(&sc->mtx);
    if (sc->active_fhs > 0) {
        mtx_unlock(&sc->mtx);
        device_printf(dev,

```

```

        "Cannot detach: %d open descriptor(s)\n",
        sc->active_fhs);
    return (EBUSY);
}
sc->is_attached = 0;
wakeup(&sc->cb);           /* release any sleepers */
mtx_unlock(&sc->mtx);

/* ... destroy_dev, cbuf_destroy, mtx_destroy, sysctl_ctx_free ... */
return (0);
}

```

Two details about this code are specific to Chapter 10.

The first is that we set `is_attached = 0` *before* calling `wakeup`. A sleeper that wakes now will see the flag and return `ENXIO` in the blocking loop; a sleeper that has not yet slept will see the flag and return `ENXIO` without ever sleeping. Setting the flag after `wakeup` would allow a race where a sleeper re-acquires the lock, finds the condition still true (buffer empty), and goes back to sleep, *while* the detach is waiting to tear down the mutex.

The second is that the detach checks `active_fhs > 0` and refuses to proceed if any descriptor is open. This is the same check from Chapter 9. It means a sleeper is always holding a descriptor open, which means the detach will not be running concurrently with a sleeper. The `wakeup` call is there as a belt-and-braces check: if a future refactor ever allows detach while a descriptor is still open, the sleepers will not be stuck.

10.6.9 Adding `d_poll` for `select(2)` and `poll(2)`

A non-blocking caller that receives `EAGAIN` needs some way to be notified when the descriptor becomes ready. `select(2)` and `poll(2)` are the classic mechanisms for that; `kqueue(2)` is the modern one. We will implement the classic two here and leave `kqueue` for Chapter 11 (where `d_kqfilter` and `knlist` infrastructure belongs).

The `d_poll` handler is simple in shape:

```

static int
myfirst_poll(struct cdev *dev, int events, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int revents = 0;

    mtx_lock(&sc->mtx);
    if (events & (POLLIN | POLLRDNORM)) {
        if (cbuf_used(&sc->cb) > 0)
            revents |= events & (POLLIN | POLLRDNORM);
    }
    else
        selrecord(td, &sc->rsel);
}

```

```

        if (events & (POLLOUT | POLLWRNORM)) {
            if (cbuf_free(&sc->cb) > 0)
                revents |= events & (POLLOUT | POLLWRNORM);
            else
                selrecord(td, &sc->wsel);
        }
        mtx_unlock(&sc->mtx);
        return (revents);
    }
}

```

`d_poll` receives the events the user is interested in and must return the subset that are currently ready. For `POLLIN/POLLRDNORM` (readable), we return ready if the buffer has any bytes. For `POLLOUT/POLLWRNORM` (writable), we return ready if the buffer has any free space. If neither is ready, we call `selrecord(td, &sc->rsl)` or `selrecord(td, &sc->wsl)` to register the calling thread so that we can wake it later.

Two new fields are needed in the `softc`: `struct selinfo rsl;` and `struct selinfo wsl;`. `selinfo` is the kernel's per-condition record of pending `select(2)/poll(2)` waiters. It is declared in `/usr/src/sys/sys/selinfo.h`.

The read and write handlers need a matching `selwakeup(9)` call whenever the buffer transitions from empty to non-empty or from full to non-full. `selwakeup(9)` is the plain form; FreeBSD 14.3 also exposes `selwake-uppri(9)`, which wakes the registered threads at a specified priority and is commonly used by network and storage code that wants latency-sensitive wakeups. For a general-purpose pseudo-device, plain `selwakeup` is the right default. We add the calls next to the `wakeup(&sc->cb)` calls:

```

/* In myfirst_read, after a successful cbuf_read: */
mtx_unlock(&sc->mtx);
wakeup(&sc->cb);
selwakeup(&sc->wsl); /* space is now available for writers */

/* In myfirst_write, after a successful cbuf_write: */
mtx_unlock(&sc->mtx);
wakeup(&sc->cb);
selwakeup(&sc->rsl); /* data is now available for readers */

```

`Attach` initialises the `selinfo` fields with `knlist_init_mtx(&sc->rsl.si_note, &sc->mtx);` and `knlist_init_mtx(&sc->wsl.si_note, &sc->mtx);` if you plan to support `kqueue(2)` later. For pure `select(2)/poll(2)` support, the `selinfo` structure is zero-initialised by the `softc` allocation and needs no further setup.

`Detach` must call `seldrain(&sc->rsl);` and `seldrain(&sc->wsl);` before freeing the `softc`, to tear down any lingering selection records.

Add `.d_poll = myfirst_poll,` to the `myfirst_cdevsw` initialiser, and the driver's `select(2)/poll(2)` story is complete.

10.6.10 How a Non-Blocking Caller Uses All of This

Putting the pieces together, here is what a well-written non-blocking reader looks like against `myfirst`:

```
int fd = open("/dev/myfirst", O_RDONLY | O_NONBLOCK);
char buf[1024];
ssize_t n;
struct pollfd pfd = { .fd = fd, .events = POLLIN };

for (;;) {
    n = read(fd, buf, sizeof(buf));
    if (n > 0) {
        /* got some bytes; process them */
    } else if (n == 0) {
        /* EOF; our driver never reaches this case yet */
        break;
    } else if (errno == EAGAIN) {
        /* no data; wait for readiness */
        poll(&pfd, 1, -1);
    } else if (errno == EINTR) {
        /* signal; retry */
    } else {
        perror("read");
        break;
    }
}
close(fd);
```

The loop reads until it gets data or `EAGAIN`. On `EAGAIN`, it calls `poll(2)` to wait until the kernel reports the descriptor readable, then loops back. The `POLLIN` event will be reported when `myfirst_write` runs the `selwakeup(&sc->rsl)` call that follows a successful `cbuf_write`. The driver's `d_poll` is the bridge between the kernel's `select/poll` machinery and the buffer's state.

This is the canonical shape of event-driven UNIX I/O, and your driver now participates in it correctly.

10.6.11 A Note About `O_NONBLOCK` and `select/poll` Composition

It is worth understanding how `select(2)` / `poll(2)` and `O_NONBLOCK` interact. The conventional rule is that a program uses both together: it registers the descriptor with `poll` and then reads from it. Using either alone is valid but less common.

If a program uses `O_NONBLOCK` without `poll`, it will busy-spin. On every `EAGAIN` it will have to `sleep` or `usleep` before retrying, wasting cycles for no good reason. This is almost always wrong, but it works.

If a program uses `poll` without `O_NONBLOCK`, the `poll` reports readiness and then `read(2)` does a blocking call. The blocking call will complete almost immediately in the normal case, because the condition was just reported

ready. However, in the rare case where the kernel's state changes between the `poll` return and the `read` call (another thread drained the buffer, for instance), the `read` will block indefinitely. This is a subtle bug, and most event-driven libraries defend against it by always combining `poll` with `O_NONBLOCK`.

The `myfirst` driver supports both patterns correctly. A well-written program combines the two; a less-careful program will work in simple cases and have the corner case described above.

10.6.12 Observing the Blocking Path in Action

Load the Stage 3 driver and run a quick experiment:

```
$ kldload ./myfirst.ko
$ cat /dev/myfirst &
[1] 12345
```

The `cat` is now blocked inside `myfirst_read`, sleeping on `&sc->cb`. You can confirm with `ps`:

```
$ ps -AxH | grep cat
12345  -  S+      0:00.00 myfrd
```

The `S+` state indicates that the process is sleeping, and the `wmesg` column shows `myfrd`, which is exactly the string we passed to `mtx_sleep`. Now write into the driver from another terminal:

```
$ echo hello > /dev/myfirst
```

The `cat` wakes up, reads `hello`, and either prints it and blocks again, or (if the device is closed by the writer) reaches end-of-file and exits. In our current Stage 3 there is no “writer has closed” mechanism, so the `cat` blocks again after printing. Use `Ctrl-C` in its terminal to interrupt it:

```
$ kill -INT %1
```

Because we passed `PCATCH` to `mtx_sleep`, the signal wakes the sleeper, which returns `EINTR`, which propagates out to `cat` as a failed `read(2)`. `cat` sees it, notices the signal, and exits cleanly.

This is the whole blocking path in action. Nothing mysterious happened; each piece is visible in the source and in `ps`.

10.6.13 Common Mistakes in the Blocking Path

Two mistakes are especially common in this material.

Mistake 1: forgetting to release the mutex before returning `EAGAIN`. The code above explicitly unlocks before every return in the sleep loop. If you forget one of those unlocks, subsequent attempts to take the mutex will panic or deadlock. A `WITNESS` kernel will catch this immediately in a lab environment.

Mistake 2: using `tsleep(9)` when you should use `mtx_sleep(9)`. `tsleep` does not take a mutex argument; it assumes the caller is not holding any interlock. In a driver that uses `mtx_sleep`, the mutex is dropped atomically with the sleep; with `tsleep`, you would have to drop the mutex yourself and then re-acquire it after waking, introducing a race window where a producer can add data and call wakeup before you are back on the sleep queue. `mtx_sleep` is the correct primitive for every case where you hold a mutex and want to sleep while releasing it.

Mistake 3: not handling the `PCATCH` return values. `mtx_sleep` with `PCATCH` can return 0, `EINTR`, `ERESTART`, or `EWOULDBLOCK` (for timeouts). In driver code the conventional thing is to return error without inspecting it further; the kernel knows how to translate `ERESTART` into a syscall restart when the process's signal disposition allows it. Inspecting the value and returning 0 only for `error == 0` is the pattern in the Stage 3 code above.

Mistake 4: using different “channels” for `mtx_sleep` and wakeup. The sleeper uses `&sc->cb` as the channel; the waker must use exactly the same address. A common bug is for one site to use `sc` (the softc pointer) and another to use `&sc->cb`. The sleepers will never wake until a timeout fires or a different wakeup happens to match. Double-check that every `mtx_sleep` / wakeup pair uses the same channel.

10.6.14 Wrapping Up Section 5

The driver now handles both blocking and non-blocking callers correctly. A blocking reader sleeps on an empty buffer and wakes when a writer deposits data. A non-blocking reader receives `EAGAIN` immediately on an empty buffer. The symmetric pair applies to writers. `select(2)` and `poll(2)` are supported through `d_poll` and the `selinfo` machinery, and a well-behaved event-loop program can now multiplex `/dev/myfirst` with other descriptors. `Detach` releases any sleepers before tearing the driver down.

What you have built is a competently behaved character device. It moves bytes efficiently, cooperates with the kernel's readiness and sleep primitives, and honours the user-facing conventions of UNIX I/O. What remains in the rest of the chapter is to test it rigorously (Section 6), refactor it for concurrency work (Section 7), and explore three supplementary topics that often appear alongside this material in real drivers (`d_mmap`, zero-copy thinking, and the throughput patterns of readahead and write coalescing).

10.7 Section 6: Testing Buffered I/O with User Programs

A driver is only as reliable as the tests you run against it. Chapters 7 through 9 established a small test kit (a short `rw_myfirst` exerciser, plus `cat`, `echo`, `dd`, and `hexdump`). Chapter 10 pushes that kit further because the new behaviour the driver now exhibits (blocking, non-blocking, partial I/O, wrap-around) only shows up under realistic load. This section builds out three new user-space tools and walks through a consolidated test plan you can work through after each stage.

The tools in this section live under `examples/part-02/ch10-handling-io-efficiently/userland/`. They are deliberately small. The longest is under 150 lines. Each one exists to exercise a specific pattern the driver is now supposed to handle, and each one produces output that you can read and verify.

10.7.1 Three Tools We Will Build

`rw_myfirst_nb.c` is a non-blocking tester. It opens the device with `O_NONBLOCK`, issues a read, expects `EAGAIN`, writes some bytes, issues another read, expects to receive them, and reports a one-line summary of each step.

This is the smallest tool that exercises the non-blocking path end to end.

`producer_consumer.c` is a fork-based load harness. It spawns a child process that writes random bytes into the driver at a configurable rate, while the parent reads them out and verifies integrity. The purpose is to exercise the circular buffer's wrap-around and the blocking path under real concurrent load.

`stress_rw.c` (evolved from Chapter 9's version) is a single-process stress tester that runs through a table of (block size, transfer count) combinations and prints aggregate timing and byte-counter statistics. The purpose is to catch performance cliffs that a single interactive test would not reveal.

All three compile with a short Makefile that we will show at the end.

10.7.2 Updating `rw_myfirst` for Larger Inputs

The existing `rw_myfirst` from Chapter 9 handles text-sized transfers well but does not stress the buffer at volume. A simple extension lets it take a size argument on the command line:

```
/* rw_myfirst_v2.c: an incremental improvement on Chapter 9's tester. */
#include <sys/types.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH "/dev/myfirst"

static int
do_fill(size_t bytes)
{
    int fd = open(DEVPATH, O_WRONLY);
    if (fd < 0)
        err(1, "open %s", DEVPATH);

    char *buf = malloc(bytes);
    if (buf == NULL)
        err(1, "malloc %zu", bytes);
    for (size_t i = 0; i < bytes; i++)
        buf[i] = (char)('A' + (i % 26));

    size_t left = bytes;
    ssize_t n;
    const char *p = buf;
    while (left > 0) {
```

```
        n = write(fd, p, left);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            warn("write at %zu left", left);
            break;
        }
        p += n;
        left -= n;
    }
    size_t wrote = bytes - left;
    printf("fill: wrote %zu of %zu\n", wrote, bytes);
    free(buf);
    close(fd);
    return (0);
}

static int
do_drain(size_t bytes)
{
    int fd = open(DEVPATH, O_RDONLY);
    if (fd < 0)
        err(1, "open %s", DEVPATH);

    char *buf = malloc(bytes);
    if (buf == NULL)
        err(1, "malloc %zu", bytes);

    size_t left = bytes;
    ssize_t n;
    char *p = buf;
    while (left > 0) {
        n = read(fd, p, left);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            warn("read at %zu left", left);
            break;
        }
        if (n == 0) {
            printf("drain: EOF at %zu left\n", left);
            break;
        }
        p += n;
    }
```

```
        left -= n;
    }
    size_t got = bytes - left;
    printf("drain: read %zu of %zu\n", got, bytes);
    free(buf);
    close(fd);
    return (0);
}

int
main(int argc, char *argv[])
{
    if (argc != 3) {
        fprintf(stderr, "usage: %s fill|drain BYTES\n", argv[0]);
        return (1);
    }
    size_t bytes = strtoul(argv[2], NULL, 0);
    if (strcmp(argv[1], "fill") == 0)
        return (do_fill(bytes));
    if (strcmp(argv[1], "drain") == 0)
        return (do_drain(bytes));
    fprintf(stderr, "unknown mode: %s\n", argv[1]);
    return (1);
}
```

With this tool, you can drive the driver with realistic sizes. For example:

```
$ ./rw_myfirst_v2 fill 4096
fill: wrote 4096 of 4096
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 4096
$ ./rw_myfirst_v2 drain 4096
drain: read 4096 of 4096
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 0
```

Now try to fill the buffer beyond its capacity and watch what happens at each stage.

10.7.3 Why a Round-Trip Test Matters

Every serious test you write should have a *round-trip* component: write a known pattern into the driver, read it back, and compare. The pattern matters because if you write “Hello, world!” ten times you cannot tell whether the buffer got 140 bytes of “Hello, world!” or 130 or 150 or some weird interleaving. A unique per-position

pattern (like 'A' + (i % 26) above) lets you spot misalignment, missing bytes, and duplicated bytes at a glance.

Round-trip testing is especially important for circular buffers, because the wrap-around arithmetic is the thing that beginner code gets wrong. A write that pushes past the end of the underlying storage and a read that picks up from before the start are the two failure modes you most want to catch. Both appear as “the bytes I read are not the bytes I wrote”, and a round-trip test makes them visible immediately.

10.7.4 Building `rw_myfirst_nb`

This is the non-blocking tester. It is slightly longer than the previous file but still short enough to read in one sitting.

```
/* rw_myfirst_nb.c: non-blocking behaviour tester for /dev/myfirst. */
#include <sys/types.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <poll.h>
#include <stdio.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH "/dev/myfirst"

int
main(void)
{
    int fd, error;
    ssize_t n;
    char rbuf[128];
    struct pollfd pfd;

    fd = open(DEVPATH, O_RDWR | O_NONBLOCK);
    if (fd < 0)
        err(1, "open %s", DEVPATH);

    /* Expect EAGAIN when the buffer is empty. */
    n = read(fd, rbuf, sizeof(rbuf));
    if (n < 0 && errno == EAGAIN)
        printf("step 1: empty-read returned EAGAIN (expected)\n");
    else
        printf("step 1: UNEXPECTED read returned %zd errno=%d\n", n, errno);

    /* poll(POLLIN) with timeout 0 should show not-readable. */
```

```

    pfd.fd = fd;
    pfd.events = POLLIN;
    pfd.revents = 0;
    error = poll(&pfd, 1, 0);
    printf("step 2: poll(POLLIN, 0) = %d revents=0x%x\n",
        error, pfd.revents);

    /* Write some bytes. */
    n = write(fd, "hello world\n", 12);
    printf("step 3: wrote %zd bytes\n", n);

    /* poll(POLLIN) should now show readable. */
    pfd.events = POLLIN;
    pfd.revents = 0;
    error = poll(&pfd, 1, 0);
    printf("step 4: poll(POLLIN, 0) = %d revents=0x%x\n",
        error, pfd.revents);

    /* Non-blocking read should now succeed. */
    memset(rbuf, 0, sizeof(rbuf));
    n = read(fd, rbuf, sizeof(rbuf));
    if (n > 0) {
        rbuf[n] = '\0';
        printf("step 5: read %zd bytes: %s", n, rbuf);
    } else
        printf("step 5: UNEXPECTED read returned %zd errno=%d\n",
            n, errno);

    close(fd);
    return (0);
}

```

Expected output against Stage 3 (non-blocking support) is:

```

step 1: empty-read returned EAGAIN (expected)
step 2: poll(POLLIN, 0) = 0 revents=0x0
step 3: wrote 12 bytes
step 4: poll(POLLIN, 0) = 1 revents=0x41
step 5: read 12 bytes: hello world

```

The 0x41 in step 4 is POLLIN | POLLRDNORM, which is exactly what our `d_poll` handler sets when the buffer has live bytes.

If step 1 fails (i.e. `read(2)` returns 0 instead of `-1/EAGAIN`), your driver is still running the Stage 2 semantics. Go back and add the `IO_NDELAY` check in the handlers.

If step 2 succeeds with `revents != 0`, your `d_poll` is wrongly reporting readable on an empty buffer. Check the condition in `myfirst_poll`.

If step 4 returns zero (i.e. `poll(2)` did not find the descriptor readable), your `d_poll` is not reflecting the buffer state correctly, or the `selwakeup` call is missing from the write path.

These are the three most common non-blocking bugs. The tester catches all of them in under fifty lines of output.

10.7.5 Building `producer_consumer.c`

This is the fork-based load harness. The shape is straightforward: fork a child that writes, have the parent read, and compare what comes out against what went in.

```
/* producer_consumer.c: a two-process load test for /dev/myfirst. */
#include <sys/types.h>
#include <sys/wait.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <signal.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH      "/dev/myfirst"
#define TOTAL_BYTES (1024 * 1024)
#define BLOCK       4096

static uint32_t
checksum(const char *p, size_t n)
{
    uint32_t s = 0;
    for (size_t i = 0; i < n; i++)
        s = s * 31u + (uint8_t)p[i];
    return (s);
}

static int
do_writer(void)
{
    int fd = open(DEVPATH, O_WRONLY);
    if (fd < 0)
        err(1, "writer: open");
}
```

```
char *buf = malloc(BLOCK);
if (buf == NULL)
    err(1, "writer: malloc");

size_t written = 0;
uint32_t sum = 0;
while (written < TOTAL_BYTES) {
    size_t left = TOTAL_BYTES - written;
    size_t block = left < BLOCK ? left : BLOCK;
    for (size_t i = 0; i < block; i++)
        buf[i] = (char)((written + i) & 0xff);
    sum += checksum(buf, block);

    const char *p = buf;
    size_t remain = block;
    while (remain > 0) {
        ssize_t n = write(fd, p, remain);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            warn("writer: write");
            close(fd);
            return (1);
        }
        p += n;
        remain -= n;
    }
    written += block;
}

printf("writer: %zu bytes, checksum 0x%08x\n", written, sum);
close(fd);
free(buf);
return (0);
}

static int
do_reader(void)
{
    int fd = open(DEVPATH, O_RDONLY);
    if (fd < 0)
        err(1, "reader: open");
}
```

```
char *buf = malloc(BLOCK);
if (buf == NULL)
    err(1, "reader: malloc");

size_t got = 0;
uint32_t sum = 0;
int mismatches = 0;
while (got < TOTAL_BYTES) {
    ssize_t n = read(fd, buf, BLOCK);
    if (n < 0) {
        if (errno == EINTR)
            continue;
        warn("reader: read");
        break;
    }
    if (n == 0) {
        /* Only reached if driver signals EOF. */
        printf("reader: EOF at %zu\n", got);
        break;
    }
    for (ssize_t i = 0; i < n; i++) {
        if ((uint8_t)buf[i] != (uint8_t)((got + i) & 0xff))
            mismatches++;
    }
    sum += checksum(buf, n);
    got += n;
}

printf("reader: %zu bytes, checksum 0x%08x, mismatches %d\n",
       got, sum, mismatches);
close(fd);
free(buf);
return (mismatches == 0 ? 0 : 2);
}

int
main(void)
{
    pid_t pid = fork();
    if (pid < 0)
        err(1, "fork");
    if (pid == 0) {
        /* child: writer */
        _exit(do_writer());
    }
}
```

```
    }  
    /* parent: reader */  
    int rc = do_reader();  
    int status;  
    waitpid(pid, &status, 0);  
    int wexit = WIFEXITED(status) ? WEXITSTATUS(status) : -1;  
    printf("exit: reader=%d writer=%d\n", rc, wexit);  
    return (rc || wexit);  
}
```

The test works best against Stage 3 or Stage 4 of the chapter. Against Stage 2 (no blocking), the writer will receive short writes and the reader will occasionally see zero-byte reads, and the total bytes transferred may be less than TOTAL_BYTES. Against Stage 3, both sides block and unblock at the right times, the test runs to completion, and the two checksums match.

A successful run looks like:

```
$ ./producer_consumer  
writer: 1048576 bytes, checksum 0x12345678  
reader: 1048576 bytes, checksum 0x12345678, mismatches 0  
exit: reader=0 writer=0
```

Mismatches are the killer. If the writer's checksum matches the reader's but mismatches are non-zero, it means a byte drifted in position during the round trip (likely a wrap-around bug). If the checksums differ, a byte was lost or duplicated (likely a locking bug). If the test hangs forever, the blocking path's condition never becomes true (likely a missing wakeup).

10.7.6 Using dd(1) for Volume Tests

The base-system `dd(1)` is the fastest way to push volume through the driver without writing any new code. A few patterns are especially useful.

Pattern 1: writer-only. Push a large amount of data into the driver while a reader keeps up.

```
$ dd if=/dev/myfirst of=/dev/null bs=4k &  
$ dd if=/dev/zero of=/dev/myfirst bs=4k count=100000
```

This produces 400 MB of traffic through the driver. Watch `sysctl dev.myfirst.0.stats.bytes_written` grow, and compare it against `bytes_read`; the difference is roughly the buffer fill level.

Pattern 2: rate-limited. Some tests want to stress the driver at a steady rate rather than at maximum throughput. Use `rate` or the GNU `pv(1)` utility (available as `ports/sysutils/pv`) to cap:

```
$ pv -L 10m < /dev/zero | dd of=/dev/myfirst bs=4k
```

This caps the write rate at 10 MB/s. A slower rate lets you observe the buffer’s fill level in `sysctl` and see the blocking path engage when the rate approaches the consumer’s rate.

Pattern 3: full-block. As mentioned in Section 4, default `dd` does not loop on short reads. Use `iflag=fullblock` to make it do so:

```
$ dd if=/dev/myfirst of=/tmp/out bs=4k count=100 iflag=fullblock
```

Without `iflag=fullblock`, the output file might be shorter than the requested 400 KB because of short reads.

10.7.7 Using `hexdump(1)` to Verify Content

`hexdump(1)` is the right tool for verifying the *content* of what the driver delivers. If you write a known byte sequence and want to confirm it comes back intact, `hexdump` shows you.

```
$ printf 'ABCDEFGH' > /dev/myfirst
$ hexdump -C /dev/myfirst
00000000  41 42 43 44 45 46 47 48          |ABCDEFGH|
$
```

The `hexdump -C` output is the canonical “here are the bytes and their ASCII interpretation” format. It is especially useful when the driver is emitting binary data that text-based tools cannot display.

10.7.8 Using `truss(1)` to See Syscall Traffic

`truss(1)` traces the system calls made by a process. Running a test under `truss` shows you exactly what each `read(2)` and `write(2)` returned, including partial transfers and error codes.

```
$ truss -t read,write -o /tmp/trace ./rw_myfirst_nb
$ head /tmp/trace
read(3,0x7fffffffeca0,128)          ERR#35 'Resource temporarily
↳ unavailable'
write(3,"hello world\n",12)          = 12 (0xc)
read(3,0x7fffffffeca0,128)          = 12 (0xc)
...
```

ERR#35 is EAGAIN. Seeing it confirms that the non-blocking path is engaging. Running `producer_consumer` under `truss` shows the pattern of short writes and short reads very clearly; it is a good diagnostic for debugging buffer sizing issues.

A related tool is `kttrace(1)` / `kdump(1)`, which produces a more detailed and decoded trace, at the cost of being a bit more verbose. Either is fine for this level of work.

10.7.9 Using `sysctl(8)` to Watch State Live

The `sysctl` tree `dev.myfirst.0.stats.*` is the driver's live state. Watching it in real time during a test tells you a great deal about what the driver is doing.

```
$ while true; do
    clear
    sysctl dev.myfirst.0.stats | egrep 'cb_|bytes_'
    sleep 1
done
```

Run this in one terminal while a test runs in another. You will see `cb_used` rise as the writer gets ahead, fall as the reader catches up, and oscillate around some steady-state level. The byte counters only ever increase. A stalled test shows up as frozen counters.

10.7.10 Using `vmstat -m` to Watch Memory

If you suspect a leak (maybe you forgot `cbuf_destroy` in the error path of `attach`), `vmstat -m` shows it:

```
$ vmstat -m | grep cbuf
      cbuf      1      4K      1  4096
```

After `kldunload`:

```
$ vmstat -m | grep cbuf
$
```

The tag should disappear entirely when the driver is unloaded. If a count is non-zero, something still holds the allocation. This is the kind of regression you want to catch immediately; it gets worse silently over time.

10.7.11 Building the Test Kit

Here is a Makefile that builds all the userland test programs at once. Place it in `examples/part-02/ch10-handling-io-efficiently/userland/`:

```
# Makefile for Chapter 10 userland testers.

PROGS= rw_myfirst_v2 rw_myfirst_nb producer_consumer stress_rw cb_test

.PHONY: all
all: ${PROGS}

CFLAGS?= -O2 -Wall -Wextra -Wno-unused-parameter
```

```
rw_myfirst_v2: rw_myfirst_v2.c
    ${CC} ${CFLAGS} -o $@ $<

rw_myfirst_nb: rw_myfirst_nb.c
    ${CC} ${CFLAGS} -o $@ $<

producer_consumer: producer_consumer.c
    ${CC} ${CFLAGS} -o $@ $<

stress_rw: stress_rw.c
    ${CC} ${CFLAGS} -o $@ $<

cb_test: ../cbuf-userland/cbuf.c ../cbuf-userland/cb_test.c
    ${CC} ${CFLAGS} -I../cbuf-userland -o $@ $^

.PHONY: clean
clean:
    rm -f ${PROGS}
```

Running make builds all four tools. make cb_test builds only the standalone cbuf test. Keep the two userland directories (cbuf-userland/ for the buffer, userland/ for the driver testers) separate; the first one is the prerequisite for the later stages, and building it in isolation mirrors the order we introduced them in the chapter.

10.7.12 A Consolidated Test Plan

With the tools in place, here is a test plan you can run against each stage of the driver. Run each pass after loading the corresponding myfirst.ko.

Stage 2 (circular buffer, no blocking):

1. ./rw_myfirst_v2 fill 4096; sysctl dev.myfirst.0.stats.cb_used should report 4096.
2. ./rw_myfirst_v2 fill 4097 should show a short write (wrote 4096 of 4097).
3. ./rw_myfirst_v2 drain 2048; sysctl dev.myfirst.0.stats.cb_used should report 2048.
4. ./rw_myfirst_v2 fill 2048; sysctl dev.myfirst.0.stats.cb_used should report 4096, but cb_head should be non-zero (proving wrap-around worked).
5. dd if=/dev/myfirst of=/dev/null bs=4k: should drain 4096 bytes and then return zero.
6. producer_consumer with TOTAL_BYTES = 8192: should complete successfully.

Stage 3 (blocking and non-blocking support):

1. cat /dev/myfirst & should block.
2. echo hi > /dev/myfirst should produce output in the cat terminal.
3. kill -INT %1 should unblock cat cleanly.
4. ./rw_myfirst_nb should print the six-line output above.

5. `producer_consumer` with `TOTAL_BYTES = 1048576`: should complete with no mismatches and matching checksums.

Stage 4 (poll support, refactored helpers):

All Stage 3 tests, plus:

1. `./rw_myfirst_nb` step 4 should show `revents=0x41 (POLLIN|POLLRDNORM)`.
2. A small program that opens one descriptor read-only non-blocking, registers it with `poll(POLLIN)` with timeout -1, and calls `write` from the same process on a second descriptor: the `poll` should return promptly with `POLLIN` set.
3. `dd if=/dev/zero of=/dev/myfirst bs=1m count=10` & paired with `dd if=/dev/myfirst of=/dev/null bs=4k`: should move 10 MB with no errors, roughly in the time the slower side takes.

This plan is by no means exhaustive. The Labs section later in the chapter gives you a deeper sequence. But these are the smoke tests: run them after every non-trivial change, and if they pass, you have not broken anything fundamental.

10.7.13 Debugging When a Test Fails

When a test fails, the sequence of inspection is usually:

1. **`dmesg | tail -100`**: check for kernel warnings, panics, or your own `device_printf` output. If the kernel is complaining about a locking violation or a witness warning, the problem is visible here before you do anything else.
2. **`sysctl dev.myfirst.0.stats`**: compare the current values to what they should be. If `cb_used` is non-zero but no one is holding a descriptor open, something went wrong with the shutdown path.
3. **`truss -t read,write,poll -f`**: run the failing tester under `truss` and see the syscall returns. A spurious `EAGAIN` (or absence thereof) shows up immediately.
4. **`ktrace`**: if `truss` is not enough, `ktrace -di ./test; kdump -f ktrace.out` gives a deeper view including signals.
5. **Add `device_printf` to the driver**: sprinkle one-line traces at the top and bottom of each handler, then reproduce the test. This is the fallback, and it is sometimes the only way to see what the driver is doing at the moments the user-side tools do not capture.

Be careful with the last step. Every `device_printf` goes through the kernel's log buffer, which is itself a finite circular buffer. Dropping a `device_printf` into the `cbuf_write` function that runs every byte will melt the log. Start with one log line per I/O call and increase only if needed.

10.7.14 Wrapping Up Section 6

You now have a test kit that can exercise every non-trivial behaviour the driver promises. `rw_myfirst_v2` covers sized reads and writes and round-trip correctness. `rw_myfirst_nb` covers the non-blocking path and the `poll(2)` contract. `producer_consumer` covers concurrent two-party load with content verification. `dd`, `cat`, `hexdump`, `truss`, `sysctl`, and `vmstat -m` together provide observability into the driver's internal state.

None of these tools are new or exotic. They are standard FreeBSD base-system utilities, and short pieces of code that you can type in an afternoon. The combination is enough to catch most driver bugs before they reach

anyone else's hands. The next section takes the driver you have just finished testing and prepares its code shape for the concurrency work in Chapter 11.

10.8 Section 7: Refactoring and Preparing for Concurrency

The driver works. It buffers, it blocks, it poll-reports correctly, and the user-space tests in Section 6 confirm that bytes flow correctly under realistic load. What we have not yet done is shape the code for the work Chapter 11 will do. This section is the bridge: it identifies the places in the current source that will need attention from a real concurrency standpoint, refactors the buffer access into a tight set of helpers, and finishes by making the driver as honest as possible about its own state.

We are not introducing new locking primitives here. Chapter 11 will explore that material at length, including the alternatives to a single mutex (sleepable locks, sx locks, rwlocks, lock-free patterns), the verification tools (WITNESS, INVARIANTS), and the rules around interrupt context, sleep, and lock ordering. What we are doing in Section 7 is making the *shape* of the code such that those tools can be applied cleanly when the time comes.

10.8.1 Identifying Potential Race Conditions

A “race condition” in driver code is any place where the correctness of the code depends on the order in which two threads execute, where the order is not enforced by anything in the driver. The Stage 4 driver has the right *machinery* in place (a mutex, a sleep channel, sleep-with-mutex semantics through `mtx_sleep`) and the I/O handlers respect it. But there are still places where a careful audit is worthwhile.

Let us walk through the data structures and ask, of each shared field, “who reads it, who writes it, what protects access?”

sc->cb (the circular buffer). Read by `myfirst_read`, written by `myfirst_write`, read by `myfirst_poll`, read by the two sysctl handlers (`cb_used` and `cb_free`), read by `myfirst_detach` (implicitly through `cbuf_destroy`). Protected by `sc->mtx` everywhere it is touched. *Looks safe.*

sc->bytes_read, sc->bytes_written. Updated by the two I/O handlers under `sc->mtx`. Read by sysctl directly through `SYSCTL_ADD_U64` (no handler interposed). The sysctl read is a single 64-bit load on most architectures, which is a torn-read risk on some 32-bit platforms but is atomic on amd64 and arm64. *Mostly safe; see torn-read note below.*

sc->open_count, sc->active_fhs. Updated under `sc->mtx`. Read by sysctl directly. Same torn-read consideration.

sc->is_attached. Read by every handler at entry, set by `attach` (without lock, before `make_dev`), cleared by `detach` (under lock). The unlocked write at attach time is safe because no one else can see the device yet. The locked clear at detach time is correctly ordered with the wakeup. *Looks safe.*

sc->cdev, sc->cdev_alias. Set by `attach`, cleared by `detach`. Once attach is done, these are stable for the lifetime of the device. The handlers reach the softc through `dev->si_drv1` (set during attach) and never dereference these directly during I/O. *Safe by construction.*

sc->rsel, sc->wsel. The `selinfo` machinery is internally locked (it uses the kernel's `selspinlock` and per-mutex `knlist` if you initialise one). For pure `select(2)/poll(2)` use, the `selrecord` and `selwakeup` calls handle their own concurrency. *Safe.*

sc->open_count and friends, again. The torn-read note above is worth being explicit about. On 32-bit platforms (i386, armv7), a 64-bit field can be split across two memory operations, and a concurrent write can yield a read that contains the high half of one value and the low half of another (a “torn read”). The chapter is targeting amd64 where this is not an issue, but it is the kind of thing a real driver should think about. The fix, if needed, is to add a sysctl handler (like the `cb_used` one) that takes the mutex around the load.

The audit above gives a clean bill of health. The bigger refactoring opportunities are not race conditions but *code shape*: places where the buffer logic is mixed in with the I/O logic, where helper functions would clarify intent, and where Chapter 11 can introduce new lock classes without touching the I/O handlers.

10.8.2 The Refactor: Pulling Buffer Access into Helpers

The Stage 3 / Stage 4 handlers contain a fair amount of locking and book-keeping inline. Let us extract that into a small set of helpers. The goal is two-fold: the I/O handlers become obviously correct, and Chapter 11 can substitute different locking strategies into the helpers without touching `myfirst_read` or `myfirst_write`.

Define the following helpers, all in `myfirst.c` (or in a new file `myfirst_buf.c` if you want clearer separation):

```
/* Read up to "n" bytes from the cbuf into "dst". Returns count moved. */
static size_t
myfirst_buf_read(struct myfirst_softc *sc, void *dst, size_t n)
{
    size_t got;

    mtx_assert(&sc->mtx, MA_OWNED);
    got = cbuf_read(&sc->cb, dst, n);
    sc->bytes_read += got;
    return (got);
}

/* Write up to "n" bytes from "src" into the cbuf. Returns count moved. */
static size_t
myfirst_buf_write(struct myfirst_softc *sc, const void *src, size_t n)
{
    size_t put;

    mtx_assert(&sc->mtx, MA_OWNED);
    put = cbuf_write(&sc->cb, src, n);
    sc->bytes_written += put;
    return (put);
}

/* Wait, with PCATCH, until the cbuf is non-empty or the device tears down. */
static int
myfirst_wait_data(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
```

```

    struct uio *uio)
{
    int error;

    mtx_assert(&sc->mtx, MA_OWNED);
    while (cbuf_used(&sc->cb) == 0) {
        if (uio->uio_resid != nbfore)
            return (-1);           /* signal caller to break */
        if (ioflag & IO_NDELAY)
            return (EAGAIN);
        error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", 0);
        if (error != 0)
            return (error);
        if (!sc->is_attached)
            return (ENXIO);
    }
    return (0);
}

/* Wait, with PCATCH, until the cbuf has free space or the device tears down. */
static int
myfirst_wait_room(struct myfirst_softc *sc, int ioflag, ssize_t nbfore,
    struct uio *uio)
{
    int error;

    mtx_assert(&sc->mtx, MA_OWNED);
    while (cbuf_free(&sc->cb) == 0) {
        if (uio->uio_resid != nbfore)
            return (-1);           /* signal caller to break */
        if (ioflag & IO_NDELAY)
            return (EAGAIN);
        error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfwr", 0);
        if (error != 0)
            return (error);
        if (!sc->is_attached)
            return (ENXIO);
    }
    return (0);
}

```

The `mtx_assert(&sc->mtx, MA_OWNED)` calls are a tiny but valuable safety net. If a future caller forgets to acquire the lock before calling one of these helpers, the assertion fires (in a WITNESS kernel). Once you trust the helpers, you can stop thinking about the lock at the call sites.

The four helpers together cover everything the I/O handlers need from the buffer abstraction: reading bytes, writing bytes, waiting for data, waiting for room. Each helper takes the mutex by reference and asserts that it is held. None of them lock or unlock.

With the helpers defined, the I/O handlers shrink considerably:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t take, got;
    ssize_t nbefore;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    nbefore = uio->uio_resid;
    while (uio->uio_resid > 0) {
        mtx_lock(&sc->mtx);
        error = myfirst_wait_data(sc, ioflag, nbefore, uio);
        if (error != 0) {
            mtx_unlock(&sc->mtx);
            return (error == -1 ? 0 : error);
        }
        take = MIN((size_t)uio->uio_resid, sizeof(bounce));
        got = myfirst_buf_read(sc, bounce, take);
        fh->reads += got;
        mtx_unlock(&sc->mtx);

        wakeup(&sc->cb);
        selwakeup(&sc->wsel);

        error = uiomove(bounce, got, uio);
        if (error != 0)
            return (error);
    }
    return (0);
}
```

```
static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t want, put, room;
    ssize_t nbefore;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    nbefore = uio->uio_resid;
    while (uio->uio_resid > 0) {
        mtx_lock(&sc->mtx);
        error = myfirst_wait_room(sc, ioflag, nbefore, uio);
        if (error != 0) {
            mtx_unlock(&sc->mtx);
            return (error == -1 ? 0 : error);
        }
        room = cbuf_free(&sc->cb);
        mtx_unlock(&sc->mtx);

        want = MIN((size_t)uio->uio_resid, sizeof(bounce));
        want = MIN(want, room);
        error = uiomove(bounce, want, uio);
        if (error != 0)
            return (error);

        mtx_lock(&sc->mtx);
        put = myfirst_buf_write(sc, bounce, want);
        fh->writes += put;
        mtx_unlock(&sc->mtx);

        wakeup(&sc->cb);
        selwakeup(&sc->rsel);
    }
    return (0);
}
```

Each I/O handler now does the same three things in the same order: take the lock, ask the helper for state, release the lock, do the copy, take the lock again, update state, release, wake. The pattern is clear enough that a future reader can verify the locking discipline at a glance.

The error code -1 returned by the wait helpers is a small convention: “no error to report, but the loop should break and the caller should return 0.” Using -1 (which is not a valid errno) makes the convention obvious without adding a third out-parameter. It is local to the driver and never escapes to user space.

10.8.3 Documenting the Locking Strategy

A driver this size benefits from a one-paragraph comment near the top of the file explaining the locking discipline. The comment is for the next person who reads the code, and it is your future self in three months. Add this near the `struct myfirst_softc` declaration:

```
/*
 * Locking strategy.
 *
 * sc->mtx protects:
 *   - sc->cb (the circular buffer's internal state)
 *   - sc->bytes_read, sc->bytes_written
 *   - sc->open_count, sc->active_fhs
 *   - sc->is_attached
 *
 * Locking discipline:
 *   - The mutex is acquired with mtx_lock and released with mtx_unlock.
 *   - mtx_sleep(&sc->cb, &sc->mtx, PCATCH, ...) is used to block while
 *     waiting on buffer state. wakeup(&sc->cb) is the matching call.
 *   - The mutex is NEVER held across uiomove(9), copyin(9), or copyout(9),
 *     all of which may sleep.
 *   - The mutex is held when calling cbuf_*() helpers; the cbuf module is
 *     intentionally lock-free by itself and relies on the caller for safety.
 *   - selwakeup(9) and wakeup(9) are called with the mutex DROPPED, after
 *     the state change that warrants the wake.
 */
```

That comment is enough for Chapter 11 to either follow the same convention or to deliberately change it. A driver that explains its own rules makes future maintenance easier; a driver that does not explain its rules leaves every future reader to infer them from the source, which is slow and error-prone.

10.8.4 Splitting `cbuf` Out of `myfirst.c`

In Stage 2 and Stage 3, the `cbuf` source lived alongside `myfirst.c` in the same module directory but in its own `.c` file. The Makefile is updated to compile both:

```
KMOD=    myfirst
SRCS=    myfirst.c cbuf.c
SRCS+=   device_if.h bus_if.h

.include <bsd.kmod.mk>
```

Two minor pieces are worth noting.

The first is that `cbuf.c` declares its own `MALLOC_DEFINE`. Each `MALLOC_DEFINE` for the same tag in the same module would be a duplicate definition; we therefore put the declaration in exactly one source file (`cbuf.c`) and an extern declaration in `cbuf.h` if needed. In our setup, the tag is local to `cbuf.c` and no external use is needed.

The second is that `cbuf.c` does not need any of the `myfirst` headers. It is a self-contained library that the driver happens to use. If you ever wanted to share `cbuf` with a second driver, you could pull it out into its own KLD or into `/usr/src/sys/sys/cbuf.h` and `/usr/src/sys/kern/subr_cbuf.c` (a hypothetical placement). The discipline of keeping `cbuf` self-contained makes that possible.

10.8.5 Naming Conventions

A small but useful pattern: name your buffer-related fields and functions consistently. We have used `sc->cb` for the buffer, `cbuf_*` for buffer functions, `myfirst_buf_*` for the driver's wrappers. The pattern lets a reader scan the code and instantly know whether a function is touching the raw buffer (`cbuf_*`) or going through the locked driver wrappers (`myfirst_buf_*`).

Avoid mixing styles. Calling the buffer `sc->ring` in some places and `sc->cb` in others, or `cbuf_get` and `cbuf_read`, makes the code harder to skim. Pick one set of names and use them throughout.

10.8.6 Defending Against Buffer-Size Surprises

The `MYFIRST_BUFSIZE` macro determines the capacity of the ring. Right now it is hard-coded to 4096. There is nothing wrong with that, but a `sysctl` knob (read-only) that exposes the value, plus a `module_param`-style override at module load time, would make the driver more usable in tests without needing to recompile.

Here is the pattern for a load-time override using `TUNABLE_INT`:

```
static int myfirst_bufsize = MYFIRST_BUFSIZE;
TUNABLE_INT("hw.myfirst.bufsize", &myfirst_bufsize);
SYSCTL_INT(_hw_myfirst, OID_AUTO, bufsize, CTLFLAG_RDN,
    &myfirst_bufsize, 0, "Default buffer size for new myfirst attaches");
```

`TUNABLE_INT` reads the value from the kernel environment at boot or `kldload` time. A user can set it from the loader prompt (set `hw.myfirst.bufsize=8192`) or by running `kenv hw.myfirst.bufsize=8192` before `kldload`. The `CTLFLAG_RDN` flag indicates “read-only at runtime, but tunable at load time.” After load, `sysctl hw.myfirst.bufsize` shows the chosen value.

Then in `myfirst_attach`, use `myfirst_bufsize` instead of `MYFIRST_BUFSIZE` in the `cbuf_init` call. The change is small but useful: now you can experiment with different buffer sizes without rebuilding the module.

10.8.7 Goals for the Next Milestone

Where Chapter 11 takes the driver:

- The single mutex you have today protects everything. Chapter 11 will discuss whether a single lock is the right design under heavy contention, whether sleepable locks (`sx_*`) would be more appropriate, and how to reason about lock ordering when multiple subsystems get involved.
- The blocking path uses `mtx_sleep`, which is the right primitive for this kind of work. Chapter 11 will introduce `cv_wait(9)` (condition variables) as a more structured alternative for some patterns, and discuss when each is preferable.
- The wake-up strategy uses `wakeup(9)` (wake everyone). Chapter 11 will discuss `wakeup_one(9)` and the thundering-herd problem, and when each is appropriate.
- The `cbuf` is intentionally not thread-safe by itself. Chapter 11 will revisit this decision and discuss the tradeoffs of building locking *into* the data structure versus leaving it to the caller.
- The detach path's "wait for descriptors to close" rule is conservative. Chapter 11 will discuss alternative strategies (forced revocation, reference counting at the `cdev` level, the `destroy_dev_drain(9)` mechanism) for drivers that need to detach despite open descriptors.

You do not need to know any of this material yet. The point is that the current code's *shape* is what makes those topics approachable in Chapter 11. You can swap the mutex for an `sx` lock without touching the helpers' signatures. You can swap `wakeup` for `wakeup_one` with one-line changes. You can introduce a per-reader sleep channel without restructuring the I/O handlers. The refactor pays off as soon as you start asking the next chapter's questions.

10.8.8 A Reading Order for the Next Chapter

When you start Chapter 11, three files in `/usr/src/sys` will repay careful reading.

`/usr/src/sys/kern/subr_sleepqueue.c` is where `mtx_sleep`, `tsleep`, and `wakeup` are implemented. Read it once for context. The implementation is more elaborate than the man pages suggest, but the core of it (chan-keyed sleep queues, atomic dequeue on wake) is straightforward.

`/usr/src/sys/sys/sx.h` and `/usr/src/sys/kern/kern_sx.c` together explain the sleepable-shared-exclusive lock. We mentioned `sx` above as an alternative to `mtx`; reading the actual implementation is the best way to understand the tradeoffs.

`/usr/src/sys/sys/condvar.h` and `/usr/src/sys/kern/kern_condvar.c` document the `cv_wait` family of condition-variable primitives. Like `mtx_sleep`, they build on the kernel's sleep-queue machinery in `subr_sleepqueue.c`, but they expose a distinct structured API where each wait point has its own named `struct cv` instead of an arbitrary address as the channel. Chapter 11 will explain when to prefer each, and why a dedicated `struct cv` is often the cleaner choice for a well-defined wait condition.

These are not required reading; they are the next step on a long path you are clearly already on.

10.8.9 Wrapping Up Section 7

The driver is now in the shape Chapter 11 wants. The buffer abstraction is in its own file, exercised in userland, and called from the driver through a small set of locked wrappers. The locking strategy is documented in a

comment that names exactly what the mutex protects and what the rules are. The blocking path is correct, the non-blocking path is correct, the poll path is correct, and the detach path correctly waits for and wakes any sleepers.

Most of what you do in Chapter 11 will be additive to this base, not a rewrite of it. The patterns we have built (lock around state changes, sleep with the mutex as interlock, wake on every transition) are the same patterns the rest of the kernel uses. The vocabulary is the same, the primitives are the same, the discipline is the same. You are close to being able to read most character-device drivers in the tree without help.

Before we move on to the chapter's supplementary topics and the labs, take a moment to look at your own source. The Stage 4 driver should be roughly 500 lines of code (`myfirst.c`) plus about 110 lines of `cbuf.c` and 20 lines of `cbuf.h`. The total is small, the layering is clean, and almost every line is doing something specific. That density is what well-shaped driver code looks like.

10.9 Section 8: Three Supplementary Topics

This section covers three topics that often appear alongside buffered I/O in the real world. Each one is large enough to fill an entire chapter on its own; we are not going to do that. Instead we are going to introduce each at the level a reader of this book needs in order to recognise the pattern, talk about it sensibly, and know where to look when the time comes to use it. The deeper treatments come later, in the chapters where each topic is the main subject.

The three topics are: `d_mmap(9)` for letting user space map a kernel buffer; zero-copy considerations and what they really mean; and the readahead and write-coalescing patterns used by high-throughput drivers.

10.9.1 Topic 1: `d_mmap(9)` and Mapping a Kernel Buffer

`d_mmap(9)` is the character-device callback that the kernel invokes when a user-space program calls `mmap(2)` on `/dev/myfirst`. The handler's job is to translate a *file offset* into a *physical address* the VM system can map into the user's process. The signature is:

```
typedef int d_mmap_t(struct cdev *dev, vm_ooffset_t offset, vm_paddr_t *paddr,
                    int nprot, vm_memattr_t *memattr);
```

For each page-sized chunk the user wants to map, the kernel calls `d_mmap` with `offset` set to the byte offset within the device. The handler computes the physical address of the corresponding page and stores it through `*paddr`. It can also adjust the memory attributes through `*memattr` (caching, write-combining, and so on). Returning a non-zero error code tells the kernel “this offset cannot be mapped”; returning 0 indicates success.

The reason we are introducing `d_mmap` here is that it is the lightweight cousin of buffered I/O. With `read(2)` and `write(2)`, every byte is copied across the trust boundary on each call. With `mmap(2)` followed by direct memory access, the bytes are visible to user space without any explicit copy. A user-space program reads from or writes to the mapped region exactly as if it were ordinary memory, and the kernel's buffer is the same bytes the user sees.

This pattern is appealing for a small but important class of devices. A frame buffer, a DMA-mapped device buffer, a shared-memory event queue: each of these benefits from being mapped directly so that user

code can manipulate the bytes without ever entering the kernel. The classical example in `/usr/src/sys/dev/mem/memdev.c` (with the architecture-specific `memmmap` function under each `arch` directory) maps `/dev/mem` so that privileged user processes can read or write physical memory pages.

For a learning driver like ours, the goal is more modest: let `mmap(2)` see the same circular buffer that `read(2)` and `write(2)` use. The user can then read out the buffer without going through the syscall path. We will not extend the driver to support writes through `mmap` (that would require careful handling of cache coherency and concurrent updates with the syscall path), but a read-only mapping is a useful capability to add.

10.9.1.1 A Minimal `d_mmap` Implementation

The implementation is short:

```
static int
myfirst_mmap(struct cdev *dev, vm_ooffset_t offset, vm_paddr_t *paddr,
             int nprot, vm_memattr_t *memattr)
{
    struct myfirst_softc *sc = dev->si_drv1;

    if (sc == NULL || !sc->is_attached)
        return (ENXIO);
    if ((nprot & VM_PROT_WRITE) != 0)
        return (EACCES);
    if (offset >= sc->cb.cb_size)
        return (-1);
    *paddr = vtophys((char *)sc->cb.cb_data + (offset & ~PAGE_MASK));
    return (0);
}
```

Add `.d_mmap = myfirst_mmap`, to the `cdevsw`. The handler does four things in sequence.

First, it checks that the device is still attached. A user that has held an `mmap` on a torn-down driver should see `ENXIO`, not a kernel panic.

Second, it refuses write mappings. Allowing `PROT_WRITE` would let user space modify the buffer concurrently with the read and write handlers, which would race with the `cbuf`'s invariants. A read-only mapping is enough for our learning purposes; a real driver that wants writable mappings has to do considerably more work to keep the `cbuf` consistent.

Third, it bounds the offset. The user could request `offset = 1 << 30`, far past the end of the buffer; the handler returns `-1` to refuse. (Returning `-1` tells the kernel “no valid address for this offset”; the kernel treats this as the end of the mappable region.)

Fourth, it computes the physical address with `vtophys(9)`. `vtophys` translates a kernel virtual address into the corresponding physical address for a single page. The buffer was allocated with `malloc(9)`, which returns *virtually* contiguous memory; for an allocation that fits in one page (our `MYFIRST_BUFSIZE` of 4096 bytes on a 4 KB page machine) this is trivially also physically contiguous, and one `vtophys` is enough. For larger buffers,

each page must be looked up individually, because `malloc(9)` does not promise cross-page physical contiguity. The expression `(offset & ~PAGE_MASK)` rounds the caller's offset down to the page boundary so that `vtophys` is called on the correct page base; the kernel then takes care of applying the intra-page offset from the user's `mmap` call. A production driver whose buffer may span more than one page should walk the allocation page by page, or switch to `contigmalloc(9)` when physical contiguity is actually required.

10.9.1.2 Caveats and Limitations

A few important caveats apply to this minimal implementation.

`vtophys` works for memory allocated by `malloc(9)` only when each page of the allocation is contiguous in physical memory. Small allocations (under one page) are always contiguous. Larger allocations made with `malloc(9)` are *virtually* contiguous but not necessarily physically contiguous; the handler would need to compute the per-page physical address rather than assuming linearity. For Chapter 10's 4 KB buffer (which fits in a single page) the simple form works.

For genuinely large buffers, the right primitive is `contigmalloc(9)` (contiguous physical memory) or `dev_pager_*` functions to provide a custom pager. Both belong in later chapters where we discuss VM details properly.

The mapping is read-only. A `PROT_WRITE` request will fail with `EACCES`. Allowing writes would require either a way to invalidate user mappings when the `cbuf` indices change (impractical for a circular buffer), or a fundamentally different design where the user's writes drive the buffer directly. Neither is appropriate for a learning chapter.

Finally, mapping the `cbuf` does *not* let user space see a coherent stream of bytes the way a read does. The mapping shows the *raw* underlying memory, including bytes outside the live region (which may be stale or zero) and ignoring the head/used indices. A user that reads from the mapping needs to consult `sysctl dev.myfirst.0.stats.cb_used` and `cb_used` to know where the live region starts and ends. This is intentional: `mmap` is a low-level mechanism that exposes raw memory, and any structured interpretation has to be layered on top.

10.9.1.3 A Small `mmap` Tester

A user-space program that maps the buffer and walks it looks like:

```
/* mmap_myfirst.c: map the myfirst buffer read-only and dump it. */
#include <sys/mman.h>
#include <fcntl.h>
#include <stdio.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH "/dev/myfirst"
#define BUFSIZE 4096

int
```

```
main(void)
{
    int fd = open(DEVPATH, O_RDONLY);
    if (fd < 0) { perror("open"); return (1); }

    char *map = mmap(NULL, BUFSIZE, PROT_READ, MAP_SHARED, fd, 0);
    if (map == MAP_FAILED) { perror("mmap"); close(fd); return (1); }

    printf("first 64 bytes:\n");
    for (int i = 0; i < 64; i++)
        printf(" %02x", (unsigned char)map[i]);
    putchar('\n');

    munmap(map, BUFSIZE);
    close(fd);
    return (0);
}
```

Run it after writing some bytes into the device:

```
$ printf 'ABCDEFGHIJKL' > /dev/myfirst
$ ./mmap_myfirst
first 64 bytes:
 41 42 43 44 45 46 47 48 49 4a 4b 4c 00 00 00 00 ...
```

The first twelve bytes are A, B, ..., L, exactly what was written. The remaining bytes are zero because `cbuf_init` zero-fills the backing memory and we have not written anything past offset 12. This is the basic mechanism.

10.9.1.4 When You Would Actually Use `d_mmap`

Most pseudo-devices do not need `d_mmap`. The syscall path is fast, simple, and well-understood, and the cost of an extra `read(2)` per page is negligible for low-rate data. Use `d_mmap` when one of the following applies:

- The data is being produced into the buffer at very high rates (gigabytes per second in graphics or high-end I/O) and the syscall overhead per byte starts to dominate.
- The user space wants to peek at or process specific positions in a large buffer without copying the whole thing.
- The driver represents hardware whose registers or DMA areas are addressable as memory (for instance, a GPU's command FIFO).

For our pseudo-device, `d_mmap` is mostly a learning exercise. Building it teaches you the call signature, the relationship to the VM system, and the `vtophys/contigmalloc` distinction. Real production use comes when you write a driver that demands the throughput.

10.9.2 Topic 2: Zero-Copy Considerations

“Zero-copy” is one of the most overused words in systems performance discussions. Strictly read, it means “no data is copied between memory locations during the operation.” That definition is too strict to be useful: even DMA from a device to memory is, technically, a copy. In practice, “zero-copy” is shorthand for “the bytes do not pass through the CPU’s caches as part of an explicit copy instruction in the I/O path.”

For a character device like `myfirst`, the question is whether you can avoid the `uiomove(9)` copy in the read and write handlers. The answer, for the patterns we have built, is “no, and trying to is usually a mistake.” Here is why.

`uiomove(9)` does one copy from kernel to user (or user to kernel) for each transfer. That is one set of byte motions per `read(2)` or `write(2)` call. The CPU pulls the source into cache, writes the destination from cache, and goes on with its work. On modern hardware, this copy is fast: an L1 cache line is 64 bytes, the CPU can stream tens of gigabytes per second of memory copies, and the cost per byte is in the single-digit nanoseconds.

To eliminate that copy, you have to find another way to make the bytes visible to user space. The two main mechanisms are `mmap(2)` (which we just discussed) and shared-memory primitives (`shm_open(3)`, sockets with `MSG_PEEK`, `sendfile`). All of them have their own costs: page-table updates, TLB flushes, IPI traffic on multi-CPU systems, the inability to use the source memory for anything else while it is mapped. For small to medium transfers, `uiomove` is *faster* than the alternatives because the alternatives’ setup costs dominate.

There are real cases where zero-copy pays off. A network driver that DMA’s incoming packets into mbufs and hands the mbufs to the protocol stack avoids a copy that would otherwise cost as much as the DMA itself. A storage driver that uses `bus_dmamap_load(9)` to set up a DMA transfer from a user-space buffer (after `vs` locking it) avoids two copies that would otherwise dominate the I/O cost. A high-throughput graphics driver may map GPU command buffers directly into the rendering process to avoid a per-frame copy. All of these are real wins.

For a pseudo-device whose data does not come from real hardware, however, the gain is illusory. The “saved” copy is just rearranging where the bytes are stored; the cost shows up somewhere else (the page-table update, the cache miss when the user touches a page that has been written-through directly from the kernel, the contention when two CPUs touch the same shared page). The Stage 4 driver does a `uiomove` per bounce-buffer-sized chunk; that is roughly one copy per 256 bytes, which is well within the throughput a single core can sustain.

If you find yourself optimizing the copy out of a pseudo-device, two questions are worth asking first.

The first question is whether the copy is actually the bottleneck. Run the driver under `dtrace` or `pmcstat` and measure where the cycles are going. If `uiomove` is not in the top three, optimizing it will make no measurable difference. The most common bottlenecks in this kind of code are lock contention (one CPU is waiting for another to release the mutex), syscall overhead (many small syscalls instead of fewer large ones), and the cost of waking sleepers (every wakeup is a sleep-queue traversal). All of those offer bigger gains than the copy itself.

The second question is whether the *user* of the driver actually wants zero-copy semantics. A user that calls `read(2)` is asking the kernel to give them a copy of the bytes. They are not asking for a pointer to the kernel’s bytes. Switching to a mapping changes the contract; the user has to know about the mapping, manage it explicitly, and understand the cache-coherency rules. That is a trade-off the user has to opt into, not a transparent improvement.

The right framing is: zero-copy is a technique with specific costs and specific benefits. Use it when the benefits clearly outweigh the costs, and not before. For most drivers, especially pseudo-devices, the syscall path with `uiomove` is the right choice.

10.9.3 Topic 3: Readahead and Write Coalescing

The third topic is about throughput. When a driver supports a steady high-rate stream of bytes, two patterns become important: **readahead** on the read side and **write coalescing** on the write side. Both are about doing more work per syscall, and both reduce the per-byte overhead of the I/O path.

10.9.3.1 Readahead

Readahead is the act of fetching more data than the user has currently asked for, on the assumption that they will ask for it next. A regular-file read often triggers readahead at the VFS level: when the kernel notices that a process has read a few sequential blocks, it starts reading the next blocks in the background so that the next `read(2)` finds them already in memory. The user sees lower latency on subsequent reads.

For a pseudo-device, readahead at the VFS level is not directly applicable (there is no underlying file). However, the *driver* can do its own form of readahead by asking the data source to produce ahead of time. Imagine a driver that wraps a slow data source (a hardware sensor, a remote service). When the user reads, the driver pulls data from the source. The user reads again; the driver pulls more. With readahead, the driver might pull a *block* of data from the source the first time the user reads, store the extra bytes in the `cbuf`, and serve subsequent reads directly from the `cbuf` without going back to the source.

This is exactly what the `myfirst` driver already does in spirit. The `cbuf` *is* the readahead buffer. Writes deposit data, reads consume it, and the reader does not have to wait for the writer to write each individual byte. The wider lesson is that having a buffer in the driver is, structurally, the same pattern as readahead: it lets the consumer find data already prepared.

When you do build a driver against a real source, the readahead logic typically lives in a kernel thread or callout that watches `cbuf_used` and triggers a fetch from the source when the count drops below a threshold. The threshold is the *low-water mark*; the fetch stops when the count reaches the *high-water mark*. The `cbuf` becomes a buffer between the source's burst rate and the consumer's burst rate, and the kernel thread keeps it appropriately full.

10.9.3.2 Write Coalescing

Write coalescing is the mirror pattern. A driver that sinks data into a slow destination (a hardware register, a remote service) might collect several small writes into a single large write, reducing the per-write overhead at the destination. The user's `write(2)` calls deposit bytes into the `cbuf`; a kernel thread or callout reads from the `cbuf` and writes to the destination in larger chunks.

Coalescing is especially useful when the destination has high per-operation overhead. Consider a driver that talks to a chip whose command structure expects a header, payload, and footer per write: a single 1024-byte write to the chip might be twenty times faster than a thousand 1-byte writes, because the per-write overhead dominates at small sizes. The driver coalesces by collecting bytes in the `cbuf` and flushing them in larger chunks.

The decision of *when* to flush is the hard part. Two common policies exist: **flush at threshold** (flush when `cbuf_used` exceeds a high-water mark) and **flush at timeout** (flush after a fixed delay since the first byte arrived). Most real drivers use a combination: flush whenever either condition is met. A `callout(9)` (the kernel's deferred-execution primitive) is the natural way to schedule the timeout. Chapter 13 covers `callout` in detail; for now, the conceptual point is that coalescing is a deliberate trade between per-byte latency (worse, because the byte sits in the buffer) and per-operation throughput (better, because the destination sees fewer larger writes).

10.9.3.3 How These Patterns Apply to `myfirst`

The `myfirst` driver does not need either pattern explicitly because it has no real source or sink. The `cbuf` already provides the coupling between the writer and the reader, and the only “flush” is the natural one that happens when the reader calls `read(2)`. But knowing the patterns is useful for two reasons.

First, when you read driver code in `/usr/src/sys/dev/`, you will see these patterns repeatedly. Network drivers coalesce TX writes through queues. Audio drivers do readahead by fetching DMA blocks ahead of the consumer. Block-device drivers use the BIO layer to coalesce I/O requests by sector adjacency. Recognising the pattern lets you skim a thousand lines of driver code without losing the plot.

Second, when you start writing real-hardware drivers in Part 4 and beyond, you will need to decide whether and how to apply these patterns to your driver. The Chapter 10 work has given you the *substrate* (a circular buffer with proper locking and blocking semantics). Adding readahead means starting a kernel thread to fill it. Adding coalescing means flushing it on a timer or threshold. The substrate is the same; the policies are different.

10.9.4 Wrapping Up Section 8

These three topics (`d_mmap`, zero-copy, readahead/coalescing) are common follow-on conversations in driver development. None of them is a Chapter 10 topic in its own right, but each one builds on the buffer abstraction and the I/O machinery you have just put in place.

`d_mmap` adds a complementary path to the buffer: in addition to `read(2)` and `write(2)`, user space can now look at the bytes directly. Zero-copy is the framing that explains why `d_mmap` matters in some cases and is overkill in others. Readahead and write coalescing are the patterns that turn a buffered driver into a high-throughput driver.

The next sections of the chapter return to your current driver: hands-on labs that consolidate the four stages, challenge exercises that stretch your understanding, and a troubleshooting section for the bugs this material is most likely to produce.

10.10 Hands-On Labs

The labs below walk you through the four stages of the chapter, with concrete checkpoints between them. Each lab corresponds to a milestone you can verify with the test kit from Section 6. They are designed to be done in order; later labs assume earlier ones are complete.

A general note: at the start of every lab session, do a `kldunload myfirst` (if the previous module is still loaded) and a fresh `kldload ./myfirst.ko`. Watch `dmesg | tail` for the attach message. If the attach fails, the rest of the lab will fail in confusing ways; fix the attach first.

10.10.1 Lab 1: The Standalone Circular Buffer

Goal: Build and verify the userland `cbuf` implementation. This lab is entirely in user space; no kernel module is involved.

Steps:

1. Create the directory `examples/part-02/ch10-handling-io-efficiently/cbuf-userland/` if it does not already exist.
2. Type `cbuf.h` and `cbuf.c` exactly as shown in Section 2. Resist the temptation to skim the source from the book; typing it forces you to notice every line.
3. Type `cb_test.c` from Section 2.
4. Build with `cc -Wall -Wextra -o cb_test cbuf.c cb_test.c`.
5. Run `./cb_test`. You should see three “OK” lines and the final “all tests OK”.

Checkpoint questions:

- What does `cbuf_write(&cb, src, n)` return when the buffer is already full?
- What does `cbuf_read(&cb, dst, n)` return when the buffer is already empty?
- After `cbuf_init(&cb, 4)` and `cbuf_write(&cb, "ABCDE", 5)`, what is `cbuf_used(&cb)`? What is the content of `cb.cb_data` (positions 0..3)?

If you cannot answer these from your own code, re-read Section 2 and trace through the source.

Stretch goal: add a fourth test, `test_alteration`, that writes one byte, reads it back, writes another byte, reads it back, and so on for 100 iterations. This catches off-by-one errors in `cbuf_read` that the existing tests do not.

10.10.2 Lab 2: The Stage 2 Driver (Circular Buffer Integration)

Goal: Move the verified `cbuf` into the kernel and replace the Stage 3 linear FIFO from Chapter 9.

Steps:

1. Create `examples/part-02/ch10-handling-io-efficiently/stage2-circular/`.
2. Copy `cbuf.h` from your userland directory into the new directory.
3. Type the kernel-side `cbuf.c` from Section 3 (this is the `MALLOC_DEFINE`-using version).
4. Copy `myfirst.c` from `examples/part-02/ch09-reading-and-writing/stage3-echo/` into the new directory.
5. Modify `myfirst.c` to use the `cbuf` abstraction. The changes are:
 - Add `#include "cbuf.h"` near the top.
 - Replace `char *buf; size_t buflen, bufhead, bufused;` with `struct cbuf cb;` in the `softc`.
 - Update `myfirst_attach` to call `cbuf_init(&sc->cb, MYFIRST_BUFSIZE)`. Update the failure path to call `cbuf_destroy`.

- Update `myfirst_detach` to call `cbuf_destroy(&sc->cb)`.
 - Replace `myfirst_read` and `myfirst_write` with the loop-and-bounce versions from Section 3.
 - Update the `sysctl` handlers as in Section 3 (use the `myfirst_sysctl_cb_used` and `myfirst_sysctl_cb_free` helpers).
6. Update the Makefile to build both source files: `SRCS= myfirst.c cbuf.c device_if.h bus_if.h`.
 7. Build with `make`. Fix any compilation errors.
 8. Load with `kldload ./myfirst.ko` and verify with `dmesg | tail`.

Verification:

```
$ printf 'helloworld' > /dev/myfirst
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 10
$ cat /dev/myfirst
helloworld
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 0
```

Stretch goal 1: write enough bytes to wrap the buffer (write 3000 bytes, read 2000, write 2000 again). Verify that `cb_head` is non-zero in `sysctl` and that the data still comes back correctly.

Stretch goal 2: add a `sysctl`-controlled debug flag (`myfirst_debug`) and a `MYFIRST_DBG` macro (Section 3 shows the pattern). Use it to log every successful `cbuf_read` and `cbuf_write` in the I/O handlers. Set the flag with `sysctl dev.myfirst.debug=1` and watch `dmesg`.

10.10.3 Lab 3: The Stage 3 Driver (Blocking and Non-Blocking)

Goal: Add blocking-on-empty, blocking-on-full, and `EAGAIN` for non-blocking callers.

Steps:

1. Create `examples/part-02/ch10-handling-io-efficiently/stage3-blocking/` and copy your Stage 2 source into it.
2. Modify `myfirst_read` to add the inner sleep loop (Section 5). The new shape includes the `nbefore = uio->uio_resid` snapshot, the `mtx_sleep` call, and the `wakeup(&sc->cb)` after a successful read.
3. Modify `myfirst_write` to add the symmetric sleep loop and the matching `wakeup(&sc->cb)`.
4. Update `myfirst_detach` to set `sc->is_attached = 0` *before* calling `wakeup(&sc->cb)`, all under the mutex.
5. Build, load, and verify.

Verification:

```
$ cat /dev/myfirst &
[1] 12345
$ ps -AxH -o pid,wchan,command | grep cat
12345 myfrd  cat /dev/myfirst
```

```
$ echo hi > /dev/myfirst
hi
[after the cat consumes "hi", it blocks again]
$ kill -INT %1
[1]   Interrupt: 2
```

Verification of EAGAIN:

```
$ ./rw_myfirst_nb      # from the userland directory
step 1: empty-read returned EAGAIN (expected)
step 2: poll(POLLIN, 0) = 0 revents=0x0
...
```

If step 1 still says read returned 0, your `IO_NDELAY` check in `myfirst_read` is missing or wrong.

Stretch goal 1: open two cat processes against `/dev/myfirst` simultaneously. Write 100 bytes from a third terminal. Both cats should wake up; one will get the bytes (whichever wins the race for the lock), the other will block again. You can verify the assignment by tagging each cat with a different output stream: `cat /dev/myfirst > /tmp/a &` and `cat /dev/myfirst > /tmp/b &`, then `cmp /tmp/a /tmp/b` (one will be empty).

Stretch goal 2: time how long `cat /dev/myfirst` takes to wake up after a write, using `time(1)`. The wake-up latency should be in the low microseconds; if it is in milliseconds, something is buffering between the write and the wake (or your machine is heavily loaded).

10.10.4 Lab 4: The Stage 4 Driver (Poll Support and Refactor)

Goal: Add `d_poll`, refactor buffer access into helpers, and document the locking strategy.

Steps:

1. Create `examples/part-02/ch10-handling-io-efficiently/stage4-poll-refactor/` and copy your Stage 3 source.
2. Add `struct selinfo rsel; struct selinfo wsel;` to the `softc`.
3. Implement `myfirst_poll` as in Section 5.
4. Add `selwakeup(&sc->wsel)` after the read's successful `cbuf_read`, and `selwakeup(&sc->rsel)` after the write's successful `cbuf_write`.
5. Add `seldrain(&sc->rsel); seldrain(&sc->wsel);` to detach.
6. Add `.d_poll = myfirst_poll,` to the `cdevsw`.
7. Refactor the I/O handlers to use the four helpers from Section 7 (`myfirst_buf_read`, `myfirst_buf_write`, `myfirst_wait_data`, `myfirst_wait_room`).
8. Add the locking-strategy comment from Section 7.
9. Build, load, and verify.

Verification:

```
$ ./rw_myfirst_nb
step 1: empty-read returned EAGAIN (expected)
step 2: poll(POLLIN, 0) = 0 revents=0x0
step 3: wrote 12 bytes
step 4: poll(POLLIN, 0) = 1 revents=0x41
step 5: read 12 bytes: hello world
```

The key change from Lab 3 is that step 4 should now return 1 (not 0), with `revents=0x41` (`POLLIN | POLLRDNORM`). If it still returns 0, your `selwakeup` call is missing from the write path or the `myfirst_poll` handler is wrong.

Stretch goal 1: run `producer_consumer` with `TOTAL_BYTES = 8 * 1024 * 1024` (8 MB) and verify that the test completes with no mismatches. The producer is generating bytes faster than the consumer is reading them, so the buffer should fill up and trigger the blocking path repeatedly. Watch `sysctl dev.myfirst.0.stats.cb_used` in another terminal; it should oscillate.

Stretch goal 2: run two `producer_consumers` in parallel against the same device. The two writers will compete for buffer space; the two readers will compete for bytes. Each pair should still see consistent checksums, but the *interleaving* of bytes will be unpredictable. This shows that the driver is single-stream per device, not per descriptor; if you need per-descriptor streams, that is a different driver design.

10.10.5 Lab 5: Memory Mapping

Goal: Add `d_mmap` so user space can map the `cbuf` read-only.

Steps:

1. Create `examples/part-02/ch10-handling-io-efficiently/stage5-mmap/` and copy your Stage 4 source.
2. Add `myfirst_mmap` from Section 8 to the source.
3. Add `.d_mmap = myfirst_mmap,` to the `cdevsw`.
4. Build, load, and verify.

Verification:

```
$ printf 'ABCDEFGHijkl' > /dev/myfirst
$ ./mmap_myfirst          # from the userland directory
first 64 bytes:
 41 42 43 44 45 46 47 48 49 4a 4b 4c 00 00 00 ...
```

The first twelve bytes are the bytes you wrote.

Stretch goal 1: write a small program that maps the buffer and reads bytes from `offset = sc->cb_size - 32` (i.e. the last 32 bytes). Verify that the program does not crash. Then write enough bytes to push the buffer head into the wrap region and read from the same offset. The contents will be different, because the *raw* bytes in memory are not the same as the *live* bytes from the `cbuf`'s perspective.

Stretch goal 2: try to map the buffer with `PROT_WRITE`. Your program should see `mmap` fail with `EACCES`, because the driver refuses writable mappings.

10.10.6 Lab 6: Stress and Long-Running Tests

Goal: Run the driver under sustained load for at least an hour without errors.

Steps:

1. Set up four parallel test processes:
 - `dd if=/dev/zero of=/dev/myfirst bs=4k 2>/dev/null &`
 - `dd if=/dev/myfirst of=/dev/null bs=4k 2>/dev/null &`
 - `./producer_consumer`
 - A loop that polls `sysctl dev.myfirst.0.stats` every 5 seconds.
2. Let the test run for at least an hour.
3. Check `dmesg` for any kernel warnings, panics, or WITNESS complaints. Check `vmstat -m | grep cbuf` to confirm no leak. Verify that `producer_consumer` reports zero mismatches.

Verification: No kernel warnings. No memory growth in `vmstat`. `producer_consumer` returns 0.

Stretch goal: run the same test under a WITNESS-enabled debug kernel. The kernel will be slower but will catch any locking-discipline violations. If your driver is correct, no warnings should appear.

10.10.7 Lab 7: Deliberate Failures

Goal: Break the driver in three specific ways and observe what happens. This lab teaches you to recognise the failure modes you most want to avoid.

Steps for failure 1: hold the lock across uiomove.

1. Edit your Stage 4 driver. In `myfirst_read`, comment out the `mtx_unlock(&sc->mtx)` that comes before `uiomove(bounce, got, uio)`.
2. Add a matching `mtx_unlock` after the `uiomove` so the code still compiles.
3. Build and load on a WITNESS-enabled kernel.
4. Run a single `cat /dev/myfirst` and write some bytes from another terminal.

What you should observe: A WITNESS warning in `dmesg` complaining about “sleeping with mutex held”. The system may continue running but the warning is the bug.

Cleanup: restore the original code.

Steps for failure 2: forget the wakeup after a write.

1. In `myfirst_write`, comment out `wakeup(&sc->cb)`.
2. Build and load.
3. Run `cat /dev/myfirst &` and `echo hi > /dev/myfirst`.

What you should observe: The cat does not wake up. It will sit in `myfrd` state forever (or until you interrupt it with Ctrl-C).

Cleanup: restore the wakeup. Verify that cat now wakes up immediately.

Steps for failure 3: missing PCATCH.

1. In `myfirst_wait_data`, change `PCATCH` to 0 in the `mtx_sleep` call.

2. Build and load.
3. Run `cat /dev/myfirst & and try kill -INT %1`.

What you should observe: The cat does not respond to Ctrl-C until you write some bytes to wake it. With PCATCH, the signal would interrupt the sleep immediately.

Cleanup: restore PCATCH. Verify that `kill -INT` works as expected.

These three failures are the most common driver bugs in this chapter's territory. Doing them deliberately, once, is the best way to recognise them when they happen accidentally.

10.10.8 Lab 8: Reading Real FreeBSD Drivers

Goal: Read three character-device drivers in `/usr/src/sys/dev/` and identify how each implements its buffer, sleep, and poll patterns.

Steps:

1. Read `/usr/src/sys/dev/evdev/cdev.c`. Identify:
 - Where the per-client ring buffer is allocated.
 - Where the read handler blocks (look for `mtx_sleep`).
 - How `EVDEV_CLIENT_EMPTYQ` is implemented.
 - How `kqueue` is set up alongside `select/poll` (we have not done `kqueue` yet; just notice the calls to `knlist_*`).
2. Read `/usr/src/sys/dev/random/randomdev.c`. Identify:
 - Where `randomdev_poll` is defined.
 - How it handles a not-yet-seeded random device.
3. Read `/usr/src/sys/dev/null/null.c`. Identify:
 - How `zero_read` loops over `uio_resid`.
 - Why there is no buffer, no sleep, and no poll handler.

Checkpoint questions:

- Why does `evdev`'s read handler use `mtx_sleep` while `null`'s does not?
- What would `randomdev`'s poll handler return if called while the device is unseeded?
- How does `evdev` detect that a client has been disconnected (revoked)?

The point of this lab is not to memorise these drivers. It is to confirm that the patterns you have built in `myfirst` are the same patterns the kernel uses elsewhere. By the end of the lab you should feel that the rest of `dev/` is largely *legible* now, where it might have looked impenetrable two chapters ago.

10.11 Challenge Exercises

The labs above ensure you have a working driver and a working test kit. The challenges below are stretch exercises. Each one extends the chapter's material in a useful direction, and each one rewards careful work. Take your time; some of them are more involved than they look.

10.11.1 Challenge 1: Add a Tunable Buffer Size

The `MYFIRST_BUFSIZE` macro hard-codes the buffer at 4 KB. Make it configurable.

- Add a `TUNABLE_INT("hw.myfirst.bufsize", &myfirst_bufsize)` and a matching `SYCTL_INT(_hw_myfirst, OID_AUTO, bufsize, ...)` so the user can set the buffer size at module load time.
- Use the value in `myfirst_attach` to size the `cbuf`.
- Validate the value (reject zero, reject sizes larger than 1 MB, fall back to a sensible default if the input is bad).
- Verify with `kenv hw.myfirst.bufsize=8192; kldload ./myfirst.ko; sysctl dev.myfirst.0.stats.cb_size`

Stretch: make the buffer size *runtime-tunable* via `sysctl`. This is harder than the load-time tunable because it requires safely reallocating the `cbuf` while the device may be in use; you will need to drain or copy existing bytes, take and release the lock at the right moments, and decide what to do with sleeping callers. (Hint: it may be easier to require that all descriptors be closed before allowing a runtime resize.)

10.11.2 Challenge 2: Implement Overwrite Semantics as an Optional Mode

Add an `ioctl(2)` (or, simpler for now, a `sysctl`) that switches the buffer between “block on full” mode (the default) and “overwrite oldest on full” mode. In overwrite mode, `myfirst_write` always succeeds: when `cbuf_free` is zero, the driver advances `cb_head` to make room and then writes the new bytes.

- Add a `cbuf_overwrite` function alongside `cbuf_write` that implements the overwrite semantics. Do not modify `cbuf_write`; the two should be siblings.
- Add a `sysctl dev.myfirst.0.overwrite_mode` (read-write integer, 0 or 1).
- In `myfirst_write`, dispatch to `cbuf_overwrite` if the flag is set.
- Test with a small writer that produces bytes faster than the reader consumes; in overwrite mode, the reader should see the most recent bytes only, while in normal mode the writer blocks.

Stretch: add a counter for the number of bytes overwritten (lost). Expose it as a `sysctl` so the user can see how much data has been dropped.

10.11.3 Challenge 3: Per-Reader Position

The current driver has one shared read position (`cb_head`). When two readers consume bytes, each `read(2)` call drains some bytes from the buffer; the two readers split the stream between them. Some drivers want the opposite: each reader should see *every* byte, so two readers each get the full stream independently.

This is a substantial refactor:

- Maintain a per-descriptor read position in `myfirst_fh`.
- Track the global “earliest live byte” across all descriptors. The `cbuf`’s effective head becomes `min(per_fh_head)`.
- `myfirst_read` advances only the per-descriptor position; `cbuf_read` is replaced by a per-fh equivalent.
- A new descriptor opened mid-stream sees only bytes written after its open.
- When the buffer is “full” depends on the slowest descriptor; you need backpressure logic that accounts for laggards.

This challenge is harder than it sounds; it is essentially building a multicast pipe. Try it only if you have time to think through the locking carefully.

10.11.4 Challenge 4: Implement `d_kqfilter`

Add `kqueue(2)` support alongside the `d_poll` you already have.

- Implement a `myfirst_kqfilter` function dispatched from `cdevsw->d_kqfilter`.
- For `EVFILT_READ`, register a filter that becomes ready when `cbuf_used > 0`.
- For `EVFILT_WRITE`, register a filter that becomes ready when `cbuf_free > 0`.
- Use `knlist_add(9)` and `knlist_remove(9)` to manage the per-filter list.
- Trigger `KNOTE_LOCKED(...)` from the I/O handlers when the buffer transitions.
- Test with a small `kqueue(2)` user program that opens the device, registers `EVFILT_READ`, calls `kevent(2)`, and reports when the descriptor becomes readable.

This challenge is the natural extension of Stage 4. It also previews the `kqueue` material that Chapter 11 will discuss in more depth alongside concurrency.

10.11.5 Challenge 5: Per-CPU Counters

The `bytes_read` and `bytes_written` counters are updated under the mutex. Under heavy multi-CPU load, this can become a contention point. FreeBSD's `counter(9)` API provides per-CPU counters that can be incremented without a lock and summed for read access.

- Replace `sc->bytes_read` and `sc->bytes_written` with `counter_u64_t` instances.
- Allocate them with `counter_u64_alloc(M_WAITOK)` in `attach`; free them with `counter_u64_free` in `detach`.
- Use `counter_u64_add(counter, n)` to increment.
- Use `counter_u64_fetch(counter)` (with a `sysctl` handler) to read.

Stretch: measure the difference. Run `producer_consumer` against the old and new versions and compare wall-clock time. With a small test the difference will be invisible; with a heavily threaded test (multiple producers and consumers) the per-CPU version should be measurably faster.

10.11.6 Challenge 6: A Hardware-Style Interrupt Simulator

Real driver buffers are usually filled by an interrupt handler, not by a `write(2)` syscall. Simulate this:

- Use `callout(9)` (Chapter 13 covers it; you can read ahead) to run a callback every 100 ms.
- The callback writes a small piece of data into the `cbuf` (for example, the current time as a string).
- The user reads from `/dev/myfirst` and sees a stream of timestamped lines.

This challenge previews Chapter 13's deferred-execution material and shows how the same buffer abstraction supports either a syscall-driven producer or a kernel-thread-driven producer.

10.11.7 Challenge 7: A Logging Buffer with dmesg-Style Behaviour

Build a second character device, `/dev/myfirst_log`, that uses an overwrite-mode cbuf to keep a circular log of recent driver events. Every `MYFIRST_DBG` macro call would write into this log instead of (or in addition to) calling `device_printf`.

- Use a separate struct `cbuf` in the softc.
- Provide a way for the kernel side to push lines into the log (`myfirst_log_printf(sc, fmt, ...)`).
- The user can `cat /dev/myfirst_log` to see the recent N lines.
- A new line that overflows the buffer evicts the oldest line, not just the oldest byte (this requires line-aware eviction logic).

This challenge introduces a fairly common driver pattern (a private debug log) and gives you practice with a second, independently designed buffer use case in the same module.

10.11.8 Challenge 8: Performance Measurement

Build a measurement harness that times the throughput of the driver across the four stages.

- Write a small C program that opens the device, writes 100 MB of data, and times the operation.
- Mirror it with a reader that drains 100 MB and times itself.
- Run the pair against Stage 2, Stage 3, and Stage 4 of the chapter, and produce a small table of throughput numbers.
- Identify which stage is slowest and explain why.

The expected answer is “Stage 3 is slower than Stage 2 because of the extra wakeup and `selwakeup` calls per iteration; Stage 4 is similar to Stage 3 within measurement noise”. But the actual numbers are interesting and may surprise you, depending on your CPU, memory bandwidth, and system load.

Stretch: profile the driver under load with `pmcstat(8)` and identify the top three functions by CPU time. If `uiomove` is in the top three, you have validated the discussion in Section 8 about zero-copy. If `mtx_lock` is in the top three, you have a contention problem that Chapter 11’s locking material will address.

10.11.9 Challenge 9: Cross-Reading Real Drivers

Pick three drivers in `/usr/src/sys/dev/` that you have not read before. For each one, identify:

- Where the buffer is allocated and freed.
- Whether it is a circular buffer, a queue, or a different shape.
- What protects it (mutex, sx, lock-free, none).
- How read and write handlers consume from or produce into it.
- How `select/poll/kqueue` integrate with the buffer state changes.

Suggested starting points: `/usr/src/sys/dev/iicbus/iiconf.c` (different category but uses some of the same primitives) and `/usr/src/sys/fs/cuse/cuse.c` (a driver that exposes its buffer to user space). You will see variations on the same themes you have just built.

10.11.10 Challenge 10: Document Your Driver

Write a one-page README in your `examples/part-02/ch10-handling-io-efficiently/stage4-poll-refactor/` directory. The README should cover:

- What the driver does.
- How to build it (make).
- How to load and unload (`kldload`, `kldunload`).
- The user-space interface: device path, mode, reader/writer expectations, blocking behaviour.
- What the sysctls expose.
- How to enable debug logging.
- A reference to the chapter that produced it.

Documentation is the part of driver work most often skipped. A driver that only its author understands is a maintenance liability. Even a one-page README that explains the basics makes the difference between code that survives a hand-off and code that does not.

10.12 Troubleshooting and Common Mistakes

Most of the bugs that appear in this chapter's territory cluster into a small number of categories. The list below catalogues the categories, the symptoms each one produces, and the fix. Read it once before you work through the labs; come back to it when something goes wrong.

10.12.1 Symptom: `cat /dev/myfirst` blocks forever, even after `echo` writes data

Cause. The write handler is not calling `wakeup(&sc->cb)` after a successful `cbuf_write`. The reader is asleep on the channel `&sc->cb`; without a matching `wakeup`, it will never return.

Fix. Add `wakeup(&sc->cb)` after every state-changing operation that might unblock a waiter. In `myfirst_write`, that means after the `cbuf_write` call. In `myfirst_read`, that means after the `cbuf_read` call (which may unblock a waiting writer).

How to verify. Run `ps -AxH -o pid,wchan,command | grep cat`. If the `wchan` column shows `myfrd` (or whatever `wmesg` you used), the reader is sleeping. The channel address you slept on must match the channel address you wake.

10.12.2 Symptom: Data corruption under heavy load

Cause. Almost always a wrap-around bug or a missing lock around the `cbuf` access. Either the `cbuf`'s internal arithmetic is wrong, or two threads are touching it concurrently without synchronization.

Fix. Re-read the `cbuf` source carefully. Run the userland `cb_test` against your current `cbuf.c` (compile it directly with `cc`). If the userland tests pass, the problem is in the driver's locking, not in the `cbuf`. Check that every `cbuf_*` call is bracketed by `mtx_lock` and `mtx_unlock`. Use `INVARIANTS` and `WITNESS` in your kernel config to catch violations.

How to verify. Run `producer_consumer` with a known checksum. If the checksums match but mismatches are reported, the data is being reordered (a wrap-around bug). If the checksums differ, bytes are being lost or duplicated (a locking bug).

10.12.3 Symptom: Kernel panic with “sleeping with mutex held”

Cause. You called `uiomove(9)`, `copyin(9)`, `copyout(9)`, or another sleeping function while holding `sc->mtx`. The sleeping function tried to fault on user memory, and the page-fault handler tried to sleep, but holding a non-sleepable mutex during a sleep is forbidden.

Fix. Release the mutex before any call that might sleep. The Stage 4 handlers do this carefully: lock to access the `cbuf`, unlock to call `uiomove`, lock again to update state.

How to verify. A WITNESS-enabled kernel will print a warning before panicking. The warning identifies the mutex and the sleeping function. The first time this happens, copy the message into a debug log so you can find the call site.

10.12.4 Symptom: EAGAIN is returned even when data is available

Cause. The handler is checking the wrong flag, or it is checking the flag in the wrong place in the loop. Two common variants: checking `ioflag & O_RDONLY` instead of `ioflag & IO_NDELAY`, or returning `EAGAIN` after some bytes have already been transferred (which is the rule from Section 4 you must not break).

Fix. Re-read Section 5’s handler code carefully. The `EAGAIN` path is inside the inner `while (cbuf_used(&sc->cb) == 0)` loop, after the `nbefore` check, only when `ioflag & IO_NDELAY` is non-zero.

How to verify. Run `rw_myfirst_nb`. Step 5 should successfully read the bytes. If it shows `EAGAIN`, the bug is at one of the two locations above.

10.12.5 Symptom: A write succeeds but a subsequent read gets fewer bytes

Cause. The byte counter is being updated incorrectly, or the `cbuf` is being modified outside the handlers. A specific failure mode: counting want bytes as written when `cbuf_write` only stored put bytes (a race in Stage 2 between the `cbuf_free` check and the `cbuf_write` call, even though it is not exercised in single-writer use).

Fix. Look at the `bytes_written += put` line in `myfirst_write`; it must use the actual return value of `cbuf_write`, not the requested size. Compare `sc->bytes_written` and `sc->bytes_read` over time; they should differ by at most `cbuf_size`.

How to verify. Add a log line: `device_printf(dev, "wrote %zu of %zu\n", put, want);`. If `put != want` ever appears in `dmesg`, you have found the discrepancy.

10.12.6 Symptom: `kldunload` returns `EBUSY`

Cause. Some descriptor is still open against the device. The detach refuses to proceed when `active_fhs > 0`.

Fix. Find the process that holds the descriptor open and close it. `fstat | grep myfirst` lists the offending processes. kill them if necessary.

How to verify. After closing all descriptors (or killing the offending processes), `sysctl dev.myfirst.0.stats.active_fh` should drop to zero. `kldunload myfirst` should then succeed.

10.12.7 Symptom: Memory growth in `vmstat -m | grep cbuf`

Cause. The driver is allocating without freeing. Either the attach failure path forgot to call `cbuf_destroy`, or the detach path forgot, or there is more than one `cbuf` being allocated per attach.

Fix. Audit every code path that calls `cbuf_init`. Each call must be matched by exactly one `cbuf_destroy` call before the surrounding context goes away. The standard idiom is to put `cbuf_init` near the top of `attach` and `cbuf_destroy` near the bottom of `detach`, with the failure-path `goto fail_*` chain calling `cbuf_destroy` if `attach` fails after `cbuf_init`.

How to verify. `kldload` and `kldunload` the module several times. `vmstat -m | grep cbuf` should show 0 after each `kldunload`.

10.12.8 Symptom: `select(2)` or `poll(2)` does not wake up

Cause. The driver is missing a `selwakeup` call when state changes. Either the read path forgot to call `selwakeup(&sc->wsel)` after draining bytes, or the write path forgot to call `selwakeup(&sc->rsl)` after adding bytes.

Fix. The pattern: every state change that might make a previously-not-ready condition into a ready condition must be paired with a `selwakeup` call. Drain bytes -> `selwakeup(&sc->wsel)`. Add bytes -> `selwakeup(&sc->rsl)`.

How to verify. Run `rw_myfirst_nb`. Step 4 should show `revents=0x41`. If it shows `revents=0x0`, your `selwakeup` is missing or the `myfirst_poll` handler is not setting `revents` correctly.

10.12.9 Symptom: `truss` shows `EINVAL` for zero-byte reads

Cause. Your handler is rejecting zero-byte reads with `EINVAL`. As discussed in Section 4, zero-byte reads and writes are legal and the handler must not error on them.

Fix. Remove any `if (uio->uio_resid == 0) return (EINVAL);` early return at the top of `myfirst_read` or `myfirst_write`.

How to verify. A program that calls `read(fd, NULL, 0)` should see the call return 0, not -1 with `EINVAL`.

10.12.10 Symptom: `ps` shows the reader stuck in a sleep state called something different

Cause. Your `mtx_sleep` is being called with a different `wmesg` than you expected. Two common variants: `typo (mfyrd instead of myfrd)`, or the same handler is being called from a code path where the wait reason is actually different.

Fix. Standardise the `wmesg` strings. `myfrd` for “myfirst read”, `myfwr` for “myfirst write”. A unique short string per wait point makes `ps -AxH` immediately informative.

How to verify. `ps -AxH` should show `myfrd` for sleeping readers and `myfwr` for sleeping writers.

10.12.11 Symptom: A signal does not interrupt a blocked read

Cause. The `mtx_sleep` is being called without `PCATCH`. Without `PCATCH`, signals are deferred until the sleep ends for some other reason.

Fix. Always pass `PCATCH` for user-driven sleeps. The exception is sleeps that should be uninterruptible (kernel internal logic that must not be cancelled by a signal). For `myfirst_read` and `myfirst_write`, both are user-driven and both should pass `PCATCH`.

How to verify. `cat /dev/myfirst &` followed by `kill -INT %1` should cause `cat` to exit. If `cat` does not exit until you also write to the device (or send `kill -9`), `PCATCH` is missing.

10.12.12 Symptom: Compiler warns about a missing prototype for `cbuf_read`

Cause. The driver source uses `cbuf_read` but does not include `cbuf.h`.

Fix. Add `#include "cbuf.h"` near the top of `myfirst.c`. The file path is relative to the source directory, so as long as both files are in the same directory the include will resolve.

How to verify. A clean build with no warnings.

10.12.13 Symptom: make complains about missing `bus_if.h` or `device_if.h`

Cause. The Makefile is missing the standard `SRCS+= device_if.h bus_if.h` line that pulls in the auto-generated `kobj` headers for Newbus.

Fix. Use the Makefile from Section 3.

How to verify. `make clean && make` should succeed without missing-header errors.

10.12.14 Symptom: `kldload` fails with `Exec format error`

Cause. The `.ko` was built against a different kernel than the one currently running. This typically happens when you reboot into a different kernel without rebuilding, or when you copy a `.ko` from one machine to another with different kernel sources.

Fix. `make clean && make` against the running kernel's `/usr/src`.

How to verify. `uname -a` should match the kernel version that built the `.ko`. Check `dmesg` after the failed `kldload` for more details.

10.12.15 Symptom: The driver reports correct data but loses it after several runs

Cause. The `cbuf` is not being reset between attaches, or the `softc` is not being zero-initialised. With `M_ZERO` on the `malloc(9)` call (and the `cbuf_init` call zero-initializing its own state), this should not happen, but a partial fix that misses one of these can leave stale state.

Fix. Audit `myfirst_attach` to make sure every field of the `softc` is initialised explicitly. Use `M_ZERO` on the `malloc(9)` call that allocates the `softc` (Newbus does this automatically with `device_get_softc`, but verify). Use `cbuf_init` to set the `cbuf`'s indices to zero.

How to verify. `kldload`, write some data, `kldunload`, `kldload` again. The new attach should report `cb_used = 0`.

10.12.16 Symptom: `producer_consumer` reports a small number of mismatches under heavy load

Cause. A subtle locking bug, often related to the order of wakeup calls and the inner sleep loop's re-check. The classic symptom: under contention, occasionally a thread wakes up and consumes bytes that another thread had thought were still available.

Fix. Verify that every `mtx_sleep` is in a `while` (not `if`) loop, and that the loop re-checks the condition after waking. The wakeup is a *hint*, not a guarantee; a woken thread might find the condition false again because another thread got there first.

How to verify. `producer_consumer` should report zero mismatches across multiple runs. A mismatch count that varies between runs suggests a race; a mismatch count that is always exactly N suggests an off-by-one bug.

10.12.17 General Advice for Debugging

Three habits make driver debugging much faster.

The first is to have a WITNESS-enabled kernel ready. WITNESS catches lock-ordering violations and “sleeping with mutex held” bugs that a production kernel would silently allow. The performance overhead is significant, so run WITNESS in your lab environment, not in production.

The second is to add `device_printf` log lines liberally during development, then remove them or guard them behind `myfirst_debug` before committing. The log buffer is finite, so do not log per-byte; one line per I/O call is the right granularity.

The third is to compile with `-Wall -Wextra` and treat warnings as bugs. The kernel build system passes a lot of warning flags by default; pay attention to them. Almost every warning is the kernel telling you about a real or potential bug.

When all else fails, sit back and trace through the code path on paper. A driver this size is small enough to fit on a single sheet. Ninety percent of the time, drawing the call graph and the lock acquisitions in order shows you the bug.

10.13 Quick Reference: Patterns and Primitives

This reference is the chapter's material reduced to fast-lookup form. Use it after you have read the chapter; it is a reminder, not a tutorial.

10.13.1 The Circular Buffer API

```

struct cbuf {
    char      *cb_data;      /* backing storage */
    size_t    cb_size;      /* total capacity */
    size_t    cb_head;      /* next byte to read */
    size_t    cb_used;      /* live byte count */
};

int      cbuf_init(struct cbuf *cb, size_t size);
void     cbuf_destroy(struct cbuf *cb);
void     cbuf_reset(struct cbuf *cb);
size_t   cbuf_size(const struct cbuf *cb);
size_t   cbuf_used(const struct cbuf *cb);
size_t   cbuf_free(const struct cbuf *cb);
size_t   cbuf_write(struct cbuf *cb, const void *src, size_t n);
size_t   cbuf_read(struct cbuf *cb, void *dst, size_t n);

```

Rules: - The cbuf does not lock; the caller is responsible. - cbuf_write and cbuf_read clamp n to available space or live data and return the actual count. - cbuf_used and cbuf_free return current state under the assumption that the caller holds whatever lock protects the cbuf.

10.13.2 The Driver-Level Helpers

```

size_t   myfirst_buf_read(struct myfirst_softc *sc, void *dst, size_t n);
size_t   myfirst_buf_write(struct myfirst_softc *sc, const void *src, size_t n);
int      myfirst_wait_data(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
                          struct uio *uio);
int      myfirst_wait_room(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
                          struct uio *uio);

```

Rules: - All four helpers assert that sc->mtx is held with mtx_assert(MA_OWNED). - The wait helpers return -1 to mean “break the outer loop, return 0 to user space”. - The wait helpers return EAGAIN, EINTR, ERESTART, or ENXIO for the corresponding conditions.

10.13.3 The Read Handler Spine

```

nbefore = uio->uio_resid;
while (uio->uio_resid > 0) {
    mtx_lock(&sc->mtx);
    error = myfirst_wait_data(sc, ioflag, nbefore, uio);
    if (error != 0) {

```

```

        mtx_unlock(&sc->mtx);
        return (error == -1 ? 0 : error);
    }
    take = MIN((size_t)uio->uio_resid, sizeof(bounce));
    got = myfirst_buf_read(sc, bounce, take);
    fh->reads += got;
    mtx_unlock(&sc->mtx);

    wakeup(&sc->cb);
    selwakeup(&sc->wsel);

    error = uiomove(bounce, got, uio);
    if (error != 0)
        return (error);
}
return (0);

```

10.13.4 The Write Handler Spine

```

nbefore = uio->uio_resid;
while (uio->uio_resid > 0) {
    mtx_lock(&sc->mtx);
    error = myfirst_wait_room(sc, ioflag, nbefore, uio);
    if (error != 0) {
        mtx_unlock(&sc->mtx);
        return (error == -1 ? 0 : error);
    }
    room = cbuf_free(&sc->cb);
    mtx_unlock(&sc->mtx);

    want = MIN((size_t)uio->uio_resid, sizeof(bounce));
    want = MIN(want, room);
    error = uiomove(bounce, want, uio);
    if (error != 0)
        return (error);

    mtx_lock(&sc->mtx);
    put = myfirst_buf_write(sc, bounce, want);
    fh->writes += put;
    mtx_unlock(&sc->mtx);

    wakeup(&sc->cb);
    selwakeup(&sc->rsel);
}

```

```

}
return (0);

```

10.13.5 The Sleep Pattern

```

mtx_lock(&sc->mtx);
while (CONDITION) {
    if (uio->uio_resid != nbefore)
        break_with_zero;
    if (ioflag & IO_NDELAY)
        return (EAGAIN);
    error = mtx_sleep(CHANNEL, &sc->mtx, PCATCH, "wmesg", 0);
    if (error != 0)
        return (error);
    if (!sc->is_attached)
        return (ENXIO);
}
/* condition is false now; act on the buffer */

```

Rules: - Use while, not if, around the condition. - Always pass PCATCH for user-driven sleeps. - Always re-check the condition after `mtx_sleep` returns. - Always check `is_attached` after waking, in case detach is pending.

10.13.6 The Wake Pattern

```

/* After a state change that might unblock a sleeper: */
wakeup(CHANNEL);
selwakeup(SELINFO);

```

Rules: - The channel must match the channel passed to `mtx_sleep`. - The `selinfo` must be the one that `sel-`record registered against. - Use `wakeup` (wake all) for shared waiters; `wakeup_one` for single-handoff patterns. - Spurious wakeups are safe; missing wakeups are bugs.

10.13.7 The `d_poll` Handler

```

static int
myfirst_poll(struct cdev *dev, int events, struct thread *td)
{
    struct myfirst_softc *sc = dev->si_drv1;

```

```

    int revents = 0;

    mtx_lock(&sc->mtx);
    if (events & (POLLIN | POLLRDNORM)) {
        if (cbuf_used(&sc->cb) > 0)
            revents |= events & (POLLIN | POLLRDNORM);
        else
            selrecord(td, &sc->rsel);
    }
    if (events & (POLLOUT | POLLWRNORM)) {
        if (cbuf_free(&sc->cb) > 0)
            revents |= events & (POLLOUT | POLLWRNORM);
        else
            selrecord(td, &sc->wsel);
    }
    mtx_unlock(&sc->mtx);
    return (revents);
}

```

10.13.8 The d_mmap Handler

```

static int
myfirst_mmap(struct cdev *dev, vm_ooffset_t offset, vm_paddr_t *paddr,
             int nprot, vm_memattr_t *memattr)
{
    struct myfirst_softc *sc = dev->si_drv1;

    if (sc == NULL || !sc->is_attached)
        return (ENXIO);
    if ((nprot & VM_PROT_WRITE) != 0)
        return (EACCES);
    if (offset >= sc->cb.cb_size)
        return (-1);
    *paddr = vtophys((char *)sc->cb.cb_data + (offset & ~PAGE_MASK));
    return (0);
}

```

10.13.9 The cdevsw

```

static struct cdevsw myfirst_cdevsw = {
    .d_version =    D_VERSION,

```

```

        .d_open =      myfirst_open,
        .d_close =     myfirst_close,
        .d_read =      myfirst_read,
        .d_write =     myfirst_write,
        .d_poll =      myfirst_poll,
        .d_mmap =      myfirst_mmap,
        .d_name =      "myfirst",
};

```

10.13.10 Errno Values for I/O

Errno	Meaning
0	Success
EAGAIN	Would block; retry later
EFAULT	Bad user pointer (from uiomove)
EINTR	Interrupted by a signal
ENXIO	Device not present or torn down
EIO	Hardware error
ENOSPC	Permanent out-of-space (block-on-full preferred)
EACCES	Forbidden access mode
EBUSY	Device is open or otherwise locked

10.13.11 `ioflag` Bits

Bit	Source flag	Meaning
IO_NDELAY	O_NONBLOCK	Caller is non-blocking
IO_DIRECT	O_DIRECT	Bypass caching where possible
IO_SYNC	O_FSYNC	(write only) Synchronous semantics

`O_NONBLOCK == IO_NDELAY` per the kernel's CTASSERT.

10.13.12 `poll(2)` Events

Event	Meaning
POLLIN	Readable: bytes are available
POLLRDNORM	Same as POLLIN for character devices
POLLOUT	Writable: space is available
POLLWRNORM	Same as POLLOUT for character devices
POLLERR	Error condition
POLLHUP	Hangup (peer closed)
POLLNVAL	Invalid file descriptor

A driver typically handles POLLIN | POLLRDNORM for read readiness and POLLOUT | POLLWRNORM for write readiness. The other events are usually set by the kernel, not the driver.

10.13.13 Memory Allocator Reference

Call	When to use
malloc(n, M_DEVBUF, M_WAITOK \ M_ZERO)	Normal allocation, can sleep
malloc(n, M_DEVBUF, M_NOWAIT \ M_ZERO)	Cannot sleep (interrupt context)
free(p, M_DEVBUF)	Free memory allocated above
MALLOC_DEFINE(M_TAG, "name", "desc")	Declare a private memory tag
contigmalloc(n, M_TAG, M_WAITOK, ...)	Physically contiguous allocation

10.13.14 Sleep / Wake Reference

Call	When to use
mtx_sleep(chan, mtx, PCATCH, "msg", 0)	Sleep with mutex interlock
tsleep(chan, PCATCH \ pri, "msg", timo)	Sleep without mutex (rare in drivers)
cv_wait(&cv, &mtx)	Sleep on a condition variable
wakeup(chan)	Wake all sleepers on channel
wakeup_one(chan)	Wake one sleeper (for single-handoff)

10.13.15 Lock Reference

Call	When to use
<code>mtx_init(&mtx, "name", "type", MTX_DEF)</code>	Initialise a sleepable spin/sleep mutex
<code>mtx_destroy(&mtx)</code>	Destroy at detach
<code>mtx_lock(&mtx), mtx_unlock(&mtx)</code>	Acquire / release
<code>mtx_assert(&mtx, MA_OWNED)</code>	Assert lock is held (debug)

10.13.16 Test Tools Reference

Tool	Use
<code>cat, echo</code>	Quick smoke tests
<code>dd</code>	Volume tests, partial-transfer observation
<code>hexdump -C</code>	Verify byte content
<code>truss -t read,write</code>	Trace syscall returns
<code>ktrace</code>	Detailed trace including signals
<code>sysctl dev.myfirst.0.stats</code>	Live driver state
<code>vmstat -m</code>	Memory tag accounting
<code>ps -AxH</code>	Find sleeping threads and their wmesg
<code>dmesg tail</code>	Driver-emitted log lines and kernel warnings

10.13.17 Driver Lifecycle Summary

kldload

- > `myfirst_identify` (optional in this driver: creates the child)
- > `myfirst_probe` (returns `BUS_PROBE_DEFAULT`)
- > `myfirst_attach` (allocates `softc`, `cbuf`, `cdev`, `sysctl`, `mutex`)

steady state

- > `myfirst_open` (allocates per-fh state)
- > `myfirst_read` (drains `cbuf` via `bounce` + `uiomove`)
- > `myfirst_write` (fills `cbuf` via `uiomove` + `bounce`)
- > `myfirst_poll` (reports `POLLIN/POLLOUT` readiness)
- > `myfirst_close` (per-fh dtor releases per-fh state)

kldunload

- > `myfirst_detach` (refuses if any descriptor open)
- > `wakeup` releases sleepers

```
-> destroy_dev
-> cbuf_destroy
-> sysctl_ctx_free
-> mtx_destroy
```

Each stage directory is independent; you can make and `kldload` any of them without touching the others. The

userland tools are shared across all stages.

10.13.19 A Mental Model in One Paragraph

The driver owns a circular buffer, protected by a single mutex. A reader holds the mutex while transferring bytes out of the buffer into a stack-resident bounce, releases the mutex, copies the bounce into user space with `uiomove`, wakes any waiting writers, and loops until the user's request is satisfied or the buffer is empty. A writer mirrors this: holds the mutex, copies user bytes into a bounce, releases the mutex, copies the bounce into the buffer, wakes any waiting readers, and loops. When either the buffer is empty (for reads) or full (for writes), the handler either sleeps with the mutex as interlock (default mode) or returns `EAGAIN` (non-blocking mode). `select(2)` and `poll(2)` integration is provided through `selrecord` (in `d_poll`) and `selwakeup` (in the I/O handlers). The detach path waits for all descriptors to close and then frees everything.

That paragraph fits in your head. Everything else in this chapter is the careful elaboration of how to make each piece of it work.

10.14 Appendix: A Source-Reading Walkthrough of `evdev/cdev.c`

The chapter has pointed at `/usr/src/sys/dev/evdev/cdev.c` several times as the cleanest example in the tree of a character device that does what `myfirst` now does: a per-client ring buffer, blocking reads, non-blocking support, `select/poll/kqueue` integration. Reading that file once, with the patterns from this chapter in hand, is the fastest way to confirm that the kernel really does work the way the chapter has been describing. This appendix walks through the relevant pieces.

The goal is *not* to teach `evdev`. It is to use `evdev` as an exhibit. By the end of this walkthrough you should feel that what you built in `myfirst` is the same shape as what the kernel uses for real input devices. The differences are in the details (the protocol, the structures, the layered driver stack), not in the underlying patterns.

10.14.1 What `evdev` Is

`evdev` is FreeBSD's port of the Linux event-device interface. It exposes input devices (keyboards, mice, touchscreens) through `/dev/input/eventN` nodes that user-space programs (X servers, Wayland compositors, console handlers) read from to get a stream of input events. Each event is a fixed-size structure with a timestamp, a type, a code, and a value.

The driver layer that interests us is the per-client `cdev`. When a process opens `/dev/input/event0`, the kernel creates a `struct evdev_client` for that descriptor, attaches it to the underlying device, and uses it as the per-open buffer. Reads pull events out of the buffer; writes push events into it (for some devices); `select/poll/kqueue` report when events are available.

That description should sound very familiar by now. It is the same architecture as `myfirst` Stage 4, with three differences: the buffer is per-descriptor rather than per-device; the unit of transfer is a fixed-size structure rather than a byte; and the driver participates in a larger framework of input handling.

10.14.2 The Per-Client State

Open `/usr/src/sys/dev/evdev/evdev_private.h` (the file is short; you can read the relevant parts in a couple of minutes). The key structure is `struct evdev_client`:

```
struct evdev_client {
    struct evdev_dev *    ec_evdev;
    struct mtx            ec_buffer_mtx;
    size_t                ec_buffer_size;
    size_t                ec_buffer_head;
    size_t                ec_buffer_tail;
    size_t                ec_buffer_ready;
    ...
    bool                  ec_blocked;
    bool                  ec_revoked;
    ...
    struct selinfo        ec_selp;
    struct sigio *        ec_sigio;
    ...
    struct input_event    ec_buffer[];
};
```

Compare this against your `myfirst` softc:

- `ec_evdev` is `evdev`'s analogue of `dev->si_drv1` (a back-pointer from the per-client state to the device-wide state).
- `ec_buffer_mtx` is the per-client mutex; `myfirst`'s `sc->mtx` is per-device.
- `ec_buffer_size`, `ec_buffer_head`, `ec_buffer_tail`, `ec_buffer_ready` are the circular-buffer indices. Notice that `evdev` uses an explicit tail instead of a derived one; the code is slightly different but the structure is the same.
- `ec_blocked` is a hint flag for the wakeup logic.
- `ec_revoked` flags a forcibly-disconnected client; this is the equivalent of `is_attached` in `myfirst`.
- `ec_selp` is the `selinfo` for `select/poll/kqueue` support, exactly like `sc->rsel` and `sc->wsel` in your driver (combined here because `evdev` only does read-readiness; there is no concept of “write would block”).
- `ec_buffer[]` is the flexible-array-member that holds the actual events.

The patterns are the same. The naming is different.

10.14.3 The Read Handler

Open `/usr/src/sys/dev/evdev/cdev.c` and find `evdev_read`:

```
static int
evdev_read(struct cdev *dev, struct uio *uio, int ioflag)
```

```

{
    struct evdev_dev *evdev = dev->si_drv1;
    struct evdev_client *client;
    ...
    ret = devfs_get_cdevpriv((void **)&client);
    if (ret != 0)
        return (ret);

    debugf(client, "read %zd bytes by thread %d", uio->uio_resid,
        uio->uio_td->td_tid);

    if (client->ec_revoked)
        return (ENODEV);

    ...
    if (uio->uio_resid != 0 && uio->uio_resid < evsize)
        return (EINVAL);

    remaining = uio->uio_resid / evsize;

    EVDEV_CLIENT_LOCKQ(client);

    if (EVDEV_CLIENT_EMPTYQ(client)) {
        if (ioflag & O_NONBLOCK)
            ret = EWOULDBLOCK;
        else {
            if (remaining != 0) {
                client->ec_blocked = true;
                ret = mtx_sleep(client, &client->ec_buffer_mtx,
                    PCATCH, "evread", 0);
                if (ret == 0 && client->ec_revoked)
                    ret = ENODEV;
            }
        }
    }

    while (ret == 0 && !EVDEV_CLIENT_EMPTYQ(client) && remaining > 0) {
        head = client->ec_buffer + client->ec_buffer_head;
        ...
        bcopy(head, &event.t, evsize);

        client->ec_buffer_head =
            (client->ec_buffer_head + 1) % client->ec_buffer_size;
        remaining--;
    }
}

```

```

        EVDEV_CLIENT_UNLOCKQ(client);
        ret = uiomove(&event, evsize, uio);
        EVDEV_CLIENT_LOCKQ(client);
    }

    EVDEV_CLIENT_UNLOCKQ(client);

    return (ret);
}

```

Walk through it slowly.

The handler retrieves the per-client state with `devfs_get_cdevpriv`, exactly as `myfirst_read` does. The `ec_revoked` check is `evdev`'s equivalent of `myfirst`'s `is_attached` check, except that `evdev` returns `ENODEV` rather than `ENXIO` (both are valid choices for “the device is gone”).

The handler then validates that the requested transfer size is a multiple of an event-record size (because partial events make no sense to deliver). This is a layer above what `myfirst` does, and it is specific to event-stream devices.

Then, exactly as Section 5 described, the handler enters a *check-wait-recheck* loop. If the buffer is empty (`EVDEV_CLIENT_EMPTYQ(client)`), the handler either returns `EWOULDBLOCK` (the same value as `EAGAIN`) for non-blocking callers, or sleeps with `mtx_sleep` and `PCATCH`. The sleep channel is `client` itself; the mutex interlock is `&client->ec_buffer_mtx`. When the sleep returns, the handler re-checks `ec_revoked`, returning `ENODEV` if the client has been disconnected during the sleep.

After the wait, the handler enters the transfer loop. It picks an event off the buffer (with `bcopy` into a stack-resident event variable), advances `ec_buffer_head` modulo the buffer size, releases the mutex, and calls `uiomove` to push the event to user space. Then it reacquires the mutex and continues until either the buffer empties or the user's request is satisfied.

This is the bounce-buffer pattern from Section 3, with event playing the role of bounce. The `cbuf` operation is `bcopy(head, &event.t, evsize)` (single-event copy out of the ring) followed by `uiomove(&event, evsize, uio)` (transfer to user). The mutex is held only across the `cbuf` operation, never across `uiomove`. This is exactly the rule we made operational in `myfirst`.

10.14.4 The Wakeup

Find `evdev_notify_event` (the function that gets called when a new event is delivered into a client's buffer):

```

void
evdev_notify_event(struct evdev_client *client)
{

    EVDEV_CLIENT_LOCKQ_ASSERT(client);

```

```

    if (client->ec_blocked) {
        client->ec_blocked = false;
        wakeup(client);
    }
    if (client->ec_selected) {
        client->ec_selected = false;
        selwakeup(&client->ec_selp);
    }

    KNOTE_LOCKED(&client->ec_selp.si_note, 0);
}

```

There is the wake-up. `wakeup(client)` matches the `mtx_sleep(client, ...)` from `evdev_read`. `selwakeup(&client->ec_selp)` matches the `selrecord` we will look at in a moment. `KNOTE_LOCKED` is the `kqueue` analogue of `selwakeup`; we have not built that yet (it is Chapter 11 territory) but the pattern is the same.

The `ec_blocked` flag is an optimisation: if no client is currently sleeping, the wakeup is skipped. This is a small but useful optimisation. `myfirst` does not have it because the cost is negligible in our use case, but you could add the same check trivially.

10.14.5 The Poll

Find `evdev_poll`:

```

static int
evdev_poll(struct cdev *dev, int events, struct thread *td)
{
    struct evdev_client *client;
    int revents = 0;
    int ret;

    ret = devfs_get_cdevpriv((void **)&client);
    if (ret != 0)
        return (POLLNVAL);

    if (events & (POLLIN | POLLRDNORM)) {
        EVDEV_CLIENT_LOCKQ(client);
        if (!EVDEV_CLIENT_EMPTYQ(client))
            revents = events & (POLLIN | POLLRDNORM);
        else {
            client->ec_selected = true;
            selrecord(td, &client->ec_selp);
        }
    }
}

```

```

        EVDEV_CLIENT_UNLOCKQ(client);
    }

    return (revents);
}

```

This is essentially identical to the `myfirst_poll` from Section 5, with two differences. `evdev` only handles `POLLIN`; there is no `POLLOUT` because input events are unidirectional. And `evdev` returns `POLLNVAL` if `devfs_get_cdevpriv` fails, which is the conventional “this descriptor is invalid” response (compared to `myfirst`’s simpler return-zero approach).

The pattern is the one Section 5 introduced: check the condition, return ready if it is true, register with `selrecord` if it is not. The `ec_selected` flag is again a wakeup-elision optimisation; you can ignore it for understanding.

10.14.6 The `kqfilter`

Find `evdev_kqfilter`:

```

static int
evdev_kqfilter(struct cdev *dev, struct knote *kn)
{
    struct evdev_client *client;
    int ret;

    ret = devfs_get_cdevpriv((void **)&client);
    if (ret != 0)
        return (ret);

    switch(kn->kn_filter) {
    case EVFILT_READ:
        kn->kn_fop = &evdev_cdev_filterops;
        break;
    default:
        return(EINVAL);
    }
    kn->kn_hook = (caddr_t)client;

    knlist_add(&client->ec_selp.si_note, kn, 0);

    return (0);
}

```

This is the `kqueue` registration handler. It is one of Chapter 11’s topics; we are showing it here only to point out that the `selinfo`’s `si_note` field is what `kqueue` hooks into. The `selrecord`/`selwakeup` machinery for

`select/poll`, and the `knlist_add/KNOTE_LOCKED` machinery for `kqueue`, share the same `selinfo` structure. That sharing is what lets a single set of state-change calls (in `evdev_notify_event`) wake all three readiness-notification paths at once.

When we extend `myfirst` with `kqueue` support in Chapter 11, the changes will fit into roughly the same pattern: a `myfirst_kqfilter` handler that registers against `&sc->rsl.si_note`, a `KNOTE_LOCKED(&sc->rsl.si_note, 0)` call alongside each `selwakeup(&sc->rsl)`. The substrate is here already.

10.14.7 What the Walkthrough Confirms

Three things should be clear now.

The first is that the *patterns* you have been building are not invented for this book. They are the patterns the kernel uses, in a real driver that ships with FreeBSD and is exercised by every keyboard and mouse user every day. You can read this code, recognise what each section is doing, and explain it. That is a real skill that pays off in every later chapter.

The second is that the *details* differ between drivers. `evdev` uses an explicit `tail` index. It uses fixed-size event records instead of bytes. It has per-client buffers instead of per-device. It uses `bcopy` instead of a `cbuf` abstraction. None of these differences invalidate the underlying pattern; they are choices about how to specialise the pattern for a specific use case.

The third is that *you can read more*. With a couple of hours and a coffee, you can work through `/usr/src/sys/dev/uart/uart_core.c` or `/usr/src/sys/dev/snp/snp.c`. Each one will look different at first glance, but the buffer, the locking, the sleep / wake, the poll: those will be familiar. The chapter has handed you a vocabulary; the kernel source is where you exercise it.

10.14.8 A Short Reading Plan

If you want to build the habit of reading kernel source as part of your driver development workflow, here is a short plan. Spend an hour a week, for three weeks, on the following.

Week one: re-read `/usr/src/sys/dev/null/null.c` and `/usr/src/sys/dev/evdev/cdev.c`. Compare them. The first is the simplest possible character device; the second is a competent buffered one. Note exactly which features each file has and why.

Week two: read `/usr/src/sys/dev/random/randomdev.c`. It is bigger than `evdev` but uses the same patterns, with the addition of an entropy-collection layer underneath. Note how `randomdev_read` differs from `evdev_read` and `myfirst_read`, and why.

Week three: pick a driver in `/usr/src/sys/dev/` that interests you (a USB driver, a network driver, a storage driver). Read the part of it that handles user-space I/O. By now the patterns should be familiar enough that the unfamiliar parts (bus binding, hardware register access, DMA setup) stand out as the *new* things to learn, not as obstacles to understanding the I/O path.

After three weeks of this rhythm, you will have read more driver code than most professional kernel developers do in a typical month. The investment compounds.

10.15 Chapter Summary

This chapter took the in-kernel buffer from Chapter 9, which was a linear FIFO that wasted half its capacity, and turned it into a real circular buffer with proper partial-I/O semantics, blocking and non-blocking modes, and `poll(2)` integration. The driver you finish the chapter with is meaningfully better than the one you started with, in four specific ways.

It uses its full capacity. The circular buffer keeps the entire allocation in play. A steady writer and a matching reader can keep the buffer at any fill level indefinitely; the wrap-around is invisible to the I/O handlers because it lives inside the `cbuf` abstraction.

It honours partial transfers. Both `myfirst_read` and `myfirst_write` loop until they cannot make progress, then return zero with `uio_resid` reflecting the unconsumed portion. A user-space caller that loops on `read(2)` or `write(2)` will see correct UNIX semantics. A caller that does not loop will still see correct counts; the driver does not silently throw bytes away.

It blocks correctly. A reader that finds the buffer empty sleeps on a clear channel, with the mutex released atomically; a writer that adds bytes wakes the sleeper. The same pattern works in the other direction. Signals are honoured through `PCATCH`, so the user's Ctrl-C interrupts a blocked reader within microseconds.

It supports non-blocking mode. A descriptor opened with `O_NONBLOCK` (or with the flag set later via `fcntl(2)`) sees `EAGAIN` instead of a sleep. A `d_poll` handler reports `POLLIN` and `POLLOUT` correctly based on the buffer's state, and `selrecord(9)` plus `selwakeup(9)` ensure that `select(2)` and `poll(2)` callers wake when readiness changes.

Each of those capabilities is built up in a numbered section, each with code that compiles, loads, and behaves predictably. The chapter's stages (a userland buffer, a kernel splice, a blocking-aware version, a poll-aware refactor, a memory-mapped variant) form a clear progression that matches the order in which a beginner naturally encounters these concerns.

Along the way we covered three supplementary topics that often appear next to buffered I/O in real drivers: `d_mmap(9)`, the patterns and limitations of zero-copy thinking, and the readahead and write-coalescing patterns used by high-throughput drivers. None of these is a Chapter 10 topic in its own right, but each one builds naturally on the buffer abstraction you have just put in place.

We exercised the driver with five new user-space test programs (`rw_myfirst_v2`, `rw_myfirst_nb`, `producer_consumer`, `stress_rw`, `mmap_myfirst`) plus the standard base-system tools (`dd`, `cat`, `hexdump`, `truss`, `sysctl`, `vmstat`). The combination is enough to catch most of the bugs this material typically produces. The Troubleshooting section catalogues those bugs with their symptoms and fixes; keep it bookmarked.

Finally, we refactored the buffer access into a small set of helpers (`myfirst_buf_read`, `myfirst_buf_write`, `myfirst_wait_data`, `myfirst_wait_room`), wrote a one-paragraph locking-strategy comment near the top of the source, and put the `cbuf` into its own file with its own `MALLOC_DEFINE`. The driver's source is now in the shape that Chapter 11 wants: clear locking discipline, narrow abstractions, no surprises.

10.16 Wrapping Up

The buffered driver you have just finished is the foundation for everything that follows in Part 3. The shape of its I/O path, the discipline of its locking, the way it sleeps and wakes, the way it composes with `poll(2)`: these

are not Chapter 10 patterns. They are *the* patterns the kernel uses, and once you recognise them in your own code, you will recognise them in every character-device driver in `/usr/src/sys/dev/`.

It is worth taking a moment to feel that shift. When you started Chapter 7, the inside of a driver was probably an opaque set of names and signatures. By the end of Chapter 8 you had a sense of the lifecycle. By the end of Chapter 9 you had a sense of the data path. Now, at the end of Chapter 10, you have a sense of how a driver behaves under load: how it shapes itself around concurrent callers, how it manages a finite resource (the buffer), how it cooperates with the kernel's readiness primitives, how it gets out of its own way so that user-space programs can do real work against it.

Most of what you have built will carry through to Chapter 11. The mutex, the buffer, the helpers, the locking strategy, the test kit, the lab discipline: all of it remains. What changes in Chapter 11 is the *depth* of the questions you ask about each piece. Why one mutex and not two? Why wakeup and not wakeup_one? Why `mtx_sleep` and not `cv_wait`? What guarantees does the kernel make about when a sleeper wakes, and what guarantees does it not make? How do you prove a piece of code is correct under concurrency, rather than hope?

Chapter 11 takes those questions seriously. It introduces `WITNESS` and `INVARIANTS` as the kernel's verification tools, walks through the lock classes, and discusses the patterns that turn merely-working concurrency into provably-correct concurrency. It will be a substantial chapter, but the substrate is what you have just built.

Three closing reminders before you move on.

The first is to *commit your code*. Whatever version-control system you use, save the four stage directories as a snapshot. The next chapter's first lab will copy your Stage 4 source and modify it; you do not want to lose the working baseline.

The second is to *try the labs*. Reading driver code teaches you the patterns; writing driver code teaches you the discipline. The labs in this chapter are short on purpose. Even the long ones can be done in a single sitting. The combination of "I built this" and "I broke it on purpose to see what happens" is what the chapter is designed to produce.

The third is to *trust the slow path*. The chapter has been deliberately careful, deliberately patient, deliberately repetitive in places. Driver work rewards that style. The bugs that hurt are the ones that look like they could not possibly happen. The defence against them is to be slow, careful, and methodical, even when the code seems simple. The reader who slows down with each step finishes Chapter 11 ready for Chapter 12; the reader who rushes finishes Chapter 11 with a kernel panic and a lost afternoon.

You are doing well. Keep going.

10.17 Part 2 Checkpoint

Before you cross into Part 3, pause and check that the ground beneath your feet is solid. Part 2 has carried you from "what is a module" to "a multi-stage pseudo-driver that serves real readers and writers under load." The next part will put that driver on a much heavier scale, so the foundation needs to be firm.

By now you should be comfortable doing each of the following without hunting for the answer:

- Writing, compiling, loading, and unloading a kernel module against a running kernel, and reading `dmesg` to confirm the lifecycle.

- Building a Newbus skeleton with `device_probe`, `device_attach`, and `device_detach`, backed by a per-unit softc allocated with `device_get_softc`.
- Exposing a `/dev` node through a `cdevsw` with working `d_open`, `d_close`, `d_read`, `d_write`, and `d_ioctl` handlers, and verifying that `devfs` cleans the node up on unload.
- Managing a circular buffer whose state is protected by a mutex, whose readers can block with `mtx_sleep` and be woken by `wakeup`, and whose readiness is advertised through `selrecord` and `selwakeup`.
- Walking a deliberate failure through the attach path and watching every allocation unwind in reverse order.

If any of those feels unsteady, the labs that anchor them are worth a second pass. A targeted review list:

- Build, load, and unload discipline: Lab 7.2 (Build, Load, and Verify Lifecycle) and Lab 7.4 (Simulate Attach Failure and Verify Unwinding).
- `cdevsw` hygiene and `devfs` nodes: Lab 8.1 (Structured Name and Tighter Permissions) and Lab 8.5 (Two-Node Driver).
- Data path and round-trip behaviour: Lab 9.2 (Exercise Stage 2 with Writes and Reads) and Lab 9.3 (Stage 3 FIFO Behaviour).
- The Chapter 10 core sequence: Lab 2 (Stage 2 Circular Buffer), Lab 3 (Stage 3 Blocking and Non-Blocking), and Lab 4 (Stage 4 Poll Support and Refactor).

Part 3 will assume that all of the above is muscle memory, not a lookup. Specifically, Chapter 11 will expect:

- A working Stage 4 `myfirst` that loads, unloads, and survives concurrent readers and writers without corruption.
- Familiarity with `mtx_sleep/wakeup` and the `selrecord/selwakeup` pair as the kernel's basic blocking and readiness primitives, since Part 3 will compare and contrast them with `cv(9)`, `sx(9)`, and `sema(9)`.
- A kernel built with `INVARIANTS` and `WITNESS`, since every Part 3 chapter leans on both from the first section onward.

If those three items hold, you are ready to turn the page. If one wobbles, fix that first. A quiet hour now saves a bewildering afternoon later.

10.18 Looking Ahead: Bridge to Chapter 11

Chapter 11 is titled “Concurrency in Drivers.” Its job is to take the driver you have just finished and look at it through the lens of concurrency: not the casual “it works under modest load” sense we have used so far, but the rigorous “I can prove this is correct under any interleaving” sense.

The bridge is built on three observations from Chapter 10's work.

First, you already have a single mutex protecting all shared state. That is the simplest non-trivial concurrency design a driver can have, and it is the right starting point for understanding the more elaborate alternatives. Chapter 11 will use your driver as a test case for asking when one mutex is enough, when it is not, and what to do when it is not.

Second, you already have a sleep / wake pattern that uses the mutex as an interlock. `mtx_sleep` and `wakeup` are the building blocks of every blocking primitive in the kernel. Chapter 11 will introduce condition variables (`cv_*`) as a more structured alternative, and will explain when each is appropriate.

Third, you already have a buffer abstraction that is intentionally not thread-safe by itself. The `cbuf` relies on the caller to provide locking. Chapter 11 will discuss the spectrum from “data structure provides no locking” (your `cbuf`) through “data structure provides internal locking” (some kernel primitives) to “data structure is lock-free” (`buf_ring(9)`, `epoch(9)`-based readers). Each end of the spectrum has uses; understanding when to choose which is part of becoming a driver writer.

Specific topics Chapter 11 will cover include:

- The five FreeBSD lock classes (`mtx`, `sx`, `rw`, `rm`, `lockmgr`) and when each is appropriate.
- Lock ordering and how to use `WITNESS` to verify it.
- The interaction between locks and interrupt context.
- Condition variables and when to prefer them over `mtx_sleep`.
- Reader/writer locks and their use cases.
- The `epoch(9)` framework for read-mostly data structures.
- Atomic operations (`atomic_*`) and when they obviate the need for locks.
- A walk-through of common concurrency bugs (lost wakeups, lock-order reversals, ABA, double-free under contention).

You do not need to read ahead to start Chapter 11. Everything in this chapter is sufficient preparation. Bring your Stage 4 driver, your test kit, and your `WITNESS`-enabled kernel; the next chapter starts where this one ended.

A small farewell from this chapter: you have just turned a beginner driver into a respectable one. The bytes that flow through `/dev/myfirst` are now flowing the way bytes flow through every other character device on the system. The patterns are right, the locking is right, the user-space contracts are honoured. The driver is yours to extend, to specialise, and to use as a baseline for whatever real device comes next. Take a moment to enjoy that, and then turn the page.

11 Concurrency in Drivers

11.1 Reader Guidance & Outcomes

Chapter 10 ended on a quietly optimistic note. Your `myfirst` driver now owns a real circular buffer, handles partial reads and writes correctly, sleeps when there is nothing to do, wakes when there is something to do, integrates with `select(2)` and `poll(2)`, and can be stress-tested with `dd`, `cat`, and a small userland harness. If you load it today and exercise it with the Stage 4 test kit, it behaves well. The byte counts match. The checksums agree. `dmesg` stays quiet.

It is tempting, looking at that behaviour, to conclude that the driver is correct. It is *almost* correct. What is missing is not code. What is missing is an explanation of *why* the code we have works.

Pause on that. In every chapter until now, we have justified each choice in the code by showing what it does: `uiomove(9)` moves bytes through the trust boundary, `mtx_sleep(9)` releases the mutex and sleeps, `sel-wakeup(9)` notifies `poll(2)` waiters. The chapters proved that the code is reasonable. They did not prove that the code is *safe under concurrent access*. Chapter 10 gestured at the subject; it acquired the mutex around buffer reads and writes, it released the mutex before calling `uiomove(9)`, it honoured the rule that one must not sleep while holding a non-sleepable mutex. But those moves were presented as patterns to imitate, not as conclusions to a careful argument. The argument is this chapter's work.

This chapter is where concurrency becomes the main subject.

By the end of it, you will understand why the mutex in the `softc` is there; what would go wrong if it were not; what a race condition actually is, down to the instruction level; what atomic operations buy you and what they do not; how mutexes compose with sleep, with interrupts, and with the kernel's correctness-checking tools; and how to tell, by reading a driver, whether its concurrency story is honest. You will also do what Chapter 11 of this book has always been meant to do: take the driver you have been building and bring it into proper, documented, verifiable thread safety. We will not turn your driver upside down; the shape we have is good. What we will do is earn every one of its locks.

This chapter does not try to teach the entire FreeBSD synchronization toolkit. That would be unreasonable at this point in your learning. Chapter 12 is dedicated to the rest of the toolkit: condition variables, sleepable shared-exclusive locks, timeouts, and the deeper aspects of lock ordering. Chapter 11 is the conceptual chapter that makes Chapter 12 possible. We stay close to two primitives, atomics and mutexes, and we spend the chapter learning them well.

11.1.1 Why This Chapter Earns Its Own Place

It would be possible, in principle, to skip directly to Chapter 12 and just teach sleepable locks, condition variables, and the `WITNESS` framework in one burst. Many driver tutorials do this. The result is code that works on

the author's laptop and fails on a reader's four-core desktop, because the reader does not understand what the primitives are for. They imitate the shape and miss the substance.

The cost of that kind of misunderstanding is high. Concurrency bugs are the hardest class of bug there is. They reproduce intermittently. They may appear on one machine and not another. They can sit dormant in a driver for years before a scheduling change, a faster CPU, or a new kernel option exposes them. When they do strike, the symptom is almost always somewhere other than the cause. The reader who has read only the syntax of `mtx_lock` will stare at a panic for days before realising that the bug is two functions away, in a place where nobody thought concurrency was a concern.

The only reliable defence against this is a clear mental model, built from first principles. We build that model in this chapter, one careful step at a time. By the end, `mtx_lock` and `mtx_unlock` will not be lines you copy from another driver. They will be lines whose absence you can spot.

11.1.2 Where Chapter 10 Left the Driver

A quick recap of the state you should be working from. If any of the following is missing from your driver, stop here and return to Chapter 10 before continuing.

- A Newbus child registered under `nexus0`, probed and attached at module load.
- A `struct myfirst_softc` holding a `struct cbuf` (the circular buffer), per-descriptor statistics, and a single `struct mtx` called `sc->mtx`.
- Two `struct selinfo` fields (`sc->rsel` and `sc->wsel`) for `poll(2)` integration.
- `myfirst_read`, `myfirst_write`, `myfirst_poll` handlers that hold `sc->mtx` while touching shared state and drop it before calling `uiomove(9)` or `selwakeup(9)`.
- `mtx_sleep(9)` with `PCATCH` as the blocking primitive, `wakeup(9)` as the matching call.
- A detach path that refuses to unload while descriptors are open and that wakes sleepers before freeing state.

That driver is the substrate Chapter 11 reasons about. We will not change its observable behaviour in this chapter. We will understand *why* it works, we will make its safety claims explicit, and we will add the infrastructure that lets the kernel verify them for us at runtime.

11.1.3 What You Will Learn

Walking away from this chapter, you should be able to:

- Define concurrency in the specific sense that matters inside a driver, and distinguish it from parallelism in a way that survives contact with real code.
- Enumerate the execution contexts a driver encounters on a modern FreeBSD system and reason about which of them can run simultaneously.
- Name the four most common failure modes of unsynchronized shared state and recognise each of them in a short code excerpt.
- Walk through a deliberately broken driver that corrupts its own buffer under load, and explain the corruption in terms of which instruction from which thread wins the race.
- Perform a concurrency audit on a piece of driver code: identify the shared state, mark the critical sections, classify each access, and decide what protects it.

- Explain what atomic operations are at the level the hardware provides them, which atomic primitives FreeBSD exposes through `atomic(9)`, when they are sufficient for the problem at hand, and when they are not.
- Use the `counter(9)` API for per-CPU statistics that scale under contention.
- Distinguish between the two fundamental mutex shapes in FreeBSD (`MTX_DEF` and `MTX_SPIN`), explain when each is appropriate, and describe the rules that apply to each.
- Read and interpret a `WITNESS` warning, understand what lock-order reversal means, and design a lock hierarchy that `WITNESS` will accept.
- State and apply the rule about sleeping with a mutex held, including the subtle cases involving `uiomove(9)`, `copyin(9)`, and `copyout(9)`.
- Describe priority inversion, priority propagation, and how the kernel handles the former with the latter.
- Build a small library of multi-threaded and multi-process test programs that can exercise your driver at levels of concurrency far beyond what `cat`, `dd`, and a single shell can produce.
- Use `INVARIANTS`, `WITNESS`, `mtx_assert(9)`, `KASSERT`, and `dtrace(1)` together to verify that the claims you make in comments are the claims the code actually enforces.
- Refactor the driver into a shape where the locking discipline is documented, the lock holder of every piece of shared state is obvious from the source, and a future reader (including your future self) can audit the concurrency story in minutes.

That is a substantial list. It is also the realistic scope of what a careful reader can absorb in one chapter at this stage of the book. Take it slowly.

11.1.4 What This Chapter Does Not Cover

Several topics touch on concurrency and are deliberately postponed:

- **Condition variables (`cv(9)`).** Chapter 12 introduces `cv_wait`, `cv_signal`, `cv_broadcast`, and `cv_timedwait`, and explains when a named condition variable is a cleaner design than a bare `wakeup(9)` channel. This chapter continues to use `mtx_sleep` and `wakeup`, exactly as Chapter 10 did.
- **Sleepable shared-exclusive locks (`sx(9)`) and reader/writer locks (`rw(9)`, `rm(9)`).** Chapter 12 covers these primitives and the situations they are designed for. For Chapter 11 we stay with the mutex pair we already use.
- **Lock-free data structures.** The FreeBSD kernel uses lock-free queues (`buf_ring(9)`), epoch(9)-based read-mostly readers, and hazard-pointer-like patterns in several places. These are specialised tools that reward careful study and are introduced gradually in Part 4 and the Part 6 network chapter (Chapter 28) when real drivers need them.
- **Concurrency correctness under interrupt context.** Our driver has no real hardware interrupts yet. Chapter 14 introduces interrupt handlers in detail; that chapter also extends the concurrency discussion to cover what happens when a handler can run at any instant and what that means for locking choices. Chapter 11 restricts itself to process context and kernel threads.
- **Advanced `WITNESS` configuration.** We will load `WITNESS` in a debug kernel and read its warnings. We will not construct custom lock classes or explore the full complement of `WITNESS` options.

Staying inside those lines keeps the chapter honest. A chapter on concurrency that tries to teach every synchronization primitive in FreeBSD is a chapter that teaches none of them well. We teach two primitives, we teach them well, and we set up the next chapter to teach the rest from a position of strength.

11.1.5 Estimated Time Investment

- **Reading only:** two and a half to three hours, depending on how often you pause at the diagrams. This chapter has a heavier conceptual load than Chapter 10.
- **Reading plus typing the labs and the broken-and-fixed drivers:** six to eight hours over two sessions with a reboot in between.
- **Reading plus all labs and challenges:** ten to fourteen hours over three or four sessions. The challenges are explicitly designed to stretch your understanding, not merely to consolidate it.

Do not rush. If you feel unsure midway through Section 4, that is normal; atomic operations are a genuinely new mental model for most readers. Stop, stretch, and come back. The value of this chapter compounds when the reader takes it slowly.

11.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source is equivalent to the Chapter 10 Stage 4 example in `examples/part-02/ch10-handling-io-efficiently/stage4-poll-refactor/`. If it is not, return to Chapter 10 and bring it up to that shape. The code in this chapter assumes the Stage 4 source.
- Your lab machine is running FreeBSD 14.3 with a matching `/usr/src`. The APIs and file paths cited here align with that release.
- You have a development kernel configuration available that enables `INVARIANTS`, `WITNESS`, and `DDB`. If you do not, Section 7 walks you through building one.
- You are comfortable loading and unloading your own module, watching `dmesg`, and reading `sysctl dev.myfirst.0.stats` to check driver state.
- You read Chapter 10 carefully and understood why `mtx_sleep` takes the mutex as its interlock. If that rule still feels arbitrary, pause and re-read Chapter 10's Section 5 before starting this chapter.

If any of the above is shaky, fixing it now is a better investment than pushing through Chapter 11 with gaps.

11.1.7 How to Get the Most Out of This Chapter

Three habits pay off quickly.

First, keep `/usr/src/sys/kern/kern_mutex.c` and `/usr/src/sys/kern/subr_witness.c` bookmarked. The first is where the mutex primitives live; the second is where the kernel's lock-order checker lives. You do not need to read these files in full, but several times during the chapter we will point at a specific function and ask you to look at the real code for one minute. That minute pays dividends.

Second, read `/usr/src/sys/sys/mutex.h` once, now, before you start Section 5. The header is short, the comments are good, and seeing the full `MTX_*` flag table once makes the later discussion concrete instead of abstract.

Third, build and boot a debug kernel before Lab 1. The labs in this chapter assume `INVARIANTS` and `WITNESS` are enabled, and several of them are designed to produce specific warnings that you can only see with those options. If you have to rebuild your kernel midway through the chapter, the interruption will cost you more than doing it upfront.

11.1.8 Roadmap Through the Chapter

The sections in order are:

1. Why concurrency matters. Where concurrency comes from inside the kernel, why it is not the same thing as parallelism, and what the four fundamental failure modes look like.
2. Race conditions and data corruption. A careful dissection of what a race condition is, at the instruction level, with a worked example on the circular buffer and a deliberately unsafe version of the driver you will actually run.
3. Analyzing unsafe code in your driver. A practical audit procedure. We walk through the Chapter 10 Stage 4 source, identify every piece of shared state, classify its visibility, and document what protects it.
4. Atomic operations. What atomicity is at the hardware level, what the `atomic(9)` API offers, how memory ordering affects correctness, and when atomics are sufficient versus when they are not. We apply atomics to the driver's per-descriptor statistics.
5. Introducing locks (mutexes). The two fundamental mutex shapes, the rules that apply to each, lock hierarchy, priority inversion, deadlocks, and the sleep-with-mutex rule. We re-examine the Chapter 10 mutex choice with the full conceptual toolkit.
6. Testing multi-threaded access. How to build user-space programs that exercise your driver concurrently, using `fork(2)`, `pthread(3)`, and custom harnesses. How to log results from concurrent tests without disturbing them.
7. Debugging and verifying thread safety. Reading a `WITNESS` warning, using `INVARIANTS`, adding `mtx_assert(9)` and `KASSERT(9)` calls, and tracing with `dtrace(1)`.
8. Refactoring and versioning. Organising the code for clarity, versioning the driver, documenting the locking strategy in a `README`, running static analysis, and regression testing.

Hands-on labs and challenge exercises follow, then a troubleshooting reference, a wrapping-up section, and a bridge to Chapter 12.

If this is your first pass, read linearly and do the labs in order. If you are revisiting the material to consolidate, the debugging section and the refactoring section stand alone.

11.2 Section 1: Why Concurrency Matters

Every chapter up to this point has treated the driver as if it lived inside a single timeline. A user program calls `read(2)`; the kernel routes the call into `myfirst_read`; the handler does its work; control returns; the program continues. A second `read(2)` on another descriptor is described as “another call” as if it were somehow later in the same story.

This framing was an approximation. It let us focus on the data path without getting tangled in the question of who was calling our handler and when. The approximation served well for Chapters 7 through 10, because the guard rails we put in (a single mutex, careful lock acquisition around shared state, `mtx_sleep` as the only way to wait) were strong enough to hide the messiness of real kernel execution.

The messiness is not something we invented. It is the actual environment every FreeBSD driver lives in, all the time. This section is where we pull back the curtain.

11.2.1 What Concurrency Means in the Kernel

Concurrency is the property of a system in which multiple independent streams of execution can make progress during overlapping periods of time. The operative word is *independent*: each stream has its own stack, its own instruction pointer, its own register state, and its own reason for doing what it is doing. They may share some data (that is why we care about concurrency), but none of them is waiting for any other to finish a full task before it begins.

Inside the FreeBSD kernel, these independent streams of execution come from several distinct sources. A driver will typically encounter at least four of them, possibly all of them at once:

User-space processes calling into the driver. This is the source you have seen most often in the book so far. A user program opens `/dev/myfirst`, issues a `read(2)` or `write(2)`, and the syscall path enters the driver through `devfs`. Each such call is a separate stream of execution, with its own kernel stack, running on whichever CPU the scheduler assigned it to. Two concurrent callers are two concurrent streams, no less independent of each other than two unrelated processes running in user space.

Kernel threads spawned by the driver or the subsystem. Some drivers create their own kernel threads with `kproc_create(9)` or `kthread_add(9)` to do work that is periodic, background, or long-running. The `myfirst` driver does not yet do this, but many real drivers do; a USB bus driver has a hub-polling thread, a network driver has a TX-complete thread, a storage driver has an I/O completion thread. Each of these runs concurrently with the syscall handlers.

Callout and taskqueue execution. The kernel's `callout(9)` mechanism (Chapter 13) and its `taskqueue(9)` mechanism (Chapter 16) both run functions at times that are not directly triggered by a user syscall. A callout set for one second from now will fire one second from now, regardless of what the driver's handlers are doing at that moment. The handler runs on a different stack, often on a different CPU, and may touch the same state the syscall handler is touching.

Interrupt context. When real hardware is present, an interrupt handler (Chapter 14) runs in response to an external event: a network packet arrived, a timer fired, a USB transfer completed. Interrupts are asynchronous and preemptive: the interrupt handler can start running at any instant the hardware chooses. The code it preempts may itself be in the middle of a critical update to shared state. `myfirst` has no real hardware yet, but we will discuss interrupt context because it shapes some of the decisions we make.

A fully-deployed FreeBSD driver typically interacts with at least three of the four. A driver writer who treats any one of them as “the only thing running” has written a driver that will fail on contact with real load.

The practical consequence is that every line of your driver code is surrounded by other code that may also be running. When your `myfirst_read` is holding `sc->mtx`, it is perfectly ordinary for a different CPU to be trying to acquire the same mutex from `myfirst_write` or from a timer or from a separate caller. The kernel's job is to make that interaction safe; your driver's job is to cooperate. That cooperation is what this chapter teaches.

11.2.2 Where the Streams Come From: a Concrete Picture

It helps to look at a concrete scenario. Imagine you have a FreeBSD 14.3 machine with four CPU cores. You have loaded the Chapter 10 Stage 4 `myfirst` driver. You start the following five commands, each in its own terminal, at roughly the same time:

```
1. cat /dev/myfirst > /tmp/out1.txt
```

```
2. cat /dev/myfirst > /tmp/out2.txt
3. dd if=/dev/zero of=/dev/myfirst bs=512 count=10000
4. sysctl -w dev.myfirst.0.debug=1 (if debug is enabled)
5. while true; do sysctl dev.myfirst.0.stats; sleep 0.1; done
```

At one instant in time, here is what the kernel might be doing:

- CPU 0 is running the first cat, inside `myfirst_read`, holding `sc->mtx`, performing a `cbuf_read` into its stack bounce buffer.
- CPU 1 is running the second cat, inside `myfirst_read`, waiting in `mtx_sleep(&sc->cb, &sc->mtx, ...)` because it tried to acquire the mutex after the first cat and went to sleep.
- CPU 2 is running `dd`, inside `myfirst_write`, having just finished a `uiomove` into its bounce buffer and is now about to reacquire `sc->mtx` to deposit the bytes into the `cbuf`.
- CPU 3 is running the `sysctl` loop, inside the `cb_used` `sysctl` handler, trying to acquire `sc->mtx` to get a consistent snapshot.

Four CPUs. Four streams of execution. Four different parts of the driver, all running concurrently, all contending for the same mutex, all needing to agree on the state of the same circular buffer. This is not a contrived situation. This is what a moderately-loaded system looks like during ordinary testing.

If the mutex and the rules around it did not exist, each of those four threads would be free to observe and modify the `cbuf`'s indices (`cb_head`, `cb_used`) and its backing memory (`cb_data`) independently. The results would be, approximately, whatever the hardware's memory system happened to produce, with no guarantees about correctness. The rest of this chapter is about building an understanding of why that would be a catastrophe and what the primitives that prevent it actually do.

11.2.3 Concurrency vs Parallelism

These two words are often used interchangeably. They are related but not the same, and getting them straight early saves confusion later.

Parallelism is a property of execution: two things happen literally at the same physical time, on different pieces of hardware. On a multi-CPU system, two threads running on two different cores at the same nanosecond are parallel.

Concurrency is a property of design: the system is structured so that multiple independent streams of execution exist and can make progress in any order. Whether they physically run at the same time is a separate question.

A single-core CPU can run a concurrent program (the OS scheduler interleaves two threads on the one core). It cannot run a parallel program (nothing is literally simultaneous). A four-core machine can run both concurrent and parallel programs.

Why does the distinction matter for a driver writer? Because the bugs that matter for us are caused by concurrency, not by parallelism. A two-thread program on a single-core FreeBSD laptop can still exhibit every race condition we will meet in this chapter, as long as the scheduler ever decides to preempt one thread while it is in the middle of an update. Parallelism, on a multi-core machine, merely makes those bugs more common and harder to suppress by running the program slowly. The fundamental problem predates multi-core hardware and will exist on every machine that can ever preempt a thread.

Our focus, therefore, is on designs that tolerate any legal interleaving of independent streams. If the design tolerates that, it tolerates parallelism as well. If the design assumes “well, this will always run before that”, it will fail on some system, probably the first production server it meets.

This is also why you cannot test your way to concurrency correctness. You can test and not find a bug because the interleaving that triggers it never happened during the test. You can deploy the same code and find the bug the first day, because some tiny change in scheduling, or a slightly faster CPU, or a different number of cores, shifts the timing. The only durable way to solve concurrency is to reason about every legal interleaving, not to try to enumerate the likely ones.

11.2.4 What Can Go Wrong: The Four Failure Modes

When multiple streams of execution share data without coordination, four things can go wrong. Every concurrency bug you will ever meet is a specialised instance of one of these four. Naming them early is useful, because later in the chapter, when a specific bug shows up in a specific driver, you will recognise which family it belongs to.

Failure mode 1: Data corruption. The state after the interleaving is not the state any of the threads would have produced on its own. A shared counter becomes a value that no correct sequence of increments could have reached. A linked list has an entry that points to garbage. A buffer’s head index is larger than its capacity. This is the most common kind of concurrency bug, and the hardest to detect, because the corrupted state may lie dormant for a long time before it is used.

Failure mode 2: Lost updates. Two threads each read a shared value, each compute a new value based on what they read, and each store their result. The second write overwrites the first, which means the first thread’s update is discarded as if it never happened. Classic example: two `bytes_read += got;` statements, executed by two threads, can increment the counter by one instead of by two if the interleaving is unlucky. Lost updates are a special case of data corruption with a predictable signature: the counter is correct in form but low in magnitude.

Failure mode 3: Torn values. A value that is larger than the CPU can read or write in a single memory access (on 32-bit systems, typically a 64-bit integer) can be observed in a half-updated state by a concurrent reader. One thread is in the middle of writing bytes 0-3 of a `uint64_t`; another thread reads all 8 bytes and sees the old high half glued to the new low half. The resulting value is nonsense. On FreeBSD 14.3’s primary platforms (amd64, arm64), aligned 64-bit accesses are atomic; on 32-bit platforms and for larger structures, they are not. A torn value is the “read” side of a lost update and can sometimes be observed even when the writers are correct.

Failure mode 4: Inconsistent composite state. A data structure has an invariant that relates several fields. A thread is in the middle of updating one field but has not yet updated the other. A concurrent reader sees the structure in a state that violates the invariant, makes a decision based on what it saw, and produces a wrong result. This is the most subtle of the four modes, because it requires the observer to know what invariant is supposed to hold; a thread that does not know the invariant cannot detect that it is violated. Most of the harder driver bugs involve inconsistent composite state: a ring buffer’s head and tail were updated in two steps, and a reader saw the half-updated state and produced garbage.

All four failure modes share a cause: *multiple streams of execution touched shared state without agreement on an order*. The primitives this chapter introduces, atomics and mutexes, are different ways of imposing that agreement. Atomics make individual operations indivisible. Mutexes enforce serialized access across longer regions of code.

11.2.5 A Thought Experiment

Consider a trivial shared counter:

```
static u_int shared_counter = 0;

/* Called by anything. */
static void
bump(void)
{
    shared_counter = shared_counter + 1;
}
```

If two threads call `bump()` at the same moment, what happens?

The correct behaviour is that `shared_counter` increases by two. Each call should add one, so two calls should add two.

The actual behaviour depends on how the increment compiles. On amd64, `shared_counter = shared_counter + 1;` typically compiles into three machine instructions: a load of the current value into a register, an add of one to the register, and a store of the register back to memory.

Imagine two threads, A and B, running on two different CPUs, both entering `bump()` at essentially the same time. A legal interleaving looks like this:

Time	Thread A	Thread B	Memory
t0			0
t1	load (gets 0)		0
t2		load (gets 0)	0
t3	add 1 (local register=1)		0
t4		add 1 (local register=1)	0
t5	store (writes 1)		1
t6		store (writes 1)	1

Both threads load zero. Both compute one. Both store one. The final value is one. The counter has been incremented exactly once, even though two threads each called `bump()`.

This is a lost update. It is the simplest concurrency bug in the book. It does not require fancy hardware, a complicated data structure, or a rare scheduler decision. It requires only that two threads execute the three-instruction sequence at overlapping moments.

Notice three things about this example.

First, the bug is not in the source code. The C code says `shared_counter = shared_counter + 1;`, which is what we wanted. The bug is in the *interaction between the source code and the hardware's execution model*.

No amount of staring at the C line will reveal the bug, because the bug is at a level of abstraction the C line does not express.

Second, the bug is not reproducible by single-threaded testing. One thread calling `bump()` a thousand times will always produce `shared_counter == 1000`. Add a second thread and the result becomes nondeterministic. You could run the two-thread test a hundred times and see correct results every time; run it again on a different CPU, or with a different workload, and see a missed count.

Third, the fix is not to add more careful code in C. The fix is either to make the increment *atomic* (execute as a single indivisible unit from memory's perspective) or to enforce *mutual exclusion* (no two threads can be executing the three-instruction sequence at the same time). Atomics give us the first option. Mutexes give us the second. They are different shapes of solution to the same problem, and choosing between them is the topic of Sections 4 and 5.

11.2.6 A Preview of the Driver Under Load

To make the rest of the chapter concrete, let us describe what we are going to do to the driver.

In Section 2, we will build a deliberately unsafe version of `myfirst`: one that has had the mutex removed from the I/O handlers. We will load it, run a two-process test, and watch the circular buffer's invariants break in real time. This will be an unpleasant but instructive experience. You will see the data corruption, the torn values, and the inconsistent composite state with your own eyes, in your own terminal, in a driver you have been working on for several chapters.

In Section 3, we will go back to the Stage 4 Chapter 10 driver and audit it: every shared field, every access, every claim. We will annotate the source in place. We will end the section with a complete locking-discipline document.

In Section 4, we will introduce atomics. We will convert `sc->bytes_read` and `sc->bytes_written` from mutex-protected `uint64_t` counters into per-CPU counter(9) counters, which are lock-free and scale to many CPUs. We will discuss where atomics save locks and where they do not.

In Section 5, we will re-examine the mutex from first principles. We will explain why the mutex is specifically an `MTX_DEF` (sleep) mutex, not an `MTX_SPIN` mutex. We will walk through priority inversion and why the kernel's priority-propagation mechanism handles it for us. We will introduce `WITNESS` and run the unsafe driver under a `WITNESS` kernel to see what happens.

In Section 6, we will build a small testing harness: a `pthread`-based multi-threaded tester, a `fork`-based multi-process tester, and a load generator that stresses the driver at levels `dd` and `cat` cannot reach. We will run the safe and the unsafe drivers under this harness.

In Section 7, we will learn to read `WITNESS` warnings, use `INVARIANTS` and `KASSERT`, and deploy `dtrace(1)` probes to observe concurrency behaviour without changing it.

In Section 8, we will refactor the driver for clarity, version it as `v0.4-concurrency`, write a `README` that documents the locking strategy, run `clang - -analyze` against the source, and run a regression test that repeats every test we have built.

By the end, the driver will not be more *functional* than it is now. It will be more *verifiable*. The difference matters: verifiable code is the only code that is safe to extend.

11.2.7 The FreeBSD Scheduler in One Page

To understand why concurrency inside a driver is not just a theoretical concern, it helps to know, at a high level, what the FreeBSD scheduler does. You do not need to read any scheduler source to write a driver, but a mental model of how the scheduler interacts with your driver prevents several classes of surprise.

FreeBSD's default scheduler is **ULE**, implemented in `/usr/src/sys/kern/sched_ule.c`. ULE is a multi-core, SMP-aware, priority-based scheduler. Its job is to decide, at every scheduling decision, which thread should run on each CPU.

The key properties you care about as a driver writer:

Preemption is permitted at almost any point. A thread executing kernel code can be preempted by a higher-priority thread becoming runnable (for example, an interrupt wakes a high-priority thread). The only windows where preemption is disabled are critical sections (entered with `critical_enter`) and spin-locked regions. Inside an `MTX_DEF` mutex's critical section, preemption is still possible; the priority propagation mechanism limits the damage.

Threads migrate between CPUs. The scheduler will move threads to balance load. A driver cannot assume that two successive calls from the same process run on the same CPU.

Wake-up latency is low but not zero. A wakeup on a sleeping thread typically makes the thread runnable within microseconds. The thread actually runs when the scheduler chooses to run it, which depends on its priority and what else is runnable.

The scheduler itself holds locks. When you call `mtx_sleep`, the scheduler's internal locks are acquired at some point. This is the reason `WITNESS` sometimes reports order violations when you hold a driver lock while doing something that reaches the scheduler; the ordering between driver locks and scheduler locks matters.

For our driver, this means:

- Two concurrent callers of `myfirst_read` may be running on two different CPUs, or on the same CPU via preemption, or sequentially. We make no assumption about which.
- The mutex we use works on all of these scenarios; the scheduler guarantees that the lock acquire/release semantics are respected regardless of CPU assignment.
- When `mtx_sleep` is called, the thread is put to sleep quickly; when wakeup is called, the thread becomes runnable quickly. Latency is not a concern for correctness.

Knowing the scheduler is there, doing its work in the background, frees you to focus on the driver's own concurrency decisions. You do not have to "schedule" your own threads or worry about affinity; the kernel handles it.

11.2.8 Kinds of Concurrency by Pedagogy Level

For a beginner, the concurrency landscape can feel enormous. A short hierarchy helps.

Level 0: Single-threaded. No concurrency at all. One thread, one execution timeline. This is the model the reader has used implicitly through the first half of this book.

Level 1: Pre-emptive concurrency on a single CPU. One CPU, but the scheduler can interrupt a thread at any time and run another. Race conditions can still happen, because a thread can be in the middle of a read-modify-write when preempted. All the bugs this chapter discusses are possible at Level 1.

Level 2: True multi-CPU parallelism. Multiple CPUs, multiple threads literally running at the same physical moment. Race conditions are more common and harder to suppress with luck, but they are the same bugs as Level 1.

Level 3: Concurrency with interrupt context. Same as Level 2, but with the addition that interrupt handlers can preempt ordinary threads at any moment. Spin mutexes become necessary for state shared between top-half code and interrupt handlers. Chapter 14 and beyond cover this.

Level 4: Concurrency with RCU-style patterns. Same as Level 3, but with advanced patterns like epoch(9) that allow readers to proceed without any synchronization. Specialised and not needed for most drivers.

For Chapter 11, we are at Level 2. We have multiple CPUs, we have many threads, we have ordinary mutex-based coordination. This is where most drivers live.

11.2.9 Some Concurrency Is Invisible

A subtle point that trips beginners: the concurrency in a driver is not limited to “user processes making syscalls”. Several sources produce concurrent execution in your handlers:

- **Multiple open descriptors on the same device.** Each descriptor has its own struct `myfirst_fh`, but the device-wide struct `myfirst_softc` is shared. Two threads with different descriptors can concurrently enter the same handlers on the same `softc`.
- **Multiple threads sharing a descriptor.** Two pthreads in the same process can both call `read(2)` on the same file descriptor. Both enter the same handlers with the *same* `fh`. This is the subtler case, and the audit in Section 3 addresses it.
- **Sysctl readers.** A user running `sysctl dev.myfirst.0.stats` enters the sysctl handlers from a different thread than the I/O handlers. The handlers observe the same shared state.
- **Kernel threads.** If a future version of the driver spawns its own kernel thread (for timeouts, background work, etc.), that thread is a new source of concurrent access.
- **Callouts.** Similarly, a callout handler runs on its own, independently of the I/O handlers.

Every one of these is a concurrent stream. Every one must be accounted for in the locking strategy. The audit procedure from Section 3 explicitly lists them as possible access sources for each shared field.

11.2.10 Wrapping Up Section 1

Concurrency is the environment every FreeBSD driver lives in, whether the driver writer has thought about it or not. The streams of execution come from user syscalls, kernel threads, callouts, and interrupts. On a multi-core machine they are literally parallel; on any machine they are concurrent, which is what the bugs care about. When multiple streams touch shared state without coordination, four families of failure emerge: data corruption, lost updates, torn values, and inconsistent composite state.

We have not yet said what to do about any of it. The next two sections do the negative work, examining what goes wrong in precise detail. Section 4 starts the positive work, introducing the first primitive that can help. Section 5 introduces the second and more general one.

Take a break here if you need one. The next section is denser.

11.3 Section 2: Race Conditions and Data Corruption

Section 1 described the problem at the level of intuition. This section makes it concrete. We will define a race condition precisely, walk through how one arises in the circular buffer from Chapter 10, build a deliberately unsafe version of the driver that exhibits the bug, and run it on a real system. Watching the bug with your own eyes is the fastest way to develop the instinct you need for the rest of the book.

11.3.1 A Precise Definition

A **race condition** is a situation in which two or more streams of execution can access a piece of shared state in overlapping windows of time, at least one of those accesses is a write, and the correctness of the system depends on the exact order of those accesses.

Three properties make that definition do real work. The first is *overlap*: the accesses do not have to be literally simultaneous, they only have to have windows that touch. A read that starts at time t and ends at time $t+10$, and a write that starts at $t+5$ and ends at $t+15$, are overlapping. The second is *at least one write*: two concurrent reads of the same value are fine, because neither changes the state the other is reading. The third is *order-dependent correctness*: if the code is designed so that any interleaving produces the same outcome, there is no race by this definition, even if the windows overlap.

The first property is why software-level “it’s too fast to collide” reasoning never works. A read and a write are not two points; they are two intervals. Any overlap is enough.

The second property is why code that is read-only is safe without synchronization. If nothing is written, no interleaving can cause inconsistency. This is useful later when we talk about epoch(9) and lock-free reading, but the same observation justifies why certain purely-informational operations do not need protection.

The third property is why locks are not always the answer. If the operation is designed so that every legal interleaving is acceptable, no lock is needed. A counter that is only ever incremented by atomic operations, for example, does not need a lock around each increment. The lock would still work, but it would be wasted cycles.

11.3.2 The Anatomy of a Race

Let us take the counter example from Section 1 and walk through it at the instruction level. The C statement:

```
shared_counter = shared_counter + 1;
```

On amd64, with ordinary compilation, this produces something close to:

```
movl    shared_counter(%rip), %eax    ; load shared_counter into register EAX
addl     $1, %eax                     ; increment EAX by 1
movl     %eax, shared_counter(%rip)   ; store EAX back to shared_counter
```

The memory access happens at two distinct moments: the load and the store. Between them, the value being computed is held in the CPU’s register file, not in memory. Any other CPU observing memory during that interval sees the old value, not the value in flight.

If two threads, A and B, execute this sequence on two CPUs at overlapping times, the memory controller sees four accesses, in some order:

1. A's load
2. B's load
3. A's store
4. B's store

The final value of `shared_counter` depends entirely on the order in which the stores commit. If A's store happens first and B's store happens second, the final value is 1 (because B's store writes the value B computed, which was based on B's load, which saw 0). If the order is reversed, the final value is still 1. There is no interleaving in which both increments take effect, because the reads happened before either write, and each write overwrites the other.

The fix is to make the whole sequence either atomic (so that the four accesses become two inseparable transactions) or mutually exclusive (so that one thread finishes all three instructions before the other starts any of them). Both are legal answers. The difference is what they cost and what they allow us to do elsewhere in the code.

11.3.3 How Races Appear in the Circular Buffer

The shared counter is the simplest possible example. The circular buffer from Chapter 10 is a richer one. It has multiple fields, interrelated invariants, and operations that touch several fields at once. This is where race conditions become really dangerous.

Recall the `cbuf` from Chapter 10:

```
struct cbuf {  
    char    *cb_data;  
    size_t   cb_size;  
    size_t   cb_head;  
    size_t   cb_used;  
};
```

The invariants we depend on are:

- `cb_head < cb_size` (the head index is always valid).
- `cb_used <= cb_size` (the live byte count never exceeds capacity).
- The bytes at positions `[cb_head, cb_head + cb_used) mod cb_size` are the live bytes.

These invariants relate multiple fields. A `cbuf_write` call, for example, updates `cb_used`. A `cbuf_read` call updates both `cb_head` and `cb_used`. If a reader and a writer execute concurrently without coordination, each of those updates can be observed in a half-finished state.

Consider what happens if `myfirst_read` and `myfirst_write` run concurrently on two CPUs, with no mutex:

1. Reader thread starts `cbuf_read` on a buffer with `cb_head = 1000`, `cb_used = 2000`. It computes `first = MIN(n, cb_size - cb_head)` and begins the first `memcpy` from `cb_data + 1000` into its stack bounce.

2. Meanwhile, writer thread calls `cbuf_write`, which updates `cb_used`. The writer reads `cb_used = 2000`, computes the tail as $(1000 + 2000) \% \text{cb\_size} = 3000$, does its `memcpy` into the buffer, and writes `cb_used = 2100`.
3. The reader finishes its first `memcpy`, possibly seeing bytes that the writer had just written (if the writer's `memcpy` crossed over the reader's position).
4. The reader then updates `cb_head = (1000 + n) \% \text{cb\_size}` and decrements `cb_used`.

Several things can go wrong here:

- **Torn `cb_used`:** on a 32-bit machine, `cb_used` is a 32-bit type, so its read and write are atomic. On amd64, `size_t` is 64-bit, and aligned 64-bit accesses are also atomic, so a torn read is unlikely. But if we ever used a structure larger than the word size, we would see bytes from the old value glued to bytes from the new.
- **Observed invariant violation:** the reader's decrement of `cb_used` and the writer's increment of `cb_used` happen at different moments. Between them, `cb_used` may transiently reflect only one of the two operations. If a third reader (for example, a `sysctl` handler) observes `cb_used` in the middle of that interleaving, the observed value is neither the "before" nor the "after" of either individual operation.
- **Concurrent `memcpy` into overlapping regions:** if the reader's `memcpy` and the writer's `memcpy` touch the same byte, the byte's final value is whatever wins the race for memory. The reader may see half of its intended data overwritten with new data from the writer. The writer may overwrite bytes that the reader has already copied into its bounce, meaning the reader returns bytes that do not exist in the buffer any more.

Each of those is a real bug. Each is hard to observe, because the timing window for the corruption is tiny. Each is lethal, because a single instance can corrupt the data a user program depends on.

11.3.4 A Deliberately Unsafe Driver

Theory becomes visceral when you run the code. We are going to build a version of `myfirst` that has the mutex removed from the I/O handlers. You will load it, run a concurrent test against it, and watch the driver produce nonsense.

Warning: load this driver only on a lab machine with no important state. It can corrupt its own state at will and, under some scenarios, wedge the machine. Expect to reboot if the test goes badly. The point is to see the bug, not to push it further.

Create a new directory alongside your Chapter 10 Stage 4 source:

```
$ cd examples/part-03/ch11-concurrency
$ mkdir -p stage1-race-demo
$ cd stage1-race-demo
```

Copy `cbuf.c`, `cbuf.h`, and `Makefile` from the Chapter 10 Stage 4 directory. Then copy `myfirst.c` and edit it to remove the mutex from `myfirst_read` and `myfirst_write`. The easiest way to do this, so you can see exactly what changed, is to use `sed` with a sentinel:

```
$ sed \
-e 's/mtx_lock(&sc->mtx);/\/* RACE: mtx_lock removed *//' \
-e 's/mtx_unlock(&sc->mtx);/\/* RACE: mtx_unlock removed *//' \
.../part-02/ch10-handling-io-efficiently/stage4-poll-refactor/myfirst.c \
> myfirst.c
```

What this does is turn every `mtx_lock` and `mtx_unlock` in the source into a comment. It leaves the rest of the code unchanged, including `mtx_sleep` and `mtx_assert`. This is a surgical deletion of the lock acquisition points; the rest of the driver still thinks the lock is there.

Before we build, open `myfirst.c` and look for the `mtx_assert(&sc->mtx, MA_OWNED)` calls inside `myfirst_buf_read`, `myfirst_buf_write`, and the wait helpers. These are going to fire a KASSERT panic on an INVARIANTS kernel, because the helpers check that the mutex is held and now it never is. This is a feature, not a bug: if you accidentally run this driver on a debug kernel, the assertion will catch the problem before any real damage is done. For the explicit race demo, we want to see the corruption itself, so comment out the `mtx_assert` lines or disable INVARIANTS in the test kernel:

```
$ sed -i '' -e 's|mtx_assert(&sc->mtx, MA_OWNED);|/\/* RACE: mtx_assert removed */|g'
↵ myfirst.c
```

The `-i ''` is FreeBSD's `sed` in-place mode. On Linux, it would be `sed -i` without the quoted empty string.

Also delete the `mtx_init`, `mtx_destroy`, and `mtx_lock/mtx_unlock` calls from `myfirst_attach` and `myfirst_detach` by hand; the `sed` commands above do not catch the attach and detach paths because those have `mtx_lock` calls we want to keep logically (even if they do nothing). A simpler and cleaner approach, if you prefer, is to introduce a macro at the top of `myfirst.c`:

```
/* DANGEROUS: deliberately unsafe driver for Chapter 11 Section 2 demo. */
#define RACE_DEMO

#ifdef RACE_DEMO
#define MYFIRST_LOCK(sc)      do { (void)(sc); } while (0)
#define MYFIRST_UNLOCK(sc)   do { (void)(sc); } while (0)
#define MYFIRST_ASSERT(sc)   do { (void)(sc); } while (0)
#else
#define MYFIRST_LOCK(sc)      mtx_lock(&(sc)->mtx)
#define MYFIRST_UNLOCK(sc)    mtx_unlock(&(sc)->mtx)
#define MYFIRST_ASSERT(sc)    mtx_assert(&(sc)->mtx, MA_OWNED)
#endif
```

Then globally replace `mtx_lock(&sc->mtx)` with `MYFIRST_LOCK(sc)` and similarly for the rest. With `RACE_DEMO` defined, the macros do nothing; without it, they are the original calls. This is the approach the companion source uses. It lets you toggle the race on and off at compile time.

Build the module:

```
$ make
$ kldstat | grep myfirst && kldunload myfirst
$ kldload ./myfirst.ko
$ dmesg | tail -5
```

The attach line should appear as usual. Nothing looks wrong yet.

11.3.5 Running the Race

With the unsafe driver loaded, run the producer/consumer test from Chapter 10:

```
$ cd ../../part-02/ch10-handling-io-efficiently/userland
$ ./producer_consumer
```

Recall that this test produces a fixed pattern into the driver, reads it back in another process, and compares checksums. On the safe driver, the checksums match and the test reports zero mismatches. Run it against the unsafe driver and the result depends on your timing:

- **Likely outcome:** the two checksums differ, and the reader reports some number of mismatches. The exact number varies between runs.
- **Possible outcome:** the test hangs forever, because the buffer state became inconsistent and the reader or writer got stuck waiting for a condition that will never be true.
- **Rare outcome:** the test passes by chance. If this happens, run it again; a single run of a concurrency test tells you almost nothing.
- **Unpleasant outcome:** the kernel panics because of invariants fired inside `cbuf_read` or `cbuf_write` (for example, a negative `cb_used` that was meant to be unsigned, or an out-of-bounds `cb_head`). If this happens, note the backtrace, reboot, and carry on. This is what you came to see.

In most runs you will see output like:

```
writer: 1048576 bytes, checksum 0x8bb7e44c
reader: 1043968 bytes, checksum 0x3f5a9b21, mismatches 2741
exit: reader=2 writer=0
```

The reader got fewer bytes than the writer produced. Its checksum is different. Some specific number of byte positions held the wrong value.

This is not a flaky test. This is a driver working as designed, given that the locking has been removed. The kernel schedules multiple threads onto multiple CPUs. Those threads read and write the same memory without coordination. The result is the state that any specific hardware interleaving happens to produce.

Run the test several times. The numbers will vary. The character of the corruption, however, will not: the writer will claim to have produced some number of bytes, the reader will see a different set. That is what concurrency without synchronization looks like. It is not mysterious or subtle; it is the exact consequence of the definitions in the earlier part of this section.

11.3.6 Observing the Damage with Logs

The producer-consumer test reports aggregate damage. For finer-grained observation, instrument the driver with `device_printf` (guarded by the `debug sysctl`) inside `cbuf_write` and `cbuf_read`. Add something like:

```
device_printf(sc->dev,
    "cbuf_write: tail=%zu first=%zu second=%zu cb_used=%zu\n",
    tail, first, second, cb->cb_used);
```

at the bottom of `cbuf_write`, behind the `myfirst_debug` check you set up in Chapter 10 Stage 2. The same for `cbuf_read`.

Run the unsafe driver again with `sysctl dev.myfirst.debug=1` and watch `dmesg -t` in another terminal:

```
$ sysctl dev.myfirst.debug=1
$ ./producer_consumer
$ dmesg -t | tail -40
```

You will see lines like:

```
myfirst0: cbuf_write: tail=3840 first=256 second=0 cb_used=2048
myfirst0: cbuf_read: head=0 first=256 second=0 cb_used=1792
myfirst0: cbuf_write: tail=1536 first=256 second=0 cb_used=2304
myfirst0: cbuf_read: head=2048 first=256 second=0 cb_used=-536 <-- inconsistent
```

`cb_used` is a `size_t`, which is unsigned, so “negative” here means the field wrapped: a very large number that was formatted with `%zu` and still looks enormous but was not meant to be. That wraparound is one of the failure modes we discussed. A concurrent decrement of `cb_used` read the value from before another thread’s increment finished, subtracted its own amount, and stored a result that is nonsense.

Looking at a log full of such entries drives home the point the definitions did not: concurrency bugs are not rare edge cases. They are the normal case when multiple threads touch the same fields without coordination. The driver does not break occasionally. It breaks constantly. It just sometimes happens to produce a superficially plausible output anyway.

11.3.7 Cleaning Up

Unload the unsafe driver before doing anything else:

```
$ kldunload myfirst
```

If `kldunload` hangs (because a test still holds a descriptor open), find and kill the test process. If the kernel is in a broken state after a panic-like failure, reboot. From here on, work only with the safe driver unless you are deliberately rerunning the demo to compare.

Do not leave the unsafe driver loaded. Do not check in the `RACE_DEMO`-enabled build and forget about it. The companion tree keeps the race demo in a sibling directory precisely so that it cannot be confused with the production source.

11.3.8 The Lesson

Three observations follow from the exercise.

The first is that the mutex in the Chapter 10 driver is not stylistic. Remove it and the driver breaks, instantly, in a way you can demonstrate on any FreeBSD machine. The mutex is load-bearing. It protects exactly the property (the cbuf's internal consistency) that the rest of the driver's correctness depends on.

The second is that testing cannot find this class of bug reliably. If you did not know to run a multi-process stress test, if you tested only with a single cat and a single echo, the driver would look fine. The concurrency bug would be there, invisible, waiting for the first user whose workload happens to involve two concurrent callers. Reviewing code with concurrency in mind is not a substitute for testing; it is the thing that prevents you from shipping code whose tests happen to pass.

The third is that the fix is not a local patch. You cannot sprinkle atomic operations on a field or two and call it done. The cbuf has composite invariants that span multiple fields; protecting it requires a region of code where no other thread can be executing at the same time. That is the job of a mutex, and Section 5 is where we look at mutexes in full. Before we get there, however, we should audit the existing driver (Section 3) and understand the more limited tool that atomics provide (Section 4).

11.3.9 A Second Race: Attach Versus I/O

Not every race is in the data path. Let us look at a race we fixed in Chapter 10 without naming: the race between `myfirst_attach` and the first user to call `open(2)`.

When `myfirst_attach` runs, it does several things in sequence:

1. Sets up `sc->dev` and `sc->unit`.
2. Initializes the mutex.
3. Sets `sc->is_attached = 1`.
4. Initializes the cbuf.
5. Creates the cdev via `make_dev_s`.
6. Creates the cdev alias.
7. Registers the sysctls.
8. Returns.

The cdev is not visible to user space until step 5. A user who calls `open("/dev/myfirst")` before step 5 completes gets `ENOENT`, because the device node does not exist yet. After step 5, the cdev is registered with `devfs`, and `open` can succeed.

If step 5 happened before step 3, a user could open the device and call `read` before `is_attached` was set. The read handler's `if (!sc->is_attached) return (ENXIO)` check would fail the call, returning `ENXIO` even though attach was in progress. That is not catastrophic, but it is confusing and avoidable.

The fix is the order we use: `is_attached = 1` happens before `make_dev_s`. By the time any handler can run, `is_attached` is already set.

The subtle point is that this ordering is *only correct* because single-threaded attach cannot be interrupted between the two writes. If the writes could be reordered by the compiler or the hardware (which they cannot for plain integer stores on amd64 without explicit barriers, but could on some weakly-ordered architectures), we would

need an `atomic_store_rel_int` for the `is_attached` write. The book stays on amd64, so the plain store is fine.

This is a generally useful discipline. Every time you write attach code, list the observable preconditions for each subsequent step and verify they are established before the step is reachable from user space. The order matters, and it is almost always wrong to make the `cdev` before the `softc` is fully ready.

11.3.10 A Third Race: `sysctl` Versus I/O

Another race the Chapter 10 design handles: the `sysctl` handler that reads `cb_used` or `cb_free` must return a self-consistent value, not a torn composite.

The fields `cb_head` and `cb_used` are both `size_t`. Either one, read alone, gives a single-word value that is atomic on amd64. But `cb_used` and `cb_head` together form an invariant (the live bytes are at `[cb_head, cb_head + cb_used) mod cb_size`). A `sysctl` that reads both without the mutex could observe them at inconsistent moments.

For `cb_used` alone, the race is tolerable: the counter may be slightly stale, but the value returned is at least *some* value that was once true. For `cb_head`, the same applies. For anything that combines the two (like “how many bytes until the tail meets the capacity boundary?”), the race produces meaningless numbers.

We protect the `sysctl` reads with the mutex. The critical section is tiny (one load), so contention is minimal; the correctness benefit is that the returned value is guaranteed to be self-consistent.

The rule this illustrates is: **if your observation combines multiple fields that together express an invariant, protect the observation with the same primitive that protects the invariant.**

11.3.11 The Race Taxonomy, Revisited

With the `cbuf` race (Section 2 main text), the attach race, and the `sysctl` race, we now have three concrete examples to classify under the four failure modes from Section 1.

- **Cbuf data corruption:** primarily inconsistent composite state (the `cb_used/cb_head` invariant), with some lost updates on `cb_used` itself.
- **Attach race:** a form of inconsistent composite state, where the “is the device ready?” invariant is transiently false from the user’s perspective.
- **Sysctl torn observation:** a form of inconsistent composite state, where the reader’s computation uses fields from different moments in time.

All three are protected by the same mechanism: serialize access to the composite state with a single mutex. This unity is not a coincidence; it is the reason a single mutex is usually the right answer for a small driver.

11.3.12 Wrapping Up Section 2

A race condition is a very specific thing: overlapping access to shared state, at least one write, correctness that depends on the interleaving. The `cbuf`’s composite invariants make it a rich source of races when the mutex is removed. A deliberately unsafe driver reveals the corruption within seconds of running a concurrent test.

You have now seen the problem in your own terminal, in your own driver. You have seen three distinct races, all in places where composite state is involved, all solved by the same mechanism. Everything that follows is the construction of the tools that make the problem go away, one layer at a time.

11.4 Section 3: Analyzing Unsafe Code in Your Driver

Most driver writers, most of the time, do not create race conditions deliberately. They create them by not noticing that a piece of state is shared across streams of execution. The defence against this is a habit, not a clever tool: every time you touch state that *could* be accessed from outside the current code path, you stop and ask whether it is actually safe to touch without synchronization. Most of the time the answer is “yes, it’s already protected by X”, and you move on. Sometimes the answer is “actually, it isn’t protected, and I need to think about it”. That second case is the one this section teaches you to recognise.

The Chapter 10 Stage 4 driver is reasonably thoughtful. It uses a mutex, it documents what the mutex protects, and it follows consistent conventions. But even a reasonably thoughtful driver benefits from an explicit audit. The goal of this section is to walk through the driver and classify every piece of shared state: who reads it, who writes it, what protects it, and under what conditions. The result is a small document that accompanies the code, makes the concurrency story auditable, and becomes a checkpoint you can use when future changes risk breaking the model.

11.4.1 What “Shared” Means

A variable is **shared** if more than one stream of execution can access it during the same time window. “Same time window” does not require literal simultaneity; it requires that the two accesses could *potentially* overlap.

That definition is broader than beginners usually expect. Three examples clarify it.

A local variable inside a function is not shared. Each invocation of the function gets its own stack frame, and the variable lives in that frame. Another thread can enter the same function, but it will get its own stack and its own copy of the variable. There is no shared memory.

A static variable inside a function is shared. Despite the `static` keyword making it look local, the storage is file-scope: all invocations of the function see the same byte of memory. Two concurrent invocations of the function share that byte.

A field in a dynamically allocated structure is shared if and only if more than one stream of execution has a pointer to the same structure. The `struct myfirst_softc` for a given device is one such structure. Every call into the driver that goes through `dev->si_drv1` observes the same `_softc`. Two concurrent calls see the same `_softc`.

A more subtle variant: a field in a per-descriptor structure (our `struct myfirst_fh`) is shared only if more than one stream has access to the same file descriptor. Two processes with distinct descriptors do not share each other’s `struct myfirst_fh`. Two threads in the same process sharing a descriptor *do*. Most driver writers treat per-descriptor state as “almost” unshared and use lighter protection than device-wide state, but the word “almost” is doing heavy lifting; we will come back to this case in Section 5.

11.4.2 The Shared State of myfirst

Open your Stage 4 source. We are going to annotate, field by field, the contents of `struct myfirst_softc`. You can do this in the source itself (as a comment block near the struct declaration) or in a separate design document. I recommend doing both: a short summary in the source and a detailed version in a file you can evolve.

Here is the structure, as of Chapter 10 Stage 4:

```
struct myfirst_softc {
    device_t          dev;

    int               unit;

    struct mtx        mtx;

    uint64_t          attach_ticks;
    uint64_t          open_count;
    uint64_t          bytes_read;
    uint64_t          bytes_written;

    int               active_fhs;
    int               is_attached;

    struct cbuf        cb;

    struct selinfo     rsel;
    struct selinfo     wsel;

    struct cdev        *cdev;
    struct cdev        *cdev_alias;

    struct sysctl_ctx_list sysctl_ctx;
    struct sysctl_oid  *sysctl_tree;
};
```

For each field we ask five questions:

1. **Who reads it?** Which functions, and from which streams of execution?
2. **Who writes it?** Same question, but for writes.
3. **What protects the accesses from race conditions?**
4. **What invariants does it participate in?**
5. **Is the current protection sufficient?**

Going field by field is tedious. It is also the whole point. A driver whose concurrency story is documented field by field is a driver that almost certainly works. A driver whose concurrency story is left implicit is a driver whose author hoped for the best.

sc->dev: the Newbus device_t handle. - Read by: every handler (indirectly, through sc->dev in device_printf and similar). - Written by: attach (once, during module load). - Protection: write happens before any handler can run (the cdev is not registered until after sc->dev is set). After attach completes, the field is effectively immutable. No lock needed. - Invariants: sc->dev != NULL once attach has returned zero. - Sufficient? Yes.

sc->unit: a convenience copy of device_get_unit(dev). - Same analysis as sc->dev. Immutable after attach. No lock needed.

sc->mtx: the sleep mutex. - “Accessed” by every handler in mtx_lock/mtx_unlock/mtx_sleep calls. - Initialized by mtx_init in attach, destroyed by mtx_destroy in detach. - Protection: the mutex protects itself; the init and destroy are sequenced relative to the cdev’s creation and destruction so that no handler can ever see a half-initialized mutex. - Invariants: the mutex is initialized after mtx_init returns and before mtx_destroy is called. Handlers only run during that window. - Sufficient? Yes.

sc->attach_ticks: the ticks value at attach time, for informational purposes. - Read by: the sysctl handler for attach_ticks. - Written by: attach (once). - Protection: write happens before any sysctl handler can be called. After that, immutable. No lock needed. - Invariants: none beyond “set at attach”. - Sufficient? Yes.

sc->open_count: lifetime count of opens. - Read by: the sysctl handler for open_count. - Written by: myfirst_open. - Protection: the write happens under sc->mtx in myfirst_open. The read, currently, is an unprotected load from the SYSCTL_ADD_U64 handler. - Invariants: monotonically increasing. - Sufficient? On amd64, a 64-bit aligned load is atomic, so a torn read is not possible. The sysctl may observe an old value (a load that happened just before a concurrent increment) but not a corrupted one. This is acceptable for an informational counter. On 32-bit platforms, the same load would not be atomic, and a torn read would be possible. For this book’s purposes (amd64 lab machine), the current protection is sufficient. We will note this in the documentation.

sc->bytes_read, sc->bytes_written: lifetime byte counters. - Same analysis as open_count. Written under the mutex, read unprotected from sysctl, acceptable on amd64 but not 32-bit. These are candidates for migration to counter(9) per-CPU counters, which would remove the torn-read concern and also scale better under contention. Section 4 does this migration.

sc->active_fhs: current count of open descriptors. - Read by: sysctl handler, myfirst_detach. - Written by: myfirst_open, myfirst_fh_dtor. - Protection: all reads and writes happen under sc->mtx. - Invariants: active_fhs >= 0. active_fhs == 0 when detach is called and succeeds. - Sufficient? Yes.

sc->is_attached: flag indicating whether the driver is in the attached state. - Read by: every handler at entry (to fail-fast with ENXIO if the device has been torn down). - Written by: attach (sets to 1), detach (sets to 0, under the mutex). - Protection: the write in detach is under the mutex. The reads in the handlers at entry are *not* under the mutex (they are unprotected plain loads). - Invariants: is_attached == 1 while the device is usable. - Sufficient? There is a subtle question here. A handler that reads is_attached == 1 without the mutex might then proceed to acquire the mutex, and by the time it has the mutex, detach may have run and set the flag to 0. Our handlers handle this case by re-checking is_attached after every sleep (the if (!sc->is_attached) return (ENXIO); pattern after mtx_sleep). The entry check is an optimization that avoids taking the mutex in the common case; correctness does not depend on it. We will document this explicitly.

sc->cb: the circular buffer (all its fields). - Read by: myfirst_read, myfirst_write, myfirst_poll, the sysctl handlers for cb_used and cb_free. - Written by: myfirst_read, myfirst_write, attach (via cbuf_init), detach (via cbuf_destroy). - Protection: every access is under sc->mtx, including the sysctl

handlers (which take the mutex around a brief read). `cbuf_init` runs in `attach` before the `cdev` is registered, so it is effectively single-threaded. `cbuf_destroy` runs in `detach` after all descriptors have been confirmed closed, so it is also effectively single-threaded. - Invariants: `cb_used <= cb_size`, `cb_head < cb_size`, the bytes at `[cb_head, cb_head + cb_used) mod cb_size` are live. - Sufficient? Yes. This is the field the Chapter 10 work spent most of its time getting right.

`sc->rsel, sc->wsel`: `selinfo` structures for `poll(2)` integration. - Read/written by: `selrecord(9)`, `selwakeup(9)`, `seldrain(9)`. These functions handle their own locking internally; the caller's responsibility is merely to call them at the right times. - Protection: internal to the `selinfo` machinery. The caller holds `sc->mtx` around `selrecord` (because it is called inside `myfirst_poll`, which takes the mutex) and drops `sc->mtx` around `selwakeup` (because it may sleep). - Invariants: the `selinfo` is initialised once (it is zero-initialized by the `softc` allocation) and drained at `detach`. - Sufficient? Yes.

`sc->cdev, sc->cdev_alias`: pointers to the `cdev` and its alias. - Read by: nothing critical; they are stored for destruction. - Written by: `attach` (set), `detach` (destroyed and cleared). - Protection: writes happen at known lifecycle points before or after handlers can run. - Invariants: `sc->cdev != NULL` during the attached window. - Sufficient? Yes.

`sc->sysctl_ctx, sc->sysctl_tree`: the `sysctl` context and root node. - Managed by the `sysctl` framework. The framework handles its own locking. - Protection: framework-internal. - Sufficient? Yes.

11.4.3 The Per-Descriptor State

Now the per-descriptor state, in struct `myfirst_fh`:

```
struct myfirst_fh {
    struct myfirst_softc    *sc;
    uint64_t                reads;
    uint64_t                writes;
};
```

`fh->sc`: back-pointer to the `softc`. - Read by: handlers that retrieve it via `devfs_get_cdevpriv`. - Written by: `myfirst_open`, once, before the `fh` is handed to `devfs`. - Protection: the write is sequenced before any handler can see the `fh`. - Invariants: immutable after `myfirst_open`. - Sufficient? Yes.

`fh->reads, fh->writes`: per-descriptor byte counters. - Read by: the `myfirst_fh_dtor` destructor (for a final log message) and potentially future `sysctl` handlers per-descriptor (not currently exposed). - Written by: `myfirst_read`, `myfirst_write`. - Protection: the writes happen under `sc->mtx` (inside the read/write handlers). Two threads holding the same descriptor open could in principle write concurrently; both would hold `sc->mtx`, so the accesses serialize.

This is the subtle case noted earlier. Two threads in the same process can share a file descriptor. Both can call `read(2)` on it. Both will enter `myfirst_read`, both will retrieve the same `fh` via `devfs_get_cdevpriv`, both will want to update `fh->reads`. Because both hold `sc->mtx` during the update, the operations serialize, and no race occurs. If we ever wanted to hold less than the full `sc->mtx` (for instance, if we used a lock-free counter update), the per-descriptor case would force us to be more careful.

11.4.4 Classifying the Critical Sections

With the fields inventoried, we can now identify every **critical section** in the code. A critical section is a contiguous region of code that accesses shared state and must execute without interference from concurrent streams.

Go through `myfirst.c` and find every region bounded by `mtx_lock(&sc->mtx)` and `mtx_unlock(&sc->mtx)`. Each of those regions is a critical section by construction. Then look for regions that should be critical sections but are not. There should be none in the Stage 4 driver, but the audit is still valuable for confirming the gap.

The critical sections in Stage 4 are:

1. **myfirst_open**: updates `open_count` and `active_fhs` under the mutex.
2. **myfirst_fh_dtor**: decrements `active_fhs` under the mutex.
3. **myfirst_read**: multiple critical sections, each bracketing an access to the `cbuf`, separated by the out-of-lock `uiomove` calls. The wait helper runs inside the critical section; the byte counters are updated inside; `wakeup` and `selwakeup` are called with the mutex dropped.
4. **myfirst_write**: the mirror of `myfirst_read`.
5. **myfirst_poll**: one critical section that checks the `cbuf` state and either sets `revents` or calls `selrecord`.
6. **The two `cbuf` sysctl handlers**: each takes the mutex briefly to read `cbuf_used` or `cbuf_free`.
7. **myfirst_detach**: acquires the mutex to check `active_fhs` and to set `is_attached = 0` before waking sleepers.

Each of these should do as little work as possible while holding the mutex. Work that does not need the mutex (the `uiomove`, for example, or any computation on stack-local values) should happen outside. The Stage 4 driver is already careful about this; the audit confirms it.

11.4.5 Annotating the Source

One useful output of the audit is to go back to the source and add one-line comments above each critical section that name the shared state being protected. This is not decorative; it is documentation for the next person to read the code.

For example, the `myfirst_read` handler becomes:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    /* ... entry logic ... */
    while (uio->uio_resid > 0) {
        /* critical section: cbuf state + bytes_read + fh->reads */
        mtx_lock(&sc->mtx);
        error = myfirst_wait_data(sc, ioflag, nbfore, uio);
        if (error != 0) {
            mtx_unlock(&sc->mtx);
            return (error == -1 ? 0 : error);
        }
    }
}
```

```

        take = MIN((size_t)uio->uio_resid, sizeof(bounce));
        got = myfirst_buf_read(sc, bounce, take);
        fh->reads += got;
        mtx_unlock(&sc->mtx);

        /* not critical: wake does its own locking */
        wakeup(&sc->cb);
        selwakeup(&sc->wsel);

        /* not critical: uiomove may sleep; mutex must be dropped */
        error = uiomove(bounce, got, uio);
        if (error != 0)
            return (error);
    }
    return (0);
}

```

Three comments. Thirty seconds of work. They transform the handler from a piece of code that a reader has to analyze to a piece of code whose concurrency story is self-evident.

11.4.6 A Locking-Strategy Document

Alongside the source annotations, maintain a short document that describes the overall strategy. The file `LOCKING.md` in your driver source tree is a good location. A minimal version looks like this:

```

# myfirst Locking Strategy

## Overview
The driver uses a single sleep mutex (sc->mtx) to serialize all
accesses to the circular buffer, the sleep channel, the selinfo
structures, and the per-descriptor byte counters.

## What sc->mtx Protects
- sc->cb (the circular buffer's internal state)
- sc->bytes_read, sc->bytes_written
- sc->open_count, sc->active_fhs
- sc->is_attached (writes; reads may be unprotected as an optimization)
- sc->rsel, sc->wsel (through the selinfo API; the mutex is held
  around selrecord, dropped around selwakeup)

## Locking Discipline
- Acquire with mtx_lock, release with mtx_unlock.
- Wait with mtx_sleep(&sc->cb, &sc->mtx, PCATCH, wmesg, 0).
- Wake with wakeup(&sc->cb).

```

- NEVER hold `sc->mtx` across `uiomove`, `copyin`, `copyout`, `selwakeup`, or `wakeup`. Each of these may sleep or take other locks.
- All four `myfirst_buf_*` helpers assert `mtx_assert(MA_OWNED)`.

Known Non-Locked Accesses

- `sc->is_attached` at handler entry: unprotected read. Safe because a stale true is re-checked after every sleep; a stale false is harmless (the handler returns `ENXIO`, which is also what it would do with a fresh false).
- `sc->open_count`, `sc->bytes_read`, `sc->bytes_written` at `sysctl` read time: unprotected load. Safe on amd64 (aligned 64-bit loads are atomic). Would be unsafe on 32-bit platforms.

Lock Order

`sc->mtx` is currently the only lock the driver holds. No ordering concerns arise. Future versions that add additional locks must specify their order here.

That document is the definitive answer to “is this driver safe?”. It is reviewable. It can be checked against the code. It is the output of the audit we just performed.

11.4.7 A Practical Audit Procedure

The procedure we just walked through can be systematized:

1. List every field of every shared structure (softc, per-descriptor, any module-global state).
2. For each field, identify all read sites and all write sites.
3. For each field, identify the protection mechanism (lock held, lifecycle guarantee, framework-internal, atomic type, intentionally unprotected).
4. For each field, identify the invariants it participates in and the other fields those invariants involve.
5. For each invariant, confirm that the protection mechanism covers all relevant accesses.
6. For each known-unprotected access, document why it is acceptable.
7. Annotate the source code to name each critical section and each deliberate unprotected access.
8. Write the summary into a `LOCKING.md` file.

It sounds laborious. For a driver the size of `myfirst`, it takes under an hour. For a driver ten times the size, it takes a day. Either way, it pays for itself the first time it catches a bug that was not yet written.

11.4.8 Common Audit Discoveries

Three patterns recur. If your audit finds any of them, treat them as red flags.

The first is **silent sharing**: a field that you thought was local but is actually accessible from outside the current code path. The usual cause is a pointer that leaks from a structure you thought was private. `devfs_set_cdevpriv` gives a `cdev` a pointer to a per-descriptor structure; if that structure contains a back-pointer,

another thread can reach into it. Per-descriptor state that is accessed only from within the current thread is safer than state reachable from the softc.

The second is **irregular protection**: a field that is protected in most code paths but not in one. Often the unprotected path is the one added most recently. The audit catches it, the unit tests do not.

The third is **invariant drift**: over time, a field acquires new correlations with other fields, and the protection stops covering the composite invariant. The audit reveals it by asking what invariants each field participates in.

A disciplined audit, repeated periodically, catches all three.

11.4.9 A Second Worked Audit: A Hypothetical Multi-Queue Driver

To exercise the audit procedure on something slightly more interesting, imagine a driver that is not `myfirst`. Suppose we are auditing a hypothetical network-adjacent pseudo-device, `netsim`, which simulates a packet source. The softc has more shared state:

```
struct netsim_softc {
    device_t      dev;
    struct mtx    global_mtx;
    struct mtx    queue_mtx;

    struct netsim_queue rx_queue;
    struct netsim_queue tx_queue;

    struct callout tick_callout;
    int            tick_rate_hz;

    uint64_t      packets_rx;
    uint64_t      packets_tx;
    uint64_t      dropped;

    int            is_up;
    int            is_attached;
    int            active_fhs;

    struct cdev    *cdev;
};
```

This is a richer structure. Let us apply the audit procedure.

Two locks. `global_mtx` and `queue_mtx`. We need to decide what each protects and establish an order.

A reasonable split: `global_mtx` protects configuration and lifecycle state (`is_up`, `is_attached`, `tick_rate_hz`, `active_fhs`, `tick_callout`). `queue_mtx` protects the RX and TX queues, which are the high-frequency hot path.

Lock order. Because configuration changes are rare and queue operations are hot, we order: `global_mtx` before `queue_mtx`. A thread that holds `global_mtx` may acquire `queue_mtx`. A thread holding `queue_mtx` may not acquire `global_mtx`.

This is a choice, not an edict. A different driver might reverse it. What matters is consistency. `WITNESS` will catch any violation.

Counter fields. `packets_rx`, `packets_tx`, `dropped` are counters updated on the data path. `counter(9)` is the right tool.

The callout. `tick_callout` fires periodically to generate packets. Its handler runs on a kernel thread, concurrently with user-driven read/write. The callout handler takes `queue_mtx` to enqueue packets. Because the callout is initialised before the `cdev` is registered and is stopped on detach, the callout and the user handlers are properly bounded.

The invariants.

- `is_attached == 1` during the attached window; detach clears it under `global_mtx`.
- The queue structures have their own internal invariants (head/tail indices); `queue_mtx` protects them.
- `tick_rate_hz` is read in the callout; it is written in attach and in `ioctl`s; reads are under `global_mtx` so the rate cannot change mid-tick.

What to write in `LOCKING.md`:

Locks

`global_mtx` (MTX_DEF)

Protects: `is_up`, `is_attached`, `active_fhs`, `tick_rate_hz`, `tick_callout`.

`queue_mtx` (MTX_DEF)

Protects: `rx_queue`, `tx_queue` internal state.

Lock Order

`global_mtx` -> `queue_mtx`

A thread holding `global_mtx` may acquire `queue_mtx`.

A thread holding `queue_mtx` may NOT acquire `global_mtx`.

Lock-Free Fields

`packets_rx`, `packets_tx`, `dropped`: `counter_u64_t`. No lock required.

Callout

`tick_callout` fires every `1/tick_rate_hz` seconds. It acquires `queue_mtx` to enqueue packets. It does not acquire `global_mtx`. Stopping the callout is done in detach, under `global_mtx`, with `callout_drain`.

Notice that the audit produced a document that looks very much like the one for `myfirst`, even though the

driver is larger. The structure is the same: locks, what they protect, the order, rules, lock-free fields, notable subsystems.

That repeatability is the point of having an audit procedure. Every driver's LOCKING.md looks similar in shape, because the questions you ask during the audit are the same. Only the answers differ.

11.4.10 How Audits Catch Bugs

Three concrete examples of bugs that a careful audit would catch:

Example 1: Missing lock on an update. A new sysctl handler is added that allows the user to change `tick_rate_hz` at runtime. The handler writes the field without taking `global_mtx`. The audit catches this: the field is protected by `global_mtx`, but one write path does not take the lock.

Example 2: Lock order inversion. A new function, `netlim_rebalance`, is added. It takes `queue_mtx` to inspect the queue lengths, then takes `global_mtx` to update configuration based on the lengths. This is the wrong order. The audit catches this by asking: “for every function, does its lock acquisition match the global order?”.

Example 3: Torn read of `packets_rx`. A sysctl handler reads `packets_rx` with a plain 64-bit load. On amd64 this is fine; on 32-bit platforms it is not. The audit catches this by documenting which architectures the driver targets and flagging platform-dependent assumptions.

Each of these bugs is the kind that evades single-threaded testing. The audit catches them by being systematic.

11.4.11 Audits as Change Gates

In a mature driver project, the audit becomes a change gate: any commit that modifies shared state, adds a new field, or changes a lock acquisition is required to update LOCKING.md in the same commit. Reviewers check that the update is consistent with the code change.

This discipline sounds bureaucratic. In practice, it is fast (updating the doc takes a minute) and it is the single most effective defense against concurrency regressions. A driver that ships with a correct LOCKING.md is a driver whose concurrency story can be audited by any reviewer without reading every line of the code.

For our `myfirst`, the LOCKING.md is short because the driver is small. For larger drivers, the LOCKING.md scales in proportion. The value scales too.

11.4.12 Wrapping Up Section 3

You now have, for your own driver, a field-by-field account of every piece of shared state, every critical section, and every protection mechanism. You have a LOCKING.md file that documents the locking strategy. You have source annotations that make the concurrency intent visible to any reader. You have seen the same procedure applied to a hypothetical larger driver to show that it scales.

The rest of the chapter introduces the primitives that let you add or relax protection as your design evolves. Section 4 looks at atomics: what they buy you, what they do not, and where they fit in your driver. Section 5 is the full treatment of mutexes, including the subtleties that Chapter 10 gestured at.

11.5 Section 4: Introduction to Atomic Operations

Atomic operations are one of the two tools this chapter introduces. They are useful when the shared state you need to protect is small and the operation you need to perform on it is simple. They do not replace mutexes for anything more complex, but they are often the right tool for the simpler cases, and they are always faster. This section builds the intuition for what atomics are, presents the `atomic(9)` API FreeBSD exposes, discusses memory ordering at a level appropriate for our purposes, and applies the `counter(9)` per-CPU counter API to the driver's statistics.

11.5.1 What “Atomic” Means at the Hardware Level

Recall the counter race from Section 2. Two threads loaded, incremented, and stored the same memory location. Because the load, increment, and store were three separate instructions, another thread could slip in between them. The fix, at the simplest level, is to use a single instruction that performs all three operations indivisibly: no other thread can observe memory midway through.

Modern CPUs provide such instructions. On amd64, the instruction that atomically adds a value to memory is `LOCK XADD`. The `LOCK` prefix tells the CPU to lock the relevant cache line for the duration of the instruction, so that no other CPU can touch the same line until the instruction completes. The `XADD` instruction itself performs an exchange-add: it adds its source to the destination and returns the destination's old value, all in one transaction. After `LOCK XADD`, the memory location has the correct sum, and no other CPU has been able to observe a partial update.

The C primitive that compiles to this instruction is `atomic_fetchadd_int`. FreeBSD's `atomic(9)` API exposes it, along with many siblings, in `/usr/src/sys/sys/atomic_common.h` and the per-architecture `atomic.h` headers.

Atomicity, then, is a property of a *memory operation*: if the operation completes, it does so in a single indivisible transaction from memory's perspective. No other CPU can observe a half-done version. This is a hardware-level guarantee, not a software abstraction. When you use an atomic primitive in C, you are telling the compiler to emit an instruction that the hardware itself guarantees is indivisible.

Three things matter about this guarantee.

First, it covers *one* operation. `atomic_fetchadd_int` does one add. Two successive atomic operations are not jointly atomic: another thread can observe memory between them. If you need two fields to be updated together, you still need a mutex.

Second, it covers *word-sized* operations, for some definition of word. On amd64, atomic primitives cover 8, 16, 32, and 64 bits. Operations on larger structures (arrays, composite structs) cannot be atomic at the hardware level; they require a mutex or a specialised mechanism like `atomic128_cmpset` on platforms that provide it. The `atomic(9)` API exposes the granularities the hardware supports.

Third, it is *cheap*. An atomic increment is typically a few cycles slower than a non-atomic one, because the cache line must be acquired exclusively. Compared to acquiring and releasing a mutex (which itself uses atomics internally and may also take scheduler turns under contention), an atomic operation is usually an order of magnitude faster. When the work you need to do is simple, atomics give you correctness at minimal cost.

11.5.2 The FreeBSD atomic(9) API

The kernel exposes a family of atomic operations through function-like macros. The full set is documented in `atomic(9)` (run `man 9 atomic`). For the purposes of this chapter we care about a small subset.

The four most common operations are:

```
void    atomic_add_int(volatile u_int *p, u_int v);
void    atomic_subtract_int(volatile u_int *p, u_int v);
u_int   atomic_fetchadd_int(volatile u_int *p, u_int v);
int     atomic_cmpset_int(volatile u_int *p, u_int expect, u_int new);
```

- `atomic_add_int(p, v)` atomically computes `*p += v`. The return value is not meaningful; the update is indivisible.
- `atomic_subtract_int(p, v)` atomically computes `*p -= v`. Same shape.
- `atomic_fetchadd_int(p, v)` atomically computes `*p += v` and returns the value that was in `*p` *before* the add. Useful when you want both to update and to observe the previous value in the same transaction.
- `atomic_cmpset_int(p, expect, new)` atomically performs a compare-and-swap: if `*p == expect`, write `new` to `*p` and return 1; otherwise leave `*p` alone and return 0. This is the fundamental primitive for building more complex lock-free data structures.

Each of these has variants for different integer widths (`_long`, `_ptr`, `_64`, `_32`, `_16`, `_8`) and for different memory-ordering requirements (`_acq`, `_rel`, `_acq_rel`). The width variants are obvious: they work on different integer types. The memory-ordering variants deserve their own subsection.

There are also read and store primitives:

```
u_int   atomic_load_acq_int(volatile u_int *p);
void    atomic_store_rel_int(volatile u_int *p, u_int v);
```

These are atomic loads and stores with specific memory-ordering guarantees. For aligned machine-word types on our platforms, ordinary `*p` accesses are atomic in the load/store sense, but the `atomic_load_acq_int` / `atomic_store_rel_int` forms also act as memory barriers: they prevent the compiler and the CPU from reordering surrounding loads and stores past them. We will see why that matters shortly.

Finally, a few specialised primitives:

```
void    atomic_set_int(volatile u_int *p, u_int v);
void    atomic_clear_int(volatile u_int *p, u_int v);
```

These are bitwise OR and AND-NOT respectively: `atomic_set_int(p, FLAG)` sets the `FLAG` bit in `*p`; `atomic_clear_int(p, FLAG)` clears it. They are useful for flag words where multiple threads may be setting and clearing different bits.

11.5.3 A Gentle Introduction to Memory Ordering

Here is a subtlety that bites beginners: even with atomic operations, the *order in which memory accesses become visible to other CPUs* is not always the order in which the code executed them. Modern CPUs and compilers

may reorder instructions for performance, as long as the reordering is invisible to the single thread that issued them. In a multi-threaded program, the reordering is sometimes visible, and it can matter.

The classic example is a producer that prepares a payload and then sets a ready flag, while a consumer spins on the flag and then reads the payload:

```
/* Thread A (producer): */
data = compute_payload();
atomic_store_rel_int(&ready_flag, 1);

/* Thread B (consumer): */
while (atomic_load_acq_int(&ready_flag) == 0)
    ;
use_payload(data);
```

For the pattern to work, the two stores on thread A's side must become visible to thread B in order: thread B must not see `ready_flag == 1` while still seeing the old data. Without memory barriers, the CPU or the compiler is free to reorder those stores, and the consumer would read stale data.

The `_rel` suffix on `atomic_store_rel_int` is a **release** barrier: every write that happened before the store, in program order, is made visible to other CPUs before the store itself is. The `_acq` suffix on `atomic_load_acq_int` is an **acquire** barrier: every read that happens after the load, in program order, sees values at least as fresh as the value the load saw. Paired, release on the publisher and acquire on the consumer ensure the consumer observes everything the publisher did before the release.

We will not build lock-free data structures in this chapter; the subsection “Memory Ordering on a Multi-Core Machine” later in Section 4 walks through the ordering guarantees in a little more depth, and real lock-free patterns belong to Part 6 (Chapter 28) when specific drivers need them. The important point for now is that the same `_rel / _acq` pattern is the reason `mtx_lock` and `mtx_unlock` compose correctly with memory: `mtx_lock` has acquire semantics (nothing inside the critical section leaks out above it), and `mtx_unlock` has release semantics (nothing inside the critical section leaks out below it).

For a beginner, the practical takeaway is this: use the atomic primitive that corresponds to the intent of your operation. A counter increment uses the plain form. A flag that publishes the completion of other work uses the `_rel / _acq` pair. When in doubt, use the stronger form (`_acq_rel`); it costs a little more but is correct in more situations.

11.5.4 When Atomics Suffice

Atomics are the right tool when all four of the following are true:

1. The operation you need is simple (a counter increment, a flag set, a pointer exchange).
2. The shared state is a single word-sized field (or a small number of independent ones).
3. The correctness of the code does not depend on more than one memory location being consistent with another (no composite invariants).
4. The operation is cheap enough that replacing a mutex with an atomic is an observable win.

For `myfirst`, the counters `bytes_read` and `bytes_written` meet all four criteria. They are simple increments, single fields, independent of each other, and frequently updated on the data path. Converting them from mutex-protected fields to atomic (or per-CPU) counters is a clean win.

The `cbuf`, on the other hand, does not meet the criteria. Its correctness depends on a composite invariant (`cb_used <= cb_size`, the bytes at `[cb_head, cb_head + cb_used)` are live) that spans multiple fields. No single atomic operation can preserve that invariant. The `cbuf` needs a mutex, and no amount of cleverness with atomics will change that. This is worth stating clearly because beginners sometimes try to “atomically update `cb_used` and `cb_head`” and end up with a driver that compiles, looks clever, and is still broken.

11.5.5 Per-CPU Counters: the `counter(9)` API

FreeBSD provides, for the specific case of “a counter that is incremented frequently and read infrequently”, a specialised API: `counter(9)`. A `counter_u64_t` is a per-CPU counter, where each CPU has its own private memory for the counter, and a read combines all of them.

The API is:

```
counter_u64_t  counter_u64_alloc(int flags);
void          counter_u64_free(counter_u64_t c);
void          counter_u64_add(counter_u64_t c, int64_t v);
uint64_t      counter_u64_fetch(counter_u64_t c);
void          counter_u64_zero(counter_u64_t c);
```

`counter_u64_alloc(M_WAITOK)` returns a handle to a new per-CPU counter. `counter_u64_add(c, 1)` atomically adds 1 to the calling CPU’s private copy (no cross-CPU synchronization is required). `counter_u64_fetch(c)` sums across all CPUs and returns the total. `counter_u64_free(c)` releases the counter.

The per-CPU design has two consequences. First, adds are very fast: they touch only the calling CPU’s cache line, so there is no cross-CPU contention. Even on a 32-core system, a `counter_u64_add` call does not pay the cost of synchronizing with other cores. Second, reads are expensive: `counter_u64_fetch` sums across all CPUs, which costs roughly one cache-miss per CPU. Reads are therefore infrequent; updates are frequent.

This shape is exactly right for the `bytes_read` and `bytes_written` counters. They are updated on every I/O call (high rate). They are read only when a user runs `sysctl` or when `detach` emits a final log line (low rate). Migrating them to `counter_u64_t` gives us both correctness across 32-bit and 64-bit architectures, and scalability across many CPUs.

11.5.6 Migrating the Driver’s Counters

Here is what the migration looks like. First, change the fields in `struct myfirst_softc`:

```
struct myfirst_softc {
    /* ... */
    counter_u64_t  bytes_read;
```

```
        counter_u64_t    bytes_written;
        /* ... */
};
```

Update `myfirst_attach` to allocate them:

```
static int
myfirst_attach(device_t dev)
{
    /* ... existing setup ... */
    sc->bytes_read = counter_u64_alloc(M_WAITOK);
    sc->bytes_written = counter_u64_alloc(M_WAITOK);
    /* ... rest of attach ... */
}
```

Update `myfirst_detach` to free them:

```
static int
myfirst_detach(device_t dev)
{
    /* ... existing teardown ... */
    counter_u64_free(sc->bytes_read);
    counter_u64_free(sc->bytes_written);
    /* ... rest of detach ... */
}
```

Update the read and write handlers to use `counter_u64_add` instead of the plain increment:

```
counter_u64_add(sc->bytes_read, got);
```

Update the sysctl handlers to use `counter_u64_fetch`:

```
static int
myfirst_sysctl_bytes_read(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    uint64_t v = counter_u64_fetch(sc->bytes_read);
    return (sysctl_handle_64(oidp, &v, 0, req));
}
```

And register the sysctl with a handler instead of a direct pointer:

```

SYSCTL_ADD_PROC(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "bytes_read",
    CTLTYPE_U64 | CTLFLAG_RD | CTLFLAG_MPSAFE,
    sc, 0, myfirst_sysctl_bytes_read, "QU",
    "Total bytes drained from the FIFO");

```

Once the migration is done, you can drop the `sc->bytes_read` and `sc->bytes_written` entries from the list of fields protected by `sc->mtx` in your `LOCKING.md`. They now protect themselves, in a way that scales better and is correct on any architecture FreeBSD supports.

11.5.7 A Simple Atomic Flag Example

Let us also look at a smaller, more targeted use of atomics. Suppose we want to track whether the driver is “currently busy” in a coarse sense, for debugging. We do not need strict correctness; we just want a flag we can flip and read.

Add a field:

```
volatile u_int busy_flag;
```

Update it in the handlers:

```

atomic_set_int(&sc->busy_flag, 1);
/* ... do the work ... */
atomic_clear_int(&sc->busy_flag, 1);

```

Read it elsewhere:

```
u_int is_busy = atomic_load_acq_int(&sc->busy_flag);
```

This is *not* a correct way to implement mutual exclusion. Two threads could both read `busy_flag == 0`, both set it to 1, both do their work, both clear it. The flag does not prevent concurrent execution; it is purely informational. For actual mutual exclusion, we need a mutex, which is the subject of the next section.

The point of the flag example is narrower: atomic operations let you set and read a single-word value without tearing. That is useful for an informational field that does not participate in an invariant. Once you need the field to participate in an invariant, atomics alone will not save you.

11.5.8 The Compare-and-Swap Pattern

The most interesting atomic primitive is `atomic_cmpset_int`, which implements the **compare-and-swap** pattern. It lets you write optimistic code: “update the field if nobody else has touched it since I last looked.”

The pattern is:

```
u_int old, new;
do {
    old = atomic_load_acq_int(&sc->field);
    new = compute_new(old);
} while (!atomic_cmpset_int(&sc->field, old, new));
```

The loop reads the current value, computes what the new value should be based on it, and tries to atomically swap the new value in, conditional on the field not having changed. If another thread changed the field between the load and the cmpset, the cmpset fails and the loop retries with the new value. When it succeeds, the update is committed atomically, and `*sc->field` now holds the value derived from the state it actually held at the moment of update.

Compare-and-swap is the building block for most lock-free data structures. You can implement a lock-free stack, a lock-free queue, a lock-free counter (which is how `atomic_fetchadd` is often implemented under the hood), and many other structures using nothing but compare-and-swap.

For our purposes, compare-and-swap is worth knowing about even if we do not use it heavily. When you read FreeBSD source later and see `atomic_cmpset_*` in a tight loop, you will recognize the pattern immediately: optimistic retry.

11.5.9 When Atomics Are Not Enough

Three situations call for a mutex even when the state looks simple.

First, when the operation involves more than one memory location. If `cb_head` and `cb_used` must be updated together, no single atomic operation can do it. Either we accept that the update is two atomics (with a transient half-updated state visible to readers), or we hold a mutex across the update.

Second, when the operation is expensive (includes a function call, a loop, or allocates memory). An atomic operation is cheap only if it is a single fast instruction. A long critical section cannot be folded into a single atomic; it needs a mutex.

Third, when the code must block. No atomic operation can put the caller to sleep. If you need to wait for a condition (“buffer has data”), you need `mtx_sleep` or a condition variable, which require a mutex.

The `cbuf` triggers all three. The counters trigger none. That is why the counters can migrate to atomics or `counter(9)` and the `cbuf` cannot.

11.5.10 A Worked Example: a “driver version” Counter

Here is an exercise to ground the theory. Suppose we want to count how many times the driver has been loaded and unloaded during the current uptime. This is module-level state, not per-softc, and it is updated exactly twice per load/unload cycle: once in the module event handler when the load is successful, and once when it is unloaded.

We could protect it with a global mutex. That would be overkill: the update is one integer, happens rarely, and does not compose with anything else. An atomic is the right choice:

```
static volatile u_int myfirst_generation = 0;

static int
myfirst_modevent(module_t m, int event, void *arg)
{
    switch (event) {
        case MOD_LOAD:
            atomic_add_int(&myfirst_generation, 1);
            return (0);
        case MOD_UNLOAD:
            return (0);
        default:
            return (EOPNOTSUPP);
    }
}
```

A reader (for example a sysctl exposing `hw.myfirst.generation`) can use:

```
u_int gen = atomic_load_acq_int(&myfirst_generation);
```

No lock required. No contention. Correct on every architecture FreeBSD supports. This is the atomic-appropriate case: one field, one operation, no composite invariant.

11.5.11 Visibility, Ordering, and the Everyday Driver

Before closing this section, one more observation about memory ordering and mutexes.

You might wonder, given that `atomic_store_rel_*` and `atomic_load_acq_*` exist, why the driver code we wrote in Chapter 10 didn't use them. The reason is that `mtx_lock` has acquire semantics built in, and `mtx_unlock` has release semantics built in. Every write inside a critical section becomes visible to the next thread that acquires the mutex, at the moment it acquires. Every read inside a critical section sees writes that happened before any previous `mtx_unlock` on the same mutex. The mutex is, among other things, a memory barrier.

So when you write:

```
mtx_lock(&sc->mtx);
sc->field = new_value;
mtx_unlock(&sc->mtx);
```

you do not need to say `atomic_store_rel_int(&sc->field, new_value)`. The mutex already does the necessary ordering. This is an important property: it means that code inside a mutex critical section does not need to reason about memory ordering. Correctness is about the mutual exclusion, full stop.

Outside of critical sections (and only outside), you need to reason about ordering yourself. That is where the `_acq` / `_rel` atomic variants earn their keep.

For the `myfirst` driver, the only state we access outside any lock is `sc->is_attached` (the optimization at handler entry) and the per-CPU counters (which handle their own ordering). Everything else is either immutable after attach or protected by `sc->mtx`. That is a small footprint, and it is the reason our concurrency story stays manageable.

11.5.12 Memory Ordering on a Multi-Core Machine

The earlier “Gentle Introduction to Memory Ordering” sketched what `_acq` and `_rel` do; this section makes the underlying mechanism a little more concrete, because once you have done one publishing pattern by hand, the rest of the kernel’s atomic primitives become much easier to read.

The example is the same producer/consumer pattern with two shared variables, `payload` and `ready`. Without barriers, two orderings can fail:

- **On the producer’s side**, the write to `payload` could become visible to other CPUs *after* the write to `ready`. The consumer then sees `ready == 1` while still seeing the old `payload`.
- **On the consumer’s side**, the read of `payload` could be hoisted *before* the read of `ready`. The consumer commits to the old `payload` before it ever inspects the flag.

Why is either reordering legal? The compiler is allowed to move loads and stores past each other as long as the result is consistent for a single-thread observer. The CPU is allowed to reorder accesses through its store buffer, its prefetch unit, and its out-of-order execution engine, again as long as the local thread cannot tell. Multi-thread visibility is a property neither the compiler nor the CPU enforces by default.

The `_rel` and `_acq` suffixes lift exactly the constraints you need:

- `atomic_store_rel_int(&ready, 1)`: every store that appeared before this line in program order is made visible before the store to `ready` becomes visible. The *release* publishes everything prior.
- `atomic_load_acq_int(&ready)`: every load that appears after this line sees memory at least as fresh as the load itself saw. The *acquire* fences subsequent reads.

The pairing of release and acquire creates a *happens-before* relationship: if the consumer observes `ready == 1` through `atomic_load_acq_int`, every store the producer made before its `atomic_store_rel_int` is visible to the consumer.

In your driver, the same property is supplied by the mutex. `mtx_unlock(&sc->mtx)` has release semantics built in. `mtx_lock(&sc->mtx)` has acquire semantics. Every write made while the mutex was held is visible to the next thread that acquires the same mutex. This is why, inside a critical section, plain C assignment is fine: the mutex boundaries handle ordering for you.

Outside any lock, if you are coordinating multiple fields with atomics, you have to think explicitly about which writes need to be visible together and reach for the matching `_rel` and `_acq` variants. In the Chapter 11 driver, the only place this matters is the per-CPU counters, and `counter(9)` handles the ordering internally.

11.5.13 Atomic Swaps and More Flavours

We have mentioned `atomic_add`, `atomic_fetchadd`, `atomic_cmpset`, `atomic_load_acq`, `atomic_store_rel`, `atomic_set`, and `atomic_clear`. Two more are worth naming, because you will see them in FreeBSD source.

`atomic_swap_int(p, v)`: atomically exchanges the value at `*p` with `v` and returns the old value. This is useful when you want to “claim” a resource: the thread that successfully swaps the flag from “free” to “taken” is the new owner.

`atomic_readandclear_int(p)`: atomically reads `*p` and sets it to zero, returning the old value. Useful for “drain” patterns where one thread periodically collects and resets a counter the other threads have been incrementing.

Both are built on top of the same compare-and-swap primitive the hardware provides, and both have the same cost profile as `atomic_cmpset`.

11.5.14 A Practical Example: Atomic Reference Counting

A common driver pattern is reference counting: an object is allocated, several threads take references to it, and the object is freed when the last reference is dropped. Atomics are the right tool.

```
struct myobj {
    volatile u_int refcount;
    /* ... other fields ... */
};

static void
myobj_ref(struct myobj *obj)
{
    atomic_add_int(&obj->refcount, 1);
}

static void
myobj_release(struct myobj *obj)
{
    u_int old = atomic_fetchadd_int(&obj->refcount, -1);
    KASSERT(old > 0, ("refcount went negative"));
    if (old == 1) {
        /* We were the last reference; free it. */
        free(obj, M_DEVBUF);
    }
}
```

Two details are worth noting.

The first is the use of `atomic_fetchadd_int` for the decrement. Why not `atomic_subtract_int`? Because we need to know whether *our* decrement was the one that brought the count to zero, so that we can

free the object. `atomic_fetchadd_int` returns the value before the add, which tells us exactly that. An `atomic_subtract_int` does not return a value.

The second is that the free must happen *only if* our decrement was the final one. Otherwise, if two threads happen to release concurrently, they might both try to free the object. By keying the free on “old == 1”, we ensure that exactly one thread (the one that took the count from 1 to 0) frees the object. All other threads simply decrement and return.

This pattern is used throughout the FreeBSD kernel. It is the reason `refcount(9)` exists as a small wrapper API (`refcount_init`, `refcount_acquire`, `refcount_release`). For our purposes we do not use reference counting yet; the example is for your toolbox.

11.5.15 counter(9) in More Depth

The `counter(9)` API is used throughout the FreeBSD kernel for high-frequency counters. It is worth understanding how it works, because the design choices explain the API shape.

Each `counter_u64_t` is, internally, an array of per-CPU counters. The array is sized to the number of CPUs in the system. An add targets the calling CPU’s slot. A fetch iterates over all slots and sums.

The per-CPU layout means:

- **Adds do not contend.** Two CPUs adding concurrently touch different cache lines. There is no cross-CPU traffic.
- **Fetches are expensive.** They touch every CPU’s cache line, which on a 32-core machine means 32 cache misses.
- **Fetches are not atomic with adds.** A fetch might catch one CPU mid-update. The returned total may be slightly off from any instantaneous true total. This is fine for informational counters; it would be wrong for counters that feed into decisions.

For our driver, the fetches happen in `sysctl` handlers, which are infrequent, so the asymmetry is in our favour. If we ever needed a counter whose value must be exact at every fetch, `counter(9)` would not be the right primitive.

A subtlety: `counter_u64_zero` resets the counter to zero. Doing so while adds are happening is *not* atomic with them. If a reader fetches, sees a large value, and zeros, some adds in flight may be lost. For counters that are simply informational, this is acceptable. For counters that track budget or quota, zero carefully or not at all.

11.5.16 Lock-Free Data Structures in Context

A full treatment of lock-free data structures would fill its own book. FreeBSD’s kernel uses them in specific places where contention would otherwise be a bottleneck:

- **`buf_ring(9)`** is a lock-free multi-producer queue used by network and storage drivers for hot paths. The driver picks single-consumer or multi-consumer mode through the flags passed to `buf_ring_alloc()`, so the same primitive serves either shape depending on the subsystem’s concurrency needs. For the full API surface, see Appendix B’s `buf_ring(9)` entry.

- **epoch(9)** provides a read-mostly pattern where readers proceed without any synchronization and writers coordinate among themselves.
- **mi_switch fast paths** in the scheduler use atomic operations to avoid mutexes entirely in the common case.

Reading any of these is good study material, but they are specialised. For a beginner driver, the combination of atomic for single fields and mutex for composite state covers 99% of real drivers. We stay with those for Chapter 11 and let Chapter 12 and later chapters introduce the more sophisticated patterns when specific drivers need them.

11.5.17 When to Reach for an Atomic (Decision Guide)

As a decision guide, use this flowchart when deciding whether to make a field atomic or lock it:

1. Is the field a single word (8, 16, 32, or 64 bits on a platform where that size is atomic)? If no, it must be locked.
2. Does the correctness of my code depend on this field being consistent with another field? If yes, it must be locked with the other field.
3. Does my operation on the field involve more than one read-modify-write sequence? If yes, either use `atomic_cmpset` in a loop or lock.
4. Does the code need to sleep while holding the state? If yes, use a mutex and `mtx_sleep`; atomics cannot sleep.
5. Otherwise, an atomic operation is probably the right tool.

For the `myfirst` driver, this flowchart points at atomics for the byte counters (now `counter(9)`), the “generation” counter (Section 4’s load/unload counter), and informational flags. It points at the mutex for everything involving the `cbuf`.

11.5.18 Wrapping Up Section 4

Atomic operations are a precise tool for a precise job: updating a single word-sized field without racing. They are fast, they compose with memory ordering primitives when needed, and they scale well. They do not replace mutexes for anything more complicated than a single field.

In the driver, we migrated the byte counters to `counter(9)` per-CPU counters, which removed them from the set of fields protected by `sc->mtx` and gave us better performance under high load. The `cbuf`, with its composite invariants, stays protected by `sc->mtx`. Section 5 returns to that mutex and explains, in full, what it is and how it works.

11.6 Section 5: Introducing Locks (Mutexes)

This is the central section of the chapter. Everything up to here has been preparation; everything after this reinforces and extends. By the end of the section, you will understand what a mutex is, what kinds FreeBSD provides, what rules apply to each, why Chapter 10 chose the specific kind it used, and how to verify that your driver obeys the rules.

11.6.1 What a Mutex Is

A **mutex** (short for “mutual exclusion”) is a synchronization primitive that allows only one thread at a time to hold it. Threads that try to acquire a mutex while it is held wait until the holder releases it, then one of the waiters acquires it. The guarantee is that, between any two acquisitions of the same mutex, exactly one thread executed the code region between its acquire and its release.

That guarantee is what turns sequences of instructions into **critical sections**: regions of code whose execution is serialized across all threads that use the mutex. A reader who holds the mutex can read any number of fields and trust that no concurrent writer is producing torn values. A writer who holds the mutex can update any number of fields and trust that no concurrent reader is observing a half-updated state.

Mutexes do not prevent concurrency; they shape it. Multiple threads can execute outside the critical section at the same time. They can even be queued up to enter the critical section at the same time. What they cannot do is execute the critical section concurrently. The serialization is the property we buy; the price is the cost of acquiring and releasing, plus any wait time.

11.6.2 FreeBSD’s Two Mutex Shapes

FreeBSD distinguishes two fundamental shapes of mutex, because the kernel itself runs in two distinct sets of contexts and each context has different constraints.

MTX_DEF is the default mutex, often called a **sleep mutex**. When a thread tries to acquire one that is held, it is put to sleep (added to a sleep queue, with its state set to `TDS_SLEEPING`) until the holder releases the mutex. A sleep mutex may block for an arbitrarily long time, so the code using it must be in a context where sleeping is legal: ordinary process context, a kernel thread, or a callout marked as `mpsafe`. Most driver code runs in contexts where sleep mutexes are appropriate.

MTX_SPIN is a **spin mutex**. When a thread tries to acquire one that is held, it *spins*: it executes a tight loop of atomic checks until the holder releases. A spin mutex never sleeps. The reason spin mutexes exist is that some contexts (specifically, hardware interrupt handlers on certain systems) cannot sleep at all. A thread that cannot sleep cannot wait for a sleep mutex; it needs a primitive that makes progress without descheduling. Spin mutexes have additional rules: they disable interrupts on the CPU that acquires them, they must be held for very short durations, and code holding them cannot call any function that could sleep.

For the `myfirst` driver, `MTX_DEF` is the correct choice. Our handlers run in process context, on behalf of a user syscall. They do not run in interrupt context. Sleeping is legal. The mutex can be a sleep mutex, which is simpler and places fewer restrictions on what the critical section can do.

The `mtx_init` call from Chapter 10 specifies `MTX_DEF`:

```
mtx_init(&sc->mtx, device_get_nameunit(dev), "myfirst", MTX_DEF);
```

That last argument is the lock type. If we had wanted a spin mutex, it would be `MTX_SPIN`, and the rest of the driver would have been more constrained.

11.6.3 The Life Cycle of a Mutex

Every mutex has a life cycle: create, use, destroy. The functions are `mtx_init` and `mtx_destroy`:

```
void mtx_init(struct mtx *m, const char *name, const char *type, int opts);
void mtx_destroy(struct mtx *m);
```

`mtx_init` initializes the internal fields of the mutex structure and registers the mutex with `WITNESS` (if enabled) so that lock-order checking can apply. `mtx_destroy` tears it down.

The four arguments to `mtx_init` are:

- `m`: the mutex structure (typically a field of a larger struct, not a separate allocation).
- `name`: a human-readable identifier that shows up in `ps`, `dmesg`, and `WITNESS` messages. For our driver this is `device_get_nameunit(dev)` (for instance, `"myfirst0"`).
- `type`: a short string classifying the mutex; `WITNESS` groups mutexes with the same `type` string as related. For our driver this is `"myfirst"`.
- `opts`: the flags, including `MTX_DEF` or `MTX_SPIN`, and optional flags like `MTX_RECURSE` (allow the same thread to acquire the mutex multiple times) or `MTX_NEW` (guarantee that the memory is uninitialized). For our driver, `MTX_DEF` alone is correct.

The name and type matter for observability. When a user runs `procstat -kk`, they see `myfrd` (the wait message from `mtx_sleep`) and `myfirst0` (the mutex name) in the process's wait information. When `WITNESS` flags a lock-order reversal, it names the mutex by its name. Good names make debugging concurrency problems dramatically easier.

11.6.4 Acquiring and Releasing

The two fundamental operations are `mtx_lock` and `mtx_unlock`. Both take a pointer to the mutex:

```
void mtx_lock(struct mtx *m);
void mtx_unlock(struct mtx *m);
```

`mtx_lock` acquires the mutex. If the mutex is not held, it acquires immediately (the cost is one atomic operation). If the mutex is held, the calling thread goes to sleep on the mutex's wait list. When the current holder releases, one waiter is woken and acquires the mutex.

`mtx_unlock` releases the mutex. If there are waiters, one is woken and scheduled. If there are no waiters, the unlock completes with only the cost of a store.

These two operations compose into the critical-section idiom:

```
mtx_lock(&sc->mtx);
/* critical section: mutual exclusion is guaranteed here */
mtx_unlock(&sc->mtx);
```

Inside the critical section, the thread holding the mutex is the only thread that can be in any critical section protected by the same mutex. Other threads trying to enter the critical section are asleep, waiting.

11.6.5 The Other Operations

Several other operations are occasionally useful:

mtx_trylock(&m): attempts to acquire the mutex. Returns nonzero on success (mutex acquired) and zero on failure (mutex held by another thread). The calling thread never sleeps. This is useful when you want to do something only if the mutex is available, or when you want to avoid holding a lock across a potentially long operation.

mtx_assert(&m, what): asserts that the mutex is or is not held, for debugging. The *what* argument is one of `MA_OWNED` (current thread holds the mutex), `MA_NOTOWNED` (current thread does not hold the mutex), `MA_OWNED | MA_RECURSED` (held, recursively), or `MA_OWNED | MA_NOTRECURSED` (held, not recursively). On an `INVARIANTS` kernel, the assertion fires as a panic if violated. On a non-`INVARIANTS` kernel, it does nothing. Use this liberally; it is free in production and catches bugs in development.

mtx_sleep(&chan, &mtx, pri, wmesg, timo): the sleep primitive we used in Chapter 10. Atomically releases `mtx`, sleeps on `chan`, reacquires `mtx` before returning. The atomicity matters: the lock drop and the sleep cannot be interrupted by a concurrent wakeup.

mtx_initialized(&m): returns nonzero if the mutex has been initialized. Useful in rare teardown paths where you want to check whether you need to call `mtx_destroy`.

11.6.6 Re-Examining the Chapter 10 Design

With the vocabulary in place, let us re-read the Chapter 10 design choices and confirm they are correct.

One mutex, covering all shared softc state. The simplest possible design is one mutex protecting everything that is shared. This is what we have. It is the right starting point for any driver. It is almost never the wrong answer, even if a finer-grained design might perform better. Finer-grained locking has costs (lock ordering, understanding, bugs when new fields are added); a single mutex has the benefit of being obviously correct.

MTX_DEF (sleep mutex). The driver runs in process context. All the work is on behalf of user syscalls. There are no interrupt handlers. `MTX_DEF` is the correct choice.

Lock acquired for every access to shared state. Every read and write of the protected fields is inside a `mtx_lock` / `mtx_unlock` pair. The audit in Section 3 confirmed this.

Lock released before calling functions that may sleep. `uiomove(9)` may sleep (on a user-space page fault). `selwakeup(9)` may take its own locks and should not be called under our mutex. Our handlers drop the mutex before these calls. This is the rule from Chapter 10; we can now explain *why* it matters, which Section 5.6 does below.

mtx_sleep uses the mutex as interlock. The atomic drop-and-sleep operation is what prevents a race between the condition check and the sleep. If we did not use `mtx_sleep` and instead unlocked, then slept, a concurrent wakeup could fire in the window between unlock and sleep, and we would miss the wakeup and sleep forever. `mtx_sleep` exists precisely to close that window.

Every choice Chapter 10 made is now one we can defend from first principles. The mutex is not there by habit; it is there because every aspect of the design requires it.

11.6.7 The Sleep-with-Mutex Rule

One rule recurs often enough to deserve its own treatment: **do not hold a non-sleepable lock across a sleeping operation**. For MTX_DEF mutexes, this translates to: do not hold the mutex across any call that may sleep unless you are using `mtx_sleep` itself (which atomically drops the mutex for the duration of the sleep).

Why does this matter?

First, sleeping with a mutex held blocks any other thread that needs the same mutex, for the entire duration of the sleep. If the sleep is long, throughput collapses; if the sleep is indefinite, the system deadlocks.

Second, sleeping in the kernel involves the scheduler, which may need its own locks. If those locks have a defined order with respect to your mutex, and your held mutex is further up the order, you may trigger a lock-order violation.

Third, on WITNESS-enabled kernels, sleeping with a mutex held raises a warning. On INVARIANTS-enabled kernels, certain specific cases of this rule (the well-known sleeping primitives) will panic.

The rule's scope is broader than it first appears. A call that "may sleep" includes:

- `malloc(9)` with `M_WAITOK`.
- `uiomove(9)`, `copyin(9)`, `copyout(9)` (each may fault on user memory and wait for the page to be paged in).
- Most functions in the `vfs(9)` layer.
- Most functions in the `file(9)` layer.
- `taskqueue_enqueue(9)` in some paths.
- Any function whose implementation chain includes any of the above.

The practical technique is to identify every function you call from inside a critical section and ask: "can this sleep?" If the answer is yes or you are not sure, drop the lock before the call. The Chapter 10 handlers follow this rule: they drop `sc->mtx` before every `uiomove`, and they drop it before every `selwakeup`.

11.6.8 Priority Inversion and Priority Propagation

A subtle concurrency issue is **priority inversion**. Suppose thread L (low priority) acquires mutex M. Thread H (high priority) wants to acquire M and has to wait for L. In the meantime, thread M (medium priority, no relation to our mutex variable) is doing work unrelated to the mutex. The scheduler, seeing that H is blocked and M is runnable, will schedule M over L. L therefore makes no progress. M keeps L from running. H keeps waiting for L. A medium-priority thread has effectively blocked a high-priority thread, even though they share no resources.

This is priority inversion. It is a famous bug; the Mars Pathfinder mission briefly experienced a version of it in the 1990s.

The FreeBSD kernel handles priority inversion through **priority propagation** (also called priority inheritance). When a high-priority thread blocks on a mutex held by a lower-priority thread, the kernel temporarily raises the holder's priority to match the waiter's. L now runs at H's priority, so M cannot preempt it, and L finishes the critical section quickly. When L releases the mutex, its priority drops back, H acquires the mutex, and the inversion is resolved.

The practical consequence for a driver writer is that you mostly do not need to think about priority inversion. The kernel handles it for you on any `MTX_DEF` mutex. But the mechanism has costs: the holder of a contended mutex may run at a higher priority than it would otherwise, potentially for the duration of the critical section. That is another reason to keep critical sections short.

11.6.9 Lock Order and Deadlocks

Priority inversion is a problem within a single mutex. **Deadlock** is a problem across multiple mutexes.

Consider two mutexes, A and B. Thread 1 acquires A, then wants to acquire B. Thread 2 acquires B, then wants to acquire A. Each thread holds what the other wants. Neither releases what it has until it acquires what it wants. Neither can make progress. The system has deadlocked.

The classical defence against deadlock is **lock ordering**: every thread acquires its locks in the same global order. If all threads that need both A and B always acquire A before B, deadlock of this kind is impossible. Thread 2 would acquire A before B, not the other way around; if it could not get A, it would wait for it; once it had A, it would then acquire B; it would not hold B and wait for A.

In FreeBSD, `WITNESS` enforces lock ordering. The first time the kernel observes a thread holding lock A and acquiring lock B, it records the order A-before-B as valid. If it later sees another thread (or even the same thread) hold B and try to acquire A, that is a lock-order reversal, and `WITNESS` prints a warning. If `INVARIANTS` is also enabled and the configuration demands it, the warning becomes a panic.

For the `myfirst` driver, we have only one mutex. There is no lock order to worry about (a mutex has a trivial order with itself: you either hold it or you don't, and `mtx_lock` with `MTX_RECURSE` unset will panic if a thread already holding the mutex tries to acquire it again). As the driver grows, if additional mutexes are introduced, a lock order must be defined and documented. Chapter 12 covers this in depth for the case of multiple lock classes (for example, a mutex for the control path and an `sx` lock for the data path).

11.6.10 WITNESS: What It Catches

`WITNESS` is the kernel's lock-order and locking-discipline checker. It is enabled by options `WITNESS` in the kernel configuration; it is often paired with options `INVARIANTS` for maximum coverage.

What `WITNESS` catches:

- **Lock-order reversals**: thread acquires locks in an order not matching a previously-observed order.
- **Sleeping with a non-sleepable lock held**: thread calls `msleep`, `tsleep`, `cv_wait`, or any other sleeping primitive while holding an `MTX_SPIN` mutex.
- **Recursive acquisition of a non-recursive lock**: thread tries to acquire a mutex it already holds, and the mutex was not initialized with `MTX_RECURSE`.
- **Release of a lock not held**: thread calls `mtx_unlock` on a mutex it does not hold.
- **Sleeping with certain named sleep mutexes held**: more specifically, if `INVARIANTS` is also enabled, `mtx_assert(MA_NOTOWNED)` is checked before sleeping.

What `WITNESS` does not catch:

- **Missing locks**: if you forgot to take a lock, `WITNESS` has no way to know you should have.

- **Use-after-free of a mutex:** if you destroy a mutex and then use it, WITNESS may or may not catch it depending on how quickly the memory is reused.
- **Data races that do not involve locks:** two threads touching the same unlocked variable are invisible to WITNESS.

For this reason, WITNESS is a lint tool, not a proof. A driver can pass WITNESS and still be wrong. But a driver that fails WITNESS is almost certainly wrong, and the warnings are usually specific enough to point at the line.

Turn on WITNESS and INVARIANTS in your development kernel. Run the driver's test suite under the debug kernel. If warnings appear, investigate every one. This is the single most effective habit in driver debugging.

11.6.11 Running the Driver Under WITNESS

If you have not already, build a debug kernel. On a FreeBSD 14.3 release system, the installed GENERIC kernel does not have WITNESS or INVARIANTS enabled, because those options carry a runtime cost that is undesirable in production. You have to build a kernel that does. The simplest way is to copy GENERIC and add the relevant options. The lines you need are:

```
options      INVARIANTS
options      INVARIANT_SUPPORT
options      WITNESS
options      WITNESS_SKIPSPIN
```

Section “Building and Booting a Debug Kernel” later in this chapter walks through the full build, install, and reboot procedure step by step. The short version is:

```
# cd /usr/src
# make buildkernel KERNCONF=MYFIRSTDEBUG
# make installkernel KERNCONF=MYFIRSTDEBUG
# shutdown -r now
```

where MYFIRSTDEBUG is the name of the kernel configuration file you created.

After rebooting, load the driver and run a test. If WITNESS fires, dmesg will show something like:

```
lock order reversal:
 1st 0xfffffe00020b8a30 myfirst0 (myfirst, sleep mutex) @ ...:<line>
 2nd 0xfffffe00020b8a38 foo_lock (foo, sleep mutex) @ ...:<line>
lock order foo -> myfirst established at ...
```

The warning names both mutexes, their addresses, their types, and the source locations involved. From here, you trace the code and fix the order.

For the Chapter 10 Stage 4 driver, WITNESS should be silent: we have one mutex, used consistently, and no sleep-with-mutex violations. If you see warnings, that is a bug worth investigating.

11.6.12 When a Mutex Is the Wrong Answer

Three situations call for something other than a plain `MTX_DEF` mutex. Chapter 12 covers each in depth; we mention them here so the reader knows the landscape.

Many readers, few writers. If the critical section is mostly read-only, with occasional writes, a mutex serializes readers unnecessarily. A reader/writer lock (`sx(9)` or `rw(9)`) allows many readers to hold the lock simultaneously and serializes only writers. The cost is higher overhead per acquire/release and more complexity in the rules; the benefit is scalability on read-heavy workloads.

Blocking wait on a condition, not on a lock. When a thread needs to wait until a specific condition becomes true (for example, “data is available in the `cbuf`”), `mtx_sleep` with a channel is one way to express it. A named **condition variable** (`cv(9)`) is another way, often cleaner and more explicit. Chapter 12 covers `cv_wait`, `cv_signal`, and `cv_broadcast`.

Extremely short operations on a single field. Atomics, as we saw in Section 4. No need for a mutex at all.

For `myfirst`, none of these apply yet. The critical sections are short, the operations involve composite invariants, and neither read-heavy nor condition-variable patterns fit better than the mutex we have. Chapter 12 will introduce the alternatives when the driver evolves to a point where they are justified.

11.6.13 A Mini-Walkthrough: Tracing a Lock

To make the mechanics concrete, let us trace what happens when two threads race for the mutex.

Thread A calls `myfirst_read`. It reaches `mtx_lock(&sc->mtx)`. The mutex is not held (the initial state is “owner = NULL, waiters = none”). `mtx_lock` executes an atomic compare-and-swap: “if owner is NULL, set owner to `curthread`.” It succeeds. A is now in the critical section.

Thread B calls `myfirst_read` on a different CPU. It reaches `mtx_lock(&sc->mtx)`. The mutex is held (owner = A). The compare-and-swap fails. `mtx_lock` now has to arrange for B to wait.

B enters the slow path. It adds itself to the mutex’s wait list. It sets its thread state to blocked. It calls the scheduler, which picks some other runnable thread (possibly none, in which case the CPU idles).

Time passes. A finishes its critical section and calls `mtx_unlock(&sc->mtx)`. `mtx_unlock` sees that there are waiters. It picks one (usually the highest-priority waiter, with FIFO among equal priorities) and wakes it. That waiter, probably B, is made runnable.

The scheduler sees B runnable and schedules it. B resumes inside `mtx_lock`’s slow path. `mtx_lock` now records that the mutex is held by B and returns. B is in the critical section.

Between A’s `mtx_unlock` and B’s `mtx_lock` returning, the mutex was unowned for a brief moment. No other thread could have slipped in, because the unlock and the wakeup are arranged so that whoever wakes up next is the next owner. This is one of the things `mtx_lock` does that a hand-rolled “check a flag, sleep, check again” implementation would not get right.

All of this is happening inside `/usr/src/sys/kern/kern_mutex.c`. If you open that file and look for `__mtx_lock_sleep`, you can see the slow path’s code. It is more elaborate than the sketch above; it handles priority propagation, adaptive spinning, and several corner cases. The core idea, though, is what the sketch describes.

11.6.14 Reading a Lock Contention Story

When a driver performs poorly under load, one of the first things to check is whether the mutex is contended: how often threads have to wait for it and for how long. FreeBSD provides this information through the `debug.lock.prof.*` `sysctl` tree, which is enabled by the `LOCK_PROFILING` kernel option, and through the `lockstat(1)` user-space tool, which is part of the DTrace toolkit.

We will not build a full performance-analysis story in this chapter; that is Chapter 12 and Part 4 material. But if you are curious, on a kernel built with options `LOCK_PROFILING`, try:

```
# sysctl debug.lock.prof.enable=1
# ./producer_consumer
# sysctl debug.lock.prof.enable=0
# sysctl debug.lock.prof.stats
```

The output lists every lock the kernel has seen, the maximum and total wait time, the maximum and total hold time, the acquisition count, and the source file and line number where the lock was last touched. For our driver, `myfirst0` should appear with modest numbers, because the critical sections are short. If the numbers were large, we would have a signal that the mutex is contended and a finer-grained design might help. For Chapter 11's purposes, we are not optimizing; we are ensuring correctness.

11.6.15 Applying What We Have Learned

Let us consolidate. In the driver as of Chapter 10 Stage 4, the mutex `sc->mtx` is:

- An `MTX_DEF` sleep mutex, created in `myfirst_attach` and destroyed in `myfirst_detach`.
- Named "`myfirst0`" (and similar for other unit numbers), typed "`myfirst`".
- Held by the I/O handlers around every access to the `cbuf`, the byte counters, and the other protected fields.
- Released before every call that may sleep (`uiomove`, `selwakeup`).
- Used as the interlock argument to `mtx_sleep`.
- Asserted as held inside the helper functions via `mtx_assert(MA_OWNED)`.
- Documented in the locking comment at the top of the file and in `LOCKING.md`.

With the concepts in Section 4 and Section 5, every one of those properties is defensible from first principles. The mutex is not ceremony. It is the infrastructure that turns a driver that happens to work into a driver that is correct.

11.6.16 Spin Mutexes in More Detail

We have said that spin mutexes (`MTX_SPIN`) exist because some contexts cannot sleep. Let us look more closely at why.

The FreeBSD kernel has several execution contexts. Most driver code runs in **thread context**: the kernel is executing on behalf of some thread (a user thread that made a syscall, a kernel thread dedicated to some task, or a callout running in mpsafe mode). In thread context, sleeping is legal: the scheduler can park the thread and schedule another one.

A small but critical set of contexts cannot sleep. The most important is **hardware interrupt context**: the code that runs when a hardware interrupt fires. An interrupt may preempt any thread at any instant, run a short handler (called an *ithread* or *filter*), and return. While the handler runs, the thread it preempted cannot make progress. The handler must finish quickly, and it must not block. Sleeping would mean calling the scheduler, and calling the scheduler from inside an interrupt is not safe on the platforms FreeBSD supports.

Another non-sleep context is **critical sections** entered with `critical_enter(9)`. These disable preemption on the current CPU; the code inside runs to completion without the scheduler being allowed to pick a different thread. Critical sections are rarely used by driver writers directly; they appear more in low-level kernel code.

For code in any non-sleep context, a sleep mutex is the wrong tool. Acquiring a sleep mutex that is held would require sleeping, and you cannot. You need a mutex that spins: tries in a tight loop until it succeeds.

MTX_SPIN mutexes do exactly that. When you call `mtx_lock_spin(&m)`, the code:

1. Disables interrupts on the current CPU (because otherwise an interrupt handler could preempt you while you hold the spin mutex, leading to deadlock if the handler wants the same mutex).
2. Tries an atomic compare-and-swap to acquire the mutex.
3. If it fails, spins in a loop, periodically retrying.
4. Once acquired, proceeds with the critical section. Interrupts remain disabled.
5. `mtx_unlock_spin(&m)` releases the mutex and re-enables interrupts.

The rules for spin mutexes are strict:

- The critical section must be **very short**: holding a spin mutex is holding back every other CPU that wants it plus disabling interrupts on the current CPU. Microseconds matter.
- You **cannot sleep** while holding a spin mutex. `malloc(9)` with `M_WAITOK` is illegal. `mtx_sleep(9)` is illegal. Even a page fault is illegal (you must not touch user memory or paged kernel memory under a spin mutex).
- You **cannot acquire a sleep mutex** while holding a spin mutex. The sleep mutex would try to sleep if contended, and you cannot sleep.

For the `myfirst` driver, spin mutexes are the wrong choice. We never run in interrupt context. Our critical sections may call into the `cbuf` helpers, which contain `memcpy` loops that are short but not microsecond-tiny. `MTX_DEF` is correct.

For a driver that *does* run in interrupt context (Chapter 14 will cover this), spin mutexes often appear on the shortest critical sections: the ones between the interrupt handler and the top-half code. Longer critical sections can be protected by an `MTX_DEF` mutex that the interrupt handler does not take; the handler simply queues work for the top-half to do under its sleep mutex.

11.6.17 The MTX_RECURSE Flag and Lock Recursion

A subtle flag in `mtx_init` is `MTX_RECURSE`. Without it, a thread that already holds a mutex and tries to acquire it again will panic (under `INVARIANTS`) or deadlock (without `INVARIANTS`). With `MTX_RECURSE`, the second acquisition is counted; the mutex is released only when every acquire has been matched with an unlock.

Most drivers do not need `MTX_RECURSE`. The fact that a function tries to acquire a lock it already holds usually means the code is structured badly: a helper is being called from both lock-holding and non-lock-holding contexts, and the helper does not know which it is.

Fix the structure, not the mutex. Split the helper into a “with lock” and a “without lock” version. Name them `_locked` and `_unlocked` respectively, matching FreeBSD convention. Example:

```
static size_t
myfirst_buf_read_locked(struct myfirst_softc *sc, void *dst, size_t n)
{
    mtx_assert(&sc->mtx, MA_OWNED);
    /* ... buffer logic ... */
}

static size_t
myfirst_buf_read(struct myfirst_softc *sc, void *dst, size_t n)
{
    size_t got;

    mtx_lock(&sc->mtx);
    got = myfirst_buf_read_locked(sc, dst, n);
    mtx_unlock(&sc->mtx);
    return (got);
}
```

Now the two call sites are explicit: one takes the lock, the other does not. Neither needs `MTX_RECURSE`. Neither confuses the reader. This is how you should structure code as your driver grows.

There are rare exceptions where `MTX_RECURSE` is legitimately useful. A complex data structure with internal recursion (for example, a tree that uses the same lock at every node) may need it. `buf_ring`’s drain operation uses it. Those are specialised cases; for the ordinary driver, structure your code to avoid recursion and do not add the flag.

11.6.18 Adaptive Spinning

FreeBSD’s sleep mutexes include an optimization called **adaptive spinning**. When `mtx_lock` cannot acquire an `MTX_DEF` mutex because another CPU holds it, the lock does not immediately put the thread to sleep. It first spins for a short time, hoping that the holder will release the mutex quickly. Only if the spin exceeds a threshold does the lock fall through to the sleep path.

The rationale: most mutex-held intervals are short (microseconds), and sleeping plus waking is expensive. Spinning for a few microseconds usually beats going through the scheduler. Adaptive spinning recovers most of the performance benefit of spin mutexes without the constraints.

You can see the implementation in `/usr/src/sys/kern/kern_mutex.c`, in the function `__mtx_lock_sleep`. The code checks whether the holder is currently running on another CPU and spins as long as it is. If the holder descheduled (went to sleep itself), spinning is pointless and the waiter goes to sleep too.

For the driver writer, adaptive spinning means the mutex performance is better than a naive analysis would suggest. A short critical section on a low-contention mutex costs roughly the atomic compare-and-swap, nothing more. Only under real contention do you pay the full sleep/wake cost.

11.6.19 A Closer Look at `mtx_sleep`'s Atomicity

Chapter 10 explained that `mtx_sleep` atomically drops the mutex and puts the caller on the sleep queue. The atomicity matters because the alternative, drop-then-sleep, has a window through which a wakeup can escape unheard.

Consider the alternative sequence:

```
mtx_unlock(&sc->mtx);  
sleep_on(&sc->cb);  
mtx_lock(&sc->mtx);
```

Between the unlock and the sleep, another CPU could acquire the mutex, observe that the condition we were waiting for has become true, call `wakeup(&sc->cb)`, and return. Our wakeup has been delivered to a sleep queue we have not yet joined. We sleep on a condition that, from our thread's perspective, will never again become true: the signal has already been missed.

This is the classical **lost wakeup** race. It is one of the core reasons the atomic drop-and-sleep operation exists. `mtx_sleep` closes the window by enqueueing the caller on the sleep queue *before* it drops the outer mutex. The “Reference: A Closer Look at Sleep Queues” section later in this chapter walks through the sequence of locks and state transitions in more detail for readers who want to see exactly how the kernel arranges this. For the body of the chapter, the rule is enough: use `mtx_sleep` with the outer mutex as its interlock, and the lost-wakeup race disappears.

11.6.20 A Guided Tour Through `kern_mutex.c`

If you have an hour of patience, opening `/usr/src/sys/kern/kern_mutex.c` is worth the investment. You do not need to understand every line. Three functions are particularly illuminating:

`__mtx_lock_flags`: the fast path for acquiring a mutex. The interesting thing is how short it is. In the uncontested case, acquiring a mutex is essentially one atomic compare-and-swap plus some lock-profiling bookkeeping. That is all.

`__mtx_lock_sleep`: the slow path, reached only when the fast path's compare-and-swap fails. This is where adaptive spinning, priority propagation, and the actual sleep queue work happen. The code is elaborate, but the structure is: try a few spins, hand off to the sleep queue, re-enter the scheduler, eventually acquire.

`__mtx_unlock_flags` and **`__mtx_unlock_sleep`**: the release paths. Also mostly fast: atomic release, then, if waiters exist, wake one up.

You are not expected to read every line. You are expected to be able to say: “this is where the atomic I use actually lives, and this is what it does”. Twenty minutes of skimming gets you that.

11.6.21 Comparing Mutex to Semaphore, Monitor, and Binary Flag

For readers who have encountered other synchronization primitives, it helps to situate FreeBSD's mutex.

A **semaphore** is a counter. Threads “P” (decrement) and “V” (increment) it; a P that would go negative blocks. A binary semaphore (counter values 0 or 1) is similar to a mutex, but semaphores typically allow the “release” to be done by a thread other than the one that acquired. Mutexes require the same thread to release.

A **monitor** is a language-level construct combining a mutex and one or more condition variables, with the mutex automatically acquired on entry and released on exit. C does not have monitors as a language feature, but the pattern of “mutex + condition variable” is the same idea.

A **binary flag** (a `volatile int` that threads set and clear) is what naive programmers sometimes use to implement mutual exclusion. It does not work: two threads can both see the flag as zero and both set it to one, both proceed as if they were exclusive. This is the race we saw with the counter in Section 2. Real mutexes use atomic compare-and-swap, not naked flags.

FreeBSD’s mutex is a traditional mutex: only the acquiring thread may release, recursive acquisition requires explicit opt-in, the primitive integrates with the scheduler for blocking, and priority propagation is built in. It is the simplest and most commonly appropriate tool for driver synchronization.

11.6.22 Mutex Lifetime Rules

Every mutex has a lifetime. The rules are:

1. Call `mtx_init` exactly once before any use.
2. Acquire and release the mutex any number of times.
3. Call `mtx_destroy` exactly once after all use. Calling `mtx_destroy` while any thread is blocked on the mutex is undefined.
4. After `mtx_destroy`, the memory may be reused. Do not access the mutex again.

The third rule is why our detach path is careful about the order: destroy the `cdev` (which stops new handlers from starting and waits for running ones to finish), then destroy the mutex. If we destroyed the mutex first, running handlers could still be inside `mtx_lock` or `mtx_unlock` on an already-destroyed mutex.

Lifetime bugs with mutexes tend to be catastrophic (memory corruption, use-after-free panics). They are easier to avoid than to debug, so the standard advice applies: always think carefully about the order of teardown.

11.6.23 The MTX_NEW Option

`mtx_init`’s last argument can include `MTX_NEW`, which tells the function “this memory is fresh; you do not need to check for a prior initialization”. On an `INVAARIANTS` kernel, `mtx_init` verifies that the mutex was not previously initialized without a matching `mtx_destroy`. `MTX_NEW` skips this check.

Use `MTX_NEW` when you are initializing a mutex in memory that you know has not been used for this purpose before. Use the default (no `MTX_NEW`) when the mutex might be re-initialized (for example, in a handler that attaches and detaches repeatedly on the same softc). For our driver, the softc is re-allocated on each attach, so the mutex memory is always fresh; `MTX_NEW` is harmless but not required.

11.6.24 Nested Locks and Deadlock Patterns

A thread that holds lock A and wants to acquire lock B is performing a **nested lock acquisition**. Nested acquisitions are where deadlocks and lock-order violations live. Four patterns cover nearly all of them.

Pattern 1: Simple two-lock deadlock. Thread 1 holds A, wants B. Thread 2 holds B, wants A. Neither makes progress. Fix: globally order the locks so every thread acquires A before B.

Pattern 2: Lock order across subsystems. Subsystem X always acquires its lock first; subsystem Y always acquires its lock first. If they ever need each other's locks, the order depends on which of X and Y happens to call into the other. Fix: document a subsystem ordering that is consistent across every cross-subsystem path.

Pattern 3: Lock inversion via callback. A function is called with lock A held. Inside, it calls a callback, which tries to acquire A again. If A is not recursive, deadlock. Fix: drop A before the callback, or split the function so the callback is invoked outside the lock.

Pattern 4: Sleep-with-lock deadlock. A function holds a mutex and then calls something that sleeps. If the sleeper needs the same mutex (perhaps through a different code path), deadlock. Fix: drop the mutex before sleeping, or use `mtx_sleep` so the drop happens atomically.

For the `myfirst` driver, we have one lock and no nested acquisitions; none of the patterns apply. Chapter 12 introduces `sx` locks; as soon as we have a second lock class, patterns 1 and 3 become relevant, and `WITNESS` becomes critical.

11.6.25 Wrapping Up Section 5

A mutex is a tool for serializing access to shared state. FreeBSD provides two shapes (`MTX_DEF` for sleep mutexes, `MTX_SPIN` for spin mutexes), and `MTX_DEF` is the correct choice for our driver. The API is small: `mtx_init`, `mtx_lock`, `mtx_unlock`, `mtx_destroy`, `mtx_assert`, `mtx_sleep`. The rules are precise: hold short, do not sleep while holding a non-sleepable lock, acquire locks in a consistent order, release what you acquire, and use `WITNESS` to check.

Section 6 takes the theory we have built and exercises it: how to write user-space programs that actually stress the driver, and how to observe the results.

11.7 Section 6: Testing Multi-threaded Access

Building a correct driver is half the work. The other half is developing tests that can catch the mistakes that slip through the design review. Chapter 10 introduced `producer_consumer.c`, a two-process round-trip test that is the single best test in this book's kit for detecting buffer-level correctness problems. Chapter 11 takes that foundation and adds the tools you need for concurrency specifically: multi-threaded tests using `pthread(3)`, multi-process tests using `fork(2)`, and a load harness that can sustain pressure on the driver for long enough to expose rare timing bugs.

The goal is not to exhaustively test every possible interleaving. That is impossible. The goal is to increase the rate at which the scheduler visits interleavings the driver has not seen, so that, if a bug is present, we are likely to observe its effects.

11.7.1 The Testing Ladder

Concurrency testing climbs a ladder. At the bottom is a single-threaded test: one process, one thread, one call at a time. This is what `cat` and `echo` do. At the top is a distributed multi-process, multi-threaded, timing-varying,

long-running test. The higher you climb, the more likely you are to catch concurrency bugs; the more expensive each test becomes to set up and interpret.

The rungs, from bottom to top:

1. **Single-threaded smoke tests.** One cat, one echo. Useful for confirming the driver is alive; useless for concurrency.
2. **Two-process round trip.** `producer_consumer` from Chapter 10. One writer, one reader, content verification. Catches most single-lock issues.
3. **Multi-threaded within a process.** pthread-based tests where multiple threads in the same process talk to the same descriptor or to distinct descriptors. Exposes intra-process concurrency.
4. **Many-process stress.** fork-based tests with N producers and M consumers. Exposes inter-process concurrency and lock contention.
5. **Long-running stress.** Any of the above, run for hours. Exposes timing-sensitive bugs that are rare on the per-operation basis but certain given enough time.

We will build rungs 3, 4, and 5 in this section. Rung 2 already exists from Chapter 10.

11.7.2 Multiple Threads in One Process

A single process with multiple threads is useful because the threads share file descriptors. Two threads can read from the same descriptor; both calls go into `myfirst_read` with the same `dev` and (critically) the same per-descriptor `fh`.

Here is a minimal multi-threaded reader:

```
/* mt_reader.c: multiple threads reading from one descriptor. */
#include <sys/types.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <inttypes.h>
#include <pthread.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH        "/dev/myfirst"
#define NTHREADS       4
#define BYTES_PER_THR  (256 * 1024)
#define BLOCK          4096

static int      g_fd;
static uint64_t total[NTHREADS];
static uint32_t sum[NTHREADS];
```

```
static uint32_t
checksum(const char *p, size_t n)
{
    uint32_t s = 0;
    for (size_t i = 0; i < n; i++)
        s = s * 31u + (uint8_t)p[i];
    return (s);
}

static void *
reader(void *arg)
{
    int tid = *(int *)arg;
    char buf[BLOCK];
    uint64_t got = 0;
    uint32_t sm = 0;

    while (got < BYTES_PER_THR) {
        ssize_t n = read(g_fd, buf, sizeof(buf));
        if (n < 0) {
            if (errno == EINTR)
                continue;
            warn("thread %d: read", tid);
            break;
        }
        if (n == 0)
            break;
        sm += checksum(buf, n);
        got += n;
    }
    total[tid] = got;
    sum[tid] = sm;
    return (NULL);
}

int
main(void)
{
    pthread_t tids[NTHREADS];
    int ids[NTHREADS];

    g_fd = open(DEVPATH, O_RDONLY);
    if (g_fd < 0)
```

```

        err(1, "open %s", DEVPATH);

    for (int i = 0; i < NTHREADS; i++) {
        ids[i] = i;
        if (pthread_create(&tids[i], NULL, reader, &ids[i]) != 0)
            err(1, "pthread_create");
    }
    for (int i = 0; i < NTHREADS; i++)
        pthread_join(tids[i], NULL);

    uint64_t grand = 0;
    for (int i = 0; i < NTHREADS; i++) {
        printf("thread %d: %" PRIu64 " bytes, checksum 0x%08x\n",
            i, total[i], sum[i]);
        grand += total[i];
    }
    printf("grand total: %" PRIu64 "\n", grand);

    close(g_fd);
    return (0);
}

```

The companion file under `examples/part-03/ch11-concurrency/userland/mt_reader.c` is identical to this listing; you can either type it from the book or copy it from the examples tree.

Build with:

```
$ cc -Wall -Wextra -pthread -o mt_reader mt_reader.c
```

Start a writer in another terminal (or fork one before creating threads), then run this tester. Each thread pulls bytes out of the driver. Because the driver has one mutex, the reads serialize; there is no concurrency benefit, but there is also no incorrectness. Each thread sees a subset of the stream, and the concatenation of all threads' bytes is the full stream.

This is an important property. The driver makes no promise about which thread sees which bytes; it only promises that the total is conserved. If you want per-reader streams, you need a different driver design (Challenge exercise 3 in Chapter 10 explored this). For now, the test confirms that multiple readers in one process behave correctly.

11.7.3 Many Processes in Parallel

A fork-based test spawns *N* children, each doing its own thing against the device. This gives us independent processes, independent file descriptors, and independent schedule decisions. The kernel is more likely to interleave them in novel ways.

Here is the skeleton:

```
/* mp_stress.c: N processes hammering the driver concurrently. */
#include <sys/types.h>
#include <sys/wait.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH        "/dev/myfirst"
#define NWRITERS       2
#define NREADERS       2
#define SECONDS        30

static volatile sig_atomic_t stop;

static void
sigalrm(int s __unused)
{
    stop = 1;
}

static int
child_writer(int id)
{
    int fd;
    char buf[1024];
    unsigned long long written = 0;

    fd = open(DEVPATH, O_WRONLY);
    if (fd < 0)
        err(1, "writer %d: open", id);
    memset(buf, 'a' + id, sizeof(buf));

    while (!stop) {
        ssize_t n = write(fd, buf, sizeof(buf));
        if (n < 0) {
            if (errno == EINTR)
                continue;
            break;
        }
    }
}
```

```
        written += n;
    }
    close(fd);
    printf("writer %d: %llu bytes\n", id, written);
    return (0);
}

static int
child_reader(int id)
{
    int fd;
    char buf[1024];
    unsigned long long got = 0;

    fd = open(DEVPATH, O_RDONLY);
    if (fd < 0)
        err(1, "reader %d: open", id);

    while (!stop) {
        ssize_t n = read(fd, buf, sizeof(buf));
        if (n < 0) {
            if (errno == EINTR)
                continue;
            break;
        }
        got += n;
    }
    close(fd);
    printf("reader %d: %llu bytes\n", id, got);
    return (0);
}

int
main(void)
{
    pid_t pids[NWRITERS + NREADERS];
    int n = 0;

    signal(SIGALRM, sigalrm);

    for (int i = 0; i < NWRITERS; i++) {
        pid_t pid = fork();
        if (pid < 0)
            err(1, "fork");
    }
}
```

```
        if (pid == 0) {
            signal(SIGALRM, sigalrm);
            alarm(SECONDS);
            _exit(child_writer(i));
        }
        pids[n++] = pid;
    }
    for (int i = 0; i < NREADERS; i++) {
        pid_t pid = fork();
        if (pid < 0)
            err(1, "fork");
        if (pid == 0) {
            signal(SIGALRM, sigalrm);
            alarm(SECONDS);
            _exit(child_reader(i));
        }
        pids[n++] = pid;
    }

    for (int i = 0; i < n; i++) {
        int status;
        waitpid(pids[i], &status, 0);
    }
    return (0);
}
```

The companion source under `examples/part-03/ch11-concurrency/userland/mp_stress.c` matches this listing. The `signal(SIGALRM, sigalrm)` reinstall after `fork(2)` is intentional; `fork(2)` inherits the parent's signal disposition, but reinstalling makes the intent explicit and survives the (rare) case where the parent's handler had been changed in between.

Build and run:

```
$ cc -Wall -Wextra -o mp_stress mp_stress.c
$ ./mp_stress
writer 0: 47382528 bytes
writer 1: 48242688 bytes
reader 0: 47669248 bytes
reader 1: 47956992 bytes
```

Look at the totals. The sum of readers should equal the sum of writers (plus or minus whatever is left in the buffer at the end of the test window). If they do not, we have either a driver bug or a reporting bug; neither is acceptable.

This test, run for thirty seconds, produces roughly one hundred million bytes of traffic through the driver, with

four concurrent processes. On a four-core machine, all four can be making progress at any instant. If there is a concurrency bug that our review missed, it has thirty seconds of real compute to find it.

11.7.4 Extended-Duration Tests

For the most elusive bugs, run the tests for hours. A simple wrapper:

```
$ for i in $(seq 1 100); do
    echo "iteration $i" >> /tmp/mp_stress.log
    ./mp_stress >> /tmp/mp_stress.log 2>&1
    sleep 1
done
```

After fifty iterations (roughly twenty-five minutes of cumulative driver stress), review the log. If every iteration's byte counts are internally consistent, you have a strong signal that the driver is not suffering from frequent concurrency bugs. If any iteration shows inconsistency, you have a bug; save the log, reproduce with lower NWRITERS/NREADERS, and investigate.

A script like the above is a cheap substitute for a proper continuous-integration pipeline. For serious driver work, a CI that runs the stress suite nightly on multiple hardware configurations is the gold standard. For learning, the script above is enough.

11.7.5 Observing Without Disturbing

A subtle issue: adding logging to a concurrent test can itself disturb the timing and mask the bug. If your test prints a line for every operation, the printing becomes a bottleneck, the threads serialize around stdout, and the interesting interleavings no longer happen.

Techniques that reduce observer effect:

- **Buffer logs in memory; flush at the end.** Each thread appends to its own local array; main prints the arrays after all threads finish.
- **Use `ktrace(1)` instead of in-process printing.** `ktrace` captures syscalls from a running process without modifying the process; the dump can be analyzed afterward.
- **Use `dtrace(1)` probes.** `dtrace` is designed to have minimal impact on the observed code path.
- **Keep counters, not line-by-line logs.** A mismatch count is a single integer; it compresses a lot of information into something cheap to update.

`producer_consumer` from Chapter 10 uses the counter approach: it updates a checksum per block and a total byte count, then reports both at the end. The test is effectively invisible to the driver's timing.

11.7.6 A Testing Workflow

Putting it together, here is a reasonable workflow for a new change to the driver:

1. **Smoke test.** Load the driver, `printf 'hello' > /dev/myfirst`, `cat /dev/myfirst`. Confirm basic operation.

2. **Round-trip test.** Run `producer_consumer`. Confirm zero mismatches.
3. **Multi-threaded in-process.** Run `mt_reader` against a continuously-running `cat /dev/zero > /dev/myfirst`. Confirm the total matches.
4. **Multi-process stress.** Run `mp_stress` for thirty seconds. Confirm the byte counts are consistent.
5. **Long-running stress.** Run the loop wrapper for thirty minutes to an hour.
6. **Debug-kernel regression.** Repeat steps 1-4 on a WITNESS-enabled kernel. Confirm no warnings.

If every step passes, the change is likely to be safe. If any step fails, the failure mode tells you where to look.

11.7.7 A Latency-Measuring Tester

Sometimes what you want to know is not “does the driver work” but “how quickly does it respond under load”. The mutex’s cost, the sleep queue’s wake-up latency, and the scheduler’s decisions all combine to produce a distribution of response times that is worth observing directly.

Here is a simple latency tester. It opens the device, measures how long each `read(2)` takes, and prints a histogram.

```
/* lat_tester.c: measure read latency against /dev/myfirst. */
#include <sys/types.h>
#include <sys/time.h>
#include <err.h>
#include <fcntl.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <unistd.h>

#define DEVPATH "/dev/myfirst"
#define NSAMPLES 10000
#define BLOCK 1024

static uint64_t
nanos(void)
{
    struct timespec ts;
    clock_gettime(CLOCK_MONOTONIC, &ts);
    return ((uint64_t)ts.tv_sec * 1000000000 + ts.tv_nsec);
}

int
main(void)
{
    int fd = open(DEVPATH, O_RDONLY | O_NONBLOCK);
    if (fd < 0)
```

```

        err(1, "open");
char buf[BLOCK];
uint64_t samples[NSAMPLES];
int nvalid = 0;

for (int i = 0; i < NSAMPLES; i++) {
    uint64_t t0 = nanos();
    ssize_t n = read(fd, buf, sizeof(buf));
    uint64_t t1 = nanos();
    if (n > 0)
        samples[nvalid++] = t1 - t0;
    else
        usleep(100);
}
close(fd);

/* Simple bucketed histogram. */
uint64_t buckets[10] = {0};
const char *labels[10] = {
    "<1us   ", "<10us  ", "<100us ", "<1ms   ",
    "<10ms  ", "<100ms ", "<1s    ", ">=1s   ",
    "", ""
};

for (int i = 0; i < nvalid; i++) {
    uint64_t us = samples[i];
    int b = 0;
    if (us < 1000) b = 0;
    else if (us < 10000) b = 1;
    else if (us < 100000) b = 2;
    else if (us < 1000000) b = 3;
    else if (us < 10000000) b = 4;
    else if (us < 100000000) b = 5;
    else if (us < 1000000000) b = 6;
    else b = 7;
    buckets[b]++;
}

printf("Latency histogram (%d samples):\n", nvalid);
for (int i = 0; i < 8; i++)
    printf("  %s %6llu\n",
        labels[i], (unsigned long long)buckets[i]);
return (0);
}

```

Run with a concurrent writer:

```
$ dd if=/dev/zero of=/dev/myfirst bs=1k &
$ ./lat_tester
Latency histogram (10000 samples):
<1us      3421
<10us     6124
<100us    423
<1ms      28
<10ms     4
<100ms    0
<1s       0
>=1s      0
```

Most reads complete in a microsecond or two. A handful take longer, usually because the reader had to wait on the mutex while the writer was inside. Very occasionally, a read takes milliseconds; that is usually because the thread was preempted or had to sleep.

This is the distribution of your driver's responsiveness under load. If the long tail is unacceptably long, the driver needs finer-grained locking or fewer critical-section operations. For our `myfirst`, the tail is short enough that nothing needs changing.

11.7.8 A Tester That Probes for Torn Reads

If your driver has any unprotected multi-field reads (the book's recommendation is never, but real drivers sometimes have them), you can detect torn reads with a targeted tester.

Imagine we had a field that could be torn on a 32-bit platform. The tester would:

1. Fork a writer that continuously updates the field with known patterns.
2. Fork a reader that continuously reads the field and checks the pattern.
3. Report every read that does not match any valid pattern.

For our driver, no such field exists (all `uint64_t` counters are per-CPU, all composite state is under the mutex). But building the tester is a valuable exercise, because it trains you to write probes for specific classes of bug.

11.7.9 Multi-Core Scaling

A test we have not yet written: does the driver scale as you add more cores?

The idea is simple: run `mp_stress` with increasing `NWRITERS/NREADERS` and observe the total throughput. Ideally, throughput should grow linearly with core count up to some saturation point. In practice, single-mutex drivers saturate early, because every operation serializes on the one mutex.

Build a scaling test:

```
$ for n in 1 2 4 8 16; do
    NWRITERS=$n NREADERS=$n ./mp_stress > /tmp/scale_${n}.txt
    total=$(grep ^writer /tmp/scale_${n}.txt | awk '{s+=$3} END {print s}')
    echo "$n writers, $n readers: $total bytes"
done
```

The `mp_stress` program needs to accept `NWRITERS` and `NREADERS` from environment variables for this to work; exercise for the reader.

On a four-core machine, a single-mutex driver typically saturates around 2-4 writers plus 2-4 readers. Beyond that, throughput flattens or drops, because the mutex becomes the bottleneck. This is the signal that finer-grained locking (Chapter 12's `sx` locks, for example) might be justified. For `myfirst` at this stage, saturation is not a concern; the teaching pedagogy matters more than absolute throughput.

11.7.10 Coverage of the Failure Modes

A final check: does the test kit cover every failure mode we enumerated in Section 1?

- **Data corruption:** `producer_consumer` catches this directly by comparing checksums.
- **Lost updates:** if a counter is wrong, the `producer_consumer` total will not match.
- **Torn values:** not directly tested, but any torn read that affects correctness propagates to a wrong checksum.
- **Inconsistent composite state:** if the `cbuf` indices become inconsistent, the driver will either corrupt data (caught by checksum) or deadlock (caught by the test hanging and our timeout).

The test kit is comprehensive against the failure modes we know about. It is not comprehensive against unknown bugs, but no test kit can be. The combination of debug-kernel runs, regression tests, and long-running stress tests is as close as we can get.

11.7.11 Wrapping Up Section 6

Testing is the fastest-feedback part of driver work. The tests we have just built cover three orders of magnitude more interleavings than a single cat could. Running them on both a production and a debug kernel gives you verification from both angles.

Section 7 takes the next step: what do you do when a test fails?

11.8 Section 7: Debugging and Verifying Thread Safety

A concurrency bug's most reliable signature is that it does not reproduce on demand. You run the test; it fails. You run it again; it passes. You run it a hundred times; it fails twice, on different lines. This section is about the tools and techniques that let you corner such bugs despite their unreliability.

11.8.1 Typical Symptoms

Before we get to tools, let us catalogue the symptoms. Each symptom suggests a specific class of bug.

Symptom: the test intermittently reports corrupted data, but the driver does not panic. This is usually a missed lock: a field that is accessed without synchronization from more than one stream. The corruption is the result of the race; the driver survives because the corrupted value does not immediately cause a derivable failure.

Symptom: the driver panics with a backtrace inside `mtx_lock` or `mtx_unlock`. This is often a use-after-free of the mutex itself. The most common cause is that `mtx_destroy` was called while another thread was still using the mutex. The cure is to re-examine the detach path: the mutex must outlive every use of it.

Symptom: `WITNESS` reports a lock-order reversal. A thread acquired locks in an order inconsistent with an earlier-observed order. The fix is to define a global lock order and make every code path obey it.

Symptom: `KASSERT` fires inside `mtx_assert(MA_OWNED)`. A helper expected the mutex to be held and it was not. The fix is to find the call site of the helper and add the missing `mtx_lock`.

Symptom: the test hangs forever. A thread is sleeping on a channel and nobody ever calls wakeup on that channel. The fix is usually a missing `wakeup(&sc->cb)` in the I/O path (or equivalent). Chapter 10 Section 5 enumerated the rules.

Symptom: the driver performs very poorly under load. The mutex is contended more heavily than it needs to be. The fix is usually to shorten critical sections (move more work outside the lock) or to split the lock into finer pieces (Chapter 12 material).

Symptom: the driver crashes weeks after deployment, with a backtrace that does not obviously involve concurrency. This is the worst-case scenario and almost always a concurrency bug whose effects finally compounded. The fix is to audit as in Section 3 and run stress tests as in Section 6.

11.8.2 INVARIANTS and KASSERT

INVARIANTS is a kernel build option that enables assertions throughout the kernel. When INVARIANTS is set, `KASSERT(cond, args)` evaluates `cond` and panics with `args` if the condition is false. When INVARIANTS is not set, `KASSERT` compiles to nothing.

This makes `KASSERT` nearly free in production and extremely valuable in development. Every invariant your code depends on should be a `KASSERT`. For example:

```
KASSERT(sc->cb.cb_used <= sc->cb.cb_size,  
        ("cbuf used exceeds size: %zu > %zu",  
         sc->cb.cb_used, sc->cb.cb_size));
```

This says “I believe `cb_used` never exceeds `cb_size`. If the code that produces this truth is ever broken, I want to know immediately, not hours later when something else fails.”

Add `KASSERT` calls liberally to your driver. Every precondition, every invariant, every “this cannot happen” branch. The cost is zero in production; the benefit is that development bugs get caught at the moment they appear, not downstream.

For the `myfirst` driver, some useful additions:

```
/* In cbuf.c, at the top of cbuf_write: */
KASSERT(cb->cb_used <= cb->cb_size,
    ("cbuf_write: cb_used %zu exceeds cb_size %zu",
     cb->cb_used, cb->cb_size));
KASSERT(cb->cb_head < cb->cb_size,
    ("cbuf_write: cb_head %zu not less than cb_size %zu",
     cb->cb_head, cb->cb_size));

/* In myfirst_buf_read and myfirst_buf_write: */
mtx_assert(&sc->mtx, MA_OWNED);
```

Every such check is a small bet that catches a future mistake.

11.8.3 WITNESS in Action

When WITNESS warns, the output is detailed. A typical warning for a lock-order reversal looks like this:

```
lock order reversal:
 1st 0xfffffe000123a000 foo_lock (foo, sleep mutex) @ /usr/src/sys/dev/foo/foo.c:100
 2nd 0xfffffe000123a080 bar_lock (bar, sleep mutex) @ /usr/src/sys/dev/bar/bar.c:200
lock order reversal detected for lock group "bar" -> "foo"
stack backtrace:
...
```

The key pieces are:

- The two locks involved, with their names, types, and the source locations where they were acquired.
- The conflicting order (`bar -> foo`), which is the reverse of a previously-established order (`foo -> bar`).
- A stack backtrace showing the path that led to the reversal.

The fix is one of two things: either change one of the acquisition sites to match the existing order, or recognize that the two code paths should not both be holding both locks. The stack backtrace tells you which code path is involved; reading the source tells you which change is the right one.

For the `myfirst` driver, which has one lock, WITNESS cannot report a lock-order reversal. The only WITNESS warnings we could see relate to sleeping with a lock held or recursive acquisition. Both are worth testing deliberately, as we do in Lab 7.3.

11.8.4 Reading a Kernel Panic Backtrace

Sometimes a bug produces a panic. The kernel prints a backtrace, enters the debugger (if DDB is configured), or reboots (if not). Your job is to extract as much information as possible from the backtrace before the system goes away.

The first lines of a panic typically identify the failure:

```
panic: mtx_lock() of spin mutex @ ...: recursed on non-recursive mutex myfirst0 @ ...
cpuid = 2
...
```

From here:

- The panic message is the most important line. `mtx_lock of spin mutex` hints at one kind of bug; sleeping with mutex held at another; general protection fault at a different class entirely.
- The `cpuid` tells you which CPU experienced the panic, which can matter if the bug is specific to a particular scheduling environment.
- The stack backtrace shows the functions on the way down. Read it top-to-bottom: the bottom is where the panic was detected; the top is where the execution began. The function just above the panic function is usually the one that made the mistake.

If DDB is configured, you can interact with the debugger at panic time: `bt` (backtrace), `show mutex <addr>` (inspect a mutex), `show alllocks` (every lock held by every thread). This is the ninja mode of driver debugging; Chapter 12 and the debugging references touch it.

11.8.5 dtrace(1) as a Silent Observer

`dtrace(1)` is FreeBSD's dynamic tracing framework. It lets you attach probes to kernel functions (and user-space functions, with the right libraries) and collect data with minimal impact on the observed code.

A simple `dtrace` command to count mutex acquisitions on `myfirst`'s mutex:

```
# dtrace -n 'fbt::__mtx_lock_flags:entry /arg0 != 0/ { @[execname] = count(); }'
```

Run the driver under load, then Ctrl-C the `dtrace`. You get a table of per-process lock acquisition counts. If one process dominates, that's the source of contention.

Another useful one-liner: trace when threads enter and exit our read handler:

```
# dtrace -n 'fbt::myfirst_read:entry { printf("%d reading %d bytes", tid, arg1); }'
```

The exact arg indices depend on the function's ABI; `dtrace -l | grep myfirst` lists the probes available.

`dtrace` is not magic: it uses real kernel mechanisms (typically the function-boundary-tracing provider) that have nonzero cost. But that cost is dramatically lower than `printf`-based logging, and it can be turned on and off without modifying the driver.

Chapter 15 will cover `dtrace` in more detail. For Chapter 11, the key idea is that `dtrace` is your friend for observing a live driver under load.

11.8.6 A Debugging Checklist

When a concurrency bug appears, work through this checklist in order:

1. **Can you reproduce it reliably?** If yes, great; if no, run the test in a loop and find the failure rate.
2. **Does `WITNESS` report anything?** Boot with options `WITNESS INVARIANTS`. Rerun. Collect every warning.
3. **Are there `KASSERT` failures?** These fire as panics; the message identifies the invariant.
4. **Is the bug deterministic given sufficient stress?** If it appears every time with four writers and four readers, you have a workload to bisect; if it appears only under specific conditions, start isolating those conditions.
5. **Which field is corrupted?** Add targeted logging or `dtrace` probes around the suspect accesses.
6. **What is the missing synchronization?** Audit the access paths against the rules in Section 3.
7. **Is the fix consistent with the rest of the driver's locking strategy?** Document the change in `LOCKING.md`.
8. **Does the test now pass reliably?** Run the stress tests for twice as long as you would otherwise to confirm.

Most concurrency bugs yield to this process. Some require deep diving into the specific driver or the kernel; those are the ones Chapter 12 and later material help you prepare for.

11.8.7 A Walkthrough: Diagnosing a Missing Wakeup

To make the debugging process concrete, let us walk through a hypothetical bug. Suppose you have modified `myfirst_write` to update some auxiliary state, and after the change, a two-terminal test (one cat, one echo) hangs. The cat is asleep, the echo has returned, and the bytes are not coming out.

Step 1: confirm the symptom.

```
$ ps -AxH -o pid,wchan,command | grep cat
12345  myfrd  cat /dev/myfirst
```

The cat is sleeping on `myfrd`. That is our sleep channel name. It is waiting for data.

Step 2: inspect the driver state.

```
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 5
```

The buffer has 5 bytes in it. The reader should be able to drain those bytes and return them to cat. So why isn't it?

Step 3: look at the code. The cat's thread is in `mtx_sleep(&sc->cb, ..., "myfrd", ...)`. It is waiting for `wakeup(&sc->cb)`. Who calls that?

Grep the source:

```
$ grep -n 'wakeup(&sc->cb)' myfirst.c
180:         wakeup(&sc->cb);
220:         wakeup(&sc->cb);
```

Two call sites. One is in `myfirst_read` (after a successful read, to wake writers waiting for space). The other is in `myfirst_write` (after a successful write, to wake readers waiting for data).

Step 4: inspect the write path. Did the write actually run the wakeup?

```
mtx_lock(&sc->mtx);
put = myfirst_buf_write(sc, bounce, want);
/* ... update aux state ... */
mtx_unlock(&sc->mtx);

/* new code: do some bookkeeping */
update_stats(sc, put);

wakeup(&sc->cb);
selwakeup(&sc->rsel);
```

Looks fine. The wakeup is there. The `selwakeup` is there.

Step 5: trace deeper. Maybe the wakeup is being called before the bytes are actually in the buffer. In the original code, the order was: add bytes under lock, unlock, wakeup. In the modified code, you inserted `update_stats` between the unlock and the wakeup. That should be fine; the bytes are in the buffer, just waiting for a waker to call wakeup.

But wait: `update_stats` is new. What does it do?

```
static void
update_stats(struct myfirst_softc *sc, size_t n)
{
    mtx_lock(&sc->mtx);
    sc->aux_counter++;
    mtx_unlock(&sc->mtx);
}
```

It takes the mutex. And then releases it. That is a full acquire/release cycle. Could it change anything?

Actually, look closer. In the write path, the sequence is:

1. Take mutex.
2. Write bytes to `cbuf`.
3. Release mutex.
4. Call `update_stats`, which re-acquires and re-releases.
5. Call wakeup.

Between steps 3 and 5, there is a window where a reader could acquire the mutex, observe the new bytes, and proceed. In most cases this is fine: the reader does not care about the auxiliary statistics. But if the reader is currently inside `mtx_sleep`, waiting for wakeup, it is stuck until step 5.

That looks normal; step 5 always runs. So the wakeup does fire. But why is the reader not waking?

Step 6: add a `device_printf` at the start of `update_stats` and at the wakeup call:

```
device_printf(sc->dev, "update_stats called\n");
/* ... */
device_printf(sc->dev, "wakeup(&sc->cb) called\n");
wakeup(&sc->cb);
```

Reload, retest. Watch dmesg:

```
myfirst0: update_stats called
```

Only one message. The wakeup is never called.

Step 7: look at update_stats again. Could it have a path that returns early?

```
static void
update_stats(struct myfirst_softc *sc, size_t n)
{
    if (n == 0)
        return;
    mtx_lock(&sc->mtx);
    sc->aux_counter++;
    mtx_unlock(&sc->mtx);
}
```

Ah, a short-circuit for `n == 0`. What if put was zero for some reason? Then update_stats returns. The caller continues, but wait, wakeup is still after update_stats, so it should fire anyway.

Unless the caller's code also has a short-circuit:

```
update_stats(sc, put);
if (put < want)
    break;
wakeup(&sc->cb);
```

That's the bug. The early break skips the wakeup. Under most conditions `put == want`, and the wakeup runs. Under the rare condition where `put < want` (for example, the buffer filled up during this iteration), the wakeup is skipped. A reader waiting for data never sees the bytes that did make it in.

Step 8: fix it. Move the wakeup before the break:

```
update_stats(sc, put);
wakeup(&sc->cb);           /* must happen even on short write */
selwakeup(&sc->rsl);
if (put < want)
    break;
```

Test again. The hang is gone.

This is a realistic debugging story. The bug is not in the concurrency machinery; it is in the business logic that controls when the wakeup fires. The fix is local. The debugging process was: observe, narrow, trace, inspect, fix.

11.8.8 Patterns for Adding Debug Traces

When you add debug traces to a driver, several patterns pay off.

Traces behind a debug flag. We saw this in Chapter 10: a `myfirst_debug` integer controlled by `sysctl`, and a `MYFIRST_DBG` macro that compiles to nothing when the flag is zero. With the flag off, traces have no cost; with it on, they emit to `dmesg`. This lets you ship the driver with traces included and turn them on only when needed.

One line per meaningful event. The temptation is to trace every byte transferred. Resist it. Trace once per handler invocation, not once per byte. Trace once per lock acquisition during debugging of a specific bug, then remove. A log flooded with lines tells you nothing.

Include the thread ID. `curthread->td_tid` is the current thread's ID. Printing it in traces lets you distinguish concurrent activities in the log. Useful format: `device_printf(dev, "tid=%d got=%zu\n", curthread->td_tid, got)`.

Include before/after state. For a state change, log both the old and new values. `device_printf(dev, "cb_used: %zu -> %zu\n", before, after)` is more useful than `cb_used: %zu`, because you can see the transition.

Remove or guard before shipping. Trace lines are development aids. Either remove them or put them behind `MYFIRST_DBG` before the code is deployed. A shipping driver that emits debug output per I/O is wasting the log buffer.

11.8.9 Debugging the Hard Cases

Some concurrency bugs resist all the techniques we have discussed. They reproduce on a specific machine, with a specific workload, on a specific kernel, and nowhere else. When you encounter such a bug, the options are:

Bisect the workload. If the bug occurs with *X* concurrent readers and *Y* concurrent writers, try to reduce *X* and *Y* until the bug no longer occurs. The minimal reproducer is the easiest to reason about.

Bisect the kernel. If the bug occurs on version *N* but not on *N-1*, find the change in the kernel that introduced it. `git bisect` is the tool. This is slow but effective.

Inspect the hardware. Some bugs are caused by specific CPU features (cache coherency quirks, TSO behavior, weakly-ordered memory models). If the bug occurs on ARM64 but not amd64, memory ordering is suspect.

Ask on the mailing lists. The FreeBSD community includes many people who have seen similar bugs. `freebsd-hackers` and `freebsd-current` lists welcome detailed bug reports. The more information you provide (exact kernel version, workload, failure mode, what you have tried), the more likely someone will recognize the pattern.

Concurrency debugging is, ultimately, a skill. The tools help, but the skill is built by doing it, writing tests that fail, writing fixes, and confirming the tests pass. The chapters ahead will give you more opportunities.

11.8.10 Wrapping Up Section 7

Debugging concurrency is a trade of patience for tooling. `INVARIANTS`, `WITNESS`, `KASSERT`, `mtx_assert`, and `dtrace` are the tools FreeBSD gives you. Used in combination, they can corner bugs that would otherwise go undetected until production.

Section 8 closes the chapter with the housekeeping: refactoring the driver, versioning it, documenting it, running static analysis, and regression-testing the whole lot.

11.9 Section 8: Refactoring and Versioning Your Concurrent Driver

The driver now has well-understood concurrency semantics and a locking strategy that can be defended from first principles. This final section of the chapter is the hygiene pass: organizing the code for clarity, versioning the driver so future-you can tell what changed when, writing a README that documents the design, running static analysis, and regression-testing the whole thing.

This is not glamorous work. It is also what separates a driver that is delivered once from a driver that lives usefully for years.

11.9.1 8.1: Organizing the Code for Clarity

The Stage 4 driver from Chapter 10 was already well-organized. The `cbuf` is in its own file. The I/O handlers use helper functions. The locking discipline is documented in a comment at the top. For Chapter 11, the organizational work is marginal: improving commenting, grouping related code, and ensuring naming consistency.

Three improvements are worth making.

Group related code. Reorder the functions in `myfirst.c` so related ones live next to each other. Lifecycle (`attach`, `detach`, `modevent`) at the top; I/O handlers (`read`, `write`, `poll`) in the middle; helpers and `sysctl` callbacks near the end. The compile order does not matter; what matters is that a reader scrolling through the file encounters related functions together.

Isolate locking into inline wrappers. Instead of repeating `mtx_lock(&sc->mtx)` and `mtx_unlock(&sc->mtx)` throughout the code, define:

```
#define MYFIRST_LOCK(sc)      mtx_lock(&(sc)->mtx)
#define MYFIRST_UNLOCK(sc)    mtx_unlock(&(sc)->mtx)
#define MYFIRST_ASSERT(sc)    mtx_assert(&(sc)->mtx, MA_OWNED)
```

Use the macros throughout. If you ever need to change the lock type (for example, to an `sx` lock in a future refactor), you change one place, not twenty.

Name things consistently. All driver-level buffer helpers are `myfirst_buf_*`. All wait helpers are `myfirst_wait_*`. All `sysctl` handlers are `myfirst_sysctl_*`. A reader scanning the function names can tell what category each function falls into without reading the body.

None of these is a correctness improvement. All of them are readability improvements that pay off when you come back to the code in six months.

11.9.2 8.2: Versioning the Driver

The driver should expose its version so that you can tell at load time what you are running. Add a version string:

```
#define MYFIRST_VERSION "0.4-concurrency"
```

Print it at attach:

```
device_printf(dev,
    "Attached; version %s, node /dev/%s (alias /dev/myfirst), "
    "cbuf=%zu bytes\n",
    MYFIRST_VERSION, devtoname(sc->cdev), cbuf_size(&sc->cb));
```

Expose it as a read-only sysctl:

```
SYSCTL_STRING(_hw_myfirst, OID_AUTO, version, CTLFLAG_RD,
    MYFIRST_VERSION, 0, "Driver version");
```

A user can now query `sysctl hw.myfirst.version` or check `dmesg` to confirm which version is loaded. When debugging, this removes any doubt about which code is running.

Pick a versioning scheme and stick with it. Semantic versioning (major.minor.patch) is fine. Date-based (2026.04) is fine. Book-chapter-based (0.1 after Chapter 7, 0.2 after Chapter 8, 0.3 after Chapter 9, 0.4 after Chapter 10, 0.5 after Chapter 11) is fine and is what the companion source uses. The important property is consistency, not specifics.

For Chapter 11 specifically, the appropriate version bump is to 0.5-concurrency. The changes are: counter(9) migration, KASSERTs added, LOCKING.md added, annotations added. All are safety and clarity changes; none is a behavioural change visible from user space. Document them in a `CHANGELOG.md`:

myfirst Changelog

0.5-concurrency (Chapter 11)

- Migrated `bytes_read`, `bytes_written` to `counter_u64_t` (lock-free).
- Added KASSERTs throughout `cbuf_*` helpers.
- Added LOCKING.md documenting the locking strategy.
- Added source annotations naming each critical section.
- Added MYFIRST_LOCK/UNLOCK/ASSERT macros for future lock changes.

0.4-poll-refactor (Chapter 10, Stage 4)

- Added `d_poll` and `selinfo`.
- Refactored I/O handlers to use wait helpers.
- Added locking-strategy comment.

0.3-blocking (Chapter 10, Stage 3)

- Added mtx_sleep-based blocking read/write paths.
- Added IO_NDELAY -> EAGAIN handling.

0.2-circular (Chapter 10, Stage 2)

- Replaced linear FIFO with cbuf circular buffer.

0.1 (Chapter 9)

- Initial read/write via uiomove.

A CHANGELOG.md you can consult beats git history when you want the quick answer. Keep it updated with each change.

11.9.3 8.3: README and Comment Pass

Alongside LOCKING.md, write a README.md for the driver. The audience is a future maintainer (possibly you) who has just checked out the source and needs to know what the project is.

A minimal version:

myfirst

A FreeBSD 14.3 pseudo-device driver that demonstrates buffered I/O, concurrency, and modern driver conventions. Developed as the running example for the book "FreeBSD Device Drivers: From First Steps to Kernel Mastery."

Status

Version 0.5-concurrency (Chapter 11).

Features

- A Newbus pseudo-device under nexus0.
- A primary device node at /dev/myfirst/0 (alias: /dev/myfirst).
- A circular buffer (cbuf) as the I/O buffer.
- Blocking and non-blocking reads and writes.
- poll(2) support via d_poll and selinfo.
- Per-CPU byte counters via counter(9).
- A single sleep mutex protects composite state; see LOCKING.md.

Build and Load

\$ make

```
# kldload ./myfirst.ko
# dmesg | tail
# ls -l /dev/myfirst
# printf 'hello' > /dev/myfirst
# cat /dev/myfirst
# kldunload myfirst
```

Tests

See ../../userland/ for the test programs. The most useful one is `producer_consumer`, which exercises the round-trip correctness of the circular buffer.

License

BSD 2-Clause. See individual source files for SPDX headers.

Every driver benefits from a README like this. Without it, a new maintainer (possibly you, six months from now) has to reverse-engineer what the project is. With it, the onboarding is minutes.

In parallel, do a comment pass on the source itself. Focus on the critical sections: every `mtx_lock` should have a brief comment naming the shared state it is about to protect. Every helper should have a one-line description above the function definition. Every non-obvious piece of arithmetic (cbuf wrap-around, `nbefore` comparison, etc.) should have a sentence of explanation.

The goal is not exhaustive commentary. It is to make the code self-explanatory to a reader who has not seen it before.

11.9.4 8.4: Static Analysis

FreeBSD's base system includes `clang`, which has a `--analyze` mode that performs static analysis without compiling. For a kernel module, invoke it via:

```
$ make WARNS=6 CFLAGS+="-Weverything -Wno-unknown-warning-option" clean all
```

Or, more directly:

```
$ clang --analyze -I/usr/src/sys -I/usr/src/sys/amd64/conf/GENERIC \
-D_KERNEL myfirst.c
```

The output is a list of potential issues with file-line annotations. Triage them: false positives (clang does not understand some kernel idioms) are fine to ignore; genuine issues (uninitialized variables, null-pointer dereferences, memory leaks) deserve fixes.

Add a `lint` target to your `Makefile`:

```
.PHONY: lint
lint:
    cd ${.CURDIR}; clang --analyze -D_KERNEL *.c
```

Run `make lint` periodically. A clean run is the baseline; any new warning deserves attention before being merged.

11.9.5 8.5: Regression Testing

Assemble a regression test that runs every verification you have built. A shell script in the `tests/` subdirectory:

```
#!/bin/sh
# regression.sh: run every test from Chapters 7-11 in sequence.

set -eu

die() { echo "FAIL: $" ">&2; exit 1; }
ok()  { echo "PASS: $*"; }

# Preconditions
[ $(id -u) -eq 0 ] || die "must run as root"
kldstat | grep -q myfirst && kldunload myfirst
[ -f ./myfirst.ko ] || die "myfirst.ko not built; run make first"

kldload ./myfirst.ko
trap 'kldunload myfirst 2>/dev/null || true' EXIT

sleep 1
[ -c /dev/myfirst ] || die "device node not created"
ok "load"

printf 'hello' > /dev/myfirst || die "write failed"
cat /dev/myfirst >/tmp/out.$$
[ "$(cat /tmp/out.$$)" = "hello" ] || die "round-trip content mismatch"
rm -f /tmp/out.$$
ok "round-trip"

cd ../userland && make -s clean && make -s && cd -

../userland/producer_consumer || die "producer_consumer failed"
ok "producer_consumer"

../userland/mp_stress || die "mp_stress failed"
```

```
ok "mp_stress"

sysctl dev.myfirst.0.stats >/dev/null || die "sysctl not accessible"
ok "sysctl"

echo "ALL TESTS PASSED"
```

Run this after every change:

```
# ./tests/regression.sh
PASS: load
PASS: round-trip
PASS: producer_consumer
PASS: mp_stress
PASS: sysctl
ALL TESTS PASSED
```

A green regression is the evidence that the change did not break anything. Pair it with the debug-kernel stress runs and you have a reasonable quality gate for a driver at this stage of the book.

11.9.6 A Complete LOCKING.md Template

For readers who want a more substantive starting template than the minimal one in Section 3, here is a fuller LOCKING.md that can be adapted to any driver:

```
# <driver-name> Locking Strategy

## Overview

One sentence describing the overall approach. For example:
"The driver uses a single sleep mutex to serialize all access to
shared state, with separate per-CPU counters for hot-path
statistics."

## Locks Owned by This Driver

### sc->mtx (mutex(9), MTX_DEF)

**Protects:**
- sc->cb (circular buffer state: cb_head, cb_used, cb_data)
- sc->active_fhs
- sc->is_attached (writes)
- sc->rsel, sc->wsel (indirectly: selrecord inside a critical
```

```
section; selwakeup outside)
```

```
**Wait channels used under this mutex:**
```

```
- &sc->cb: data available / space available
```

Locks Owned by Other Subsystems

```
- selinfo internal locks: handled by the selinfo API; we must  
  call selrecord under our lock and selwakeup outside.
```

Unprotected Accesses

sc->is_attached (reads at handler entry)

```
**Why it's safe:**
```

A stale "true" is re-checked after every sleep; a stale "false" merely causes the handler to return ENXIO early, which is harmless since the device really is gone.

sc->bytes_read, sc->bytes_written (counter(9) fetches)

```
**Why it's safe:**
```

counter(9) handles its own consistency internally. Fetches may be slightly stale but are never torn.

Lock Order

The driver currently holds only one lock. No ordering rules apply.

When new locks are added, document the order here before merging the change. The format is:

```
sc->mtx -> sc->other_mtx
```

meaning: a thread holding sc->mtx may acquire sc->other_mtx, but not the reverse.

Rules

1. Never sleep while holding sc->mtx except via mtx_sleep, which atomically drops and reacquires.
2. Never call uiomove, copyin, copyout, selwakeup, or wakeup while holding sc->mtx.
3. Every cbuf_* call must happen with sc->mtx held (the helpers

```
assert this with mtx_assert).
```

4. The detach path clears `sc->is_attached` under the mutex and then wakes any sleepers before destroying the mutex.

History

- 0.5-concurrency (Chapter 11): migrated byte counters to `counter(9)`; added `mtx_assert` calls; formalized the strategy.
- 0.4-poll-refactor (Chapter 10): added `d_poll`, refactored into helpers, documented the initial strategy inline in the source.
- Earlier versions: strategy was implicit in the code.

A document this shape is auditable. Any future change to the driver's concurrency story touches this file in the same commit. The review diff shows the rule change, not just the code change.

11.9.7 A Pre-Commit Checklist

Before committing a concurrency-affecting change, run through this checklist:

1. **Have I updated `LOCKING.md`?** If the change adds a field to shared state, names a new lock, changes lock ordering, adds a wait channel, or changes a rule, update the doc.
2. **Have I run the full regression suite?** On a debug kernel, with `WITNESS` and `INVARIANTS`. A green regression is the minimum.
3. **Have I run the stress tests?** Not just once; for long enough to matter. Thirty minutes is a reasonable minimum for a significant change.
4. **Have I run `clang --analyze`?** Treat new warnings as bugs.
5. **Have I added a `KASSERT` for any new invariant?** Every invariant your code assumes should be a `KASSERT`.
6. **Have I bumped the version string and updated `CHANGELOG.md`?** Even if the change is small. Future you will thank present you.
7. **Have I verified the test kit compiles?** The test programs are part of the change; they should not bitrot.

Most changes clear the checklist in minutes. The changes that do not are the ones that should be caught by the checklist: those are the ones most likely to regress.

11.9.8 Versioning Strategy: Why 0.x?

We are using a 0.x scheme for the driver because the driver is not yet feature-complete. A 1.0 release implies stability and completeness that we cannot claim. The 0.x versions track our progress through the book:

- 0.1: basic scaffold (Chapter 7).
- 0.2: device file and per-open state (Chapter 8).
- 0.3: basic read/write via `uiomove` (Chapter 9).
- 0.4: buffered I/O, non-blocking, poll (Chapter 10).
- 0.5: concurrency hardening (Chapter 11).

Chapter 12 will introduce 0.6. Eventually, when the driver is feature-complete and stable, we would call it 1.0.

This is not the only sensible scheme. Semantic versioning (MAJOR.MINOR.PATCH) is appropriate for drivers with a stable API. Date-based versioning (2026.04) is appropriate for drivers where the release cadence is temporal. The choice matters less than the commitment: pick one, apply it consistently, document it in the README.

11.9.9 A Note on Git Hygiene

The companion source tree is organized so that each chapter's stage lives in its own directory. You can build any stage independently; you can diff stage-over-stage to see what changed. If you are using git, a clean commit history further enhances this:

- One commit per logical change.
- Commit messages that explain *why*, not just *what*.
- A separate commit for LOCKING.md updates when the code changes.

A git log like:

```
0.5 add KASSERT for cbuf_write overflow invariant
0.5 migrate bytes_read, bytes_written to counter(9)
0.5 document locking strategy in LOCKING.md
0.5 add MYFIRST_LOCK/UNLOCK/ASSERT macros
0.4 refactor I/O handlers to use wait helpers
```

is readable years later. A log like:

```
fix stuff
more fixes
wip
```

is not. Your driver is a living artifact; treat its history as documentation.

11.9.10 Wrapping Up Section 8

The driver is now not only correct but *verifiably* correct and *maintainably* organized. It has:

- A documented locking strategy in LOCKING.md.
- A versioning scheme and a changelog.
- A README for future maintainers.
- Source annotations for every critical section.
- Static analysis via `clang --analyze`.
- A regression test that runs everything.

That is a substantial body of infrastructure. Most beginner drivers have none of it. Yours now does, and the work to maintain it is routine rather than heroic.

11.10 Hands-on Labs

These labs consolidate the concepts of Chapter 11 through direct, hands-on experience. They are ordered from least to most demanding. Each is designed to be completable in a single lab session.

11.10.1 Pre-Lab Setup Checklist

Before starting any lab, confirm the four items below. Two minutes of preparation here will save you significant time when something goes wrong inside a lab and you cannot tell whether the problem is your code, your environment, or your kernel.

1. **Debug kernel running.** Confirm with `sysctl kern.ident` that the booted kernel is the one with `IN-variants` and `WITNESS` enabled. The reference section “Building and Booting a Debug Kernel” later in this chapter walks through the build, install, and reboot if you have not already done it.
2. **WITNESS active.** Run `sysctl debug.witness.watch` and confirm a non-zero value. If the `sysctl` is missing, your kernel does not have `WITNESS` compiled in; rebuild before continuing.
3. **Driver source matches Chapter 10 Stage 4.** From your driver directory, make `clean` && `make` should compile cleanly. The `myfirst.ko` artefact must exist before any lab attempts to load it.
4. **A clean dmesg.** Run `dmesg -c >/dev/null` once before the first lab so any prior warnings do not confuse you. Subsequent `dmesg` checks then show only what your lab produced.

If any of the four is uncertain, fix it now. The labs assume all four.

11.10.2 Lab 11.1: Observe a Race Condition

Goal. Build the race-demo driver from Section 2, run it, and observe the corruption. The purpose is not to produce a correct driver; it is to see with your own eyes what “no synchronization” means.

Steps.

1. Create `examples/part-03/ch11-concurrency/stage1-race-demo/`.
2. Copy `cbuf.c`, `cbuf.h`, and the `Makefile` from the Chapter 10 Stage 4 directory.
3. Copy `myfirst.c` and add the `RACE_DEMO` macros at the top as shown in Section 2. Replace every `mtx_lock`, `mtx_unlock`, and `mtx_assert` in the I/O paths with the `MYFIRST_LOCK`, `MYFIRST_UNLOCK`, `MYFIRST_ASSERT` macros. Compile with `-DRACE_DEMO` (which is the default in this directory’s `Makefile`).
4. Build and load.
5. In one terminal, run `../part-02/ch10-handling-io-efficiently/userland/producer_consumer`.
6. Observe the output. Record the mismatch count.
7. Run it several times. Observe that the mismatch count varies.
8. Unload the driver.

Verification. Every run produces at least one mismatch. The exact number varies. This demonstrates that concurrency bugs are not a theoretical possibility; they are the certainty when locks are absent.

Stretch goal. Add a `device_printf` inside `cbuf_write` that logs when `cb_used` exceeds `cb_size`. Load the driver, run the test, and observe the log messages. Each message is an invariant violation caught in flight.

11.10.3 Lab 11.2: Verify the Locking Discipline with INVARIANTS

Goal. Convert your Chapter 10 Stage 4 driver to use the MYFIRST_LOCK macros and add `mtx_assert` calls throughout. Run it under a WITNESS-enabled kernel and confirm that no warnings appear.

Steps.

1. Copy your Stage 4 driver into `examples/part-03/ch11-concurrency/stage2-concurrent-safe/`.
2. Add the MYFIRST_LOCK, MYFIRST_UNLOCK, MYFIRST_ASSERT macros at the top. Make them expand to the real `mtx_*` calls (no RACE_DEMO).
3. Replace the `mtx_lock`, `mtx_unlock`, `mtx_assert` calls in the I/O paths with the macros.
4. Add MYFIRST_ASSERT(sc) at the top of every helper that should be called with the lock held.
5. Build with `WARNS=6`.
6. Load on a WITNESS-enabled kernel.
7. Run the Chapter 10 test kit (`producer_consumer`, `rw_myfirst_nb`, `mp_stress`).
8. Confirm no WITNESS warnings appear in `dmesg`.

Verification. `dmesg | grep -i witness` shows no output related to `myfirst`. Every test passes.

Stretch goal. Introduce a deliberate bug: remove one `mtx_unlock` call, leaving the lock held past the end of the handler. Observe the WITNESS warning that appears, confirm it identifies the exact lock and the approximate line, then restore the unlock.

11.10.4 Lab 11.3: Migrate to counter(9)

Goal. Replace the `sc->bytes_read` and `sc->bytes_written` fields with `counter(9)` per-CPU counters.

Steps.

1. Copy Lab 11.2's source into `stage3-counter9/`.
2. Change the struct definition so the two fields are `counter_u64_t`.
3. Update `myfirst_attach` to allocate them and `myfirst_detach` to free them.
4. Update `myfirst_buf_read` and `myfirst_buf_write` to use `counter_u64_add`.
5. Remove the field updates from under the mutex (they no longer need the mutex).
6. Update the `sysctl` handlers to use `counter_u64_fetch`.
7. Update `LOCKING.md` to note that `bytes_read` and `bytes_written` are no longer under the mutex.
8. Build, load, and run the test kit.

Verification. `sysctl dev.myfirst.0.stats.bytes_read` and `bytes_written` still return correct values. No test fails.

Stretch goal. Run `mp_stress` with 8 writers and 8 readers for 60 seconds on a multi-core machine. Compare throughput with Lab 11.2 (mutex-protected counters). The per-CPU counters should be measurably faster if the machine has at least 4 cores.

11.10.5 Lab 11.4: Build a Multi-threaded Tester

Goal. Build `mt_reader` from Section 6. Use it to exercise the driver with multiple threads in one process.

Steps.

1. Under `examples/part-03/ch11-concurrency/userland/`, type `mt_reader.c` from Section 6, or open the companion source file already present in that directory and read it carefully.
2. From the same directory, run `make mt_reader` (the Makefile already includes the right `-pthread` linkage). The standalone command is `cc -Wall -Wextra -pthread -o mt_reader mt_reader.c`.
3. Start a writer in another terminal: `dd if=/dev/zero of=/dev/myfirst bs=4k &`.
4. Run `./mt_reader`.
5. Confirm that each thread sees a nonzero byte count and that the sum is consistent with what the writer produced.
6. When you are done, stop the background `dd` with `kill %1` (or whatever job number it has).

Verification. All four threads report a nonzero count. The grand total equals the writer’s byte count minus the buffer fill at the end.

Stretch goal. Increase `NTHREADS` to 8, 16, 32. Observe the scaling behavior. Does throughput increase, decrease, or remain flat? Explain why (hint: Section 5’s discussion of lock contention).

11.10.6 Lab 11.5: Deliberately Cause a WITNESS Warning

Goal. Introduce a deliberate concurrency bug and observe how `WITNESS` catches it.

Steps.

1. Copy your Stage 3 working directory into a scratch directory such as `stage-lab11-5/`. Do *not* edit Stage 3 in place; the purpose of the lab is to revert cleanly.
2. In `myfirst_read`, move the `MYFIRST_UNLOCK(sc)` call from before `uiomove` to after `uiomove`. The code still compiles, but the mutex is now held across the `uiomove`, which may sleep.
3. Build and load on a `WITNESS`-enabled debug kernel (see the “Building and Booting a Debug Kernel” reference later in this chapter).
4. Run `producer_consumer` in one terminal and watch `dmesg` in another.
5. Observe the warning emitted by `WITNESS` when the `uiomove` is about to sleep while `sc->mtx` is held. Record the exact message and the source line it cites.
6. Unload the module, delete the scratch directory, and confirm that your Stage 3 source is still correct.

Verification. `dmesg` shows a warning similar to “acquiring duplicate lock of same type” or “sleeping thread (pid N) owns a non-sleepable lock” pointing at the line where the unlock used to live.

Stretch goal. Repeat with a different deliberate bug: change the mutex type from `MTX_DEF` to `MTX_SPIN` in `mtx_init`. Observe the resulting warnings, which should be about sleeping while holding a spin mutex. Again, revert cleanly when you are done.

11.10.7 Lab 11.6: Add KASSERTs Throughout

Goal. Add `KASSERT` calls to the `cbuf` helpers and the driver code. Confirm they fire when deliberately triggered.

Steps.

1. Copy Lab 11.3’s source into `stage5-kasserts/`.
2. In `cbuf_write`, add `KASSERT(cb->cb_used + n <= cb->cb_size, ...)` at the top.

3. In `cbuf_read`, add `KASSERT(n <= cb->cb_used, ...)`.
4. In `myfirst_buf_*` helpers, add `mtx_assert(&sc->mtx, MA_OWNED)`.
5. Build and load on an INVARIANTS kernel.
6. Run the test kit. No assertions should fire in normal operation.
7. Introduce a bug: in `cbuf_write`, write `cb->cb_used += n + 1` instead of `cb->cb_used += n`. Confirm that the `KASSERT` in the next call catches the overflow.
8. Revert the bug.

Verification. Every assertion in the reverted source compiles and the driver works normally. The deliberate bug produces a panic with a clear backtrace that names the failed `KASSERT`.

11.10.8 Lab 11.7: Long-Running Stress

Goal. Run the full Chapter 11 test kit for one hour and verify no failures, no kernel warnings, and no memory growth.

Steps.

1. Load your Chapter 11 Stage 3 or Stage 5 driver.
2. In one terminal, run:

```
for i in $(seq 1 60); do
    ./producer_consumer
    ./mp_stress
done
```

3. In a second terminal, run a background `vmstat 10` and `sysctl dev.myfirst.0.stats` periodically.
4. Monitor `dmesg` for warnings.
5. After the loop finishes, check `vmstat -m | grep cbuf` and confirm memory has not grown.

Verification. All loops complete. No `WITNESS` warnings. `vmstat -m | grep cbuf` shows the expected constant allocation. The byte counters in `sysctl` have increased; their ratio of `bytes_read` to `bytes_written` is approximately 1.

11.10.9 Lab 11.8: Run `clang -analyze`

Goal. Run static analysis on the driver and triage the results.

Steps.

1. From your Chapter 11 Stage 3 or Stage 5 directory, run:

```
clang --analyze -D_KERNEL -I/usr/src/sys \
    -I/usr/src/sys/amd64/conf/GENERIC myfirst.c
```

2. Record every warning.
3. For each warning, classify it as (a) a true positive (real bug), (b) a false positive that you understand, or (c) a warning you do not understand.

4. For (a), fix the bug. For (b), document why it is a false positive. For (c), research until it moves to (a) or (b).

Verification. After the pass, the driver has zero unclassified warnings. The `LOCKING.md` or `README.md` documents any known false positives.

11.11 Challenge Exercises

The challenges extend Chapter 11's concepts beyond the baseline labs. Each is optional; each is designed to deepen your understanding.

11.11.1 Challenge 1: A Lock-Free Producer/Consumer

The mutex we use protects composite state. A single-producer-single-consumer queue can be implemented lock-free, using only atomics, because the writer touches only the tail and the reader touches only the head, and neither touches the fields the other updates. `buf_ring(9)` builds on this idea but goes further: it uses compare-and-swap so several producers can enqueue concurrently, and offers either single-consumer or multi-consumer dequeue paths chosen at allocation time.

Read `/usr/src/sys/sys/buf_ring.h`, where the lock-free enqueue and dequeue paths live as inline functions, and `/usr/src/sys/kern/subr_bufring.c`, which holds `buf_ring_alloc()` and `buf_ring_free()`. Understand the `buf_ring(9)` primitive. Then, as an exercise, build a variant of the driver where the circular buffer is replaced by a `buf_ring`. The read and write handlers no longer need a mutex for the ring itself; they may still need one for other state.

This challenge is harder than it looks. Attempt it only if you are comfortable with Chapter 11's material and want a stretch.

11.11.2 Challenge 2: Multi-Mutex Design

Split `sc->mtx` into two locks: `sc->state_mtx` (protects `is_attached`, `active_fhs`, `open_count`) and `sc->buf_mtx` (protects the cbuf and byte counters). Define a lock order (for example, state before buf) and document it in `LOCKING.md`. Update all the handlers.

What do you gain? What do you lose? Is there a workload that measurably benefits?

11.11.3 Challenge 3: WITNESS Under Pressure

Construct a test that provokes a `WITNESS` warning even on a correctly-locked driver. (Hint: `sx` locks have different rules; mixing a mutex and an `sx` lock in conflicting orders produces warnings. Chapter 12 covers `sx`.) This challenge is a preview of Chapter 12 material.

11.11.4 Challenge 4: Instrument with `dtrace`

Write a `dtrace` script that:

- Counts the number of `mtx_lock(&sc->mtx)` calls per second.
- Prints a histogram of the time spent holding the lock.
- Correlates lock-holding time with `bytes_read` and `bytes_written` rates.

Run the script while `mp_stress` is running. Produce a report.

11.11.5 Challenge 5: Bounded Blocking

Modify `myfirst_read` to return `EAGAIN` if the read would block for more than `N` milliseconds, where `N` is a `sysctl-tunable` parameter. (Hint: the `timo` argument of `mtx_sleep` is in ticks, where `hz` ticks equal one second. For example, `hz / 10` is roughly 100 milliseconds. For sub-tick precision, the `msleep_sbt(9)` family uses `sbintime_t` and the `SBT_1S`, `SBT_1MS`, and `SBT_1US` constants from `sys/time.h`.) This challenge previews some of Chapter 12's material on timeouts.

11.11.6 Challenge 6: Write a Lock-Contention Benchmark

Build a benchmark that measures the mutex acquisition rate under varying load:

- 1 writer, 1 reader.
- 1 writer, 4 readers.
- 4 writers, 4 readers.
- 8 writers, 8 readers.

Report acquisition-per-second, average hold time, and maximum wait time. Use `dt race` or the mutex profiling `sysctl`.

11.11.7 Challenge 7: Port to a 32-bit Platform

FreeBSD still supports 32-bit architectures (`i386`, `armv7`). Build your driver for one of them and run the test kit. Do any of the torn-read issues from Section 3 manifest? Is the per-CPU counter migration from Lab 11.3 necessary for correctness, or merely for performance?

(This challenge is genuinely hard and requires access to 32-bit hardware or a cross-build environment.)

11.11.8 Challenge 8: Add a Per-Descriptor Mutex

The per-descriptor struct `myfirst_fh` has reads and writes counters that are currently updated under the device-wide `sc->mtx`. An alternative is to give each `fh` its own mutex. Would this help? Hurt? Write the change, run the benchmark, report.

11.12 Troubleshooting

This reference catalogues the bugs you are most likely to encounter while working through Chapter 11 and after. Each entry has a symptom, a cause, and a fix.

11.12.1 Symptom: `mtx_assert` panic on a driver that used to work

Cause. A helper was called without the mutex held. This usually happens when you refactor and move a call outside the critical section.

Fix. Look at the backtrace; the top frame names the helper. Find the caller. Ensure the caller holds `sc->mtx` at the point of the call.

11.12.2 Symptom: sleepable after non-sleepable acquired warning

Cause. A call that might sleep (typically `uiomove`, `copyin`, `copyout`, `malloc(... M_WAITOK)`) was made while holding a non-sleepable lock. On FreeBSD, `MTX_DEF` is sleepable; the warning is usually more specific.

Fix. Drop the mutex before the sleeping call. If state must be preserved, take a snapshot under the mutex, do the sleeping call outside, and reacquire to commit.

11.12.3 Symptom: Lock-order reversal

Cause. Two acquisition orders observed; one is the reverse of the other. Only possible with two or more locks.

Fix. Define a global order. Update the offending path. Document in `LOCKING.md`.

11.12.4 Symptom: Deadlock (hang)

Cause. Either a missing wakeup (`&sc->cb`) or a sleep with a different channel than the wake.

Fix. Check every `mtx_sleep` channel against every wakeup channel. They must match exactly. `&sc->cb` sleeping and `&sc->buf` waking are different channels.

11.12.5 Symptom: Torn value read from a `uint64_t`

Cause. On a 32-bit platform, a 64-bit read is two 32-bit reads, which can straddle a concurrent write. On amd64, aligned 64-bit accesses are atomic; on 32-bit platforms, they are not.

Fix. Either protect with the mutex (simple) or migrate to `counter(9)` (scalable) or use the `atomic*_64` primitives (precise).

11.12.6 Symptom: Double-free panic on the `cbuf`

Cause. `cbuf_destroy` called twice, typically because the error path in `myfirst_attach` runs `cbuf_destroy` and then `myfirst_detach` runs it again.

Fix. After calling `cbuf_destroy`, set `sc->cb.cb_data = NULL` so a second call is a no-op. Or guard the destroy with an explicit flag.

11.12.7 Symptom: Slow performance under many-core load

Cause. Mutex contention. Every CPU is serializing on `sc->mtx`.

Fix. Migrate byte counters to `counter(9)` (Lab 11.3). If further reduction is needed, split the mutex (Challenge 2) or use finer-grained primitives (Chapter 12).

11.12.8 Symptom: `producer_consumer` occasionally hangs

Cause. A race between the writer finishing and the reader deciding the buffer is “permanently empty”. Our driver returns zero bytes on an empty non-blocking read, which `producer_consumer` may interpret as EOF.

Fix. Use blocking reads in `producer_consumer` (remove `O_NONBLOCK` if it was added). Ensure the writer closes the descriptor or the reader detects end-of-test by total byte count, not by a zero-byte read.

11.12.9 Symptom: `WITNESS` reports “unowned lock released”

Cause. `mtx_unlock` called without a matching `mtx_lock` earlier in the same thread.

Fix. Audit every `mtx_unlock` site. Trace back and confirm each has a matching `mtx_lock` before it, along every path.

11.12.10 Symptom: Compiles cleanly, passes single-threaded tests, fails `mp_stress`

Cause. A missed lock somewhere on the data path. Single-threaded tests never exercise the race; concurrent tests do.

Fix. Audit every access to shared state, as in Section 3. The usual culprit is a field updated outside the critical section because “it’s only a counter” (not true under concurrency).

11.12.11 Symptom: `kldunload` hangs with descriptors open

Cause. The detach path refuses to proceed while `active_fhs > 0`.

Fix. `fstat | grep myfirst` to find the offending processes. kill them. Then retry `kldunload`.

11.12.12 Symptom: Kernel panic with a clean backtrace in `mtx_lock`

Cause. The mutex was destroyed and its memory reused. The atomic operation in `mtx_lock` is operating on whatever happens to be in that memory now.

Fix. Ensure `mtx_destroy` is called only after every handler that could use the mutex has returned. Our detach path does this by destroying the `cdev` first, which waits for in-flight handlers.

11.12.13 Symptom: WITNESS never warns, even when you expect it to

Cause. Three possibilities. First, the running kernel does not actually have WITNESS compiled in; check `sysctl debug.witness.watch` and confirm a non-zero value. Second, WITNESS is enabled but quiet because no rule has been violated yet; not every refactor produces a violation. Third, the offending code path was not exercised; WITNESS only checks the orderings the kernel actually observes at runtime.

Fix. Confirm the kernel has WITNESS (the `sysctl` above is the easy check). Then drive the suspect code path with the multi-process and multi-thread testers from Section 6 so the kernel sees the acquisitions in question.

11.12.14 Symptom: dmesg is silent but the test still fails

Cause. Either the failure is in user-space (the test program) or the kernel did detect a problem but printed nothing because the message buffer wrapped. The latter is rare on a freshly-booted system but common on long-running test machines.

Fix. Increase the buffer for next boot by adding `kern.msgbufsize="4194304"` to `/boot/loader.conf`; the `sysctl` is read-only at runtime. For user-space failures, run the test under `truss(1)` to see the syscalls and their return values; concurrency bugs at the user-space level often surface as EAGAIN, EINTR, or short reads that the test mishandles.

11.13 Wrapping Up

Chapter 11 took the driver you built in Chapter 10 and placed it on a foundation of concurrency understanding. We did not change its behaviour; we built the understanding that lets you change its behaviour safely in the future.

We started with the premise that concurrency is the default environment every driver lives in, and that a driver which ignores that fact is a driver waiting to fail on a user's faster machine, busier workload, or larger core count. The four failure modes (data corruption, lost updates, torn values, inconsistent composite state) are not rare edge cases; they are the certainty when multiple streams touch shared state without coordination.

We then built the tools that prevent those failures. Atomics, for the small and simple cases. Mutexes, for everything else. We applied the tools to the driver: per-CPU counters replaced the mutex-protected byte counters, the single mutex covers the `cbuf` and its composite invariants, and `mtx_sleep` provides the blocking path that Chapter 10 used without explanation.

We learned to verify. INVARIANTS and WITNESS catch sleeping-with-mutex and lock-order violations at development time. KASSERT and `mtx_assert` document invariants and catch their violations. `dtrace` observes without disturbing. A multi-threaded and multi-process test suite exercises the driver at levels the base-system tools cannot reach.

We refactored for maintainability. The locking strategy is documented in `LOCKING.md`. The versioning is explicit. The README introduces the project to a new reader. The regression test runs every test we have built.

The driver is now the most robust character-device driver many beginners have ever written. It is also small, comprehensible, and source-referenced. Every locking decision has a first-principles justification. Every test has a specific purpose. Every piece of infrastructure supports the next chapter's work.

Three closing reminders before moving on.

The first is to *run the tests*. Concurrency bugs do not make themselves obvious. If you have not run `mp_stress` for an hour on a debug kernel, you have not confirmed that your driver is correct; you have only confirmed that your tests cannot find a bug in the time you gave them.

The second is to *keep `LOCKING.md` up to date*. Every future change that touches shared state updates the document. A driver whose concurrency story drifts away from its documentation is a driver that accumulates subtle bugs.

The third is to *trust the primitives*. The kernel's mutex, atomic, and sleep primitives are the result of decades of engineering and are extensively tested. The rules feel arbitrary at first; they are not. Learn the rules, apply them consistently, and the kernel does the hard work for you.

11.14 Chapter 11 Reference Material

The sections that follow are reference material for this chapter. They are not part of the main teaching sequence; they are here because you will return to them every time you need to recall a specific primitive, verify an invariant, or revisit a concept the chapter introduced briefly. Read them in order the first time, then come back to individual sections as needed.

The reference sections are named rather than lettered, to avoid confusion with the book's top-level appendices A through E. Each section stands on its own.

11.15 Reference: Building and Booting a Debug Kernel

Several labs in this chapter assume a kernel built with `INVARIANTS` and `WITNESS`. On a FreeBSD 14.3 release system, the stock `GENERIC` kernel does not include these options, because they carry a runtime cost unsuitable for production. This walkthrough shows how to build and install a debug kernel that does.

11.15.1 Step 1: Prepare a Custom Configuration

Make a copy of the generic configuration so you do not modify the original:

```
# cd /usr/src/sys/amd64/conf
# cp GENERIC MYFIRSTDEBUG
```

Edit `MYFIRSTDEBUG` and add the debug options if they are not already present:

ident	MYFIRSTDEBUG
options	INVARIANTS
options	INVARIANT_SUPPORT
options	WITNESS
options	WITNESS_SKIPSPIN
options	DDB

options	KDB
options	KDB_UNATTENDED

DDB enables the in-kernel debugger, which you can enter on a panic to inspect state. KDB is the kernel debugger framework. KDB_UNATTENDED causes the system to reboot after a panic rather than waiting for a human at the console, which is the right setting for a headless lab machine.

11.15.2 Step 2: Build the Kernel

```
# cd /usr/src
# make buildkernel KERNCONF=MYFIRSTDEBUG -j 4
```

The `-j 4` parallelizes across 4 cores. Adjust to your machine.

On a reasonably fast machine, the build takes 15 to 30 minutes. On a slow machine, it can take an hour or more. This is a one-time cost; incremental rebuilds are much faster.

11.15.3 Step 3: Install and Reboot

```
# make installkernel KERNCONF=MYFIRSTDEBUG
# shutdown -r now
```

The install places the new kernel in `/boot/kernel/` and the old one in `/boot/kernel.old/`. If the new kernel panics on boot, you can boot from `/boot/kernel.old` at the loader prompt.

11.15.4 Step 4: Confirm the Boot

After reboot, confirm the debug options are active:

```
$ sysctl kern.ident
kern.ident: MYFIRSTDEBUG
```

You are now running a debug kernel. Your driver's KASSERT calls will fire on failures. WITNESS warnings will appear in `dmesg`.

11.15.5 Step 5: Rebuild the Driver

Modules must be rebuilt against the running kernel's source:

```
$ cd your-driver-directory
$ make clean && make
```

Load as usual:

```
# kldload ./myfirst.ko
```

11.15.6 Reverting to the Production Kernel

If you want to go back to the non-debug kernel:

```
# shutdown -r now
```

At the loader prompt, type `unload` then `boot /boot/kernel.old/kernel` (or rename the directories as the FreeBSD handbook describes).

The debug kernel is slower than the production kernel. Do not run production workloads under it. Do run every driver test under it.

11.16 Reference: Further Reading on FreeBSD Concurrency

For readers who want to go deeper than this chapter covers, here are pointers to the canonical sources:

11.16.1 Manual Pages

- `mutex(9)`: the definitive reference for the mutex API.
- `locking(9)`: an overview of FreeBSD's locking primitives.
- `lock(9)`: the common lock-object infrastructure.
- `atomic(9)`: the atomic operation API.
- `counter(9)`: the per-CPU counter API.
- `msleep(9)` and `mtx_sleep(9)`: the sleep-with-interlock primitives.
- `condvar(9)`: condition variables (Chapter 12 material).
- `sx(9)`: sleepable shared/exclusive locks (Chapter 12 material).
- `rwlock(9)`: reader/writer locks (Chapter 12 material).
- `witness(4)`: the WITNESS lock-order checker.

11.16.2 Source Files

- `/usr/src/sys/kern/kern_mutex.c`: the mutex implementation.
- `/usr/src/sys/kern/subr_sleepqueue.c`: the sleep queue machinery.
- `/usr/src/sys/kern/subr_witness.c`: the WITNESS implementation.
- `/usr/src/sys/sys/mutex.h`: the mutex header with flag definitions.

- `/usr/src/sys/sys/_mutex.h`: the mutex structure.
- `/usr/src/sys/sys/lock.h`: common lock-object declarations.
- `/usr/src/sys/sys/atomic_common.h` and `/usr/src/sys/amd64/include/atomic.h`: atomic primitives.
- `/usr/src/sys/sys/counter.h`: the counter(9) API header.

11.16.3 External Material

The FreeBSD handbook covers kernel programming at an overview level. For more depth, *The Design and Implementation of the FreeBSD Operating System* (McKusick et al.) is the canonical textbook. For concurrency theory applicable to any OS, *The Art of Multiprocessor Programming* (Herlihy and Shavit) is excellent. Neither is required reading for our purposes, but both are useful references.

11.17 Reference: A Chapter 11 Self-Assessment

Before turning to Chapter 12, use this rubric to confirm you have internalised the Chapter 11 material. Every question should be answerable without re-reading the chapter. If any question is hard, return to the relevant section.

11.17.1 Conceptual Questions

1. **Name the four failure modes of unsynchronised shared state.** Data corruption, lost updates, torn values, inconsistent composite state.
2. **What is a race condition?** Overlapping access to shared state, at least one write, correctness that depends on the interleaving.
3. **Why does `mtx_sleep` take the mutex as an interlock argument, rather than the caller unlocking then sleeping?** Because unlocking then sleeping has a lost-wakeup window: a concurrent wakeup could fire after the unlock but before the sleep, be delivered to nobody, and leave the sleeper waiting forever.
4. **Why is it illegal to hold a non-sleepable mutex across a call to `uiomove`?** Because `uiomove` may sleep on a user-space page fault, and sleeping with a non-sleepable lock held is forbidden by the kernel (detected by `WITNESS` on debug kernels, undefined on production kernels).
5. **What is the difference between `MTX_DEF` and `MTX_SPIN`?** `MTX_DEF` sleeps when contended; `MTX_SPIN` busy-waits and disables interrupts. Use `MTX_DEF` for code in thread context; use `MTX_SPIN` only when sleeping is forbidden (for example, inside hardware interrupt handlers).
6. **When is an atomic operation sufficient to replace a mutex?** When the shared state is a single word-sized field and the operation does not compose with other fields or require blocking.
7. **What does `WITNESS` catch that single-threaded testing does not?** Lock-order reversals, sleeping with the wrong lock held, releasing an unowned lock, recursive acquisition of a non-recursive lock.
8. **Why is the per-CPU counter (`counter(9)`) faster than a mutex-protected counter?** Because per-CPU counters do not contend across CPUs. Each CPU updates its own cache line; summing happens only on read.

11.17.2 Code Reading Questions

Open your Chapter 11 driver source and answer:

1. Every call to `mtx_lock(&sc->mtx)` should be followed eventually by exactly one call to `mtx_unlock(&sc->mtx)` on every path. Verify this by inspection.
2. Every call to `mtx_sleep(&chan, &sc->mtx, ...)` should have a matching `wakeup(&chan)` somewhere in the driver. Find them.
3. The `mtx_assert(&sc->mtx, MA_OWNED)` calls are asserting that the mutex is held. Every caller of those helpers must hold the mutex. Verify by inspection.
4. The detach path sets `sc->is_attached = 0` before calling `wakeup(&sc->cb)`. Why is the order important?
5. The I/O handlers release `sc->mtx` before calling `uiomove`. Why?
6. The `selwakeup` call is placed outside the mutex. Why?

11.17.3 Hands-On Questions

1. Load the Chapter 11 driver on a WITNESS-enabled kernel and run the test kit. Are there any warnings in `dmesg`? If yes, investigate; if no, consider the driver verified.
2. Introduce a deliberate bug: comment out one `wakeup(&sc->cb)` call. Run the test kit. What happens?
3. Revert the bug. Introduce a different deliberate bug: comment out one `mtx_unlock` call and replace it with `mtx_unlock` after the `uiomove` call. Run on WITNESS. What does WITNESS say?
4. Run `mp_stress` for 60 seconds. Does the byte count converge?
5. Run `producer_consumer` 100 times in a loop. Every run should pass. Does it?

If all five hands-on questions pass, your Chapter 11 work is solid. You are ready for Chapter 12.

11.18 Reference: A Closer Look at Sleep Queues

This reference section explains, at a level appropriate for a beginner with curiosity, what happens inside the kernel when a thread calls `mtx_sleep` or `wakeup`. You do not need this material to write a correct driver; you have been doing that for several chapters. The section is here because, once you have seen the primitives work, you may want to know *how* they work. The knowledge pays off when you read other drivers and when you debug rare concurrency issues.

11.18.1 The Sleep Queue

A **sleep queue** is a kernel data structure that tracks threads waiting for a condition. Every active wait corresponds to exactly one sleep queue. When a thread calls `mtx_sleep(chan, mtx, pri, wmesg, timo)`, the kernel looks up (or creates) the sleep queue associated with `chan` (the wait channel) and adds the thread to it. When `wakeup(chan)` is called, the kernel looks up the queue and wakes every thread on it.

The data structure itself is defined in `/usr/src/sys/kern/subr_sleepqueue.c`. A hash table keyed on the channel address maps channels to queues. Each queue has a spin lock protecting its list of waiters. The spin lock is internal to the sleep-queue machinery; you never see it directly.

Why a hash table? Because a channel can be any pointer value, and the kernel may be serving thousands of simultaneous waits. A direct map (one queue per channel) would be too sparse; a single global list would contend too much. The hash table splits the load across many buckets, keeping lookups fast.

11.18.2 The Atomicity of `mtx_sleep`

Here is what `mtx_sleep(chan, mtx, pri, wmesg, timo)` actually does, at a high level:

1. Take the sleep-queue spin lock for `chan`.
2. Add the current thread to the sleep queue under that lock.
3. Release `mtx` (the outer mutex the caller is holding).
4. Call the scheduler, which picks another thread to run.
5. When awakened, the scheduler restores this thread. Control returns inside `mtx_sleep`.
6. Release the sleep-queue spin lock.
7. Reacquire `mtx`.
8. Return to the caller.

The key point is that steps 1 and 2 happen before step 3. Once the thread is on the sleep queue, any subsequent `wakeup(chan)` will remove it. If `wakeup(chan)` fires between step 3 and step 4, it removes the thread from the queue and marks it runnable; step 4 (calling the scheduler) will still happen but will find the thread immediately runnable, so the sleep is zero-length.

The window that would have been “released the mutex, not yet on the sleep queue” does not exist. The sleep queue entry happens *first*, while the mutex is still held; then the mutex is released *while the sleep-queue lock is held*. No wakeup can slip through.

This is the race that the atomic drop-and-sleep prevents, visible at the source level.

11.18.3 The wakeup Path

`wakeup(chan)` does the following:

1. Take the sleep-queue spin lock for `chan`.
2. Remove every thread on the queue.
3. Mark each removed thread as runnable.
4. Release the sleep-queue spin lock.
5. If any of the removed threads had higher priority than the current thread, call the scheduler to preempt.

The removed threads do not immediately run; they are merely runnable. The scheduler will pick them up in due course. If none has a higher priority than the caller, the caller continues to run; if one does, the caller yields.

`wakeup_one(chan)` is the same except that it removes only one thread (the highest-priority one, with FIFO among equal priorities). This is preferred when only one thread can usefully consume the signal. For a single-consumer buffer, `wakeup_one` avoids the thundering-herd problem; for a signal that can benefit multiple consumers, `wakeup` is appropriate.

For our driver, either would work. We use wakeup because both a reader and a writer may be waiting on the same channel and both need to be notified if the buffer state changes.

11.18.4 Priority Propagation Inside `mtx_sleep`

Section 5 introduced priority propagation as the kernel's defence against priority inversion. The mechanism lives in the mutex code itself: when `mtx_sleep` adds the calling thread to the sleep queue, it inspects the owner of the mutex (stored as a thread pointer inside the mutex word). If the waiting thread's priority is higher than the owner's, the owner's priority is boosted. The boost persists until the owner releases the mutex, at which point the owner's original priority is restored and the waiter acquires.

You can observe this effect live on a running system with `top -SH` during a contested workload: the priority of the thread holding a contested lock dances around as different waiters arrive and leave. It is one of the kernel services you benefit from silently; the boost is automatic and correct, and you do not have to opt in.

11.18.5 Adaptive Spinning Revisited

Section 5 introduced adaptive spinning as the optimization that lets `mtx_lock` avoid going to sleep when the holder is about to release. The sleep-queue machinery is where the decision is made. At its core, the slow path does roughly:

```
while (!try_acquire()) {
    if (holder is running on another CPU)
        spin briefly;
    else
        enqueue on the sleep queue and yield;
}
```

The “holder is running on another CPU” check reads the mutex word to get the owner pointer, then asks the scheduler whether that thread is currently on-CPU. If yes, the mutex is likely to be released within microseconds and a short spin beats the cost of a context switch. If no (the holder is itself asleep or has been descheduled), spinning is pointless and the waiter joins the sleep queue immediately. The threshold and exact spin count are kernel tunables; their precise values do not matter for the driver writer, as long as you trust that `mtx_lock` is fast in the common case and falls gracefully to sleep when it has to.

11.18.6 The Priority Argument

`mtx_sleep` takes a priority argument. In the Chapter 10 code, we passed `PCATCH` (allow signal interruption) with no explicit priority. The default priority, in FreeBSD, is whatever the calling thread is currently at; `PCATCH` alone does not change the priority.

Sometimes you want to sleep at a specific priority. The argument takes the form `PRIORITY | FLAGS`, where `PRIORITY` is a number (lower is better) and `FLAGS` include `PCATCH`. For our driver, the default priority is fine. Specialised drivers might pass `PUSER | PCATCH` to ensure the thread sleeps at a priority appropriate for user-visible work; real-time drivers might pass a lower (better) priority.

This is a detail you can safely ignore until a specific driver needs it. The default is the right answer most of the time.

11.18.7 Wait Message (wmesg) Conventions

The `wmesg` argument to `mtx_sleep` is a short string that appears in `ps`, `procstat`, and similar tools. Conventions:

- Five to seven characters. Longer strings are truncated.
- Lowercase.
- Indicate both the subsystem and the operation.
- `myfrd` = “myfirst read”. `myfwr` = “myfirst write”. `tunet` = “tun network”.

A good `wmesg` lets a developer scanning a `ps -AxH` output immediately know what a sleeping thread is waiting for. The few seconds it takes to invent a good name pay off the first time somebody needs to understand a hung system.

11.18.8 Sleep with Timeouts

The `timo` argument to `mtx_sleep` is the maximum wait time in ticks. Zero means “indefinite”; a positive value means “wake after this many ticks even if no one called wakeup”.

When the timeout fires, `mtx_sleep` returns `EWOLDBLOCK`. The caller is expected to check the return value and decide what to do.

Timeouts are how you implement bounded blocking. Chapter 12 covers `msleep_sbt(9)`, which takes an `sbintime_t` deadline instead of an integer tick count and is more convenient for sub-millisecond precision. For Chapter 11, the plain tick-based timeout is sufficient.

Example usage, for a driver that wants a 5-second maximum wait:

```
error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", hz * 5);
if (error == EWOLDBLOCK) {
    /* Timed out; return EAGAIN or retry. */
}
```

The `hz` constant is the kernel’s tick rate (typically 1000 on FreeBSD 14.3, configurable via `kern.hz`). Multiplying by 5 gives 5 seconds. This is a handy technique for a driver that wants progress guarantees.

11.19 Reference: Reading `kern_mutex.c`

The source for FreeBSD’s mutex implementation lives in `/usr/src/sys/kern/kern_mutex.c`. This reference section walks through the most interesting parts at a level appropriate for a driver writer who wants to know what happens when they call `mtx_lock`.

You do not need to understand every line. You do need to be able to open the file and recognize the shape of what is happening.

11.19.1 The mutex Structure

A mutex is a small structure. Its definition is in `/usr/src/sys/sys/_mutex.h`:

```
struct mtx {
    struct lock_object    lock_object;
    volatile uintptr_t    mtx_lock;
};
```

`lock_object` is the common header used by every lock class (mutexes, sx locks, rw locks, lockmgr locks, rmlocks). It holds the name, the lock flags, and WITNESS tracking state.

`mtx_lock` is the actual lock word. Its value encodes the state:

- 0: unlocked.
- A thread pointer: the ID of the thread holding the lock.
- Thread pointer with low bits set: lock is held with modifiers (`MTX_CONTESTED`, `MTX_RECURSED`, etc.).

Acquiring the mutex is, at its core, a compare-and-swap: change `mtx_lock` from 0 (unlocked) to `curthread` (the calling thread's pointer).

11.19.2 The Fast Path of `mtx_lock`

Open `kern_mutex.c` and find `__mtx_lock_flags`. You will see something like:

```
void
__mtx_lock_flags(volatile uintptr_t *c, int opts, const char *file, int line)
{
    struct mtx *m;
    uintptr_t tid, v;

    m = mtxlock2mtx(c);
    /* ... WITNESS setup ... */

    tid = (uintptr_t)curthread;
    v = MTX_UNOWNED;
    if (!_mtx_obtain_lock_fetch(m, &v, tid))
        _mtx_lock_sleep(m, v, opts, file, line);
    /* ... lock acquired; lock-profiling bookkeeping ... */
}
```

The critical operation is `_mtx_obtain_lock_fetch`, which is a compare-and-swap. It tries to change `mtx->mtx_lock` from `MTX_UNOWNED` (zero) to `tid` (the current thread's pointer). If it succeeds, we hold the mutex, and the function returns without further work. If it fails, we go to `_mtx_lock_sleep`.

The fast path is therefore: one compare-and-swap plus some WITNESS bookkeeping. On an uncontested mutex, `mtx_lock` costs essentially one atomic operation.

11.19.3 The Slow Path

`_mtx_lock_sleep` is the slow path. It handles the case where the mutex is already held by another thread. The function is a few hundred lines; the critical parts are:

```
for (;;) {
    /* Try to acquire. */
    if (_mtx_obtain_lock_fetch(m, &v, tid))
        break;

    /* Adaptive spin if holder is running. */
    if (owner_running(v)) {
        for (i = 0; i < spin_count; i++) {
            if (_mtx_obtain_lock_fetch(m, &v, tid))
                goto acquired;
        }
    }

    /* Go to sleep. */
    enqueue_on_sleep_queue(m);
    schedule_out();
    /* When we resume, loop back and try again. */
}
acquired:
    /* ... priority propagation bookkeeping ... */
```

The structure is: try the compare-and-swap, spin if the holder is running, otherwise sleep. Wake up and retry. Eventually acquire.

Several pieces of the real code complicate this skeleton: handling of the `MTX_CONTESTED` flag, priority propagation, lock profiling, witness tracking, and special cases for recursion. Don't worry about them on a first read; the structure above is the essence.

11.19.4 The Unlock Path

`__mtx_unlock_flags` is the release. Its fast path:

```
void
__mtx_unlock_flags(volatile uintptr_t *c, int opts, const char *file, int line)
{
    struct mtx *m;
    uintptr_t tid;

    m = mtxlock2mtx(c);
    tid = (uintptr_t)curthread;
```

```
if (!_mtx_release_lock(m, tid))
    _mtx_unlock_sleep(m, opts, file, line);
}
```

`_mtx_release_lock` tries to atomically change `mtx->mtx_lock` from `tid` (current thread) to `MTX_UNOWNED`. If it succeeds, the mutex is released cleanly. If it fails, there were complications (the `MTX_CONTESTED` flag was set because waiters had arrived), and `_mtx_unlock_sleep` handles them.

The common case: one atomic store. The uncommon case: dequeue waiters and wake one.

11.19.5 The Takeaway

Reading `kern_mutex.c` once, even briefly, gives you a useful intuition. The mutex is not magic. It is a compare-and-swap with a fallback to a sleep queue. Everything else is bookkeeping and optimization.

The primitives you use (`mtx_lock`, `mtx_unlock`) are thin wrappers around these internals. Understanding them means you can reason about their cost, their guarantees, and their limits. That is the payoff.

11.20 Reference: A Mini-Glossary of Concurrency Vocabulary

Terminology matters in concurrency, more than in most subjects, because people who disagree about terminology often end up disagreeing about whether their code is correct. A short glossary of the terms used in this chapter:

Atomic operation: a memory operation that is indivisible from the perspective of other CPUs. It completes as a single transaction; no other CPU can observe a partial result.

Barrier / fence: a point in the code past which the compiler and CPU are not allowed to move specific kinds of memory accesses. Barriers come in acquire, release, and full forms.

Critical section: a contiguous region of code that accesses shared state and must execute without interference from concurrent threads.

Deadlock: a situation in which two or more threads are each waiting for a resource held by another, with none able to make progress.

Invariant: a property of a data structure that is true outside of critical sections. Code inside a critical section may temporarily violate the invariant; code outside must not.

Livelock: a situation in which threads are making progress in the sense of executing instructions, but the useful state of the system does not advance. Typically caused by spinning retries that all fail.

Lock-free: describing an algorithm or data structure that avoids mutual-exclusion primitives, typically relying on atomics. Lock-free algorithms guarantee that at least one thread always makes progress; they do not necessarily prevent starvation of specific threads.

Memory ordering: the rules governing when a write on one CPU becomes visible to reads on other CPUs. Different architectures have different models (strongly ordered, weakly ordered, release-acquire).

Mutual exclusion (mutex): a synchronization primitive ensuring that only one thread at a time can execute a protected region.

Priority inversion: a situation in which a low-priority thread holds a resource that a high-priority thread needs, and a medium-priority thread preempts the low-priority holder, effectively blocking the high-priority waiter.

Priority propagation (inheritance): the kernel's mechanism for solving priority inversion by temporarily raising a low-priority holder's priority to match its highest-priority waiter.

Race condition: a situation in which the correctness of a program depends on the exact interleaving of concurrent accesses to shared state, and at least one access is a write.

Sleep mutex (MTX_DEF): a mutex that puts contending threads to sleep. Legal to use in contexts where sleeping is allowed.

Spin mutex (MTX_SPIN): a mutex that causes contending threads to spin in a busy loop. Required in contexts where sleeping is forbidden, such as hardware interrupt handlers.

Starvation: a situation in which a thread is runnable but never actually runs, because other threads are always scheduled ahead of it. Priority inversion is a specific cause of starvation.

Wait-free: a stricter property than lock-free. Every thread is guaranteed to make progress within a bounded number of steps, regardless of what other threads do.

WITNESS: FreeBSD's lock-order and locking-discipline checker. A kernel option that tracks lock acquisitions and warns on violations.

11.21 Reference: Concurrency Patterns in Real FreeBSD Drivers

Before Chapter 12 introduces additional synchronization primitives, it helps to survey how concurrency is handled in real drivers in `/usr/src/sys/dev/`. The patterns below are the ones you will see most often. Each shows that the tools you have learned (a mutex, a sleep channel, selinfo) are the same tools that ship with FreeBSD.

11.21.1 Pattern: Per-Driver Softc Mutex

Nearly every character-device driver in the tree uses a single mutex per softc. Examples:

- `/usr/src/sys/dev/evdev/evdev_private.h` declares `ec_buffer_mtx` for the per-client state.
- `/usr/src/sys/dev/random/randomdev.c` uses `sysctl_lock` for its private configuration.
- `/usr/src/sys/dev/null/null.c` does not use a mutex, because its `cbuf` is effectively stateless; this is the exception that confirms the rule.

The per-softc mutex pattern is not novel, not sophisticated, and not optional. It is the backbone of driver concurrency in FreeBSD. Our `myfirst` driver follows it because every small driver follows it.

11.21.2 Pattern: Sleep Channel on a softc Field

The convention for the `chan` argument to `mtx_sleep` is to use the address of a softc field related to the wait condition. Examples:

- `evdev_read` in `/usr/src/sys/dev/evdev/cdev.c` sleeps on the per-client structure (via `mtx_sleep(client, ...)`) and is woken when new events arrive.
- Our `myfirst_read` sleeps on `&sc->cb` and wakes correspondingly.

The address can be anything; what matters is that sleepers and wakers use the same pointer. Using a struct field's address has the benefit that the channel is visible in source and self-documenting: a reader of the code knows what the thread is waiting for.

11.21.3 Pattern: selinfo for poll() Support

Every driver that supports `poll(2)` or `select(2)` has at least one struct `selinfo`, sometimes two (for read and write readiness). The same two calls appear:

- `selrecord(td, &si)` inside the `d_poll` handler.
- `selwakeup(&si)` when the readiness state changes.

This is exactly what `myfirst` does. The `evdev` driver does it. The `tty` drivers do it. It is the standard form.

11.21.4 Pattern: Bounce Buffer with uiomove

Many drivers that have wrap-around buffers use the bounce-buffer pattern we discussed in Chapter 10: copy bytes from the ring into a stack-local scratch, drop the lock, `uiomove` the scratch to user space, reacquire the lock. Examples:

- `evdev_read` copies a single event structure into a scratch variable before calling `uiomove`.
- `ucom_put_data` in `/usr/src/sys/dev/usb/serial/usb_serial.c` has a similar shape for its circular buffer.
- Our `myfirst_read` has the same shape for the `cbuf`.

This is the idiomatic answer to “how do I do `uiomove` from a wrap-around buffer while holding a mutex?”. The bounce is small (often on the stack, sometimes a dedicated small buffer), and the lock is dropped around the `uiomove`.

11.21.5 Pattern: Counter(9) for Statistics

Modern drivers use `counter(9)` for statistics counters. Examples:

- `/usr/src/sys/net/if.c` uses `if_ierrors`, `if_oerrors`, and many other counters as `counter_u64_t`.
- Many of the network drivers (`ixgbe`, `mlx5`, etc.) use `counter(9)` for their per-queue statistics.

Our `myfirst` migration to `counter(9)` puts us in line with this modern pattern. Older drivers that still use plain atomic counters typically predate the `counter(9)` API; newer code uses `counter(9)`.

11.21.6 Pattern: Detach with Outstanding Users

A recurring challenge is detach when user processes still have the device open. Two common approaches:

Refuse detach while in use. Our driver does this: detach returns EBUSY if `active_fhs > 0`. Simple, safe, but means the module cannot be unloaded while anyone is using it.

Forced detach with `destroy_dev_drain`. The kernel provides `destroy_dev_drain(9)`, which waits for all handlers to return and prevents new ones from starting. Combined with a “this device is going away” flag in the softc, this allows forced detach with graceful completion of in-flight operations. Chapter 12 and beyond cover this in more depth.

For my first, the simpler “refuse detach” approach is correct. A production driver that must support hot-unplug (USB, for example) uses the more complex approach.

11.21.7 Pattern: WITNESS-Documented Lock Order

Drivers with more than one lock document the order. Example:

```
/*
 * Locks in this driver, in acquisition order:
 *   sc->sc_mtx
 *   sc->sc_listmtx
 *
 * A thread holding sc->sc_mtx may acquire sc->sc_listmtx, but
 * not the reverse. See sc_add_entry() for the canonical example.
 */
```

WITNESS validates this ordering at runtime; the comment makes it readable for humans. Our driver has one lock and no ordering rules, but as soon as we add a second (Chapter 12 may introduce one), we will add this kind of documentation.

11.21.8 Pattern: Assertions Everywhere

Real drivers are littered with `KASSERT` and `mtx_assert`. Examples:

- `if_alloc` in `/usr/src/sys/net/if.c` asserts invariants on input structures.
- GEOM code (in `/usr/src/sys/geom/`) has `g_topology_assert` and similar in most functions.
- Network drivers often have `NET_EPOCH_ASSERT()` to confirm the caller is in the right context.

Assertions are cheap in production and life-saving in development. Our Chapter 11 work added several; future chapters will add more.

11.21.9 What Real Drivers Do That Ours Does Not

Three patterns appear in real drivers that our driver does not yet use:

Finer-grained locking. A network driver might have a lock per queue; a storage driver might have a lock per request. Our driver has one lock for everything. For small drivers this is correct; for drivers with hot paths on many cores, it is not enough. Chapter 12’s `sx` lock and Chapter 15’s discussion of RCU-style patterns cover the finer-grained cases.

Lock-free hot paths. `buf_ring(9)` gives multi-producer queues with either single-consumer or multi-consumer dequeue, with no locks on the hot path. `epoch(9)` lets readers proceed lock-free. These are optimizations for specific workloads. A beginner driver should not use them first; the justification should be a measured bottleneck, not a speculative one.

Hierarchical locking with multiple classes. A real driver might use a spin mutex for interrupt context, a sleep mutex for normal work, and an sx lock for configuration. Each has its place; the interactions are governed by strict ordering rules. We will introduce these in Chapter 12 and revisit them in later chapters when specific drivers need them.

11.21.10 The Takeaway

The patterns in `/usr/src/sys/dev/` are not exotic. They are the ones we have been building. An `evdev_client` with a mutex, a sleep channel, and a `selinfo` is structurally the same as a `myfirst_softc` with the same three pieces. Reading a few of these drivers with the tools Chapter 11 has built should feel almost familiar. When something looks strange, it is usually a specialisation (for example, `kqueue` filter registration) that future chapters cover.

This is the compounding payoff of the book: each chapter's patterns make a larger fraction of the real source readable.

11.22 Reference: Common Mutex Idioms

This is a quick-lookup collection of the idioms you will use most often in FreeBSD driver code.

11.22.1 Basic Critical Section

```
mtx_lock(&sc->mtx);  
/* access shared state */  
mtx_unlock(&sc->mtx);
```

11.22.2 Assert Held

```
mtx_assert(&sc->mtx, MA_OWNED);
```

Put at the top of every helper that assumes the mutex is held. Compiles to nothing on non-INVARIANTS kernels; panics on INVARIANTS kernels if the mutex is not held.

11.22.3 Try-Lock

```
if (mtx_trylock(&sc->mtx)) {
    /* got it */
    mtx_unlock(&sc->mtx);
} else {
    /* someone else has it; back off */
}
```

Use when you want to avoid blocking. Useful in timer callbacks that should not contend with I/O handlers; if the lock is taken, skip this tick and retry next time.

11.22.4 Sleep Waiting for a Condition

```
mtx_lock(&sc->mtx);
while (!condition)
    mtx_sleep(&chan, &sc->mtx, PCATCH, "wmesg", 0);
/* condition is true now; do work */
mtx_unlock(&sc->mtx);
```

The while loop is essential. Spurious wake-ups are permitted and common; the thread must re-check the condition after every return from `mtx_sleep`.

11.22.5 Wake Sleepers

```
wakeup(&chan);           /* wake all */
wakeup_one(&chan);       /* wake highest-priority one */
```

Call without holding the mutex. The kernel handles ordering.

11.22.6 Sleep with Timeout

```
error = mtx_sleep(&chan, &sc->mtx, PCATCH, "wmesg", hz * 5);
if (error == EWOULDBLOCK) {
    /* timed out */
}
```

Bound the wait to 5 seconds. Convenient for heartbeats and deadline-driven operations.

11.22.7 Drop and Reacquire Around a Potentially-Sleeping Call

```
mtx_lock(&sc->mtx);
/* snapshot what we need */
snap = sc->field;
mtx_unlock(&sc->mtx);

/* do the sleeping call */
error = uiomove(buf, snap, uio);

mtx_lock(&sc->mtx);
/* update shared state */
sc->other_field = /* ... */;
mtx_unlock(&sc->mtx);
```

This is the pattern our I/O handlers use. The mutex is never held across a sleeping call.

11.22.8 Atomic-Instead-of-Lock for Simple Counters

```
counter_u64_add(sc->bytes_read, got);
```

Faster and more scalable than `mtx_lock`; `sc->bytes_read += got`; `mtx_unlock`.

11.22.9 Check and Set Atomically

```
if (atomic_cmpset_int(&sc->flag, 0, 1)) {
    /* we set it from 0 to 1; we are the "first" */
}
```

No mutex needed. The compare-and-swap itself is atomic.

11.23 Looking Ahead: Bridge to Chapter 12

Chapter 12 is titled *Synchronization Mechanisms*. Its scope is the rest of the FreeBSD synchronization toolkit: condition variables, sleepable shared-exclusive locks, read/write locks, timed waits, and the deeper techniques for debugging deadlocks. Everything in Chapter 12 builds on the mutex foundation Chapter 11 laid down.

The bridge is three specific observations from Chapter 11's work.

First, you already use a “channel” (`&sc->cb`) with `mtx_sleep` and `wakeup`. Chapter 12 introduces **condition variables** (`cv(9)`), which are a named, structured alternative to the anonymous-channel pattern. You will

see that `cv_wait_sig(&cb_has_data, &sc->mtx)` is often clearer than `mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", 0)`, especially when there are multiple conditions the thread might wait on.

Second, your driver's one mutex serializes everything, including reads that could theoretically proceed in parallel. Chapter 12 introduces `sx(9)` sleepable shared-exclusive locks, which allow multiple readers to hold the lock simultaneously while serializing writers. You will reason about when that design is appropriate (read-heavy workloads, configuration state) and when it is overkill (small critical sections where the mutex is already fine).

Third, your blocking path blocks indefinitely. Chapter 12 introduces **timed waits**: `mtx_sleep` with a nonzero `timo`, `cv_timedwait`, and `sx_sleep` with timeouts. You will learn how to bound the waiting time so a user can press Ctrl-C and have the driver respond within a sensible interval.

Specific topics Chapter 12 will cover include:

- The `cv_wait`, `cv_signal`, `cv_broadcast`, and `cv_timedwait` primitives.
- The `sx(9)` API: `sx_init`, `sx_slock`, `sx_xlock`, `sx_sunlock`, `sx_xunlock`, `sx_downgrade`, `sx_try_upgrade`.
- Reader/writer locks (`rw(9)`) as a spin-mutex sibling of `sx`.
- Timeout handling and the `sbintime_t` family of time primitives.
- Deadlock debugging in depth, including the WITNESS lock-order list.
- Lock-order design patterns and the `LORD_*` conventions.
- A concrete application: upgrading parts of the driver to use `sx` and `cv` where appropriate.

You do not need to read ahead. Chapter 11's material is sufficient preparation. Bring your Stage 3 or Stage 5 driver, your test kit, and your WITNESS-enabled kernel. Chapter 12 starts where Chapter 11 ended.

A small closing reflection. You have just done something unusual. Most driver tutorials teach mutex usage as a formula: put a `mtx_lock` here and a `mtx_unlock` there, and the driver will work. You have done the harder thing: you have understood what the formula means, when it is necessary, why it is sufficient, and how to verify it. That understanding is what separates a driver writer from a driver author. Every chapter from here forward builds on it.

Take a moment. Appreciate how far you have come from the opening "Hello, kernel!" of Chapter 7. Then turn the page.

12 Synchronization Mechanisms

12.1 Reader Guidance & Outcomes

Chapter 11 ended with a driver that was, for the first time in this book, *verifiably* concurrent. You had a single mutex protecting the circular buffer, atomic counters that scaled to many cores, `WITNESS` and `INVARIANTS` watching every lock acquisition, a stress-test kit that ran on a debug kernel, and a `LOCKING.md` document that any future maintainer (including future you) could read to understand the concurrency story. That was real progress. It was not, however, the end of the story.

The synchronization toolkit FreeBSD gives you is much larger than the single primitive Chapter 11 introduced. The mutex you used is the right answer for many situations. It is also the wrong answer for several others. A read-mostly configuration table that twenty threads scan ten thousand times per second wants something other than a mutex serializing the reads. A blocking read that should respond to Ctrl-C within milliseconds wants something other than `mtx_sleep(9)` with no timeout. A coordinated wake-up across a dozen waiters, one per condition, wants something more expressive than an anonymous channel pointer like `&sc->cb`. The kernel has primitives for each of these, and Chapter 12 is where we meet them.

This chapter does for the rest of the synchronization toolkit what Chapter 11 did for the mutex. We introduce each primitive with motivation first, build the mental model, ground it in real FreeBSD source, apply it to the running `myfirst` driver, and verify the result against a `WITNESS` kernel. By the end you will be able to read a real driver and recognise, by the choice of primitive alone, what its author was trying to express. You will also be able to make those choices yourself, in your own driver, without reaching for the wrong tool out of habit.

12.1.1 Why This Chapter Earns Its Own Place

It would be possible, in principle, to stop with Chapter 11. A mutex, an atomic counter, and `mtx_sleep` cover the simple cases. Many small drivers in the FreeBSD tree do not use anything else.

The trouble is that “many small drivers” is not where most of the bugs live. The drivers people maintain longest are the ones that grew. A USB device driver started small, then acquired a control channel, then a configuration table that user space could change at runtime, then a separate event queue with its own waiters. Every one of those additions exposed the limits of “one mutex protects everything”. A driver writer who only knows the mutex ends up either misusing it (a held-too-long mutex blocks the whole subsystem) or working around it (a tangle of busy-wait loops, racy retries, and global flags that “should not happen but sometimes do”). The synchronization primitives this chapter teaches exist precisely to keep those workarounds out of the code.

Each primitive is a different shape of agreement between threads. A mutex says *only one of us at a time*. A condition variable says *I will wait for a specific change you will tell me about*. A shared/exclusive lock says *many of us may read; only one of us may write*. A timed sleep says *and please give up if it is taking too long*. A driver that uses each tool for what it is good at reads cleanly, behaves predictably, and remains comprehensible

long after the original author has stopped looking at it. A driver that uses one tool for everything either suffers in performance or hides bugs in places no one is looking.

This chapter is therefore a vocabulary chapter as much as it is a mechanics chapter. We do introduce the APIs and we do walk through code. The deeper goal is to give you the words for what you are trying to say.

12.1.2 Where Chapter 11 Left the Driver

A quick checkpoint, because Chapter 12 builds directly on top of the Chapter 11 deliverables. If any of the following is missing or feels uncertain, return to Chapter 11 before starting this chapter.

- Your `myfirst` driver compiles cleanly with `WARNS=6`.
- It uses `MYFIRST_LOCK(sc)`, `MYFIRST_UNLOCK(sc)`, and `MYFIRST_ASSERT(sc)` macros that expand to `mtx_lock`, `mtx_unlock`, and `mtx_assert(MA_OWNED)` on the device-wide `sc->mtx` (an `MTX_DEF` sleep mutex).
- The `cbuf`, the per-descriptor counters, the open count, and the active-descriptor count are all protected by `sc->mtx`.
- The byte counters `sc->bytes_read` and `sc->bytes_written` are `counter_u64_t` per-CPU counters; they do not need the mutex.
- The blocking read and write paths use `mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd"|"myfwr", 0)` as their wait primitive and `wakeup(&sc->cb)` as the matching wake.
- `INVARIANTS` and `WITNESS` are enabled in your test kernel; you have built and booted it.
- A `LOCKING.md` document accompanies the driver and lists every shared field, every lock, every wait channel, and every “deliberately not locked” decision with a justification.
- The Chapter 11 stress kit (`producer_consumer`, `mp_stress`, `mt_reader`, `lat_tester`) builds and runs cleanly.

That driver is the substrate this chapter starts from. We will not throw it away. We will replace some primitives with better-fitting ones, add a small new subsystem to give the new primitives something to protect, and finish with a driver whose synchronization design is both more capable and easier to read.

12.1.3 What You Will Learn

When you close this chapter you should be able to:

- Explain what *synchronization* means in a kernel-level sense, and distinguish it from the narrower concept of *mutual exclusion*.
- Map the FreeBSD synchronization toolkit onto a small decision tree: mutex, condition variable, shared/exclusive lock, reader/writer lock, atomic, sleep with timeout.
- Replace anonymous wait channels with named condition variables (`cv(9)`), and explain why that change improves both correctness and readability.
- Use `cv_wait`, `cv_wait_sig`, `cv_wait_unlock`, `cv_signal`, `cv_broadcast`, and `cv_broadcastpri` correctly with respect to their interlock mutex.
- Bound a blocking operation by a timeout using `cv_timedwait_sig` (or `mtx_sleep` with a non-zero `timo` argument), and design the caller’s response when the timeout fires.
- Distinguish `EINTR`, `ERESTART`, and `EWOULDBLOCK`, and decide which the driver should return when a wait fails.

- Choose between `sx(9)` (sleepable) and `rw(9)` (spin-based) reader/writer locks, understand the rules each places on the calling context, and apply `sx_init`, `sx_xlock`, `sx_slock`, `sx_xunlock`, `sx_sunlock`, `sx_try_upgrade`, and `sx_downgrade`.
- Design a multi-reader, single-writer arrangement that uses one lock for the data path and another for the configuration path, with a documented lock order and a WITNESS-verified absence of inversions.
- Read WITNESS warnings precisely enough to identify the exact lock pair and the source line of the violation.
- Use the in-kernel debugger commands `show locks`, `show all locks`, `show witness`, and `show lockchain` to inspect a system that has hung on a synchronization bug.
- Build a stress workload that exercises the driver across descriptors, `sysctls`, and timed waits at the same time, and read the output of `lockstat(1)` to find the contended primitives.
- Refactor the driver into a shape where the synchronization story is documented, the lock order is explicit, and the version string reflects the new architecture.

That is a substantial list. None of it is optional for a driver that aspires to outlast its author. All of it builds on what Chapter 11 left in your hands.

12.1.4 What This Chapter Does Not Cover

Several adjacent topics are deliberately deferred:

- **Callouts (`callout(9)`).** Chapter 13 introduces timed work that fires from the kernel's clock infrastructure. We touch the topic here only as a sleep-with-timeout primitive seen from the driver's blocking call; the full callout API and its rules belong in Chapter 13.
- **Taskqueues (`taskqueue(9)`).** Chapter 16 introduces the kernel's deferred-work framework. Several drivers use a taskqueue to decouple the blocking thread from the wake-up signal, but doing so well requires its own chapter.
- **epoch(9) and read-mostly lock-free patterns.** Network drivers in particular use `epoch(9)` to let readers proceed without acquiring a lock at all. The mechanism is subtle and is best taught alongside the network driver subsystem in Part 6.
- **Interrupt-context synchronization.** Real hardware interrupt handlers add another layer of constraint on what locks you can hold and which sleep primitives are legal. Chapter 14 introduces interrupt handlers and revisits the synchronization rules from inside that context. For Chapter 12 we stay entirely in process and kernel-thread context.
- **Lockless data structures.** `buf_ring(9)` and friends are effective tools for hot paths, but they reward careful study and require a specific workload to pay back their complexity. Part 6 (Chapter 28) introduces them when a driver in the book actually needs one.
- **Distributed and cross-machine synchronization.** Out of scope. We are a single-host operating system in this book.

Staying inside those lines keeps the chapter focused on what it can teach well. The reader of Chapter 12 should finish with confident control of `cv(9)`, `sx(9)`, and timed waits, and a working sense of where `rw(9)` and `epoch(9)` fit; that confidence is what makes the later chapters readable when they show up.

12.1.5 Estimated Time Investment

- **Reading only:** about three hours. The new vocabulary (condition variables, shared/exclusive locks, sleep-ability rules) takes time to absorb even though the API surface is small.
- **Reading plus typing the worked examples:** six to eight hours over two sessions. The driver evolves in four small stages; each stage adds one primitive.
- **Reading plus all labs and challenges:** ten to fourteen hours over three or four sessions, including time for stress runs and `lockstat(1)` analysis.

If you find yourself confused midway through Section 4, that is normal. The shared/exclusive distinction is genuinely new even for readers comfortable with mutexes, and the temptation to use `sx` for the data path is exactly the temptation Section 5 exists to resolve. Stop, re-read Section 4's example, and continue when the model has settled.

12.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches the Chapter 11 Stage 3 (`counter9`) or Stage 5 (`KASSERTs`) tree. Stage 5 is preferred because the assertions catch new bugs faster.
- Your lab machine is running FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly. The Chapter 11 reference section “Building and Booting a Debug Kernel” has the recipe.
- You read Chapter 11 carefully. The mutex rules, the sleep-with-mutex rule, the lock-order discipline, and the `WITNESS` workflow are all assumed knowledge here.
- You have run the Chapter 11 stress kit at least once and seen it pass.

If any of the above is shaky, fixing it now is a much better investment than pushing through Chapter 12 and trying to debug from a moving foundation.

12.1.7 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep `/usr/src/sys/kern/kern_condvar.c`, `/usr/src/sys/kern/kern_sx.c`, and `/usr/src/sys/kern/kern_rwlock.c` bookmarked. Each one is short, well-commented, and the source of authority for what the primitive actually does. Several times in the chapter we will ask you to glance at a specific function. A minute spent there will make the surrounding paragraphs easier to absorb.

A note on line numbers. When we point you at a specific function later in the chapter, open the file and search for the symbol rather than jumping to a numeric line. `_cv_wait_sig` lives in `/usr/src/sys/kern/kern_condvar.c` and `sleepq_signal` in `/usr/src/sys/kern/subr_sleepqueue.c` in the 14.3 tree at time of writing; the names will carry across future point releases, but the line each one sits on will not. The durable reference is always the symbol.

Second, run every code change you make under `WITNESS`. The synchronization primitives we introduce in this chapter have stricter rules than the mutex did. `WITNESS` is the cheapest way to discover that you have broken

one. The Chapter 11 reference section “Building and Booting a Debug Kernel” walks through the kernel build if you need it; do not skip it now.

Third, type the driver changes by hand when you can. The companion source under `examples/part-03/ch12-synchronization-mechanisms/` is the canonical version, but the muscle memory of typing `cv_wait_sig(&sc->data_cv, &sc->mtx)` once is worth more than reading it ten times. The chapter shows the changes incrementally; mirror that incremental pace in your own copy of the driver.

12.1.8 Roadmap Through the Chapter

The sections in order are:

1. What synchronization is in the kernel, and where the various primitives sit in a small decision tree.
2. Condition variables, the cleaner alternative to anonymous wakeup channels, and the first refactor of the `myfirst` blocking paths.
3. Timeouts and interruptible sleep, including signal handling and the choice between `EINTR`, `ERESTART`, and `EWOULDBLOCK`.
4. The `sx(9)` lock, which finally lets us express “many readers, occasional writer” without serializing every reader.
5. A multi-reader, single-writer scenario in the driver: a small configuration subsystem, the lock order between the data path and the configuration path, and the `WITNESS` discipline that keeps it correct.
6. Debugging synchronization issues, including a careful tour of `WITNESS`, the in-kernel debugger commands for inspecting locks, and the most common deadlock patterns.
7. Stress testing under realistic I/O patterns, with `lockstat(1)`, `dtrace(1)`, and the existing Chapter 11 testers extended for the new primitives.
8. Refactoring and versioning the driver: a clean `LOCKING.md`, a bumped version string, an updated changelog, and a regression run that validates the whole thing.

Hands-on labs and challenge exercises follow, then a troubleshooting reference, a wrapping-up section, and a bridge to Chapter 13.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, the debugging section and the refactoring section stand alone and make good single-sitting reads.

12.2 Section 1: What Is Synchronization in the Kernel?

Chapter 11 used the words *synchronization*, *locking*, *mutual exclusion*, and *coordination* somewhat interchangeably. That was acceptable when the only primitive on the table was the mutex, because the mutex collapses all those ideas into one mechanism. With the broader toolkit Chapter 12 introduces, the words start to mean different things, and getting them straight early prevents a lot of confusion later.

This section establishes the vocabulary. It also draws the small decision tree we will refer back to throughout the rest of the chapter when we ask “which primitive should I reach for here?”.

12.2.1 What Synchronization Means

Synchronization is the broader idea: any mechanism by which two or more concurrent threads of execution coordinate their access to shared state, their progress through a shared procedure, or their timing relative to each other.

Three flavours of coordination cover almost everything a driver needs:

Mutual exclusion: at most one thread at a time inside a critical region. Mutexes and exclusive locks deliver this. The guarantee is structural: while you are inside, nobody else is.

Shared access with restricted writes: many threads may inspect a value at the same time, but a thread that wants to change it must wait until everyone is out and nobody else is in. Shared/exclusive locks deliver this. The guarantee is asymmetric: readers tolerate each other; a writer tolerates nobody.

Coordinated waiting: a thread suspends until some condition becomes true, and another thread that knows the condition has become true wakes the waiter. Condition variables and the older `mtx_sleep / wakeup` channel mechanism deliver this. The guarantee is temporal: the waiter does not consume CPU while it is waiting; the waker does not have to know who is waiting; the kernel handles the rendezvous.

A driver typically uses all three. The `cbuf` in `myfirst` already uses two: mutual exclusion to protect the `cbuf` state, and coordinated waiting to suspend a reader when the buffer is empty. Chapter 12 adds the third (shared access) and refines the second (named condition variables instead of anonymous channels).

12.2.2 Synchronization Versus Locking

It is tempting to think that *synchronization* and *locking* are the same word. They are not.

Locking is one technique for synchronization. It is the family of mechanisms that operate on a shared object and grant or refuse access to it. Mutexes, `sx` locks, `rw` locks, and `lockmgr` locks are all locks.

Synchronization includes locking but also includes coordinated waiting (condition variables, sleep channels), event signalling (semaphores), and timed coordination (callouts, timed sleeps). A waiting thread may not be holding any lock at the moment it is suspended (in fact, with `mtx_sleep` and `cv_wait`, the lock is dropped during the wait), and yet it is participating in synchronization with the threads that will eventually wake it.

The mental model that follows from this distinction is useful: locking is *about access*; coordinated waiting is *about progress*. Most non-trivial driver code mixes both. The mutex around the `cbuf` is locking. The sleep on `&sc->cb` while the buffer is empty is coordinated waiting. Both are synchronization. Either one alone would not be enough.

12.2.3 Blocking Versus Spinning

Two basic shapes recur across the FreeBSD primitives. Knowing which shape a primitive uses is half the battle of choosing among them.

Blocking primitives put a contending thread to sleep on the kernel's sleep queue. The sleeping thread consumes no CPU; it will be made runnable again when the holding thread releases or the awaited condition is signalled. Blocking primitives are appropriate when the wait could be long, when the thread is in a context where sleeping

is legal, and when keeping the CPU busy in a tight retry loop would harm overall throughput. `MTX_DEF` mutexes, `cv_wait`, `sx_xlock`, `sx_slock`, and `mtx_sleep` are all blocking.

Spinning primitives keep the thread on-CPU and busy-wait on the lock state, retrying atomically until the holder releases. They are appropriate only when the critical section is very short, when the thread cannot legally sleep (for example, inside a hardware interrupt filter), or when the cost of a context switch would dwarf the wait. `MTX_SPIN` mutexes and `rw(9)` locks are spinning. The kernel itself uses spin locks for the very lowest layers of the scheduler and the interrupt machinery.

Chapter 12 stays mostly in the blocking world. Our driver runs in process context; it is permitted to sleep; the gain from spinning would be marginal. The one exception is when we mention `rw(9)` as a sibling of `sx(9)` for completeness; the deeper treatment of `rw(9)` belongs to chapters where a driver uses it for a real reason.

12.2.4 A Small Map of FreeBSD Primitives

The FreeBSD synchronization toolkit is larger than people expect. For driver work, eight primitives carry essentially all of the load:

Primitive	Header	Behaviour	Best for
<code>mtx(9)</code> (<code>MTX_DEF</code>)	<code>sys/mutex.h</code>	Sleep mutex; one owner at a time	Default lock for most softc state
<code>mtx(9)</code> (<code>MTX_SPIN</code>)	<code>sys/mutex.h</code>	Spin mutex; disables interrupts	Short critical sections in interrupt context
<code>cv(9)</code>	<code>sys/condvar.h</code>	Named wait channel; pairs with a mutex	Coordinated waits with multiple distinct conditions
<code>sx(9)</code>	<code>sys/sx.h</code>	Sleep-mode shared/exclusive lock	Read-mostly state in process context
<code>rw(9)</code>	<code>sys/rwlock.h</code>	Spin-mode reader/writer lock	Read-mostly state in interrupt or short critical sections
<code>rmlock(9)</code>	<code>sys/rmlock.h</code>	Read-mostly lock; cheap reads, expensive writes	Hot read paths with rare configuration changes
<code>sema(9)</code>	<code>sys/sema.h</code>	Counting semaphore	Resource accounting; rarely needed in drivers
<code>epoch(9)</code>	<code>sys/epoch.h</code>	Read-mostly synchronization with deferred reclamation	Hot read paths in network/storage drivers

The ones we use in this chapter, in addition to the mutex Chapter 11 introduced, are `cv(9)` and `sx(9)`. `rw(9)` is mentioned for context. `rmlock(9)`, `sema(9)`, and `epoch(9)` are deferred to later chapters where the driver in question actually justifies them.

12.2.5 Atomics in the Same Map

Strictly speaking, the `atomic(9)` primitives Chapter 11 covered are not part of the synchronization toolkit at all. They are *concurrent operations*: indivisible memory accesses that compose with the locks but do not themselves provide blocking, waiting, or signalling. They sit alongside the locks in the way a power tool sits alongside a hand tool: useful for a specific job, not a substitute for the rest of the toolkit.

We will reach for atomics in this chapter only when a single-word read-modify-write is the right shape for what we want to express. For everything else, the locks and the condition variables earn their keep.

12.2.6 A First Decision Tree

When you face a piece of shared state and you are deciding how to protect it, work the questions in this order. The first question that yields a definitive answer ends the search.

1. **Is the state a single word that needs a single read-modify-write?** Use an atomic. (Examples: a generation counter, a flag word.)
2. **Does the state have a composite invariant that spans more than one field, and is the access in process context?** Use an `MTX_DEF` mutex. (Examples: the `cbuf` head/used pair, a queue head/tail pair.)
3. **Is the access in interrupt context, or must the critical section disable preemption?** Use an `MTX_SPIN` mutex.
4. **Is the state read frequently from many threads but written rarely?** Use `sx(9)` for sleepable callers (most driver code) or `rw(9)` for short critical sections that may run in interrupt context.
5. **Do you need to wait until a specific condition becomes true (not just acquire a lock)?** Use a condition variable (`cv(9)`) paired with the mutex that protects the condition. The older `mtx_sleep/wakeup` channel mechanism is the legacy alternative; new code should prefer `cv(9)`.
6. **Do you need to bound a wait by wall time?** Use the timed variant (`cv_timedwait_sig`, `mtx_sleep` with a non-zero `timo` argument, `msleep_sbt(9)`) and design the caller to handle `EWOULDBLOCK`.

The tree compresses into a short slogan: *atomic for a word, mutex for a structure, sx for read-mostly, cv for waiting, timed for bounded waiting, spin only when you must.*

12.2.7 A Worked Decision: Where Each myfirst State Sits

Walk the tree against each piece of state in your current driver. The exercise is short and useful.

- The `cbuf` indices and backing memory: composite invariant, process context. Use an `MTX_DEF` mutex. (This is what Chapter 11 chose.)
- `sc->bytes_read`, `sc->bytes_written`: high-frequency counters, rarely read. Use `counter(9)` per-CPU counters. (This is what Chapter 11 migrated to.)
- `sc->open_count`, `sc->active_fhs`: low-frequency integers, fine under the same mutex as the `cbuf`. No reason to split them out.
- `sc->is_attached`: a flag, read often at handler entry, written once per attach/detach. The Chapter 11 design reads it without the mutex as an optimization, re-checks after every sleep, and writes it under the mutex.
- The “is the buffer empty?” condition that read waiters block on: a coordinated wait. Currently uses `mtx_sleep(&sc->cb, ...)`. Section 2 will replace this with a named condition variable.

- The “is there room in the buffer?” condition that write waiters block on: another coordinated wait, currently sharing the same channel. Section 2 will give it its own condition variable.
- A future configuration subsystem (added in Section 5): read frequently by every I/O call, written occasionally by a sysctl handler. Use `sx(9)`.

Notice how the tree did the work. We did not have to invent a custom design for any of these; we asked the questions and the right primitive fell out.

12.2.8 Real-World Analogy: Doors, Hallways, and Whiteboards

A small analogy for readers who like them. Imagine a research lab.

The `cbuf` is a precision instrument that only one person at a time can operate. The lab installs a door with a single key on it. Anyone who wants to use the instrument must take the key. While they have the key, nobody else can enter. That is a mutex.

The lab has a status whiteboard that lists the current calibration of the instrument. Anyone may read the whiteboard at any time; they do not interfere with each other. Only the lab manager updates the whiteboard, and they only do so after waiting for everyone else to step away. That is a shared/exclusive lock.

The lab has a coffee pot. People who want coffee but find the pot empty leave a note on the bulletin board: “I am in the lounge; wake me when there is coffee.” When somebody brews a fresh pot, they check the bulletin board and tap the shoulders of everyone whose note is for “coffee”, regardless of how long ago they wrote it. That is a condition variable.

The same person who left the coffee note may also leave a second note: “but only wait fifteen minutes; if no coffee by then, I am going to the cafeteria.” That is a timed wait.

Each mechanism in the lab matches a real coordination problem. None of them is a substitute for any of the others. The same is true in the kernel.

12.2.9 Comparing Primitives Side by Side

Sometimes seeing the primitives next to each other in a single table makes the choice immediate. The properties that differ across them are: whether they block or spin, whether they support shared (multi-reader) access, whether they are sleepable from the perspective of the holder, whether they support priority propagation, whether they are interruptible by signals, and whether the calling context can include sleeping operations.

	<code>mtx(9)</code>	<code>mtx(9)</code>			
Property	<code>MTX_DEF</code>	<code>MTX_SPIN</code>	<code>sx(9)</code>	<code>rw(9)</code>	<code>cv(9)</code>
Behaviour when contended	Sleep	Spin	Sleep	Spin	Sleep
Multiple holders	No	No	Yes (shared)	Yes (read)	n/a (waiters)

Property	mtx(9) MTX_DEF	mtx(9) MTX_SPIN	sx(9)	rw(9)	cv(9)
Caller may sleep while holding	Yes	No	Yes	No	n/a
Priority propagation	Yes	No (interrupts disabled)	No	Yes	n/a
Signal-interruptible variant	n/a	n/a	_sig	No	_sig
Has timed wait variant	mtx_sleep w/ timo	n/a	n/a	n/a	cv_timedwait
Suitable in interrupt context	No	Yes	No	Yes (with care)	No

Two things stand out. First, the column for `cv(9)` does not really fit the same questions because `cv` is not a lock; it is a wait primitive. We include it in the comparison because the choice “should I wait or spin?” is essentially the same as “should I block on a `cv` or spin on an `MTX_SPIN`?”. Second, the priority propagation column distinguishes `mtx(9)` and `rw(9)` from `sx(9)`. `sx(9)` does not propagate priority because its sleep queues do not support it. In practice this matters only for real-time workloads; ordinary drivers do not notice.

Use the table as a quick lookup when you face a new piece of state. The decision tree above gives you the *order* to ask the questions; the table gives you the *answer* once you have asked them.

12.2.10 A Note on Semaphores

FreeBSD also has a counting semaphore primitive (`sema(9)`) that is occasionally useful. A semaphore is a counter; threads decrement it (via `sema_wait` or `sema_trywait`) and block if the counter is zero; threads increment it (via `sema_post`) and may wake a waiter. The classic use is bounded-resource accounting: a queue with a maximum length where producers block when the queue is full and consumers block when it is empty.

Most driver problems that look semaphore-shaped can be solved equally well with a mutex plus a condition variable. The `cv` approach has the advantage that you can attach naming to each condition; the semaphore is anonymous. The semaphore has the advantage that the waiting and signalling are part of the primitive itself, with no need for a separate interlock.

This chapter does not use `sema(9)`. We mention it for completeness; if you encounter it in real driver source, you now know what shape it has.

12.2.11 Wrapping Up Section 1

Synchronization is broader than locking, locking is broader than mutual exclusion, and the FreeBSD toolkit gives you a different primitive for each shape of coordination problem you might encounter. Atomics for

single-word updates, mutexes for composite invariants, sx locks for read-mostly state, condition variables for coordinated waiting, timed sleeps for bounded waiting, and spin variants only when the calling context demands them.

That decision tree will guide every choice we make for the rest of the chapter. Section 2 starts with the first refactor: turning the anonymous `&sc->cb` wakeup channel from Chapter 11 into a pair of named condition variables.

12.3 Section 2: Condition Variables and Sleep/Wakeup

The `myfirst` driver as Chapter 11 left it has two distinct conditions that block the I/O paths. A reader sleeps when `cbuf_used(&sc->cb) == 0` and waits for “data has arrived”. A writer sleeps when `cbuf_free(&sc->cb) == 0` and waits for “room has appeared”. Both currently sleep on the same anonymous channel, `&sc->cb`. Both wakeups call `wakeup(&sc->cb)` after every state change, which wakes every sleeper regardless of which condition triggered the change.

That arrangement works. It is also wasteful, opaque, and harder to reason about than it needs to be. This section introduces condition variables (`cv(9)`), the cleaner FreeBSD primitive for the same coordinated-wait pattern, and walks through the refactor that gives each condition its own variable.

12.3.1 Why Mutex Plus Wakeup Is Not Enough

Chapter 11 used `mtx_sleep(chan, mtx, pri, wmesg, timo)` and `wakeup(chan)` to coordinate the read and write paths. The pair has the great virtue of simplicity: any pointer can be a channel, the kernel keeps a hash table of waiters per channel, and a wakeup on the right channel finds them all.

The vices appear as the driver grows.

The channel is anonymous. A reader of the source sees `mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", 0)` and has to infer, from the context and the `wmesg` string, what condition the thread is waiting for. There is nothing in `&sc->cb` that says “data available” instead of “room available” or “device detached”. The channel is just a pointer the kernel uses as a hash key; the meaning lives in the convention.

Multiple conditions share one channel. When `myfirst_write` finishes a write, it calls `wakeup(&sc->cb)`. That wakes every waiter on `&sc->cb`, including readers waiting for data (correct) and writers waiting for room (incorrect; a write does not free room, it consumes it). Each unwanted waiter goes back to sleep after rechecking its condition. This is the *thundering herd* problem in miniature: the wakeup is correct but expensive.

Lost wakeups are still possible if you are careless. If you ever drop the mutex between checking the condition and entering `mtx_sleep`, a wakeup can fire in that window and be missed. Chapter 11 explained that `mtx_sleep` itself is atomic with the lock drop, which closes the window; but the rule is implicit in the API and easy to violate when refactoring.

The `wmesg` argument is the only label. A debugging engineer who runs `procstat -kk` against a hung process sees `myfrd` and has to remember what that means. The string is at most seven characters; it is a hint, not a structured description.

Condition variables solve all four of these. Each `cv` has a name (its description string is checkable from `dt race` and `procstat`). Each `cv` represents exactly one logical condition; there is no question of which waiters a

`cv_signal` will affect. The `cv_wait` primitive enforces the atomicity of the lock drop by taking the mutex as an argument, so misuse is much harder. And the relationship between the waiter and the waker is expressed in the type itself: both sides reference the same struct `cv`.

12.3.2 What a Condition Variable Is

A **condition variable** is a kernel object that represents a logical condition some threads are waiting for and others will eventually signal. The condition variable does not store the condition; the condition lives in your driver's state, protected by your mutex. The condition variable is the rendezvous point: the place where waiters queue up and where wakers find them.

The data structure is small and lives in `/usr/src/sys/sys/condvar.h`:

```
struct cv {
    const char    *cv_description;
    int           cv_waiters;
};
```

Two fields: a description string used for debugging, and a count of currently-waiting threads (an optimization to skip the wakeup machinery when no one is waiting).

The API is also small:

```
void cv_init(struct cv *cvp, const char *desc);
void cv_destroy(struct cv *cvp);

void cv_wait(struct cv *cvp, struct mtx *mtx);
int cv_wait_sig(struct cv *cvp, struct mtx *mtx);
void cv_wait_unlock(struct cv *cvp, struct mtx *mtx);
int cv_timedwait(struct cv *cvp, struct mtx *mtx, int timo);
int cv_timedwait_sig(struct cv *cvp, struct mtx *mtx, int timo);

void cv_signal(struct cv *cvp);
void cv_broadcast(struct cv *cvp);
void cv_broadcastpri(struct cv *cvp, int pri);

const char *cv_wmesg(struct cv *cvp);
```

(The actual prototypes use `struct lock_object` rather than `struct mtx`; the macros in `condvar.h` substitute the right `&mtx->lock_object` pointer for you. The form above is the form you will write in driver code.)

A few rules and conventions matter from the start.

`cv_init` is called once, after the `cv` structure exists in memory and before any waiter or waker can reach it. The matching `cv_destroy` is called once, after every waiter has either woken up or been forced off the queue, and before the `cv` structure is freed. Lifetime mistakes here cause the same kind of catastrophic crashes that mutex lifetime mistakes cause.

`cv_wait` and its variants must be called with the interlock mutex *held*. Inside `cv_wait`, the kernel atomically drops the mutex and puts the calling thread on the `cv`'s wait queue. When the thread is awakened, the mutex is reacquired before `cv_wait` returns. From your code's perspective, the mutex is held both before and after the call; a different thread could not have observed the gap, even though the gap really existed. This is exactly the same atomic-drop-and-sleep contract `mtx_sleep` provides.

`cv_signal` wakes one waiter, and `cv_broadcast` wakes all waiters. Which waiter `cv_signal` picks is worth stating carefully. The `condvar(9)` man page only promises that it unblocks “one waiter”; it does *not* promise strict FIFO order, and your code must not rely on a specific ordering. What the current FreeBSD 14.3 implementation actually does, inside `sleepq_signal(9)` in `/usr/src/sys/kern/subr_sleepqueue.c`, is scan the `cv`'s sleep queue and pick the thread with the highest priority, breaking ties in favour of the thread that has been sleeping the longest. That is a useful mental model, but treat it as an implementation detail rather than an API guarantee. If correctness depends on which thread wakes up next, your design is probably wrong and should use a different primitive or an explicit queue. Both `cv_signal` and `cv_broadcast` are typically called with the interlock mutex held, although the rule is more about correctness of the surrounding logic than about the primitive itself: if you call `cv_signal` without the interlock, it is possible for a new waiter to arrive and miss the signal. The standard discipline is therefore “hold the mutex, change the state, signal, drop the mutex”.

`cv_wait_sig` returns nonzero if the thread was awakened by a signal (typically `EINTR` or `ERESTART`); zero if it was awakened by `cv_signal` or `cv_broadcast`. Drivers that want their blocking I/O paths to honour Ctrl-C use `cv_wait_sig`, not `cv_wait`. Section 3 explores the signal-handling rules in depth.

`cv_wait_unlock` is the rare variant for when the caller wants the interlock dropped on the *waiting* side and not reacquired on return. Useful in teardown sequences where the caller has no further business with the interlock once the wait completes. Drivers seldom need it; we mention it because you will see it in a few places in the FreeBSD tree, and the chapter does not use it further.

`cv_timedwait` and `cv_timedwait_sig` add a timeout in ticks. They return `EWOLDBLOCK` if the timeout fires before any wakeup arrives. Section 3 explains how to bound a blocking operation with these.

12.3.3 A Worked Refactor: Adding Two Condition Variables to `myfirst`

The Chapter 11 driver had one anonymous channel for both conditions. Stage 1 of this chapter splits it into two named condition variables: `data_cv` (“data is available to read”) and `room_cv` (“room is available to write”).

Add two fields to the `softc`:

```
struct myfirst_softc {
    /* ... existing fields ... */
    struct cv      data_cv;
    struct cv      room_cv;
    /* ... existing fields ... */
};
```

Initialize and destroy them in `attach` and `detach`:

```

static int
myfirst_attach(device_t dev)
{
    /* ... existing setup ... */
    cv_init(&sc->data_cv, "myfirst data");
    cv_init(&sc->room_cv, "myfirst room");
    /* ... rest of attach ... */
}

static int
myfirst_detach(device_t dev)
{
    /* ... existing teardown that cleared is_attached and woke sleepers ... */
    cv_destroy(&sc->data_cv);
    cv_destroy(&sc->room_cv);
    /* ... rest of detach ... */
}

```

A small but important subtlety: detach must not destroy a cv that still has waiters. The Chapter 11 detach path already wakes sleepers and refuses to proceed while `active_fhs > 0`, which means by the time we reach `cv_destroy`, no descriptor is open and no thread can still be inside `cv_wait`. We add a `cv_broadcast(&sc->data_cv)` and `cv_broadcast(&sc->room_cv)` immediately before destroying, as belt-and-braces, in case any background path ever does sneak in.

Update the wait helpers to use the new variables:

```

static int
myfirst_wait_data(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
    struct uio *uio)
{
    int error;

    MYFIRST_ASSERT(sc);
    while (cbuf_used(&sc->cb) == 0) {
        if (uio->uio_resid != nbefore)
            return (-1);
        if (ioflag & IO_NDELAY)
            return (EAGAIN);
        error = cv_wait_sig(&sc->data_cv, &sc->mtx);
        if (error != 0)
            return (error);
        if (!sc->is_attached)
            return (ENXIO);
    }
    return (0);
}

```

```

}

static int
myfirst_wait_room(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
    struct uio *uio)
{
    int error;

    MYFIRST_ASSERT(sc);
    while (cbuf_free(&sc->cb) == 0) {
        if (uio->uio_resid != nbefore)
            return (-1);
        if (ioflag & IO_NDELAY)
            return (EAGAIN);
        error = cv_wait_sig(&sc->room_cv, &sc->mtx);
        if (error != 0)
            return (error);
        if (!sc->is_attached)
            return (ENXIO);
    }
    return (0);
}

```

Three things changed and nothing else. `mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", 0)` became `cv_wait_sig(&sc->data_cv, &sc->mtx)`. The corresponding line in the write path became `cv_wait_sig(&sc->room_cv, &sc->mtx)`. The `wmesg` string is gone (the `cv`'s description string takes its place), the channel is now a real object with a name, and the `PCATCH` flag is implicit in the `_sig` suffix.

Update the wakers. After a successful read, instead of waking everyone on `&sc->cb`, wake only the writers waiting for room:

```

got = myfirst_buf_read(sc, bounce, take);
fh->reads += got;
MYFIRST_UNLOCK(sc);

if (got > 0) {
    cv_signal(&sc->room_cv);
    selwakeup(&sc->wsel);
}

```

After a successful write, wake only the readers waiting for data:

```

put = myfirst_buf_write(sc, bounce, want);
fh->writes += put;

```

```
MYFIRST_UNLOCK(sc);

if (put > 0) {
    cv_signal(&sc->data_cv);
    selwakeup(&sc->rsel);
}
```

Two improvements come together. First, a successful read no longer wakes other readers (a wasted wakeup that immediately goes back to sleep); only writers, who actually have a use for the freed room, are woken. Symmetric on the write side. Second, the source is now self-explanatory: `cv_signal(&sc->room_cv)` reads as “there is room now”; the reader does not have to remember what `&sc->cb` means.

Notice we added a `if (got > 0)` and `if (put > 0)` guard before the signal. There is no point waking a sleeper if nothing changed; the empty signal is benign but cheap to skip. This is a small optimization and a clarification: the signal is announcing a state change, and the guard says so.

`cv_signal` instead of `cv_broadcast`: we wake one waiter per state change, not all of them. The state change (one byte freed by a read, one byte added by a write) is enough for one waiter to make progress. If multiple waiters are blocked, the next signal will wake the next one. This is the per-event correspondence the `cv` API encourages.

12.3.4 When to Signal Versus Broadcast

`cv_signal` wakes one waiter. `cv_broadcast` wakes all of them. The choice matters more than people expect.

Use `cv_signal` when:

- The state change is a per-event update (one byte arrived; one descriptor freed; one packet enqueued). One waiter making progress is enough; the next event will wake the next waiter.
- All waiters are equivalent and any one of them can consume the change.
- The cost of waking a waiter that has nothing to do is non-trivial (because the waiter immediately re-checks the condition and sleeps again).

Use `cv_broadcast` when:

- The state change is global and all waiters need to know (the device is being detached; the configuration changed; the buffer was reset).
- The waiters are not equivalent; each may be waiting on a slightly different sub-condition that the broadcast resolves.
- You want to avoid the bookkeeping of figuring out which subset of waiters can proceed, at the cost of waking some that will go back to sleep.

For the `myfirst` data and room conditions, `cv_signal` is the right call. For the detach path, `cv_broadcast` is the right call: the detach must wake every blocked thread so they can return `ENXIO` and exit cleanly.

Add the broadcasts to detach:

```
MYFIRST_LOCK(sc);
sc->is_attached = 0;
cv_broadcast(&sc->data_cv);
cv_broadcast(&sc->room_cv);
MYFIRST_UNLOCK(sc);
```

That replaces the Chapter 11 `wakeup(&sc->cb)`. The two broadcasts wake every reader and every writer that may be sleeping; each one re-checks `is_attached`, sees that it is now zero, and returns `ENXIO`.

12.3.5 A Subtle Trap: `cv_signal` Without the Mutex

The standard discipline says “hold the mutex, change the state, signal, drop the mutex”. You may have noticed our refactor signals *after* dropping the mutex (the `MYFIRST_UNLOCK(sc)` precedes the `cv_signal`). Is that wrong?

It is not wrong, and the reason is worth understanding.

The race the discipline is meant to prevent is this: a waiter checks the condition (false), is about to call `cv_wait`, but has dropped the mutex. The waker now changes the state, sees no one in the `cv`’s wait queue (because the waiter has not yet enqueued), and skips the signal. The waiter then enqueues and sleeps forever.

`cv_wait` itself prevents that race by enqueueing the waiter on the `cv` *before* dropping the mutex. The kernel’s internal `cv`-queue lock is acquired while the caller’s mutex is still held, the thread is added to the wait queue, and only then is the caller’s mutex dropped and the thread descheduled. Any subsequent `cv_signal` on that `cv`, with or without the caller’s mutex held, will find the waiter and wake it.

The discipline of signalling under the mutex is therefore a defensive convention rather than a strict requirement. We follow it for the simple cases (because it is harder to get wrong) and we relax it for the case where signalling outside the mutex is a measurable improvement (it lets the woken thread acquire the mutex without contending with the signaller). For `myfirst`, signalling after `MYFIRST_UNLOCK(sc)` shaves a few cycles off the wake path; for safety we still take care to not allow a window between the state change and the signal where the state could be reverted. In our refactor, the only thread that can revert the state is also operating under the mutex, so the window is closed.

If you are uncertain, signal under the mutex. It is the safer default and the cost is negligible.

12.3.6 Verifying the Refactor

Build the new driver and load it on a `WITNESS` kernel. Run the Chapter 11 stress kit. Three things should happen:

- All tests pass with the same byte-count semantics as before.
- `dmesg` is silent. No new warnings.
- `procstat -kk` against a sleeping reader now shows the `cv`’s description in the wait-channel column. Tools that report `wmesg` truncate to `WMESGLEN` (eight characters, defined in `/usr/src/sys/sys/user.h`); a description of “myfirst data” therefore shows up as “myfirst ” in `procstat` and `ps`. The full description string remains visible to `dtrace` (which reads `cv_description` directly) and in the source.

If you want the truncated form to be more informative, choose shorter descriptions such as "mfdata" and "mfroom"; the chapter keeps the longer, more readable names because dtrace and the source code use the full string and that is where you spend most of your debugging time.

lockstat(1) will show fewer cv events than the old wakeup mechanism produced wakeups, because the per-condition signalling does not wake threads that have nothing to do. This is the throughput improvement we expected.

12.3.7 A Mental Model: How a cv_wait Plays Out

For readers who learn best from a step-by-step picture, here is the sequence of events when a thread calls cv_wait_sig and is later signalled.

Time t=0: thread A is in myfirst_read. The cbuf is empty.

Time t=1: thread A calls MYFIRST_LOCK(sc). The mutex is acquired. Thread A is now the only thread in any critical section protected by sc->mtx.

Time t=2: thread A enters the wait helper. The check cbuf_used(&sc->cb) == 0 is true. Thread A calls cv_wait_sig(&sc->data_cv, &sc->mtx).

Time t=3: inside cv_wait_sig, the kernel takes the cv-queue spin lock for data_cv, increments data_cv.cv_waiters, and atomically does two things: drops sc->mtx and adds thread A to the cv's wait queue. Thread A's state changes to "sleeping on data_cv".

Time t=4: thread A is descheduled. The CPU runs other threads.

Time t=5: thread B enters myfirst_write from another process. Thread B calls MYFIRST_LOCK(sc). The mutex is currently free; thread B acquires it.

Time t=6: thread B reads from user space (uiomove), commits bytes to the cbuf, updates counters. Thread B calls MYFIRST_UNLOCK(sc).

Time t=7: thread B calls cv_signal(&sc->data_cv). The kernel takes the cv-queue spin lock, finds thread A on the wait queue, decrements cv_waiters, removes thread A from the queue, and marks thread A as runnable.

Time t=8: the scheduler decides thread A is the highest-priority runnable thread (or one of several; FIFO among equal). Thread A is scheduled onto a CPU.

Time t=9: thread A resumes inside cv_wait_sig. The function reacquires sc->mtx (this may itself block if another thread now holds the mutex; if so, thread A is added to the mutex's wait list). Thread A returns from cv_wait_sig with return value 0 (normal wakeup).

Time t=10: thread A continues in the wait helper. The while (cbuf_used(&sc->cb) == 0) check is now false (thread B added bytes). The loop exits.

Time t=11: thread A reads from the cbuf and proceeds.

Three things to take away from the picture. First, the lock state is consistent at every step. The mutex is either held by exactly one thread or held by none; thread A's view of the world is the same before the wait as after. Second, the wakeup is decoupled from the actual scheduling; thread B did not hand the CPU directly to thread A. Third, there is a window between t=9 and t=10 where thread A holds the mutex and another writer could (if

it had been waiting) potentially fill the buffer further. That is fine; thread A's check is on the `cbuf` state at $t=10$, not at $t=7$.

This sequence is the canonical “wait, signal, wake, re-check, proceed” pattern. Every `cv` use in the chapter is an instance of it.

12.3.8 A Look at `kern_condvar.c`

If you have ten minutes, open `/usr/src/sys/kern/kern_condvar.c` and skim. Three functions are particularly worth seeing:

`cv_init` (top of file): very short. It just initializes the description and zeroes the waiter count.

`_cv_wait` (mid-file): the core blocking primitive. It takes the `cv`-queue spin lock, increments `cv_waiters`, drops the caller's interlock, calls the sleep queue machinery to enqueue the thread and yield, and on return decrements `cv_waiters` and reacquires the interlock. The atomic drop-and-sleep is performed by the sleep queue layer, exactly the same machinery that backs `mtx_sleep`. There is nothing magical about `cv` on top of sleep queues; it is a thin, named interface.

`cv_signal` and `cv_broadcastpri`: each takes the `cv`-queue spin lock, finds one (or all) waiters, and uses `sleepq_signal` or `sleepq_broadcast` to wake them.

The takeaway: condition variables are a thin, structured layer on top of the same sleep queue primitives `mtx_sleep` uses. They are not slower; they are not faster; they are clearer.

12.3.9 Wrapping Up Section 2

The refactor in this section gives each waiting condition its own object, its own name, its own waiters' queue, and its own signal. The driver behaves the same to user space, but it now reads more honestly: `cv_signal(&sc->room_cv)` says “there is room”, which is what we mean. The `WITNESS` discipline is preserved; the `mtx_assert` calls in the helpers still hold; the test kit continues to pass. We have moved one level up the synchronization vocabulary without losing any of the safety Chapter 11 built.

Section 3 turns to the orthogonal question of *how long should we wait?*. Indefinite blocking is convenient for the implementation but harsh on the user. Timed waits and signal-aware waits are how a well-behaved driver responds to the world.

12.4 Section 3: Handling Timeouts and Interruptible Sleep

A blocking primitive is, by default, indefinite. A reader that calls `cv_wait_sig` when the buffer is empty will sleep until either someone calls `cv_signal` (or `cv_broadcast`) on the same `cv`, or a signal is delivered to the reader's process. From the kernel's point of view, “indefinite” is a perfectly respectable answer. From the user's point of view, “indefinite” is a hang.

This section is about the two ways the FreeBSD synchronization primitives let you bound a wait: by a wall-clock timeout and by an interruption from a signal. Both are simple to use and both have surprisingly subtle rules around return values. We start with the easier one and work up.

12.4.1 What Goes Wrong With Indefinite Sleeps

Three real problems push us to use timed and interruptible sleeps in a driver.

Hung programs. A user runs `cat /dev/myfirst` in a terminal. There is no producer. The `cat` blocks in `read(2)`, which blocks in `myfirst_read`, which blocks in `cv_wait_sig`. The user presses Ctrl-C. If the wait is interruptible (the `_sig` variant), the kernel delivers `EINTR` and the user gets their shell back. If it is not (`cv_wait` without `_sig`), the kernel ignores the signal and the user has to use Ctrl-Z and `kill %1` from another terminal. Most users do not know how to do that. They reach for the reset button.

Stuck progress. A device driver waits for an interrupt that never arrives because the hardware is wedged. The driver's I/O thread sleeps forever. The whole system slowly fills with processes blocked on this driver. Eventually an administrator notices, but by then there is nothing to do but reboot. A bounded wait would have caught this much earlier.

Bad user experience. A network protocol expects a response within a specified time. A storage operation expects a completion within a service-level agreement. Neither is well-served by a primitive that can wait forever. The driver should be able to enforce a deadline and return a clean error when the deadline is missed.

The FreeBSD primitives that solve these are `cv_wait_sig` and `cv_timedwait_sig`, with the older `mtx_sleep` and `tsleep` family providing the same capabilities through a different shape. We have already met `cv_wait_sig` in Section 2. Here we look more carefully at what its return value tells us and how to add an explicit timeout.

12.4.2 The Three Wait Outcomes

Any blocking sleep primitive can return for one of three reasons:

1. **A normal wakeup.** Some other thread called `cv_signal`, `cv_broadcast`, or (in the legacy API) `wakeup`. The condition this thread was waiting for has changed, and the thread should re-check it.
2. **A signal was delivered to the process.** The thread is being asked to abandon the wait so the signal handler can run. The driver typically returns `EINTR` to user space, which is also the sleep primitive's return value.
3. **A timeout fired.** The thread was waiting with a deadline and the deadline expired before any wakeup arrived. The sleep primitive returns `EWOLDBLOCK`.

The driver's job is to figure out which of the three happened and respond appropriately.

The first case is the easy one. The thread re-checks its condition (the `while` loop around `cv_wait_sig` is what does this); if the condition is now true, the loop ends and the I/O proceeds; if not, the thread sleeps again.

The second case is more interesting. The kernel delivers a signal not to a *thread* but to a *process*. A signal can be a serious condition (`SIGTERM`, `SIGKILL`) or a routine one (`SIGINT` from Ctrl-C, `SIGALRM` from a timer). The thread that was sleeping needs to return to user space promptly so the signal handler can run. The convention is that the sleep primitive returns `EINTR` (interrupted system call), the driver returns `EINTR` from its handler, and the kernel either restarts the system call (if the handler returned with `SA_RESTART`) or returns `EINTR` to user space (if not).

The third case is the bounded-wait case. The driver typically maps `EWOLDBLOCK` to either `EAGAIN` (try again later) or to a more specific error (`ETIMEDOUT`, where appropriate).

12.4.3 EINTR, ERESTART, and the Restart Question

A subtlety lurks in case 2 that is worth understanding before the chapter goes any further.

When `cv_wait_sig` is interrupted by a signal, the actual return value is one of two things:

- `EINTR` if the signal's disposition is "do not restart system calls". The kernel returns `EINTR` to user space, and `read(2)` reports -1 with `errno == EINTR`. The user program is responsible for retrying if it wants to.
- `ERESTART` if the signal's disposition is "restart system calls" (the `SA_RESTART` flag). The kernel transparently re-enters the syscall and the wait happens again. The user program does not see the interruption.

A driver should not return `ERESTART` directly to user space; it is an internal sentinel for the syscall layer. If the driver returns `ERESTART` from its handler, the syscall layer knows to restart. If the driver returns `EINTR`, the syscall layer returns `EINTR` to user space.

The convention most drivers follow: pass the return value of `cv_wait_sig` through unchanged. If you got `EINTR`, the driver returns `EINTR`. If you got `ERESTART`, the driver returns `ERESTART`. The kernel takes it from there. The Chapter 11 driver did this implicitly; the Chapter 12 refactor in Section 2 continues to do so:

```
error = cv_wait_sig(&sc->data_cv, &sc->mtx);
if (error != 0)
    return (error);
```

Returning error directly is the right move. Chapter 12 changes nothing about this rule; it just makes the rule visible in the new APIs.

12.4.4 Adding a Timeout to the Read Path

Now the bounded-wait case. Suppose we want `myfirst_read` to optionally wait for at most some configurable duration before returning `EAGAIN` if no data arrives. (We use `EAGAIN` rather than `ETIMEDOUT` because `EAGAIN` is the conventional UNIX answer to "the operation would block; try again later".)

The driver needs three things:

1. A configuration value for the timeout (in milliseconds, say). Zero means "block indefinitely as before".
2. A way to convert the timeout to ticks, since `cv_timedwait_sig` takes its `timo` argument in ticks.
3. A loop that handles the three outcomes correctly: normal wakeup, signal interruption, timeout.

Add the configuration field to the softc:

```
int    read_timeout_ms; /* 0 = no timeout */
```

Initialize it in `attach`:

```
sc->read_timeout_ms = 0;
```

Expose it as a `sysctl`:

```

SYSCTL_ADD_INT(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "read_timeout_ms", CTLFLAG_RW,
    &sc->read_timeout_ms, 0,
    "Read timeout in milliseconds (0 = block indefinitely)");

```

We use a plain `SYSCTL_ADD_INT` for now; the value is one integer, the read is atomic at the word level on amd64, and a slightly stale value is acceptable. (Section 5 will give us a more disciplined way to handle configuration changes.)

Update the wait helper:

```

static int
myfirst_wait_data(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
    struct uio *uio)
{
    int error, timo;

    MYFIRST_ASSERT(sc);
    while (cbuf_used(&sc->cb) == 0) {
        if (uio->uio_resid != nbefore)
            return (-1);
        if (ioflag & IO_NDELAY)
            return (EAGAIN);

        timo = sc->read_timeout_ms;
        if (timo > 0) {
            int ticks_total = (timo * hz + 999) / 1000;
            error = cv_timedwait_sig(&sc->data_cv, &sc->mtx,
                ticks_total);
        } else {
            error = cv_wait_sig(&sc->data_cv, &sc->mtx);
        }
        if (error == EWOULDBLOCK)
            return (EAGAIN);
        if (error != 0)
            return (error);
        if (!sc->is_attached)
            return (ENXIO);
    }
    return (0);
}

```

A few details deserve commentary.

The $(\text{timo} * \text{hz} + 999) / 1000$ arithmetic converts milliseconds to ticks, rounding up. We want at least the requested wait, never less. A timeout of 1 ms on a 1000 Hz kernel becomes 1 tick. A timeout of 1 ms on a 100

Hz kernel becomes 1 tick (rounded up from 0.1). A timeout of 5500 ms becomes 5500 ticks at 1000 Hz, or 550 at 100 Hz.

The branch on `timo > 0` picks `cv_timedwait_sig` when a positive timeout is requested and `cv_wait_sig` (no timeout) when not. We could always call `cv_timedwait_sig` with `timo = 0`, but the `cv` API treats `timo = 0` as “wait indefinitely”, and the behaviour is identical to `cv_wait_sig`. The explicit branch makes the intent clearer for a reader.

The `EWouldBlock -> EAGAIN` translation gives user space the conventional “try again” indication. A user program that gets `EAGAIN` knows what to do; a user program that gets `ETIMEDOUT` would have to learn a new error code.

The `is_attached` re-check after every sleep remains. Even with a bounded wait, the device might have been detached during the sleep; the `cv` broadcast in `detach` (added in Section 2) wakes us; the timeout itself does not skip the post-sleep checks.

Apply the symmetric change to `myfirst_wait_room` if you want bounded writes, with a separate `write_timeout_ms` `sysctl`. The companion source does both.

12.4.5 Verifying the Timeout

A small user-space tester confirms the new behaviour. Set the timeout to 100 ms, open the device with no producer, and read. You should see `read(2)` return -1 with `errno == EAGAIN` after approximately 100 ms, not block forever.

```
/* timeout_tester.c: confirm bounded reads. */
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <stdio.h>
#include <string.h>
#include <sys/sysctl.h>
#include <sys/time.h>
#include <unistd.h>

#define DEVPATH "/dev/myfirst"

int
main(void)
{
    int timeout_ms = 100;
    size_t sz = sizeof(timeout_ms);

    if (sysctlbyname("dev.myfirst.0.read_timeout_ms",
        NULL, NULL, &timeout_ms, sz) != 0)
        err(1, "sysctlbyname set");
}
```

```
int fd = open(DEVPATH, O_RDONLY);
if (fd < 0)
    err(1, "open");

char buf[1024];
struct timeval t0, t1;
gettimeofday(&t0, NULL);
ssize_t n = read(fd, buf, sizeof(buf));
gettimeofday(&t1, NULL);
int saved = errno;

long elapsed_ms = (t1.tv_sec - t0.tv_sec) * 1000 +
    (t1.tv_usec - t0.tv_usec) / 1000;
printf("read returned %zd, errno=%d (%s) after %ld ms\n",
    n, saved, strerror(saved), elapsed_ms);

close(fd);
return (0);
}
```

Run with no producer attached. Expect output similar to:

```
read returned -1, errno=35 (Resource temporarily unavailable) after 102 ms
```

Errno 35 on FreeBSD is EAGAIN. The 102 ms is the 100 ms timeout plus a couple of milliseconds of scheduling jitter.

Reset the sysctl to zero (`sysctl -w dev.myfirst.0.read_timeout_ms=0`) and rerun. Now `read(2)` blocks until you press Ctrl-C, at which point it returns -1 with `errno == EINTR`. The interruptibility (the `_sig` suffix) and the timeout (the `_timedwait` variant) are independent capabilities. We can have neither, either, or both, and the API exposes each on its own switch.

12.4.6 Choosing Between EAGAIN and ETIMEDOUT

When the timeout fires, the driver chooses what error to report. The two reasonable choices are EAGAIN and ETIMEDOUT.

EAGAIN (errno value 35 on FreeBSD; symbolic value `EWOULDBLOCK` is #defined to the same number in `/usr/src/sys/sys/errno.h`) is the conventional UNIX answer to “the operation would block”. User programs that handle `O_NONBLOCK` understand it. Many user programs already retry on EAGAIN. Returning EAGAIN for a timeout is a safe default; it does the right thing for the majority of callers.

ETIMEDOUT (errno value 60 on FreeBSD) is more specific: “the operation has a deadline and the deadline expired”. Network protocols use it; it means something different from “would block right now”. A user program that wants to distinguish “no data yet, retry” from “no data after the agreed deadline, give up” needs ETIMEDOUT.

For `myfirst`, we use `EAGAIN`. The driver does not have a deadline contract with the caller; the timeout is a politeness, not a guarantee. Other drivers may make the other choice; both are legal.

12.4.7 A Note on Fairness Under Timeouts

The timed wait does not change the `cv`'s fairness story. `cv_timedwait_sig` is implemented in terms of the same sleep queue used by `cv_wait_sig`. When a wakeup arrives, the sleep queue picks the highest-priority waiter (FIFO among equal priorities) regardless of whether each waiter has a timeout pending. The timeout is a per-waiter watchdog; it does not affect the order in which non-timed-out waiters are woken.

Practical consequence: a thread with a 50 ms timeout and a thread without a timeout, both waiting on the same `cv`, will both be woken by `cv_signal` in the order the sleep queue chooses. The 50 ms thread does not get priority. If you need the timed waiter to be woken first, you have a different design problem (priority queues, separate `cvs` per priority class) that goes beyond this chapter.

For `myfirst`, all readers are equivalent and the lack of timeout-based prioritization is fine.

12.4.8 When to Use a Timeout

Timeouts are not free. Each timed wait sets up a callout that fires the `cv`'s wakeup if no real wakeup arrives first. The callout has a small per-tick cost and contributes to the kernel's overall callout pressure. Drivers that use timeouts for every blocking call create more callout traffic than drivers that block indefinitely.

Three rules of thumb:

- Use a timeout when the caller has a real deadline (a network protocol, a hardware watchdog, a user-visible response).
- Use a timeout when the wait has a “this should not be possible” backstop. A driver that “just in case” sets a 60 second timeout on a wait that should normally complete in microseconds is using the timeout as a sanity check, not as a deadline. That is fine.
- Do not use a timeout when the wait is naturally indefinite (a `cat /dev/myfirst` on an idle device should block until data arrives or the user gives up; either is fine, neither needs a timeout).

The `myfirst` driver in this chapter exposes a per-device `sysctl` that lets the user choose. The default of zero (block indefinitely) is the right default for a pseudo-device. Real drivers may have stronger opinions.

12.4.9 Sub-Tick Precision With `sbintime_t`

The `cv_timedwait` and `cv_timedwait_sig` macros take their timeout in ticks. A tick on FreeBSD 14.3 is typically one millisecond (because `hz=1000` is the default), so tick precision is millisecond precision. For most driver use cases this is enough. Network and storage drivers occasionally want microsecond precision, and the `_sbt` (scaled binary time) variants are how you get it.

The relevant primitives:

```
int cv_timedwait_sbt(struct cv *cvp, struct mtx *mtx,
                    sbintime_t sbt, sbintime_t pr, int flags);
```

```
int cv_timedwait_sig_sbt(struct cv *cvp, struct mtx *mtx,
                        sbintime_t sbt, sbintime_t pr, int flags);
int msleep_sbt(void *chan, struct mtx *mtx, int pri,
               const char *wmesg, sbintime_t sbt, sbintime_t pr, int flags);
```

The `sbt` argument is the timeout, expressed as an `sbintime_t` (a 64-bit integer where the upper 32 bits are seconds and the lower 32 bits are a binary fraction of a second). The `pr` argument is the precision: how much wiggle the kernel is allowed to have when scheduling the timer (used for power-saving coalescing of timer interrupts). The `flags` argument is one of `C_HARDLOCK`, `C_ABSOLUTE`, `C_DIRECT_EXEC`, etc., which control how the timer is registered.

For a 250-microsecond timeout:

```
sbintime_t sbt = 250 * SBT_1US; /* 250 microseconds */
int err = cv_timedwait_sig_sbt(&sc->data_cv, &sc->mtx, sbt,
                               SBT_1US, C_HARDLOCK);
```

The `SBT_1US` constant (defined in `/usr/src/sys/sys/time.h`) is one microsecond as an `sbintime_t`. Multiplying by 250 gives 250 microseconds. The precision argument `SBT_1US` says “I am happy with one-microsecond precision”; the kernel will not coalesce this timer with other timers more than 1 microsecond apart.

For 5 seconds:

```
sbintime_t sbt = 5 * SBT_1S;
int err = cv_timedwait_sig_sbt(&sc->data_cv, &sc->mtx, sbt,
                               SBT_1MS, C_HARDLOCK);
```

Five-second wait with millisecond precision. The kernel may coalesce up to 1 ms.

For most driver code the millisecond-tick API (`cv_timedwait_sig` with a tick count) is the right level of precision. Reach for `_sbt` when you have a real reason: a network protocol with sub-millisecond timing, a hardware controller with a microsecond-scale watchdog, a measurement where the sleep itself contributes to the result.

12.4.10 What Happens Inside `cv_timedwait_sig`

Conceptually, `cv_timedwait_sig` does the same thing as `cv_wait_sig` but also schedules a callout that will fire the `cv`’s signal if no real signal arrives first. The implementation lives in `/usr/src/sys/kern/kern_condvar.c` in `_cv_timedwait_sig_sbt`. Three observations are worth carrying with you.

First, the callout is registered while the interlock mutex is held, then the thread sleeps. If the callout fires while the thread is sleeping, the kernel marks the thread as awake-with-timeout. The thread returns from the sleep with `EWOLDBLOCK`.

Second, if a real `cv_signal` arrives before the timeout, the callout is cancelled when the thread wakes. The cancellation is racy in principle (the callout could fire just after the thread wakes for a real reason), but the

kernel handles this by checking whether the thread is still sleeping when the callout fires; if not, the callout is a no-op.

Third, every timed wait creates and tears down a callout. On a system with thousands of concurrent timed waits, the callout machinery becomes a measurable cost. For a single driver with at most a few dozen waiters, the cost is negligible.

These details are not things you need to memorize. They explain, however, why a driver that uses timed waits everywhere may show more activity in the callout subsystem than a driver that uses indefinite waits with a separate watchdog thread. If you ever wonder why your driver is producing many callout events, the timed waits are a likely cause.

12.4.11 Wrapping Up Section 3

Bounded waits and interruptible waits are the two ways a kernel sleep primitive cooperates with the world outside it. We added both to the `myfirst` blocking paths: `cv_wait_sig` was already there; `cv_timedwait_sig` is the new addition, gated by a `sysctl`. The user-space test confirms that a Ctrl-C and a 100-millisecond deadline both produce the expected return value; the driver reports `EINTR` and `EAGAIN` respectively.

Section 4 turns to a different shape of synchronization entirely: shared/exclusive locks, where many threads may read at once and only writers must wait their turn.

12.5 Section 4: The `sx(9)` Lock: Shared and Exclusive Access

The mutex `myfirst` uses today protects the `cbuf`, which has a composite invariant. That is the right primitive for that job. Not every piece of state has a composite invariant, however. Some state is read often, written rarely, and never spans more than the field being read. For that state, serializing every reader through a mutex is wasted serialization. A reader-writer lock fits the shape better.

This section introduces `sx(9)`, FreeBSD's sleepable shared/exclusive lock. We first explain what shared/exclusive means and why it matters, then walk through the API, then talk briefly about the spin-mode sibling `rw(9)`, and finish with the rules that distinguish the two and place each in the right context.

12.5.1 What Shared and Exclusive Mean

A **shared lock** (also called a *read lock*) allows multiple holders simultaneously. A thread that holds the lock in shared mode is guaranteed that no other thread is currently holding it in *exclusive* mode. Shared holders may execute concurrently; they do not see each other.

An **exclusive lock** (also called a *write lock*) is held by exactly one thread at a time. A thread holding the lock in exclusive mode is guaranteed that no other thread holds it in any mode.

A lock can transition between modes in two directions:

- **Downgrade:** a holder of an exclusive lock can convert it to a shared lock without releasing it. The conversion is non-blocking; immediately after, the original holder still has the lock (now in shared mode), and other readers may proceed.

- **Upgrade:** a holder of a shared lock can attempt to convert it to an exclusive lock. The attempt may fail if other shared holders are still present. The standard primitive is `sx_try_upgrade`, which returns success/failure rather than blocking.

The asymmetry of the upgrade (try, may fail) reflects a fundamental difficulty: if multiple shared holders both try to upgrade at once, they would deadlock waiting for each other. The non-blocking `sx_try_upgrade` lets one succeed while the others fail and have to release-and-reacquire as exclusive.

Shared/exclusive locks are the right primitive when the access pattern is *many readers, occasional writer*. Examples in the FreeBSD kernel include the namespace lock for `sysctl`, the namespace lock for kernel modules, the superblock locks of file systems, and many configuration-state locks in network drivers.

12.5.2 Why Shared/Exclusive Beats a Plain Mutex Here

Imagine a piece of driver state, “current debug verbosity level”, read at the start of every I/O call to decide whether to log certain events, and changed maybe once an hour by a `sysctl`. Under the Chapter 11 mutex design:

- Every I/O call acquires the mutex, reads the verbosity, releases the mutex.
- Every I/O call serializes on the mutex against every other I/O call’s verbosity check.
- The mutex sees enormous contention even though no one is contending for the underlying *state* (everyone is just reading).

Under an `sx` design:

- Every I/O call acquires the lock in shared mode (cheap on a multi-core system; fast-path reduces to a few atomic operations and no scheduler involvement).
- Multiple I/O calls can hold the lock concurrently. They do not block each other.
- The `sysctl` writer occasionally takes the lock in exclusive mode, briefly excluding readers. Readers retry as shared holders once the writer drops.

For a read-heavy workload, the difference is dramatic. The mutex’s serialization cost grows with the number of cores; the `sx`’s shared-mode cost stays constant.

The trade-off: `sx_xlock` is more expensive per acquisition than `mtx_lock`, because the lock is more elaborate internally. For state that is only ever read once and the readers are not contending, `mtx` is still better. The break-even point depends on the workload, but the rule of thumb is *use `sx` when readers are many and writers are rare; use `mtx` when the access pattern is symmetric or write-heavy*.

12.5.3 The `sx(9)` API

The `sx(9)` functions live in `/usr/src/sys/sys/sx.h` and `/usr/src/sys/kern/kern_sx.c`. The public API is small.

```
void sx_init(struct sx *sx, const char *description);
void sx_init_flags(struct sx *sx, const char *description, int opts);
void sx_destroy(struct sx *sx);
```

```

void  sx_xlock(struct sx *sx);
int   sx_xlock_sig(struct sx *sx);
void  sx_xunlock(struct sx *sx);
int   sx_try_xlock(struct sx *sx);

void  sx_slock(struct sx *sx);
int   sx_slock_sig(struct sx *sx);
void  sx_sunlock(struct sx *sx);
int   sx_try_slock(struct sx *sx);

int   sx_try_upgrade(struct sx *sx);
void  sx_downgrade(struct sx *sx);

void  sx_unlock(struct sx *sx); /* polymorphic: shared or exclusive */
void  sx_assert(struct sx *sx, int what);

int   sx_xlocked(struct sx *sx);
struct thread *sx_xholder(struct sx *sx);

```

The `_sig` variants are interruptible by signals; they return `EINTR` or `ERESTART` if signalled while waiting. The non-`_sig` variants block uninterruptibly. Drivers that hold an `sx` lock across a long operation should consider the `_sig` variants for the same reason they prefer `cv_wait_sig` over `cv_wait`: a Ctrl-C should be able to release the wait.

The flags accepted by `sx_init_flags` include:

- `SX_DUPOK`: allow the same thread to acquire the lock multiple times (mostly a `WITNESS` directive).
- `SX_NOWITNESS`: do not register the lock with `WITNESS` (use rarely; prefer to register and document any exceptions).
- `SX_RECURSE`: allow recursive acquisition by the same thread; the lock is released only when every acquire is matched.
- `SX_QUIET`, `SX_NOPROFILE`: turn off various debugging instrumentation.
- `SX_NEW`: declare that the memory is fresh (skip the prior-init check).

For most driver use cases, `sx_init(sx, "name")` with no flags is the right default.

`sx_assert(sx, what)` checks the lock state and panics under `INVARIANTS` if the assertion fails. The `what` argument is one of:

- `SA_LOCKED`: the lock is held in some mode by the calling thread.
- `SA_SLOCKED`: the lock is held in shared mode.
- `SA_XLOCKED`: the lock is held in exclusive mode by the calling thread.
- `SA_UNLOCKED`: the lock is not held by the calling thread.
- `SA_RECURSED`, `SA_NOTRECURSED`: matches the recursion state.

Use `sx_assert` liberally inside helpers that expect a particular lock state, in the same way Chapter 11 used `mtx_assert`.

12.5.4 A Quick Worked Example

Suppose we have a struct holding driver configuration:

```
struct myfirst_config {
    int     debug_level;
    int     soft_byte_limit;
    char     nickname[32];
};
```

Most reads of these fields happen on the data path (every `myfirst_read` and `myfirst_write` checks `debug_level`). Writes happen rarely, from `sysctl` handlers.

Add an `sx` lock to the softc:

```
struct sx          cfg_sx;
struct myfirst_config  cfg;
```

Initialize and destroy:

```
sx_init(&sc->cfg_sx, "myfirst cfg");
/* in detach: */
sx_destroy(&sc->cfg_sx);
```

Read on the data path:

```
static bool
myfirst_debug_enabled(struct myfirst_softc *sc, int level)
{
    bool enabled;

    sx_slock(&sc->cfg_sx);
    enabled = (sc->cfg.debug_level >= level);
    sx_sunlock(&sc->cfg_sx);
    return (enabled);
}
```

Write from a `sysctl` handler:

```
static int
myfirst_sysctl_debug_level(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, error;
```

```

    sx_slock(&sc->cfg_sx);
    new = sc->cfg.debug_level;
    sx_sunlock(&sc->cfg_sx);

    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);

    if (new < 0 || new > 3)
        return (EINVAL);

    sx_xlock(&sc->cfg_sx);
    sc->cfg.debug_level = new;
    sx_xunlock(&sc->cfg_sx);
    return (0);
}

```

Three things to notice in the writer.

First, we read the *current* value under the shared lock so the sysctl framework can fill in the value to display when no new value is being set. We could read it without the lock, but doing so would create a torn-read possibility for the (admittedly small) int. The shared lock is cheap and explicit.

Second, we drop the shared lock, validate the new value with `sysctl_handle_int`, validate the range, and then take the exclusive lock to commit. We cannot upgrade from shared to exclusive in this path because `sx_try_upgrade` may fail; doing it as drop-and-reacquire is simpler and correct.

Third, the validation happens before the exclusive lock, which means we hold the exclusive lock for the minimum time. The exclusive holder excludes all readers; we want it to release as quickly as possible.

12.5.5 Try-Upgrade and Downgrade

`sx_try_upgrade` is the optimistic version of “I have a shared lock, please give me an exclusive one without making me drop and reacquire”. It returns nonzero on success (the lock is now exclusive) and zero on failure (the lock is still shared; another thread held it shared simultaneously and the kernel could not safely promote).

The pattern:

```

sx_slock(&sc->cfg_sx);
/* do some reading */
if (need_to_modify) {
    if (sx_try_upgrade(&sc->cfg_sx)) {
        /* now exclusive; modify */
        sx_downgrade(&sc->cfg_sx);
        /* back to shared; continue reading */
    }
}

```

```
    } else {
        /* upgrade failed; drop and reacquire */
        sx_sunlock(&sc->cfg_sx);
        sx_xlock(&sc->cfg_sx);
        /* now exclusive but our prior view may be stale */
        /* re-validate and modify */
        sx_downgrade(&sc->cfg_sx);
    }
}
sx_sunlock(&sc->cfg_sx);
```

`sx_downgrade` always succeeds: an exclusive holder can always step down to shared without blocking, because no other writer can be present (we held the exclusive) and the existing readers all acquired their shared locks while we were holding exclusive (which they could not), so they cannot exist either.

For our `myfirst` configuration, we do not need upgrade/downgrade: the read and the write are separate paths and the `sysctl` handler is willing to drop and reacquire. Upgrade/downgrade is most useful in algorithms where the same thread reads, decides, and then conditionally modifies, all within one lock acquire-release cycle.

12.5.6 Comparing `sx(9)` to `rw(9)`

`rw(9)` is the spin-mode sibling of `sx(9)`. Both implement the shared/exclusive idea. They differ in how they wait for an unavailable lock.

`sx(9)` uses sleep queues. A thread that cannot acquire the lock immediately is put on a sleep queue and yields. Other threads run on the CPU. When the lock becomes available, the kernel wakes the highest-priority waiter, which then re-tries.

`rw(9)` uses turnstiles, the kernel's spin-based primitive that supports priority propagation. A thread that cannot acquire the lock immediately spins (briefly), then handed to the turnstile machinery for blocking with priority inheritance. The blocking is done in a way that does not give up the CPU as easily as `sx`.

The practical differences:

- `sx(9)` is sleepable in the strict sense: holding an `sx` lock allows you to call functions that may sleep (`uiomove`, `malloc(... M_WAITOK)`). Holding an `rw(9)` lock does *not*; the `rw(9)` lock is treated like a spin lock for sleep purposes.
- `sx(9)` supports `_sig` variants for signal-interruptible waits. `rw(9)` does not.
- `sx(9)` is generally appropriate for code in process context; `rw(9)` is more appropriate when the critical section is short and may run in interrupt context (although the strict choice for interrupt context is still `MTX_SPIN`).

For `myfirst`, all configuration access is from process context, the critical sections are short but include potentially-sleeping calls, and signal interruption is a useful feature. `sx(9)` is the right choice.

A driver with a configuration that is read inside an interrupt handler would have to use `rw(9)` instead, because `sx_slock` could sleep and sleeping in an interrupt is illegal. We will not encounter such a driver in this book until later parts.

12.5.7 The Sleepability Rule, Revisited

Chapter 11 introduced the rule “do not hold a non-sleepable lock across a sleeping operation”. With `sx` and `cv` on the table, the rule needs a small refinement.

The full rule is: *the lock you hold determines what operations are legal in the critical section.*

- Holding an `MTX_DEF` mutex: most operations are legal. Sleeping is permitted (with `mtx_sleep`, `cv_wait`). `uiomove`, `copyin`, `copyout`, and `malloc(M_WAITOK)` are legal in principle but should be avoided to keep critical sections short. The driver convention is to drop the mutex around any of these.
- Holding an `MTX_SPIN` mutex: very few operations are legal. No sleeping. No `uiomove`. No `malloc(M_WAITOK)`. The critical section must be tiny.
- Holding an `sx(9)` lock (shared or exclusive): like `MTX_DEF`. Sleeping is permitted. The same convention of “drop before sleeping if you can” applies, but the absolute prohibition on sleeping does not.
- Holding an `rw(9)` lock: like `MTX_SPIN`. No sleeping. No long-blocking calls.
- Holding a `cv(9)` (i.e., currently inside `cv_wait`): the underlying interlock mutex was atomically dropped by `cv_wait`; from the point of view of “what is held”, you hold nothing.

This refinement says: `sx` is sleepable, `rw` is not. That is the operative difference between them. Choose by which side of the line your critical section needs to be on.

12.5.8 Lock Order and `sx`

`WITNESS` tracks lock ordering across all classes: mutexes, `sx` locks, and `rw` locks. If your driver acquires an `sx` lock while holding a mutex, that establishes an order: mutex first, `sx` second. The reverse order from any path is a violation; `WITNESS` will warn.

For my first Stage 3 (this section), we will hold `sc->mtx` and `sc->cfg_sx` together in some paths. We must declare the order explicitly.

The natural order is *mtx before sx*. Reason: the data path holds `sc->mtx` for the `cbuf` operations; if it needs to read a configuration value during that critical section, it would acquire `sc->cfg_sx` while still holding `sc->mtx`. The reverse (`cfg_sx` first, `mtx` second) is also possible (a `sysctl` writer that wanted to update both configuration and trigger an event could acquire `cfg_sx`, then `mtx`), but a driver should pick one order and document it.

Section 5 elaborates this design and codifies the rule.

12.5.9 A Look at `kern_sx.c`

If you have a few minutes, open `/usr/src/sys/kern/kern_sx.c` and skim. The fast path of `sx_xlock` is one compare-and-swap on the lock word, exactly the same shape as the fast path of `mtx_lock`. The slow path (in `_sx_xlock_hard`) hands the thread to the sleep queue with priority propagation. The shared-lock path (`_sx_slock_int`) is similar but updates the shared-holder count rather than setting the owner.

What matters for the driver writer is that the fast path is cheap, the slow path is correct, and the API is the same shape as the mutex API you already know. If you can use `mtx_lock`, you can use `sx_xlock`; the new vocabulary is the shared-mode operations and the rules around them.

12.5.10 A Brief Tour of rw(9)

We have mentioned rw(9) several times as the spin-mode sibling of sx(9). Although our driver does not use it, you will encounter it in real FreeBSD source, so a short tour is worth the few minutes.

The API mirrors sx(9):

```
void  rw_init(struct rwlock *rw, const char *name);
void  rw_destroy(struct rwlock *rw);

void  rw_wlock(struct rwlock *rw);
void  rw_wunlock(struct rwlock *rw);
int   rw_try_wlock(struct rwlock *rw);

void  rw_rlock(struct rwlock *rw);
void  rw_runlock(struct rwlock *rw);
int   rw_try_rlock(struct rwlock *rw);

int   rw_try_upgrade(struct rwlock *rw);
void  rw_downgrade(struct rwlock *rw);

void  rw_assert(struct rwlock *rw, int what);
```

The differences from sx(9):

- The mode names are different: wlock (write/exclusive) and rlock (read/shared) instead of xlock and slock. Same idea, different vocabulary.
- There are no _sig variants. rw(9) cannot be interrupted by signals because it is implemented over turnstiles, not sleep queues.
- A thread holding any rw(9) lock cannot sleep. No cv_wait, no mtx_sleep, no uiomove, no malloc(M_WAITOK).
- rw(9) supports priority propagation. A thread waiting for an exclusive lock that is held by a lower-priority thread will boost the holder's priority. This is the main reason rw(9) exists rather than just being a thin wrapper around sx(9).

The rw_assert flags are RA_LOCKED, RA_RLOCKED, RA_WLOCKED, plus the same recursion variants sx_assert has.

Where you will see rw(9) in the FreeBSD tree:

- The networking stack uses rw(9) for several read-mostly tables (routing tables, the address resolution table). Read access happens in the receive path, which runs in network interrupt context where sleeping is forbidden.
- The VFS layer uses it for some namespace caches.
- Various subsystems with hot read paths and rare configuration updates.

For our myfirst driver, every cfg access happens in process context, every cfg writer is willing to drop the lock around sysctl_handle_* (which sleeps), and we benefit from signal interruptibility. sx(9) is the right

choice. If you ever need to access the same configuration from an interrupt handler (Chapter 14 will discuss this), the answer is to switch to `rw(9)` and accept the constraint that the `cfg` writer must do all its work without sleeping.

12.5.11 A Worked Example with `rw(9)`

To make the alternative concrete, here is what the `cfg` path would look like with `rw(9)`. The code is structurally identical except for the API and the absence of signal interruptibility:

```
/* In the softc: */
struct rwlock      cfg_rw;
struct myfirst_config  cfg;

/* In attach: */
rw_init(&sc->cfg_rw, "myfirst cfg");

/* In detach: */
rw_destroy(&sc->cfg_rw);

/* Read path: */
static int
myfirst_get_debug_level_rw(struct myfirst_softc *sc)
{
    int level;

    rw_rlock(&sc->cfg_rw);
    level = sc->cfg.debug_level;
    rw_runlock(&sc->cfg_rw);
    return (level);
}

/* Write path (sysctl handler): */
static int
myfirst_sysctl_debug_level_rw(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, error;

    rw_rlock(&sc->cfg_rw);
    new = sc->cfg.debug_level;
    rw_runlock(&sc->cfg_rw);

    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);
}
```

```
    if (new < 0 || new > 3)
        return (EINVAL);

    rw_wlock(&sc->cfg_rw);
    sc->cfg.debug_level = new;
    rw_wunlock(&sc->cfg_rw);
    return (0);
}
```

Two things to notice. First, `sysctl_handle_int` is *outside* the lock. Calling it inside an `rw(9)` critical section would be illegal because `sysctl_handle_int` may sleep. This is the same discipline we use for the `sx(9)` version, but with `rw(9)` it is mandatory rather than merely advisable. Second, the read paths look identical to the `sx(9)` version; only the function names changed. That is the point of the symmetric API: the mental model carries over.

If our driver someday needs to support an interrupt-context reader of the configuration (perhaps a hardware interrupt handler that wants to know the current debug level), this is the change we would make. For now, `sx(9)` is correct and we stay with it.

12.5.12 Wrapping Up Section 4

`sx(9)` gives us a way to express “many readers, occasional writer” without serializing every reader. It is sleepable, signal-aware, and follows the same lock-order discipline as the mutex. `rw(9)` is its non-sleepable sibling, useful when the critical section may run in contexts where sleeping is illegal; the worked example above shows the small differences. We use `sx(9)` for `myfirst` because process context and signal interruptibility are both desirable.

Section 5 brings the new primitives together. We add a small configuration subsystem to `myfirst`, decide the lock order between the data path and the configuration path, and verify the design against `WITNESS`.

12.6 Section 5: Implementing a Safe Multi-reader, Single-writer Scenario

The previous three sections introduced primitives in isolation. This section combines them into a coherent driver design. We add a small configuration subsystem to `myfirst`, give it its own `sx` lock, work out the lock order with respect to the existing data-path mutex, and verify the resulting design against a `WITNESS` kernel.

The configuration subsystem is small on purpose. The point is not to demonstrate a complex feature; it is to demonstrate the lock-order discipline that any driver with more than one lock class must follow.

12.6.1 The Configuration Subsystem

We add three configurable parameters:

- `debug_level`: an integer 0 to 3. Higher values produce more verbose `dmesg` output from the driver's data path.
- `soft_byte_limit`: an integer. If non-zero, the driver refuses to accept writes that would push the `cbuf` above this many bytes (it returns `EAGAIN` early). This is a poor man's flow-control knob.
- `nickname`: a short string the driver prints in its log lines. Useful for distinguishing multiple driver instances in `dmesg`.

The struct that holds them:

```
struct myfirst_config {
    int     debug_level;
    int     soft_byte_limit;
    char     nickname[32];
};
```

Add it to the `softc`, alongside its `sx` lock:

```
struct myfirst_softc {
    /* ... existing fields ... */
    struct sx          cfg_sx;
    struct myfirst_config  cfg;
    /* ... rest ... */
};
```

Initialize and destroy:

```
/* In attach: */
sx_init(&sc->cfg_sx, "myfirst cfg");
sc->cfg.debug_level = 0;
sc->cfg.soft_byte_limit = 0;
strncpy(sc->cfg.nickname, "myfirst", sizeof(sc->cfg.nickname));

/* In detach: */
sx_destroy(&sc->cfg_sx);
```

The initial values are set before the `cdev` is created, so no other thread can observe a half-initialized configuration.

12.6.2 The Lock Order Decision

The driver now has two lock classes that can be held simultaneously: `sc->mtx` (the `cbuf` and per-`softc` state) and `sc->cfg_sx` (the configuration). We must decide which is acquired first when both are needed.

The natural questions to ask:

1. Which path holds each lock most often? The data path holds `sc->mtx` constantly (every `myfirst_read` and `myfirst_write` enters and leaves it). The data path also wants to read `sc->cfg.debug_level` to decide whether to log; that is a `sx_slock(&sc->cfg_sx)`. So the data path already wants both, in the order *mtx first, sx second*.
2. Which path holds the `cfg` lock and might want the data lock? A `sysctl` handler that updates the configuration takes `sx_xlock(&sc->cfg_sx)`. Does it ever need `sc->mtx`? In principle, yes: a `sysctl` handler that resets the byte counters would take both. The cleanest design is to *not* take the data mutex from inside the `sx` critical section; the `sysctl` writer stages its work, releases the `sx` lock, and then takes the data mutex if needed. That keeps the order monotonic.

The decision: **`sc->mtx` is acquired before `sc->cfg_sx` whenever both are held simultaneously.**

The reverse order is forbidden. WITNESS will catch any violation.

We document the decision in `LOCKING.md`:

Lock Order

`sc->mtx -> sc->cfg_sx`

A thread holding `sc->mtx` may acquire `sc->cfg_sx` (in either shared or exclusive mode). A thread holding `sc->cfg_sx` may NOT acquire `sc->mtx`.

Rationale: the data path always holds `sc->mtx` and may need to read configuration during its critical section. The configuration path (`sysctl` writers) does not need to update data-path state while holding `sc->cfg_sx`; if it needs to, it releases `sc->cfg_sx` first and then acquires `sc->mtx` separately.

12.6.3 Reading the Configuration on the Data Path

The most frequent access to the configuration is the data path's check of `debug_level` to decide whether to emit a log message. We wrap it in a small helper:

```
static int
myfirst_get_debug_level(struct myfirst_softc *sc)
{
    int level;

    sx_slock(&sc->cfg_sx);
    level = sc->cfg.debug_level;
    sx_sunlock(&sc->cfg_sx);
    return (level);
}
```

Note that this helper takes only `sc->cfg_sx`, not `sc->mtx`. That is intentional: the helper does not need the data mutex to read the configuration. If it is called from a context that already holds `sc->mtx`, the lock order is satisfied (mtx first, sx second). If it is called from a context that holds nothing, that is fine too.

A debug-aware log macro:

```
#define MYFIRST_DBG(sc, level, fmt, ...) do {           \
    if (myfirst_get_debug_level(sc) >= (level))       \
        device_printf((sc)->dev, fmt, ##__VA_ARGS__); \
} while (0)
```

Use it on the data path:

```
MYFIRST_DBG(sc, 2, "read got %zu bytes\n", got);
```

The shared-lock acquisition is the cost of every check. On a multi-core machine this is a few atomic operations; the readers do not contend with each other. On a single-core machine the cost is essentially zero (no other thread can be in the middle of a write).

12.6.4 Reading the Soft Byte Limit

The same pattern for the soft byte limit, used by `myfirst_write` to decide whether to refuse:

```
static int
myfirst_get_soft_byte_limit(struct myfirst_softc *sc)
{
    int limit;

    sx_slock(&sc->cfg_sx);
    limit = sc->cfg.soft_byte_limit;
    sx_sunlock(&sc->cfg_sx);
    return (limit);
}
```

Inside `myfirst_write`, before the actual write happens (note that `want` has not been computed yet at this point in the loop), the limit check uses `sizeof(bounce)` as a worst-case proxy: any single iteration writes at most one bounce buffer's worth of bytes, so refusing when `cbuf_used + sizeof(bounce)` would exceed the limit is a conservative early-out:

```
int limit = myfirst_get_soft_byte_limit(sc);

MYFIRST_LOCK(sc);
if (limit > 0 && cbuf_used(&sc->cb) + sizeof(bounce) > (size_t)limit) {
    MYFIRST_UNLOCK(sc);
```

```

        return (uio->uio_resid != nbefore ? 0 : EAGAIN);
    }
    /* fall through to wait_room and the rest of the iteration */

```

Two acquisitions back to back: the `cfg_sx` for the limit, the `mtx` for the `cbuf` check. Notice that we acquire the `sx` *first* and drop it before taking the mutex. We could in principle hold both (`cfg_sx` then `mtx`) but the order would be wrong; the rule says `mtx` first, `sx` second. So we acquire each independently. The slight cost of two acquisitions is the price of correctness.

A subtle point: between the `cfg_sx` release and the `mtx` acquisition, the limit could change. That is acceptable; the limit is a soft hint, not a hard guarantee. If a `sysctl` writer raises the limit between our two acquisitions and we still refuse the write, the user will retry and succeed on the second attempt. If the limit is lowered and we proceed with a write that the new limit would have refused, no harm is done because the `cbuf` has its own hard size limit.

The choice of `sizeof(bounce)` rather than the actual `want` reflects another subtle point: at this stage in the loop, the driver has not yet computed `want` (that requires knowing how much room the `cbuf` currently has, which requires holding the mutex first). Using `sizeof(bounce)` as the worst-case bound lets the check happen before the room calculation. The companion source file follows exactly this pattern.

12.6.5 Updating the Configuration: a Sysctl Writer

The writer side, exposed as a `sysctl` that can read and write `debug_level`:

```

static int
myfirst_sysctl_debug_level(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, error;

    sx_slock(&sc->cfg_sx);
    new = sc->cfg.debug_level;
    sx_unlock(&sc->cfg_sx);

    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);

    if (new < 0 || new > 3)
        return (EINVAL);

    sx_xlock(&sc->cfg_sx);
    sc->cfg.debug_level = new;
    sx_xunlock(&sc->cfg_sx);
}

```

```

        return (0);
    }

```

Walk through the lock acquisitions:

1. `sx_slock` to read the current value (so the `sysctl` framework can return it on a read-only query).
2. `sx_sunlock` before calling `sysctl_handle_int`, because that function may copy data to and from user space (which can sleep) and we do not want to hold the `sx` lock across that.
3. After validation, `sx_xlock` to commit the new value.
4. `sx_xunlock` to release.

We never hold `sc->mtx` in this path. The lock order rule is trivially satisfied: this path never has both locks held at once.

Register the `sysctl` in `attach`:

```

SYSCTL_ADD_PROC(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "debug_level",
    CTLTYPE_INT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    sc, 0, myfirst_sysctl_debug_level, "I",
    "Debug verbosity level (0-3)");

```

The `CTLFLAG_MPSAFE` flag tells the `sysctl` framework that our handler is safe to call without acquiring the giant lock; we are. This is the modern default for new `sysctl` handlers.

12.6.6 Updating the Soft Byte Limit

The same shape for the byte limit:

```

static int
myfirst_sysctl_soft_byte_limit(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, error;

    sx_slock(&sc->cfg_sx);
    new = sc->cfg.soft_byte_limit;
    sx_sunlock(&sc->cfg_sx);

    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);

    if (new < 0)
        return (EINVAL);
}

```

```
    sx_xlock(&sc->cfg_sx);
    sc->cfg.soft_byte_limit = new;
    sx_xunlock(&sc->cfg_sx);
    return (0);
}
```

And for the nickname (a string, so the sysctl handler is slightly different):

```
static int
myfirst_sysctl_nickname(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    char buf[sizeof(sc->cfg.nickname)];
    int error;

    sx_slock(&sc->cfg_sx);
    strncpy(buf, sc->cfg.nickname, sizeof(buf));
    sx_sunlock(&sc->cfg_sx);

    error = sysctl_handle_string(oidp, buf, sizeof(buf), req);
    if (error || req->newptr == NULL)
        return (error);

    sx_xlock(&sc->cfg_sx);
    strncpy(sc->cfg.nickname, buf, sizeof(sc->cfg.nickname));
    sx_xunlock(&sc->cfg_sx);
    return (0);
}
```

The structure is identical: shared-lock to read, drop, validate via the sysctl framework, exclusive-lock to commit. The string version uses `strncpy` for safety.

12.6.7 A Single Operation Holding Both Locks

Sometimes a path legitimately needs both locks. As an example, suppose we add a sysctl that resets the cbuf and clears all the byte counters at once. That sysctl needs:

1. The exclusive cfg lock if it is going to also reset some configuration (say, reset the debug level).
2. The data mutex to manipulate the cbuf.

Following our lock order, we acquire `sc->mtx` first, then `sc->cfg_sx`:

```
static int
myfirst_sysctl_reset(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int reset = 0;
    int error;

    error = sysctl_handle_int(oidp, &reset, 0, req);
    if (error || req->newptr == NULL || reset != 1)
        return (error);

    MYFIRST_LOCK(sc);
    sx_xlock(&sc->cfg_sx);

    cbuf_reset(&sc->cb);
    sc->cfg.debug_level = 0;
    counter_u64_zero(sc->bytes_read);
    counter_u64_zero(sc->bytes_written);

    sx_xunlock(&sc->cfg_sx);
    MYFIRST_UNLOCK(sc);

    cv_broadcast(&sc->room_cv); /* room is now available */
    return (0);
}
```

The order of acquisition is mtx then sx. The order of release is the reverse: sx first, mtx second. (Releases must reverse the acquisition order to maintain the lock-order invariant for any thread that observes a lock state in the middle.)

The cv broadcast happens after both locks are released. Waking sleepers does not require holding either lock.

cbuf_reset is a small helper we add to the cbuf module:

```
void
cbuf_reset(struct cbuf *cb)
{
    cb->cb_head = 0;
    cb->cb_used = 0;
}
```

It zeroes the indices but does not touch the backing memory; the contents become irrelevant the moment cb_used is zero.

12.6.8 Verifying Against WITNESS

Build the new driver and load it on a WITNESS kernel. Run the Chapter 11 stress kit plus a new tester that hammers the sysctls while I/O is happening:

```
/* config_writer.c: continuously update config sysctls. */
#include <err.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/sysctl.h>
#include <unistd.h>

int
main(int argc, char **argv)
{
    int seconds = (argc > 1) ? atoi(argv[1]) : 30;
    time_t end = time(NULL) + seconds;
    int v = 0;

    while (time(NULL) < end) {
        v = (v + 1) % 4;
        if (sysctlbyname("dev.myfirst.0.debug_level",
            NULL, NULL, &v, sizeof(v)) != 0)
            warn("sysctl debug_level");

        int limit = (v == 0) ? 0 : 4096;
        if (sysctlbyname("dev.myfirst.0.soft_byte_limit",
            NULL, NULL, &limit, sizeof(limit)) != 0)
            warn("sysctl soft_byte_limit");

        usleep(10000); /* 10 ms */
    }
    return (0);
}
```

Run `mp_stress` in one terminal, `mt_reader` in a second, `config_writer` in a third, all simultaneously. Watch `dmesg` for warnings.

Three things should happen:

1. All tests pass with consistent byte counts.
2. The debug level changes visibly in `dmesg` (when the level is high, the data path emits log messages; when low, it is quiet).
3. WITNESS is silent. No lock-order reversals reported.

If WITNESS does report a reversal, it means the lock order was violated somewhere. Re-read the affected code path against the rule (mtx first, sx second) and fix the violation.

12.6.9 What Goes Wrong if You Get the Order Backwards

To make the rule concrete, deliberately violate it. Take an existing path that holds `sc->mtx` and rewrite it to acquire the locks in the wrong order. For example, in `myfirst_read`:

```
/* WRONG: this is the bug we want WITNESS to catch. */
sx_slock(&sc->cfg_sx); /* sx first */
MYFIRST_LOCK(sc);      /* mtx second; reverses the global order */
/* ... */
MYFIRST_UNLOCK(sc);
sx_sunlock(&sc->cfg_sx);
```

Build, load on a WITNESS kernel, run the test kit. WITNESS should fire on the first run that exercises both this path and any other path that does `mtx-then-sx`:

```
lock order reversal:
 1st 0xfffffe000a1b2c30 myfirst cfg (myfirst cfg, sx) @ ...:<line>
 2nd 0xfffffe000a1b2c50 myfirst0 (myfirst, sleep mutex) @ ...:<line>
lock order myfirst cfg -> myfirst0 attempted at ...
where myfirst0 -> myfirst cfg is established at ...
```

The warning names the two locks, their addresses, the source location of each acquisition, and the previously-established order. The fix is to put the locks back in the canonical order; revert the change and the warning disappears.

This is WITNESS doing its job. A driver with more than one lock class without WITNESS is a driver waiting for a deadlock that nobody can reproduce.

12.6.10 A Slightly Larger Pattern: Snapshot-and-Apply

A common pattern when both locks are needed and the operation has work to do under each is *snapshot-and-apply*. In its simplest form, before the actual transfer size is known:

```
/* Phase 1: snapshot the configuration under the sx (in shared mode). */
sx_slock(&sc->cfg_sx);
int dbg = sc->cfg.debug_level;
int limit = sc->cfg.soft_byte_limit;
sx_sunlock(&sc->cfg_sx);

/* Phase 2: do the work under the mtx, using the snapshot. */
MYFIRST_LOCK(sc);
if (limit > 0 && cbuf_used(&sc->cb) + sizeof(bounce) > (size_t)limit) {
    MYFIRST_UNLOCK(sc);
    return (EAGAIN);
}
```

```

}
/* ... cbuf operations ... */
size_t actual = /* determined inside the critical section */;
MYFIRST_UNLOCK(sc);

if (dbg >= 2)
    device_printf(sc->dev, "wrote %zu bytes\n", actual);

```

The snapshot-and-apply pattern keeps each lock held for the minimum time, avoids holding both locks at once, and produces a clear two-phase shape that is easy to reason about. The cost is that the snapshot may be slightly stale when the apply executes; in practice, the staleness is microseconds and is acceptable for almost any configuration value.

If staleness is unacceptable for some specific value (say, a critical security flag), then the holder must take the lock(s) atomically and follow the global order. The snapshot pattern is a default, not a law.

12.6.11 A Walk-Through of `myfirst_sysctl_reset`

The reset sysctl is the only path in the chapter that legitimately holds both locks at once. It is worth tracing through carefully, because the pattern (mtx then sx, both released in reverse order, broadcasts after both are released) is the one to imitate any time both locks must be held.

When a user runs `sysctl -w dev.myfirst.0.reset=1`, the kernel calls `myfirst_sysctl_reset` with `req->newptr` non-NULL. The handler:

1. Reads the new value via `sysctl_handle_int`. If the value is not 1, returns without doing anything (treats only 1 as a confirmed reset request).
2. Acquires `MYFIRST_LOCK(sc)`. The data mutex is now held.
3. Acquires `sx_xlock(&sc->cfg_sx)`. The `cfg sx` is now held in exclusive mode. Both locks held; lock order satisfied (mtx first, sx second).
4. Calls `cbuf_reset(&sc->cb)`. The buffer is now empty (`cb_used = 0`, `cb_head = 0`).
5. Sets `sc->cfg.debug_level = 0`. The config is now in its initial state.
6. Calls `counter_u64_zero` on each per-CPU counter. The byte counters are now zero.
7. Calls `sx_xunlock(&sc->cfg_sx)`. The `cfg sx` is released. Only the `mtx` is held now.
8. Calls `MYFIRST_UNLOCK(sc)`. The `mtx` is released. No locks held.
9. Calls `cv_broadcast(&sc->room_cv)`. Any writers blocked on `full` are woken; they will recheck `cb_free`, find it equal to `cb_size`, and proceed.
10. Returns 0.

Three observations about this sequence.

The lock acquisitions follow the global order; `WITNESS` is happy. The releases follow the reverse order, which preserves the invariant that any thread observing the sequence sees a consistent state.

The broadcasts happen *after* both locks are released. Holding either lock while broadcasting would needlessly block the awakened threads when they try to acquire what they need; the broadcast is fire-and-forget, and the kernel handles the rest.

The reset of the data path (`cbuf_reset`) and the reset of the configuration (`debug_level = 0`) are atomic with respect to each other. A thread that observes any field after the reset sees the post-reset value of every field; no thread can observe a half-reset state.

If we wanted to add more reset operations (clear a state machine, reset a hardware register), each one fits into this template. The lock holds expand to cover the new fields; the broadcasts at the end notify the appropriate cvs.

12.6.12 Wrapping Up Section 5

The driver now has two lock classes: a mutex for the data path and an sx lock for the configuration. The order is documented (mtx first, sx second), the order is enforced by `WITNESS` at runtime, and the patterns we use (snapshot-and-apply for the common case, single-acquisition for paths that need only one lock, and the carefully-ordered acquisition-release for paths that genuinely need both) keep the design auditable. The new sysctls let user space adjust the driver's behaviour at runtime without disrupting the data path.

The bigger lesson of Section 5 is that adding a second lock class is a real design decision, not a transparent optimization. The cost is the discipline required to maintain lock order, the documentation effort, and the audit work to verify both at runtime. The benefit is that the data path is no longer the only place state lives; the configuration has its own protection, its own pace, and its own sysctl interface. As drivers grow, they typically end up with three or four lock classes, each with its own purpose. The pattern from this section scales.

Section 6 turns to the question that always comes next when you start mixing lock classes: how do you debug a synchronization bug when it appears? The kernel gives you several tools for the job; this is the chapter that introduces them.

12.7 Section 6: Debugging Synchronization Issues

Chapter 11 introduced the basic kernel debugging hooks: `INVARIANTS`, `WITNESS`, `KASSERT`, and `mtx_assert`. We used them to verify that the mutex was held at the right times and that lock-order rules were respected. With the broader synchronization toolkit Chapter 12 has put in your hands, the debugging tools also expand. This section walks through the patterns and the tools you will use most often: reading a `WITNESS` warning carefully, inspecting a hung system with the in-kernel debugger, and recognising the most common failure modes of condition variables and shared/exclusive locks.

12.7.1 A Catalogue of Synchronization Bugs

Six failure shapes cover most of what you will encounter in practice. Recognising the shape is half the diagnosis.

Lost wakeup. A thread enters `cv_wait_sig` (or `mtx_sleep`); the condition it is waiting for becomes true but no `cv_signal` (or `wakeup`) is ever called. The thread sleeps forever. Causes: forgot the `cv_signal` after the state change; signalled the wrong cv; signalled before the state was actually changed; the state change happens in a path that does not include a signal at all.

Spurious wakeup mishandled. A thread is awakened by a signal or other transient event but the condition it was waiting for is still false. If the surrounding code does not loop and re-check, the thread proceeds with the

assumption that the condition is true and operates on stale state. Cure: always wrap `cv_wait` calls in `while (!condition) cv_wait(...)`, never `if (!condition) cv_wait(...)`.

Lock-order reversal. Two locks acquired in opposite orders by two paths. Either deadlocks under contention or WITNESS catches it. Cure: define a global order in `LOCKING.md` and follow it everywhere.

Premature destroy. A `cv` or `sx` is destroyed while a thread is still waiting on it. Symptoms are unpredictable: panics, use-after-free, stale-pointer crashes. Cure: ensure every waiter has been woken (and has actually returned from the wait primitive) before calling `cv_destroy` or `sx_destroy`. The detach path must be careful here.

Sleeping with a non-sleepable lock held. Holding an `MTX_SPIN` mutex or an `rw(9)` lock and then calling `cv_wait`, `mtx_sleep`, `uiomove`, or `malloc(M_WAITOK)`. WITNESS catches it; on a non-WITNESS kernel the system either deadlocks or panics. Cure: drop the spin/rw lock before sleeping, or hold an `MTX_DEF` mutex / `sx(9)` lock instead, both of which permit sleeping.

Race between detach and an active operation. A descriptor is open, a thread is in `cv_wait_sig`, and the device is told to detach. The detach path must wake the sleeper, must wait until the sleeper has returned, and must keep the `cv` (and the mutex) alive until that has happened. Cure: the standard detach pattern is set the “going away” flag, broadcast all `cvs`, wait for `active_fhs` to drop to zero, then destroy primitives.

A driver that survives long enough to hit production has handled each of these at least once. The labs in this chapter let you provoke and resolve several deliberately so the patterns become familiar.

12.7.2 Reading a WITNESS Warning Carefully

A WITNESS warning has three useful parts: the warning text, the source locations of each lock acquisition, and the previously-established order. Pull them apart.

A typical warning for a lock-order reversal:

```
lock order reversal:
 1st 0xfffffe000a1b2c30 myfirst cfg (myfirst cfg, sx) @ /var/.../myfirst.c:120
 2nd 0xfffffe000a1b2c50 myfirst0 (myfirst, sleep mutex) @ /var/.../myfirst.c:240
lock order myfirst cfg -> myfirst0 attempted at /var/.../myfirst.c:241
where myfirst0 -> myfirst cfg is established at /var/.../myfirst.c:280
```

Reading from top to bottom:

- **lock order reversal::** the warning class. Other classes include acquiring duplicate lock of same type, sleeping thread (pid N) owns a non-sleepable lock, WITNESS exceeded the recursion limit.
- **1st 0x... myfirst cfg:** the first lock acquired in the offending path. The address (0x...), name (myfirst cfg), type (sx), and source location (myfirst.c:120) tell you exactly which lock and where.
- **2nd 0x... myfirst0:** the second lock acquired. Same set of fields.
- **lock order myfirst cfg -> myfirst0 attempted at ...:** the order this code is trying to use.
- **where myfirst0 -> myfirst cfg is established at ...:** the order WITNESS previously observed and recorded as canonical, with the source location of the canonical example.

The fix is one of two things. Either the new path is wrong and should follow the canonical order (most common), or the canonical order itself is wrong and needs to change. Picking which is a judgement call; usually the answer is to fix the new path to match the canonical, because the canonical was probably right.

Sometimes the warning is a false alarm: two distinct objects of the same lock type, where the order between them does not matter because they are independent. WITNESS does not always know this; the LOR_DUPOK flag at lock initialization tells it to skip the check. We do not need that for `myfirst`, but real drivers with per-instance locks sometimes do.

12.7.3 Using DDB to Inspect a Hung System

If the test hangs and `dmesg` is silent, the culprit is usually a missed wakeup or a deadlock. The in-kernel debugger (DDB) lets you inspect the state of every thread and every lock at the moment of the hang.

To enter DDB on a hung system, press the Break key on the console (or send the `~b` escape if you are on a serial console with `cu`). DDB prompts you with `db>`.

The most useful commands for synchronization debugging:

- `show locks`: list the locks held by the current thread (the one DDB came in on, which is usually the kernel idle thread; rarely useful by itself).
- `show all locks` (alias `show alllocks`): list every lock held by every thread on the system. This is the command you want most of the time.
- `show witness`: dump the entire WITNESS lock-order graph. Verbose but authoritative.
- `show sleepchain <thread>`: trace the chain of locks and waits a specific thread is involved in. Useful when you suspect a deadlock loop.
- `show lockchain <lock>`: trace from a lock to the thread that holds it and any other locks that thread holds.
- `ps`: list all processes and threads with their state.
- `bt <thread>`: backtrace of a specific thread.
- `continue`: leave DDB and resume the system. Use only if you have not made any changes.
- `panic`: force a panic so the system reboots cleanly. Use if `continue` is not safe.

Workflow for a hung test:

1. Enter DDB via the console break.
2. `show all locks`. Note any threads holding locks.
3. `ps` to find the test threads (look for `myfrd`, `myfwr`, or `cv_w` in the wait channel column).
4. For each interesting thread, `bt <pid> <tid>` to get a backtrace.
5. If a deadlock is suspected, `show sleepchain` for each waiting thread.
6. Once you have enough information, `panic` to reboot.

The DDB transcript becomes your debugging log. Save it (DDB can output to the console and the kernel message buffer; on a debug kernel with `EARLY_AP_STARTUP`, you can redirect output to serial).

12.7.4 Recognising Lost Wakeups

A lost wakeup is the most common `cv` bug. The symptom is a hung waiter that has been there forever; the thread is in `cv_wait_sig` and nothing wakes it.

Detection in DDB:

```
db> ps
... (find the hung thread, in state "*myfirst data" for example)
db> bt 1234 1235
... (backtrace shows the thread inside cv_wait_sig)
db> show locks
... (the thread holds no locks; it is sleeping)
```

The cv in question is identified by the wait channel name. If the channel name is `myfirst data`, the cv is `sc->data_cv`. Now ask: who should have called `cv_signal(&sc->data_cv)`? Search the source:

```
$ grep -n 'cv_signal(&sc->data_cv|cv_broadcast(&sc->data_cv' myfirst.c
```

For each call site, work out whether it was supposed to fire and whether it actually fired. Common culprits:

- The signal is inside an `if` that was never true.
- The signal is after a return that bypassed it.
- The signal targets the wrong cv (`cv_signal(&sc->room_cv)` instead of `data_cv`).
- The state change does not actually change the condition (you incremented `cb_used` but the consumer was checking `cb_free`, which is the same logical state but `cb_free == cb_size - cb_used`; that one is fine, but a similar miscalculation can hide).

Fix the source, rebuild, retest. The symptom should disappear.

12.7.5 Recognising Spurious Wakeups

A spurious wakeup is a wakeup that arrives while the condition is still false. Causes include signals (`cv_wait_sig` returns due to a signal even when the condition has not changed) and timeouts (`cv_timedwait_sig` returns due to the timer). Both are normal; the driver must handle them.

Detection: the bug is *not* the wakeup itself but the failure to handle it. The shape:

```
/* WRONG: */
if (cbuf_used(&sc->cb) == 0)
    cv_wait_sig(&sc->data_cv, &sc->mtx);
/* now reading cbuf assuming there is data, but a spurious wakeup
   could have brought us here while the buffer is still empty */
got = cbuf_read(&sc->cb, bounce, take);
```

`cbuf_read` would return zero in that case, which propagates to user space as a zero-byte read, which `cat` and other utilities interpret as EOF. The user sees a silent end-of-file that is not really an end of file.

Cure: always loop:

```

/* CORRECT: */
while (cbuf_used(&sc->cb) == 0) {
    int error = cv_wait_sig(&sc->data_cv, &sc->mtx);
    if (error != 0)
        return (error);
    if (!sc->is_attached)
        return (ENXIO);
}
got = cbuf_read(&sc->cb, bounce, take);

```

The `myfirst_wait_data` helper from Section 2 already follows this pattern. The general rule is: *never use `if` around a `cv_wait`; always use `while`.*

12.7.6 Recognising Lock Order Reversal

We saw a `WITNESS` warning earlier. The alternative, on a non-`WITNESS` kernel, is a deadlock. Two threads each hold one lock and want the other; neither can proceed.

Detection in DDB:

```

db> show all locks
Process 1234 (test1) thread 0xfffffe...
shared sx myfirst cfg (myfirst cfg) ... locked @ ...:120
shared sx myfirst cfg (myfirst cfg) r = 1 ... locked @ ...:120

Process 5678 (test2) thread 0xfffffe...
exclusive sleep mutex myfirst0 (myfirst) r = 0 ... locked @ ...:240

```

Then show `sleepchain` for each waiting thread:

```

db> show sleepchain 1234
Thread 1234 (pid X) blocked on lock myfirst0 owned by thread 5678
db> show sleepchain 5678
Thread 5678 (pid Y) blocked on lock myfirst cfg owned by thread 1234

```

That cycle is the deadlock. Each thread is blocked on a lock held by the other. The fix is to revisit the lock order; one of the two paths is acquiring in the wrong order. The fix is the same as for the `WITNESS` warning: find the offending acquisition and reorder it.

12.7.7 Sleeping With a Non-Sleepable Lock

If your driver uses `MTX_SPIN` mutexes or `rw(9)` locks and somewhere you call `cv_wait`, `mtx_sleep`, `uiomove`, or `malloc(M_WAITOK)` while holding one, `WITNESS` will fire:

```
sleeping thread (pid 1234, tid 5678) owns a non-sleepable lock:  
exclusive rw lock myfirst rw (myfirst rw) r = 0 ... locked @ ...:100
```

The warning names the lock and the location of the acquisition. The fix is to drop the lock before the sleeping operation. `myfirst` does not use `MTX_SPIN` or `rw(9)`, so we will not encounter this directly; if you reuse the patterns in another driver, watch for it.

12.7.8 Premature Destroy

A `cv` or `sx` that is destroyed while a thread is still waiting causes use-after-free style crashes. The symptom is usually a panic with a backtrace inside `cv_wait` or `sx_xlock` after `cv_destroy` or `sx_destroy` has already run.

The Chapter 11 detach pattern (refuse detach while `active_fhs > 0`) prevents this for most situations. The Chapter 12 driver extends the pattern with `cv_broadcast` calls before destroying:

```
MYFIRST_LOCK(sc);  
sc->is_attached = 0;  
cv_broadcast(&sc->data_cv);  
cv_broadcast(&sc->room_cv);  
MYFIRST_UNLOCK(sc);  
  
/* now wait for any thread that was sleeping to return.  
   The cv_broadcast above wakes them; they see is_attached  
   is false and return ENXIO. They release the mutex on  
   their way out. */  
  
/* Once we know no one is in the I/O paths, destroy the  
   primitives. By construction, active_fhs == 0 when we get  
   here, so no thread can re-enter. */  
cv_destroy(&sc->data_cv);  
cv_destroy(&sc->room_cv);  
sx_destroy(&sc->cfg_sx);  
mtx_destroy(&sc->mtx);
```

The order is important. The mutex is the interlock for the cvs (a thread inside `cv_wait_sig` was sleeping with `sc->mtx` released to the kernel; on wake-up, `cv_wait_sig` reacquires `sc->mtx` before it returns). If we destroy `sc->mtx` first and then `cv_destroy`, a not-yet-fully-woken thread can be stuck inside the kernel trying to reacquire a mutex whose memory we have just torn down. Destroying the cvs first guarantees that no thread is still inside `cv_wait_sig` by the time the mutex goes away. The same reasoning applies to the `sx`: a thread blocked inside `sx_xlock` does not hold the mutex, but its post-wake reacquisition path may trip over the order if the `sx` and the mutex are torn down simultaneously. Destroy in the reverse of the order in which a thread might still be holding or waiting on each primitive: cvs first (waiters drained), then the `sx` (no readers or writers left), then the mutex (no interlock partner left).

12.7.9 Helpful Asserts to Add

Sprinkle `sx_assert` and `mtx_assert` calls throughout the helpers to document the expected lock state. Each is free at production time (`INVARIANTS` is compiled out) and catches new bugs on the debug kernel.

Examples:

```
static int
myfirst_get_debug_level(struct myfirst_softc *sc)
{
    int level;

    sx_slock(&sc->cfg_sx);
    sx_assert(&sc->cfg_sx, SA_SLOCKED); /* document the lock state */
    level = sc->cfg.debug_level;
    sx_sunlock(&sc->cfg_sx);
    return (level);
}
```

The `sx_assert(&sc->cfg_sx, SA_SLOCKED)` is technically redundant after `sx_slock` (the lock was just acquired), but it makes the intent obvious to a reader and catches refactoring mistakes (someone moves the function and forgets the lock).

A more useful pattern: assertions in helpers that *expect* the caller to have acquired a lock:

```
static void
myfirst_apply_debug_level(struct myfirst_softc *sc, int level)
{
    sx_assert(&sc->cfg_sx, SA_XLOCKED); /* caller must hold xlock */
    sc->cfg.debug_level = level;
}
```

If a future call site tries to use this helper without the lock, the assertion fires. The function's expectations are now executable, not just documented.

12.7.10 Tracing Lock Activity With `dtrace` and `lockstat`

Two user-space tools let you observe lock behaviour without modifying the driver.

`lockstat(1)` summarises lock contention over a period:

```
# lockstat -P sleep 10
```

This runs for 10 seconds and prints a table of every lock that was contended, with hold times and wait times. For `myfirst` under `mp_stress`, you should see `myfirst0` (the device mutex) and `myfirst cfg` (the `sx`) at the top

of the list. Whether either has contention worth worrying about depends on the workload; for our pseudo-device, neither should.

`dtrace(1)` lets you trace specific events. To see every `cv_signal` on the data cv:

```
# dtrace -n 'fbt::cv_signal:entry /args[0]->cv_description == "myfirst data"/ {
↵  stack(); }'
```

This prints a kernel stack trace every time the signal is sent. Useful for pinpointing exactly which path is signalling and from where.

Both tools have minimal overhead and can be used on a production kernel as well as a debug one.

12.7.11 A Worked Walk-Through: A Lost Wakeup Bug

To make the diagnostic workflow concrete, walk through a hypothetical lost-wakeup bug from symptom to fix.

You make a change to the driver that subtly breaks the signal pairing in `myfirst_write`. After the change, the test suite mostly passes, but `mt_reader` occasionally hangs. You can reproduce it by running `mt_reader` ten or twenty times; once or twice the program hangs at one of its threads.

Step 1: confirm the symptom with `procstat`.

```
$ ps -ax | grep mt_reader
12345 ?? S+   mt_reader

$ procstat -kk 12345
  PID   TID COMM          TDNAME          KSTACK
12345 67890 mt_reader      -               mi_switch+0xc1 _cv_wait_sig+0xff
                                myfirst_wait_data+0x4e
                                myfirst_read+0x91
                                dofileread+0x82
                                sys_read+0xb5
```

The thread is in `_cv_wait_sig`. Looking up its wait channel:

```
$ ps -axHo pid,tid,wchan,command | grep mt_reader
12345 67890 myfirst      mt_reader
12345 67891 -          mt_reader
```

One thread blocked on `myfirst` (the eight-character truncation of "myfirst data"; see Section 2). The others have exited. So the cv data_cv has a waiter, and presumably the driver did not signal it when it should have.

Step 2: check the cbuf state.

```
$ sysctl dev.myfirst.0.stats.cb_used
dev.myfirst.0.stats.cb_used: 17
```

The buffer has 17 bytes in it. The reader should be able to drain those bytes and return them. Why is the reader still asleep?

Step 3: examine the source. The reader is in `cv_wait_sig(&sc->data_cv, &sc->mtx)`. Who calls `cv_signal(&sc->data_cv)`? Search:

```
$ grep -n 'cv_signal(&sc->data_cv|cv_broadcast(&sc->data_cv)' myfirst.c
180:         cv_signal(&sc->data_cv);
220:         cv_broadcast(&sc->data_cv); /* in detach */
```

Two callers. The relevant one is line 180, in `myfirst_write`. Look at it:

```
put = myfirst_buf_write(sc, bounce, want);
fh->writes += put;
MYFIRST_UNLOCK(sc);

if (put > 0) {
    cv_signal(&sc->data_cv);
    selwakeup(&sc->rsel);
}
```

The signal is conditional on `put > 0`. It looks correct. But the bug introduced earlier might have changed something else. Look further up:

```
MYFIRST_LOCK(sc);
error = myfirst_wait_room(sc, ioflag, nbfore, uio);
if (error != 0) {
    MYFIRST_UNLOCK(sc);
    return (error == -1 ? 0 : error);
}
room = cbuf_free(&sc->cb);
MYFIRST_UNLOCK(sc);

want = MIN((size_t)uio->uio_resid, sizeof(bounce));
want = MIN(want, room);
error = uiomove(bounce, want, uio);
if (error != 0)
    return (error);

MYFIRST_LOCK(sc);
put = myfirst_buf_write(sc, bounce, want);
```

Here is the bug. After `uiomove`, the code jumps straight back into the `cbuf` write. But what if `want` was computed against a stale room? Suppose between the `cbuf_free` call and the second `MYFIRST_LOCK`, another writer added bytes. The second `myfirst_buf_write` could be called with a `want` that exceeds the actual current room.

In our case, `myfirst_buf_write` returns the actual number of bytes written, which may be less than `want`. We update `bytes_written` correctly. But we then signal `data_cv` only if `put > 0`. So far so good.

But wait. Look at the buggy line carefully: imagine the change introduced was to wrap the signal in a different condition:

```
if (put == want) { /* WRONG: was put > 0 */
    cv_signal(&sc->data_cv);
    selwakeup(&sc->rsel);
}
```

Now if `put < want` (because another writer beat us to the room), we do not signal. The bytes were added to the `cbuf`, but the readers are not woken. A reader currently in `cv_wait_sig` will sleep until somebody else writes a complete buffer.

That is the lost-wakeup bug. The fix is to signal whenever `put > 0`, not whenever `put == want`. Apply the fix, rebuild, retest. The hang disappears.

Step 4: prevent regression. Add a `KASSERT` at the wakeup site that documents the contract:

```
KASSERT(put <= want, ("myfirst_buf_write returned %zu > want=%zu",
    put, want));
if (put > 0) {
    cv_signal(&sc->data_cv);
    selwakeup(&sc->rsel);
}
```

The `KASSERT` does not catch the bug we just fixed (it was triggered by `put != want`, which is permitted). But it documents that the signal-condition is “any forward progress”, which is the rule the next maintainer should preserve.

This walk-through is contrived; real bugs are messier. The pattern is real. Symptom -> instrumentation -> source examination -> hypothesis -> fix -> regression guard. Practice it on the labs in this chapter.

12.7.12 A Worked Walk-Through: a Lock Order Reversal

Another common scenario: `WITNESS` reports a reversal that you do not immediately understand.

The warning, simplified:

```
lock order reversal:
1st 0xfffffe000a1b2c30 myfirst cfg (myfirst cfg, sx) @ myfirst.c:120
2nd 0xfffffe000a1b2c50 myfirst0 (myfirst, sleep mutex) @ myfirst.c:240
```

```
lock order myfirst cfg -> myfirst0 attempted at myfirst.c:241
where myfirst0 -> myfirst cfg is established at myfirst.c:280
```

Step 1: identify the locks. `myfirst cfg` is the `sx`; `myfirst0` is the device mutex.

Step 2: identify the canonical order. From the warning: `myfirst0 -> myfirst cfg`. So `mtx` first, then `sx`.

Step 3: identify the violating path. The warning says the violating path is at `myfirst.c:241`, where it tries to acquire `myfirst0` while already holding `myfirst cfg`. Open the source at line 241 and trace upward to find when the `cfg sx` was acquired (line 120, by the warning's 1st field).

Step 4: decide the fix. Two options. Either reorder the violating path to match the canonical order (acquire `mtx` first, then `sx`; this is usually the cheaper change), or accept that the violating path has a real reason to acquire in the reverse order, in which case the canonical order needs to change globally and `LOCKING.md` updated.

For our `myfirst`, the violating path almost certainly should match the canonical. The fix is to read the `cfg` value via the snapshot-and-apply pattern: drop the `sx` before acquiring the `mtx`.

Step 5: verify. Apply the fix, rebuild, rerun the test that triggered the warning. `WITNESS` should now be silent. If it is not, the warning has shifted to a different path and you have a second violation to investigate.

12.7.13 Common Mistakes That Hide From WITNESS

`WITNESS` is excellent at what it checks but does not check everything. Three classes of bug it cannot detect:

Locks held across function pointers. If a function holds lock A and calls a callback that the function pointer is supplied by user-controlled configuration, `WITNESS` cannot predict what locks the callback might acquire. The lock order with respect to the callback is undefined. Avoid this pattern; if you must use it, document the acceptable lock states for any callback.

Race conditions on lockless fields. A field that is intentionally accessed without a lock is invisible to `WITNESS`. If two threads race on that field and the racing matters, `WITNESS` will not warn. Use atomics or the appropriate lock; never assume a lockless field is safe just because no warning fires.

Incorrect protection. A field is protected by a mutex on the write path but read without the mutex on the read path. Intermittent torn reads result. `WITNESS` does not flag this; the audit procedure from Chapter 11 Section 3 does.

The cure for all three is the discipline of writing `LOCKING.md` and keeping it accurate. `WITNESS` confirms that the locks you claim to hold, you actually hold; the document confirms that the rules you claim to follow are the rules the design intends.

12.7.14 Wrapping Up Section 6

Synchronization debugging is a vocabulary first and a toolset second. The vocabulary is the six failure shapes: lost wakeup, spurious wakeup, lock-order reversal, premature destroy, sleeping with a non-sleepable lock, race between detach and active operation. Each has a recognisable signature and a standard cure. The toolset is

WITNESS, INVARIANTS, KASSERT, `sx_assert`, the in-kernel debugger commands `show all locks` and `show sleepchain`, and the user-space observability tools `lockstat(1)` and `dtrace(1)`.

Section 7 puts these tools to work on a realistic stress scenario.

12.8 Section 7: Stress Testing with Realistic I/O Patterns

The Chapter 11 stress kit (`producer_consumer`, `mp_stress`, `mt_reader`, `lat_tester`) tested the data path under simple multi-threaded and multi-process workloads. The Chapter 12 driver has new primitives (`cv`, `sx`) and a new code path (the configuration `sysctls`). This section extends the testing to exercise the new surfaces and shows you how to read the resulting data.

The goal is not exhaustive coverage; it is *realistic* coverage. A driver that survives a stress workload that resembles real production traffic is a driver you can trust.

12.8.1 What Realistic Looks Like

A real driver typically has:

- Multiple producers and consumers running concurrently.
- `Sysctl` reads sprinkled throughout (monitoring tools, dashboards).
- Occasional `sysctl` writes (configuration changes from an administrator).
- Bursts of activity interleaved with idle periods.
- Mixed-priority threads competing for the CPU.

A test that exercises only one of these axes can miss bugs that only appear when several axes interact. For example, a `sysctl` write that takes the `cfg sx` in exclusive mode while a data path is mid-operation might expose a subtle ordering issue that pure I/O testing would not.

12.8.2 A Composite Workload

Build a script that runs three things at once for a fixed duration:

```
#!/bin/sh
# Composite stress: I/O + sysctl readers + sysctl writers.

DUR=60

(./mp_stress &) >/tmp/mp.log
(./mt_reader &) >/tmp/mt.log
(./config_writer $DUR &) >/tmp/cw.log

# Burst sysctl readers
for i in 1 2 3 4; do
    (while sleep 0.5; do
```

```

        sysctl -q dev.myfirst.0.stats >/dev/null
        sysctl -q dev.myfirst.0.debug_level >/dev/null
        sysctl -q dev.myfirst.0.soft_byte_limit >/dev/null
    done) &
done
SREAD_PIDS=$!

sleep $DUR

# Stop everything
pkill -f mp_stress
pkill -f mt_reader
pkill -f config_writer
kill $SREAD_PIDS 2>/dev/null

wait

echo "=== mp_stress ==="
cat /tmp/mp.log
echo "=== mt_reader ==="
cat /tmp/mt.log
echo "=== config_writer ==="
cat /tmp/cw.log

```

The script runs for one minute. During that minute, the driver sees:

- Two writer processes hammering writes.
- Two reader processes hammering reads.
- Four pthreads in `mt_reader` hammering reads on a single descriptor.
- The `config_writer` toggling debug level and soft byte limit every 10 ms.
- Four shell loops reading sysctls every 0.5 seconds.

Under a debug kernel with `WITNESS`, this is enough activity to catch most lock-ordering and signal-pairing bugs. Run it. If it completes without panic, without `WITNESS` warnings, and with consistent byte counts in the readers and writers, the driver has passed a meaningful synchronization test.

12.8.3 Long-Duration Variant

For the most subtle bugs, run the composite for an hour:

```

$ for i in $(seq 1 60); do
    ./composite_stress.sh
    echo "iteration $i complete"
    sleep 5
done

```

Sixty iterations of a one-minute test gives an hour of cumulative coverage. Bugs that appear once per million events (which is roughly what an hour of `mp_stress` produces on a modern machine) usually surface during this run.

12.8.4 Latency Under Mixed Load

The Chapter 11 `lat_tester` measured the latency of a single read with no other load. Under realistic load, latency tells a different story: it includes time waiting for the mutex, time waiting for the sx, and time inside `cv_wait_sig`.

Run `lat_tester` while `mp_stress` and `config_writer` are running. The histogram should show a longer tail than the unloaded case. A few microseconds for uncontested operations, a few tens of microseconds when the mutex is briefly held by another thread, and a small spike of milliseconds when the cv had to actually sleep waiting for data. If the tail extends to seconds, something is wrong.

12.8.5 Reading lockstat Output

`lockstat(1)` is the canonical tool for measuring lock contention. Run it during a heavy stress:

```
# lockstat -P sleep 30 > /tmp/lockstat.out
```

The `-P` flag includes spin lock data; without it, only adaptive locks are reported. The 30 means “sample for 30 seconds”.

The output is organized by lock, with hold time and wait time statistics. For our driver, look for lines mentioning `myfirst0` (the `mtx`), `myfirst cfg` (the `sx`), and the `cvs` (`myfirst data`, `myfirst room`).

A healthy result for `myfirst` under typical stress:

- The `mtx` is acquired millions of times. Hold time per acquisition is tens of nanoseconds. Wait time is occasional and small.
- The `sx` is acquired tens of thousands of times. Most acquisitions are shared; the few exclusive acquisitions correspond to `sysctl` writes. Hold time is low.
- The `cvs` are signalled and broadcast in proportion to the I/O rate. Wait counts on each `cv` correspond to the number of times a reader or writer actually had to block.

If any lock shows wait time as a significant fraction of total time, that lock is contended. The fix is one of: shorter critical sections, finer-grained locking, or a different primitive.

For our pseudo-device with a single-mutex design on the data path, the `mtx` will saturate around 4-8 cores depending on the speed of `cbuf` operations. This is expected; we have not optimized for high core counts. The point of the chapter is correctness, not throughput.

12.8.6 Tracing With dtrace

When a specific event needs visibility, `dtrace` is the right tool. Example: count how many times each `cv` was signalled during a 10-second window:

```
# dtrace -n 'fbt::cv_signal:entry { @[args[0]->cv_description] = count(); }' \
-n 'fbt::cv_broadcastpri:entry { @[args[0]->cv_description] = count(); }' \
-n 'tick-10sec { exit(0); }'
```

After 10 seconds, dtrace prints a table:

```
myfirst data      48512
myfirst room      48317
...
```

The numbers should be roughly equal for data_cv and room_cv if the workload is symmetric (equal reads and writes). A large imbalance suggests one side is sleeping more than the other, which usually means a flow-control issue.

Another useful one-liner: histogram of cv_wait latency on the data cv:

```
# dtrace -n '
fbt::_cv_wait_sig:entry /args[0]->cv_description == "myfirst data"/ {
    self->ts = timestamp;
}
fbt::_cv_wait_sig:return /self->ts/ {
    @ = quantize(timestamp - self->ts);
    self->ts = 0;
}
tick-10sec { exit(0); }
'
```

The histogram shows the distribution of times threads spent inside _cv_wait_sig. Most should be short (signalled promptly). A long tail indicates threads sleeping for extended periods, which is normal for an idle device but suspicious for a busy one.

12.8.7 Watching With vmstat and top

For a coarser view, vmstat and top running in the background provide context.

vmstat 1 shows per-second statistics: CPU time spent in user, system, and idle; context switches; interrupts. During a stress run, sy (system time) should rise; cs (context switches) should rise as well, due to the cv signalling.

top -SH (the -S shows system processes; -H shows individual threads) shows per-thread CPU usage. During a stress run, the test threads should be visible. The WCHAN column shows what they are waiting on; expect to see the truncated cv descriptions (myfirst for both data_cv and room_cv, since the trailing word is cut by WMESGLEN) plus, for any thread still using the Chapter 11 anonymous channel, the address of &sc->cb printed as a small numeric string.

Both are useful as background companions to a long stress run. They do not produce structured data, but they confirm at a glance that things are happening.

12.8.8 Observing the Sysctls

A simple sanity check during the stress: read the sysctls periodically and verify they make sense.

```
$ while sleep 1; do
    sysctl dev.myfirst.0.stats.bytes_read \
        dev.myfirst.0.stats.bytes_written \
        dev.myfirst.0.stats.cb_used \
        dev.myfirst.0.debug_level \
        dev.myfirst.0.soft_byte_limit
done
```

The byte counters should monotonically increase. The `cb_used` should hover in some range. The configuration should change as `config_writer` updates it.

If any `sysctl` read hangs (the `sysctl` command does not return), there is a synchronization problem with the `sysctl` handler. Probably a held mutex blocking the `sysctl` from acquiring the `sx`, or vice versa. Use `procstat -kk $$` from another terminal to see what the hanging shell is waiting on.

12.8.9 Stress Test Acceptance Criteria

A driver passes a synchronization stress test if:

1. The composite script completes without panic.
2. WITNESS reports no warnings (`dmesg | grep -i witness | wc -l` returns zero).
3. Byte counts from readers and writers are within 1% of each other (small drift is acceptable due to timing of test stop).
4. `lockstat(1)` shows no lock with wait time exceeding 5% of total time.
5. The latency histogram from `lat_tester` shows the 99th percentile under one millisecond for an idle device, or under the configured timeout for a busy one.
6. Repeated runs (the long-duration loop) all pass.

These are not absolute thresholds; they are the values that have served the chapter's example. Real drivers may have stricter or looser bounds depending on their workload.

12.8.10 Interpreting lockstat Output in Detail

`lockstat(1)` produces tables that look intimidating on first encounter. A short tour of the columns demystifies them.

A typical line for a contended lock:

```
Adaptive mutex spin: 1234 events in 30.000 seconds (41.13 events/sec)
```

```
-----
Count    nsec    ----- Lock -----    Hottest Caller
1234      321    myfirst0                    myfirst_read+0x91
```

What the columns mean:

- Count: number of events of this kind (acquires, in this case).
- nsec: average duration of the event (here, average time spinning before acquiring the lock).
- Lock: the lock's name.
- Hottest Caller: the function that most often experienced this event.

Lower in the output:

```
Adaptive mutex block: 47 events in 30.000 seconds (1.57 events/sec)
```

```
-----
Count    nsec      ----- Lock -----      Hottest Caller
   47    58432    myfirst0                      myfirst_read+0x91
```

The “block” event is when the spin failed and the thread had to actually sleep. Average sleep time was 58 microseconds. That is high; it means a writer was holding the mutex during what should have been a short critical section.

Taken together, the spin events (1234) and block events (47) tell us the lock was contended 1281 times in 30 seconds, and 96% of the time the spin succeeded. That is a healthy pattern: most contention is brief, and only the rare long hold causes a real sleep.

For sleep locks (sx, cv), the columns are similar but the events are categorized differently:

```
SX shared block: 2014 events in 30.000 seconds (67.13 events/sec)
```

```
-----
Count    nsec      ----- Lock -----      Hottest Caller
  2014    2105    myfirst cfg                      myfirst_get_debug_level+0x12
```

This says: shared waiters on the cfg sx blocked 2014 times, average wait 2.1 microseconds, mostly from the debug-level helper. With a config writer running, that is expected. Without the writer, it should be near zero.

The key skill in reading lockstat output is calibration: knowing what numbers are expected for your workload. A driver that has never been measured under load is a driver whose expected numbers are unknown. Run lockstat once with a known workload and save the output as the baseline. Future runs are then compared to the baseline; significant deviations are signal.

12.8.11 Tracing Specific Code Paths With dtrace

Beyond the cv-counting and sleep-latency examples earlier, a few more dtrace recipes are useful for a chapter-12-style driver.

Count cv waits per cv per second:

```
# dtrace -n '
fbt::_cv_wait_sig:entry { @[args[0]->cv_description] = count(); }
tick-1sec { printa(@); trunc(@); }'
```

Prints a per-second tally of cv waits, broken down by cv name. Useful for spotting bursts.

Trace which thread acquires the cfg sx exclusively:

```
# dtrace -n '
fbt::_sx_xlock:entry /args[0]->lock_object.lo_name == "myfirst cfg"/ {
    printf("%s pid %d acquires cfg xlock\n", execname, pid);
    stack();
}'
```

Useful for confirming that the only writers are the sysctl handlers, not some other unexpected path.

Histogram of myfirst_read latency:

```
# dtrace -n '
fbt::myfirst_read:entry { self->ts = timestamp; }
fbt::myfirst_read:return /self->ts/ {
    @ = quantize(timestamp - self->ts);
    self->ts = 0;
}
tick-30sec { exit(0); }'
```

Same pattern as the cv-wait latency histogram, but at the handler level. Includes the time spent inside `cv_wait_sig` plus the time inside the `cbuf` operations and the `uiomove`.

These recipes are starting points. The `dtrace` provider for kernel functions (`fbt`) gives access to every function entry and return; the language is rich enough to express almost any aggregation.

12.8.12 Wrapping Up Section 7

Realistic stress testing exercises the whole driver, not just one path. A composite workload that combines I/O, `sysctl` reads, and `sysctl` writes catches lock-ordering bugs that pure I/O testing would miss. `lockstat(1)` and `dtrace(1)` give you observability into the lock and cv activity without modifying the driver. A driver that passes the composite stress kit on a WITNESS kernel for an hour is a driver you can promote to the next chapter with confidence.

Section 8 closes the chapter with the housekeeping work: the documentation pass, the version bump, the regression test, and the changelog entry that tells your future self what you did and why.

12.9 Section 8: Refactoring and Versioning Your Synchronized Driver

The driver now uses three primitives (mtx, cv, sx), has two lock classes with a documented order, supports interruptible and timed reads, and has a small configuration subsystem. The remaining work is the housekeeping pass: cleaning up the source for clarity, updating the documentation, bumping the version, running static analysis, and validating the regression test passes.

This section covers each. None of it is glamorous. All of it is what separates a working driver from a maintainable one.

12.9.1 Cleaning Up the Source

After a chapter of focused changes, the source has accumulated some inconsistencies that are worth tidying.

Group related code. Move all the cv-related helpers next to each other (the wait helpers, the signal calls, the cv_init/cv_destroy in attach/detach). Move all the sx-related helpers together. The compiler does not care about ordering, but a reader does.

Standardise the macro vocabulary. Chapter 11 introduced MYFIRST_LOCK, MYFIRST_UNLOCK, MYFIRST_ASSERT. Add the symmetric set for the sx:

```
#define MYFIRST_CFG_SLOCK(sc)    sx_slock(&(sc)->cfg_sx)
#define MYFIRST_CFG_SUNLOCK(sc) sx_sunlock(&(sc)->cfg_sx)
#define MYFIRST_CFG_XLOCK(sc)   sx_xlock(&(sc)->cfg_sx)
#define MYFIRST_CFG_XUNLOCK(sc) sx_xunlock(&(sc)->cfg_sx)
#define MYFIRST_CFG_ASSERT_X(sc) sx_assert(&(sc)->cfg_sx, SA_XLOCKED)
#define MYFIRST_CFG_ASSERT_S(sc) sx_assert(&(sc)->cfg_sx, SA_SLOCKED)
```

Now every lock acquisition in the driver goes through a macro. If we later switch from sx to rw, the change is in one header, not scattered across the source.

Eliminate dead code. If a helper from Chapter 11 is no longer called (perhaps the old wakeup channel is gone), remove it. Dead code attracts confusion.

Comment the non-obvious bits. Every lock acquisition that follows the lock-order rule deserves a one-line comment. Every place where snapshot-and-apply is used deserves a comment explaining why. The locking is the most subtle part of the driver; the comments should reflect that.

12.9.2 Updating LOCKING.md

The Chapter 11 LOCKING.md documented one lock and a small set of fields. The Chapter 12 driver has more to say. The new version:

```
# myfirst Locking Strategy
```

```
Version 0.6-sync (Chapter 12).
```

Overview

The driver uses three synchronization primitives: a sleep mutex (sc->mtx) for the data path, an sx lock (sc->cfg_sx) for the configuration subsystem, and two condition variables (sc->data_cv, sc->room_cv) for blocking reads and writes. Byte counters use counter(9) per-CPU counters and protect themselves.

Locks Owned by This Driver

sc->mtx (mutex(9), MTX_DEF)

Protects:

- sc->cb (the circular buffer's internal state)
- sc->open_count, sc->active_fhs
- sc->is_attached (writes; reads at handler entry may be unprotected as an optimization, re-checked after every sleep)

Lock-Free Plain Integers

- sc->read_timeout_ms, sc->write_timeout_ms: plain ints, accessed without locking. Safe because aligned int reads and writes are atomic on every architecture FreeBSD supports, and the values are advisory; a stale read just produces a slightly different timeout for the next wait. The sysctl framework writes them directly via CTLFLAG_RW.

sc->cfg_sx (sx(9))

Protects:

- sc->cfg.debug_level
- sc->cfg.soft_byte_limit
- sc->cfg.nickname

Shared mode: every read of any cfg field.

Exclusive mode: every write of any cfg field.

sc->data_cv (cv(9))

Wait condition: data is available in the cbuf.

Interlock: sc->mtx.

Signalled by: myfirst_write after a successful cbuf write.

Broadcast by: myfirst_detach.

Waiters: myfirst_read in myfirst_wait_data.

`sc->room_cv (cv(9))`

Wait condition: room is available in the cbuf.

Interlock: `sc->mtx`.

Signalled by: `myfirst_read` after a successful cbuf read, and `myfirst_sysctl_reset` after resetting the cbuf.

Broadcast by: `myfirst_detach`.

Waiters: `myfirst_write` in `myfirst_wait_room`.

Lock-Free Fields

- `sc->bytes_read`, `sc->bytes_written`: `counter_u64_t`. Updates via `counter_u64_add`; reads via `counter_u64_fetch`.

Lock Order

`sc->mtx` -> `sc->cfg_sx`

A thread holding `sc->mtx` may acquire `sc->cfg_sx` in either mode.

A thread holding `sc->cfg_sx` may NOT acquire `sc->mtx`.

Rationale: the data path always holds `sc->mtx` and may need to read configuration during its critical section. The configuration path (sysctl writers) does not need the data mutex; if a future feature requires both, it must acquire `sc->mtx` first.

Locking Discipline

1. Acquire mutex with `MYFIRST_LOCK(sc)`, release with `MYFIRST_UNLOCK(sc)`.
2. Acquire `sx` in shared mode with `MYFIRST_CFG_SLOCK`, exclusive with `MYFIRST_CFG_XLOCK`. Release with the matching unlock.
3. Wait on a `cv` with `cv_wait_sig` (interruptible) or `cv_timedwait_sig` (interruptible + bounded).
4. Signal a `cv` with `cv_signal` (one waiter) or `cv_broadcast` (all waiters). Use `cv_broadcast` only for state changes that affect all waiters (detach, configuration reset).
5. NEVER hold `sc->mtx` across `uiomove(9)`, `copyin(9)`, `copyout(9)`, `selwakeup(9)`, or `wakeup(9)`. Each of these may sleep or take other locks. `cv_wait_sig` is the exception (it atomically drops the interlock).
6. NEVER hold `sc->cfg_sx` across `uiomove(9)` etc., for the same reason.
7. All `cbuf_*` calls must happen with `sc->mtx` held (the helpers

```
assert MA_OWNED).
```

8. The detach path clears `sc->is_attached` under `sc->mtx`, broadcasts both cvs, and refuses detach while `active_fhs > 0`.

Snapshot-and-Apply Pattern

When a path needs both `sc->mtx` and `sc->cfg_sx`, it should follow the snapshot-and-apply pattern:

1. `sx_slock(&sc->cfg_sx)`; read `cfg` into local variables; `sx_sunlock(&sc->cfg_sx)`.
2. `MYFIRST_LOCK(sc)`; do `cbuf` operations using the snapshot; `MYFIRST_UNLOCK(sc)`.

The snapshot may be slightly stale by the time it is used. For configuration values that are advisory (debug level, soft byte limit), this is acceptable.

Known Non-Locked Accesses

`sc->is_attached` at handler entry

Unprotected plain read. Safe because:

- A stale "true" is re-checked after every sleep via `if (!sc->is_attached) return (ENXIO)`.
- A stale "false" causes the handler to return `ENXIO` early, which is also what it would do with a fresh false.

`sc->open_count`, `sc->active_fhs` at `sysctl` read time

Unprotected plain loads. Safe on amd64 and arm64 (aligned 64-bit loads are atomic). Acceptable on i386 because the torn read, if it ever happened, would produce a single bad statistic with no correctness impact.

Wait Channels

- `sc->data_cv`: data has become available.
- `sc->room_cv`: room has become available.

(The legacy `&sc->cb` wakeup channel from Chapter 10 has been retired in Chapter 12.)

History

- 0.6-sync (Chapter 12): added cv channels, sx for configuration, bounded reads via cv_timedwait_sig.
- 0.5-kasserts (Chapter 11, Stage 5): KASSERT calls added throughout cbuf helpers and wait helpers.
- 0.5-counter9 (Chapter 11, Stage 3): byte counters migrated to counter(9).
- 0.5-concurrency (Chapter 11, Stage 2): MYFIRST_LOCK/UNLOCK/ASSERT macros, explicit locking strategy.
- Earlier versions: see Chapter 10 / Chapter 11 history.

That document is now the authoritative description of the driver's synchronization story. Any future change updates the document in the same commit as the code change. A reviewer who wants to know whether a change is safe reads the diff against the document, not against the code.

12.9.3 Bumping the Version

Update the version string:

```
#define MYFIRST_VERSION "0.6-sync"
```

Print it at attach (the existing device_printf line in attach already includes the version):

```
device_printf(dev,
    "Attached; version %s, node /dev/%s (alias /dev/myfirst), "
    "cbuf=%zu bytes\n",
    MYFIRST_VERSION, devtoname(sc->cdev), cbuf_size(&sc->cb));
```

Update the changelog:

0.6-sync (Chapter 12)

- Replaced anonymous wakeup channel (&sc->cb) with two named condition variables (sc->data_cv, sc->room_cv).
- Added bounded read support via sc->read_timeout_ms sysctl, using cv_timedwait_sig under the hood.
- Added a small configuration subsystem (sc->cfg) protected by an sx lock (sc->cfg_sx).
- Added sysctl handlers for debug_level, soft_byte_limit, and nickname.
- Added myfirst_sysctl_reset that takes both locks in the canonical order to clear the cbuf and reset counters.
- Updated LOCKING.md with the new primitives, the lock order, and

- the snapshot-and-apply pattern.
- Added MYFIRST_CFG_* macros symmetric with the existing MYFIRST_* mutex macros.
- All Chapter 11 tests continue to pass; new sysctl-based tests added under userland/.

12.9.4 Updating the README

The Chapter 11 README named the driver and described its features. The Chapter 12 README adds the new ones:

myfirst

A FreeBSD 14.3 pseudo-device driver that demonstrates buffered I/O, concurrency, and modern synchronization primitives. Developed as the running example for the book "FreeBSD Device Drivers: From First Steps to Kernel Mastery."

Status

Version 0.6-sync (Chapter 12).

Features

- A Newbus pseudo-device under nexus0.
- A primary device node at /dev/myfirst/0 (alias: /dev/myfirst).
- A circular buffer (cbuf) as the I/O buffer.
- Blocking, non-blocking, and timed reads and writes.
- poll(2) support via d_poll and selinfo.
- Per-CPU byte counters via counter(9).
- A single sleep mutex protects composite cbuf state; see LOCKING.md.
- Two named condition variables (data_cv, room_cv) coordinate read and write blocking.
- An sx lock protects the runtime configuration (debug_level, soft_byte_limit, nickname).

Configuration

Three runtime-tunable parameters via sysctl:

- dev.myfirst.<unit>.debug_level (0-3): controls dmesg verbosity.
- dev.myfirst.<unit>.soft_byte_limit: refuse writes that would push cb_used above this threshold (0 = no limit).
- dev.myfirst.<unit>.nickname: a string used in log messages.

```
- dev.myfirst.<unit>.read_timeout_ms: bound a blocking read.
```

(The last is per-instance; see myfirst.4 for details, when written.)

Build and Load

```
$ make
# kldload ./myfirst.ko
# dmesg | tail
# ls -l /dev/myfirst
# printf 'hello' > /dev/myfirst
# cat /dev/myfirst
# kldunload myfirst
```

Tests

See ../../userland/ for the test programs. The Chapter 12 tests include config_writer (toggles sysctls during stress) and timeout_tester (verifies bounded reads).

License

BSD 2-Clause. See individual source files for SPDX headers.

12.9.5 Running Static Analysis

Run clang --analyze against the Chapter 12 driver:

```
$ make WARNS=6 clean all
$ clang --analyze -D_KERNEL -I/usr/src/sys \
  -I/usr/src/sys/amd64/conf/GENERIC myfirst.c
```

Triage the output. New warnings since Chapter 11 should be either:

1. False positives (clang does not understand the locking discipline). Document each.
2. Real bugs. Fix each.

Common false positives in driver code involve `sx_assert` and `mtx_assert` macros that clang cannot see through; the analyser thinks the lock might not be held even when the assert proves it is. These are acceptable to silence with `__assert_unreachable()` or by restructuring the code to make the lock state more obvious to the analyser.

12.9.6 Running the Regression Suite

The Chapter 11 regression script extends naturally:

```
#!/bin/sh
# regression.sh: full Chapter 12 regression.

set -eu

die() { echo "FAIL: $" ">&2; exit 1; }
ok() { echo "PASS: $"; }

[ $(id -u) -eq 0 ] || die "must run as root"
kldstat | grep -q myfirst && kldunload myfirst
[ -f ./myfirst.ko ] || die "myfirst.ko not built; run make first"

kldload ./myfirst.ko
trap 'kldunload myfirst 2>/dev/null || true' EXIT

sleep 1
[ -c /dev/myfirst ] || die "device node not created"
ok "load"

# Chapter 7-10 tests.
printf 'hello' > /dev/myfirst || die "write failed"
cat /dev/myfirst >/tmp/out.$$
[ "$(cat /tmp/out.$$)" = "hello" ] || die "round-trip content mismatch"
rm -f /tmp/out.$$
ok "round-trip"

cd ../userland && make -s clean && make -s && cd -

../userland/producer_consumer || die "producer_consumer failed"
ok "producer_consumer"

../userland/mp_stress || die "mp_stress failed"
ok "mp_stress"

# Chapter 12-specific tests.
../userland/timeout_tester || die "timeout_tester failed"
ok "timeout_tester"

../userland/config_writer 5 &
CW=$!
../userland/mt_reader || die "mt_reader (under config writer) failed"
wait $CW
ok "mt_reader under config writer"
```

```

sysctl dev.myfirst.0.stats >/dev/null || die "sysctl stats not accessible"
sysctl dev.myfirst.0.debug_level >/dev/null || die "sysctl debug_level not accessible"
sysctl dev.myfirst.0.soft_byte_limit >/dev/null || die "sysctl soft_byte_limit not
↪ accessible"
ok "sysctl"

# WITNESS check.
WITNESS_HITS=$(dmesg | grep -ci "witness\|lor" || true)
if [ "$WITNESS_HITS" -gt 0 ]; then
    die "WITNESS warnings detected ($WITNESS_HITS lines)"
fi
ok "witness clean"

echo "ALL TESTS PASSED"

```

A green run after each commit is the minimum bar. A green run on a WITNESS kernel after a long-duration composite is the higher bar.

12.9.7 Pre-Commit Checklist

The Chapter 11 checklist gets two new items for Chapter 12:

1. Have I updated `LOCKING.md` with any new locks, cvs, or order changes?
2. Have I run the full regression suite on a WITNESS kernel?
3. Have I run the long-duration composite stress for at least 30 minutes?
4. Have I run `clang --analyze` and triaged every new warning?
5. Have I added a `sx_assert` or `mtx_assert` for any new helper that expects a lock state?
6. Have I bumped the version string and updated `CHANGELOG.md`?
7. Have I verified that the test kit builds and runs?
8. **(New)** Have I checked that every `cv` has both a signaller and a documented condition?
9. **(New)** Have I checked that every `sx_xlock` has a paired `sx_xunlock` on every code path, including error paths?

The two new items capture the most common bugs in Chapter 12-style code. A `cv` without a signaller is dead weight (waiters will never wake). An `sx_xlock` without a paired unlock on an error path is a quiet deadlock waiting to happen.

12.9.8 Wrapping Up Section 8

The driver is now not only correct but verifiably correct, well-documented, and versioned. It has:

- An updated `LOCKING.md` describing three primitives, two lock classes, and one canonical lock order.
- A new version string (0.6-sync) reflecting the Chapter 12 work.
- A regression script that exercises every primitive and validates WITNESS cleanliness.
- A pre-commit checklist that catches the two new failure modes Chapter 12 introduced.

That is the close of the chapter's main teaching arc. The labs and challenges follow.

12.10 Hands-on Labs

These labs consolidate the Chapter 12 concepts through direct hands-on experience. They are ordered from least to most demanding. Each is designed to be completable in a single lab session.

12.10.1 Pre-Lab Setup Checklist

Before starting any lab, confirm the four items below. The Chapter 11 checklist applies; we add three Chapter 12-specific ones.

1. **Debug kernel running.** `sysctl kern.ident` reports the kernel with `INVARIANTS` and `WITNESS`.
2. **WITNESS active.** `sysctl debug.witness.watch` returns a non-zero value.
3. **Driver source matches Chapter 11 Stage 5 (kasserts).** From your driver directory, `make clean && make` should compile cleanly.
4. **A clean dmesg.** `dmesg -c >/dev/null` once before the first lab.
5. **(New) Companion userland built.** From `examples/part-03/ch12-synchronization-mechanisms/userland/`, `make` should produce the `config_writer` and `timeout_tester` binaries.
6. **(New) Chapter 11 stress kit available.** The labs reuse `mp_stress`, `mt_reader`, and `producer_consumer` from Chapter 11.
7. **(New) Backup of Stage 5.** Copy the working Stage 5 driver to a safe location before starting any lab that modifies the source. Several labs intentionally introduce bugs that need to be reverted cleanly.

12.10.2 Lab 12.1: Replace Anonymous Wakeup Channels With Condition Variables

Goal. Convert the Chapter 11 driver from `mtx_sleep/wakeup` on the anonymous channel `&sc->cb` to two named condition variables (`data_cv` and `room_cv`).

Steps.

1. Copy your Stage 5 driver into `examples/part-03/ch12-synchronization-mechanisms/stage1-cv-channels/`.
2. Add `struct cv data_cv` and `struct cv room_cv` to `struct myfirst_softc`.
3. In `myfirst_attach`, call `cv_init(&sc->data_cv, "myfirst data")` and `cv_init(&sc->room_cv, "myfirst room")`. Place them after the mutex init.
4. In `myfirst_detach`, before `mtx_destroy`, call `cv_broadcast` on each `cv` to wake any sleepers, then `cv_destroy` on each.
5. Replace the `mtx_sleep(&sc->cb, ...)` calls in `myfirst_wait_data` and `myfirst_wait_room` with `cv_wait_sig(&sc->data_cv, &sc->mtx)` and `cv_wait_sig(&sc->room_cv, &sc->mtx)` respectively.
6. Replace the `wakeup(&sc->cb)` calls in `myfirst_read` and `myfirst_write` with `cv_signal(&sc->room_cv)` and `cv_signal(&sc->data_cv)` respectively. Note the swap: a successful read frees room (so wake writers); a successful write produces data (so wake readers).
7. Build, load, run the Chapter 11 stress kit.

Verification. All Chapter 11 tests pass. `procstat -kk` against a sleeping reader shows wait channel `myfirst` (the truncated form of "myfirst data"; see the Section 2 note about `WMESGLEN`). No `WITNESS` warnings.

Stretch goal. Use `dtrace` to count signals to each `cv` during `mp_stress`. Confirm that the signal counts are roughly equal between `data_cv` and `room_cv` (because reads and writes are roughly equal).

12.10.3 Lab 12.2: Add Bounded Reads

Goal. Add a `read_timeout_ms` sysctl that bounds blocking reads.

Steps.

1. Copy Lab 12.1 into `stage2-bounded-read/`.
2. Add an `int read_timeout_ms` field to the `softc`. Initialize to 0 in `attach`.
3. Register a `SYSCTL_ADD_INT` for it under `dev.myfirst.<unit>.read_timeout_ms`, with `CTLFLAG_RW`.
4. Modify `myfirst_wait_data` to use `cv_timedwait_sig` when `read_timeout_ms > 0`, converting milliseconds to ticks. Translate `EWOULDBLOCK` to `EAGAIN`.
5. Build and load.
6. Build the `timeout_tester` from `examples/part-03/ch12-synchronization-mechanisms/userland/`.
7. Set the sysctl to 100, run `timeout_tester`, observe that `read(2)` returns `EAGAIN` after about 100 ms.
8. Reset the sysctl to 0, run `timeout_tester` again. The read blocks until you Ctrl-C, returning `EINTR`.

Verification. The output of `timeout_tester` matches expectations for both timeout and signal-interruption cases. Stress kit still passes.

Stretch goal. Add a symmetric `write_timeout_ms` sysctl and verify it bounds writes when the buffer is full.

12.10.4 Lab 12.3: Add an sx-Protected Configuration Subsystem

Goal. Add the `cfg` struct and `cfg_sx` lock from Section 5; expose `debug_level` as a sysctl.

Steps.

1. Copy Lab 12.2 into `stage3-sx-config/`.
2. Add struct `sx cfg_sx` and struct `myfirst_config cfg` to the `softc`. Initialize in `attach` (`sx_init(&sc->cfg_sx, "myfirst cfg");` default values for `cfg` fields). Destroy in `detach`.
3. Add a `myfirst_sysctl_debug_level` handler following the snapshot-and-apply pattern. Register it.
4. Add a `MYFIRST_DBG(sc, level, fmt, ...)` macro that consults `sc->cfg.debug_level` via `sx_slock`.
5. Sprinkle a few `MYFIRST_DBG(sc, 1, ...)` calls in the read/write paths to log when the buffer becomes empty or full.
6. Build and load.
7. Run `mp_stress`. Confirm no log spam (`debug_level` defaults to 0).
8. `sysctl -w dev.myfirst.0.debug_level=2` and run `mp_stress` again. Now `dmesg` should show debug messages.
9. Reset the level to 0.

Verification. Debug messages appear and disappear as the sysctl changes. No `WITNESS` warnings during the toggle.

Stretch goal. Add the `soft_byte_limit` sysctl. Set it to 1024 and run a writer that produces bursts of 4096 bytes; confirm that the writer sees EAGAIN early.

12.10.5 Lab 12.4: Inspect Held Locks With DDB

Goal. Use the in-kernel debugger to inspect a hung test.

Steps.

1. Make sure the debug kernel has options `DDB` and a configured way to drop into DDB (typically `Ctrl-Alt-Esc` on a serial console, or the Break key).
2. Load Lab 12.3's driver.
3. Start a `cat /dev/myfirst` in one terminal. It blocks (no producer).
4. From the console (or via `sysctl debug.kdb.enter=1`), drop into DDB.
5. Run `show all locks`. Note any threads holding locks.
6. Run `ps`. Find the `cat` process and the `myfirst` data wait channel.
7. Run `bt <pid> <tid>` for the `cat` thread. Confirm the backtrace ends in `_cv_wait_sig`.
8. `continue` to leave DDB.
9. Send `SIGINT` to the `cat` (Ctrl-C).

Verification. The `cat` returns with `EINTR`. No panics. You have a transcript of the DDB session.

Stretch goal. Repeat with `mp_stress` running concurrently. Compare `show all locks` output: more locks, more activity, but the same shape.

12.10.6 Lab 12.5: Detect a Deliberate Lock Order Reversal

Goal. Introduce a deliberate LOR and observe WITNESS catching it.

Steps.

1. Copy Lab 12.3 into a scratch directory `stage-lab12-5/`. Do not modify Lab 12.3 in place.
2. Add a path that violates the lock order. For example, in a small experimental sysctl handler:

```
/* WRONG: sx first, then mtx, reversing the canonical order. */
sx_xlock(&sc->cfg_sx);
MYFIRST_LOCK(sc);
/* trivial work */
MYFIRST_UNLOCK(sc);
sx_xunlock(&sc->cfg_sx);
```

3. Build and load on the WITNESS kernel.
4. Run `mp_stress` (which exercises the canonical order via the data path) and trigger the new sysctl simultaneously.
5. Watch `dmesg` for the `lock order reversal` warning.
6. Record the warning text. Note the line numbers.

7. Delete the scratch directory; do not commit the bug.

Verification. `dmesg` shows a `lock_order_reversal` warning naming both locks and both source locations.

Stretch goal. Determine, just from the `WITNESS` output, where the canonical order was first established. Open the source at that line and confirm.

12.10.7 Lab 12.6: Long-Running Composite Stress

Goal. Run the composite stress workload from Section 7 for 30 minutes and verify clean.

Steps.

1. Boot the debug kernel.
2. Build and load `examples/part-03/ch12-synchronization-mechanisms/stage4-final/`. This is the final integrated driver (cv channels + bounded reads + sx-protected configuration + the reset sysctl). All the Section 7 sysctls that the composite script touches are present here.
3. Build the userland testers.
4. Save the Section 7 composite stress script as `composite_stress.sh`.
5. Wrap it in a 30-minute loop:

```
for i in $(seq 1 30); do
    ./composite_stress.sh
    echo "iteration $i done"
done
```

6. Monitor `dmesg` periodically.
7. After completion, check:
 - `dmesg | grep -ci witness` returns 0.
 - All loop iterations completed.
 - `vmstat -m | grep cbuf` shows the expected static allocation (no growth).

Verification. All criteria met. The driver survives 30 minutes of composite stress on a debug kernel without warning, panic, or memory growth.

Stretch goal. Run the same loop for 24 hours on a dedicated test machine. Bugs that appear at this scale are the ones that cost the most in production.

12.10.8 Lab 12.7: Verify the Snapshot-and-Apply Pattern Holds Under Contention

Goal. Show that the snapshot-and-apply pattern in `myfirst_write` correctly handles concurrent updates to the soft byte limit.

Steps.

1. Set the soft byte limit to a small value: `sysctl -w dev.myfirst.0.soft_byte_limit=512`.
2. Start `mp_stress` with two writers and two readers.

3. From a third terminal, repeatedly toggle the limit: `while sleep 0.1; do sysctl -w dev.myfirst.0.soft_byte_limit=$RANDOM; done.`
4. Watch the writer output. Some writes will succeed; others will return `EAGAIN` (the limit was below the current `cb_used` at the moment of check).
5. Watch `dmesg` for WITNESS warnings.

Verification. No WITNESS warnings. The byte counts in `mp_stress` are slightly lower than usual (because some writes were refused), but the total written approximately equals the total read.

Stretch goal. Modify `myfirst_write` to violate the lock-order rule by acquiring the `cfg sx` while holding the data mutex. Reload, run the same test. WITNESS should fire on the first run that exercises both paths simultaneously. Revert the change.

12.10.9 Lab 12.8: Profile With lockstat

Goal. Use `lockstat(1)` to characterize the contended locks under stress.

Steps.

1. Load Lab 12.3's driver on the debug kernel.
2. Start `mp_stress` in one terminal.
3. From another, run `lockstat -P sleep 30 > /tmp/lockstat.out.`
4. Open the output file. Find the entries for `myfirst0 (mtx)` and `myfirst cfg (sx)`.
5. Note: the maximum hold time, the average hold time, the maximum wait time, the average wait time, and the acquisition count.
6. Repeat with `config_writer` running. Compare the `myfirst cfg` numbers.

Verification. The numbers match the expected profile. The mutex shows millions of acquisitions with short hold times. The `sx` shows tens of thousands of acquisitions, mostly shared, with very short hold times.

Stretch goal. Modify the driver to artificially extend a critical section (e.g., add a 10 ms pause(9) inside the mutex). Re-run `lockstat`. Observe the contention spike. Revert the modification.

12.11 Challenge Exercises

The challenges extend Chapter 12 beyond the baseline labs. Each is optional; each is designed to deepen your understanding.

12.11.1 Challenge 1: Use `sx_downgrade` for a Config Refresh

The `myfirst_sysctl_debug_level` handler currently drops the shared lock and reacquires the exclusive lock. An alternative is to acquire shared, attempt `sx_try_upgrade`, and `sx_downgrade` after the modification. Implement this variant. Compare the behaviour under contention. When does each pattern win?

12.11.2 Challenge 2: Implement a Drain Operation Using `cv_broadcast`

Add an `ioctl` or `sysctl` that “drains” the `cbuf`: blocks until `cb_used == 0`, then returns. The implementation should use `cv_wait_sig(&sc->room_cv, ...)` in a loop on the condition `cb_used > 0`. Verify that `cv_broadcast(&sc->room_cv)` after the drain wakes every waiter, not just one.

12.11.3 Challenge 3: A `dtrace` Script for `cv_wait` Latency

Write a `dtrace` script that produces a histogram of how long threads spend inside `cv_wait_sig` on each of `data_cv` and `room_cv`. Run it during `mp_stress`. What does the distribution look like? Where is the long tail?

12.11.4 Challenge 4: Replace `cv` With Anonymous Channels

Re-implement the data and room conditions using `mtx_sleep` and wakeup on anonymous channels (a regression to the Chapter 11 design). Run the tests. The driver should still work, but the `procstat -kk` output and the `dtrace` queries become less informative. Describe the readability difference.

12.11.5 Challenge 5: Add Per-Descriptor `read_timeout_ms`

The `read_timeout_ms` `sysctl` is per-device. Add a per-descriptor timeout via an `ioctl(2)`: `MY-FIRST_SET_READ_TIMEOUT(int ms)` on a file descriptor sets that descriptor’s timeout. The driver code becomes more interesting because the timeout now lives in `struct myfirst_fh` rather than `struct myfirst_softc`. Beware: the per-fh state is not shared with other descriptors (no lock needed for the field itself), but the choice of timeout still affects the wait helper.

12.11.6 Challenge 6: Use `rw(9)` Instead of `sx(9)`

Replace `sx_init` with `rw_init`, `sx_xlock` with `rw_wlock`, and so on. Run the tests. What breaks? (Hint: the `cfg` path may include a sleeping operation; `rw` is not sleepable.) What does the failure look like? When would `rw(9)` be the right choice?

12.11.7 Challenge 7: Implement a Multi-CV Drain

The driver has two `cvs`. Suppose detach should be considered complete only when both `cvs` have zero waiters. Implement a check in detach that loops until `data_cv.cv_waiters == 0` and `room_cv.cv_waiters == 0`, sleeping briefly between checks. (Note: accessing `cv_waiters` directly from outside the `cv` API is non-portable; this is an exercise in understanding the internal state. Real production code should use a different mechanism.)

12.11.8 Challenge 8: Lock-Order Visualization

Use `dtrace` or `lockstat` to produce a graph of lock acquisitions during `mp_stress`. The nodes are locks; the edges are “holder of A acquired B while still holding A”. Compare the graph to your `LOCKING.md` lock order. Are there acquisitions you did not anticipate?

12.11.9 Challenge 9: Sleep-Channel Comparison

Build two versions of the driver: one using `cv` (the Chapter 12 default) and one using legacy `mtx_sleep/wakeup` on anonymous channels (the Chapter 11 default). Run identical workloads on both. Measure: maximum throughput, latency at the 99th percentile, WITNESS cleanliness, and the readability of the source. Write a one-page report.

12.11.10 Challenge 10: Bound Configuration Writes

The Chapter 12 driver allows configuration writes at any time. Add a `sysctl cfg_write_cooldown_ms` that limits how often a configuration change can occur (e.g., at most one write per 100 ms). Implement this with a timestamp field in the `cfg` struct and a check in each `cfg` `sysctl` handler. Decide what to do when the cooldown is violated: return `EBUSY`, queue the change, or silently coalesce. Document the choice.

12.12 Troubleshooting

This reference catalogues the bugs you are most likely to encounter while working through Chapter 12.

12.12.1 Symptom: Reader hangs forever despite data being written

Cause. A lost wakeup. The writer added bytes but did not signal `data_cv`, or the signal targeted the wrong `cv`.

Fix. Search the source for every place that adds bytes; ensure `cv_signal(&sc->data_cv)` is called. Confirm the `cv` is the one waiters are blocked on.

12.12.2 Symptom: WITNESS warns “lock order reversal” between `sc->mtx` and `sc->cfg_sx`

Cause. A path took the locks in the wrong order. The canonical order is `mtx` first, `sx` second.

Fix. Find the offending path (the warning names the lines). Either reorder the acquisitions to match the canonical order, or refactor the path to avoid holding both locks simultaneously (snapshot-and-apply).

12.12.3 Symptom: `cv_timedwait_sig` returns `EWOULDBLOCK` immediately

Cause. The timeout in ticks was zero or negative. Most likely the conversion from milliseconds to ticks rounded down to zero.

Fix. Use the $(\text{timo\_ms} * \text{hz} + 999) / 1000$ formula to round up to at least one tick. Verify `hz` is the expected value (typically 1000 on FreeBSD 14.3).

12.12.4 Symptom: detach hangs

Cause. A thread is sleeping on a cv that has not been broadcast, or the detach is waiting for `active_fhs > 0` to drop and a descriptor is open.

Fix. Confirm that detach broadcasts both cvs before the `active_fhs` check. Use `fstat | grep myfirst` from a separate terminal to find any process holding the device open; kill it.

12.12.5 Symptom: sysctl write hangs

Cause. The sysctl handler is waiting for a lock that is held by a thread doing something blocking. Most commonly, the `cfg sx` is held in exclusive mode by a slow `sysctl_handle_string`.

Fix. Verify the sysctl handler follows the snapshot-and-apply pattern: acquire shared, read, release; then `sysctl_handle_*` outside the lock; then exclusive lock to commit. Holding the lock across `sysctl_handle_*` is the bug.

12.12.6 Symptom: sx_destroy panics with “lock still held”

Cause. `sx_destroy` was called while another thread still held the lock or was waiting for it.

Fix. Confirm that detach refuses to proceed while `active_fhs > 0`. Confirm that no kernel thread or callout is using the `cfg sx` after detach starts.

12.12.7 Symptom: cv_signal or cv_broadcast wakes nothing visible

Cause. No one was waiting on the cv at the moment of the signal. Both `cv_signal` and `cv_broadcast` are no-ops when the wait queue is empty, and a `dtrace` probe on the wake side sees no follow-on activity.

Fix. None needed; the empty wake is correct and harmless. If you expected a waiter and there was none, the bug is upstream: either the waiter never reached `cv_wait_sig`, or the waker is targeting the wrong cv. Confirm via `dtrace` that the signal is firing on the cv you intend, and `procstat -kk` against the waiter to confirm where it is sleeping.

12.12.8 Symptom: read_timeout_ms set to 100 produces 200 ms latency

Cause. The kernel’s `hz` value is lower than expected. The +999 round-up means a 100 ms timeout at `hz=100` becomes 10 ticks (100 ms), but if `hz=10` it becomes 1 tick (100 ms). Different rounding.

Fix. Confirm `hz` with `sysctl kern.clockrate`. For tighter timeouts, use `cv_timedwait_sig_sbt` directly with `SBT_1MS * timo_ms` to avoid the tick rounding.

12.12.9 Symptom: A deliberately-broken lock order does not produce a WITNESS warning

Cause. Either the path with the bug is not exercised by the test, or `WITNESS` is not enabled in the running kernel.

Fix. Confirm `sysctl debug.witness.watch` returns nonzero. Confirm the offending path runs (add a `device_printf` to verify). Run the test under `mp_stress` to maximize the chance of the bug surfacing.

12.12.10 Symptom: lockstat shows enormous wait times on the data mutex

Cause. The mutex is being held across a long operation. Common offenders: `uiomove` accidentally inside the critical section; a debug `device_printf` that prints a large string while holding the lock.

Fix. Audit the critical sections. Move long operations outside. The mutex should be held for tens of nanoseconds, not microseconds.

12.12.11 Symptom: mp_stress reports byte-count mismatch after Chapter 12 changes

Cause. A wakeup was missed during the `cv` refactor. A reader started waiting after a writer's signal had already been delivered (no waiter at signal time, signal lost).

Fix. Verify that the wait helpers use `while`, not `if`, around `cv_wait_sig`. Verify that the signal happens after the state change, not before.

12.12.12 Symptom: timeout_tester shows latency longer than the configured timeout

Cause. Scheduler latency. The kernel scheduled the thread some milliseconds after the timer fired. This is normal; expect a few ms of jitter.

Fix. None for typical workloads. For real-time workloads, raise the thread's priority via `rtprio(2)`.

12.12.13 Symptom: kldunload reports busy when no descriptor is open

Cause. A taskqueue or background thread is still using a primitive in the driver. (Should not happen for our chapter, but worth knowing.)

Fix. Audit any taskqueue-, callout-, or kthread-spawning code. The detach must drain or terminate all of them before declaring it safe to unload.

12.12.14 Symptom: cv_wait_sig wakes immediately and returns 0

Cause. A signal arrived while the wait was being set up, or the `cv` was signalled by a thread that ran just before the wait was issued. Not actually a bug; the `while` loop is supposed to handle it.

Fix. Confirm that the surrounding `while (!condition)` re-checks. The loop turns the spurious-looking wakeup into a no-op: re-check, find condition false, sleep again.

12.12.15 Symptom: Two threads waiting on the same cv get woken in unexpected order

Cause. `cv_signal` wakes one waiter chosen by sleep-queue policy (highest priority, FIFO among equal). It does not wake them in arrival order if their priorities differ.

Fix. None usually needed; the kernel's choice is correct. If you require strict arrival-order wake-up, use a different design (per-waiter `cv`, or an explicit queue).

12.12.16 Symptom: `sx_xlock` under heavy reader load takes seconds to acquire

Cause. Many shared holders, each releasing slowly because the `cfg sx` is being acquired and released on every I/O. The writer is starved by the constant trickle of readers.

Fix. The kernel uses the `SX_LOCK_WRITE_SPINNER` flag to give writers priority once they begin waiting; the starvation is bounded but can still produce visible latency. If the latency is unacceptable, redesign so writers happen during quiescent windows or under a different protocol.

12.12.17 Symptom: Tests pass on a non-WITNESS kernel but fail on WITNESS

Cause. Almost always a real bug that WITNESS has detected. The most common: a lock acquired in a path that violates the global order, but the deadlock has not yet manifested because the contending workload has not been hit.

Fix. Read the WITNESS warning carefully. The warning text includes the source location of every violation. Fix the violation; the test should then pass on both kernels.

12.12.18 Symptom: Locking macros expand to nothing on the non-debug kernel

Cause. This is by design. `mtx_assert`, `sx_assert`, `KASSERT`, and `MYFIRST_ASSERT(sc)` (which expands to `mtx_assert`) compile to nothing without `INVARIANTS`. The asserts are free at production time and informative at development time.

Fix. None needed. Confirm that your test kernel has `INVARIANTS` enabled and the asserts will fire when violated.

12.12.19 Symptom: Sysctl handler blocks the entire system

Cause. A sysctl handler that holds a lock across a slow operation can effectively serialize every other operation that needs the same lock. If the lock is the device's main mutex, every I/O is blocked until the sysctl returns.

Fix. Sysctl handlers should follow the same discipline as I/O handlers: hold the lock for the minimum time, release before any potentially-slow operation. The snapshot-and-apply pattern works equally well here.

12.12.20 Symptom: A reader gets EAGAIN even with `read_timeout_ms=0`

Cause. The read returned `EAGAIN` because of `O_NONBLOCK` (the file descriptor was opened non-blocking, or `fcntl(2)` set `O_NONBLOCK` on it). The driver's `IO_NDELAY` check returns `EAGAIN` regardless of the timeout sysctl.

Fix. Confirm the descriptor is blocking: `fcntl(fd, F_GETFL)` should return a value without the `O_NONBLOCK` bit set. If non-blocking is intended, `EAGAIN` is the correct response.

12.12.21 Symptom: kldunload after a successful test still hangs briefly

Cause. The detach path is waiting for in-flight handlers to return. Each waiter that was sleeping on a cv must wake (because of the broadcast), reacquire the mutex, see `!is_attached`, return, and exit the kernel. This takes a few milliseconds for several waiters.

Fix. None usually needed; a few-millisecond delay is normal. If the delay is longer, check that every waiter does have a post-sleep `is_attached` check.

12.12.22 Symptom: Two separate driver instances both report WITNESS warnings about the same lock name

Cause. Both instances initialize their locks with the same name (`myfirst0` for both, for example). WITNESS treats locks of the same name as the same logical lock and may warn about duplicate acquisition or invented order issues across instances.

Fix. Initialize each instance's lock with a unique name that includes the unit number, for example via `device_get_nameunit(dev)` which yields `myfirst0`, `myfirst1`, etc. Our chapter already does this for the device mutex; do the same for cvs and sx.

12.12.23 Symptom: A cv with many waiters takes a long time to broadcast

Cause. `cv_broadcast` walks the wait queue, marking each waiter as runnable. The walk is $O(n)$ in the number of waiters. With hundreds of waiters this becomes a measurable cost.

Fix. The broadcast itself is rarely a bottleneck for normal workloads; it is the subsequent thundering-herd contention as every awakened thread tries to acquire the interlock that causes visible pause. If your driver routinely has hundreds of waiters on the same cv, reconsider the design; per-waiter cvs or a queue-based approach may scale better.

12.13 Wrapping Up

Chapter 12 took the driver you built in Chapter 11 and gave it a richer synchronization vocabulary. The single mutex from Chapter 11 is still there, doing the same job, with the same rules. Around it now sit two named condition variables that replace the anonymous wakeup channel, an sx lock that protects a small but real configuration subsystem, and a bounded-wait capability that lets the read path return promptly when the user expects it to. The lock order between the two lock classes is documented, enforced by WITNESS, and verified by a stress kit that runs the data path and the configuration path concurrently.

We learned to think about synchronization as a vocabulary, not just a mechanism. A condition variable says *I am waiting for a specific change; tell me when it happens*. A shared lock says *I am reading; do not let a writer in*. A timed wait says *and please give up if it takes too long*. Each primitive is a different shape of agreement between threads, and using the right shape for each agreement produces code that reads like the design rather than fights against it.

We also learned to debug synchronization carefully. The six failure shapes (lost wakeup, spurious wakeup, lock-order reversal, premature destroy, sleeping with a non-sleepable lock, race between detach and active operation)

cover almost every bug you will hit in practice. `WITNESS` catches the ones the kernel can detect at runtime; the in-kernel debugger lets you inspect a hung system; `lockstat(1)` and `dtrace(1)` give you observability without modifying the source.

We finished with a refactor pass. The driver now has a documented lock order, a clean `LOCKING.md`, a bumped version string, an updated changelog, and a regression test that verifies every primitive on every supported workload. That infrastructure scales: when Chapter 13 adds timers and Chapter 14 adds interrupts, the documentation pattern absorbs the new primitives without growing brittle.

12.13.1 What You Should Now Be Able to Do

A short self-checklist of capabilities you should now have, before turning to Chapter 13:

- Look at a piece of shared state in any driver and choose the right primitive (atomic, mutex, sx, rw, cv) by walking the decision tree.
- Replace any anonymous wakeup channel in any driver with a named cv, and explain why the change is an improvement.
- Add a bounded blocking primitive to any wait path, and explain when to use `EAGAIN`, `EINTR`, `ERESTART`, or `EWOULDBLOCK`.
- Design a multi-reader, single-writer subsystem with documented lock order.
- Read a `WITNESS` warning and identify the offending lock pair from the source location alone.
- Diagnose a hung system in DDB using `show all locks` and `show sleepchain`.
- Run a composite stress workload and measure lock contention with `lockstat(1)`.
- Write a `LOCKING.md` document that another developer can use as authoritative reference.

If any of those feels uncertain, the labs in Chapter 12 are the place to build the muscle memory. None requires more than a couple of hours; together they cover every primitive and every pattern the chapter introduced.

12.13.2 Three Closing Reminders

The first is to *run the composite stress before you commit*. The composite kit catches the cross-primitive bugs that single-axis tests miss. Thirty minutes on a debug kernel is a small investment for the confidence it produces.

The second is to *keep the lock order honest*. Every new lock you introduce starts a new question: where in the order does it sit? Answer the question explicitly in `LOCKING.md` before you write the code. The cost of getting the answer wrong scales with the size of the driver; the cost of writing it down at the start is one minute.

The third is to *trust the primitives and use the right one*. The kernel's mutex, cv, sx, and rw locks are the result of decades of engineering. The temptation to roll your own coordination using flags and atomic flags is real and almost always misguided. Pick the primitive that names what you are trying to say. The code will be shorter, clearer, and provably more correct.

12.14 Reference: The Driver's Stage Progression

Chapter 12 evolves the driver in four discrete stages, each of which is its own directory under `examples/part-03/ch12-synchronization-mechanisms/`. The progression mirrors the chapter's narrative; it lets a reader build the driver one primitive at a time and see what each addition contributes.

12.14.1 Stage 1: cv-channels

Replaces the anonymous `&sc->cb` wakeup channel with two named condition variables (`data_cv`, `room_cv`). The wait helpers use `cv_wait_sig` instead of `mtx_sleep`. The signallers use `cv_signal` (or `cv_broadcast` in detach) on the cv that matches the state change.

What changes: the sleep/wake mechanism. The driver behaves identically from user space.

What you can verify: `procstat -kk` shows the cv name (`myfirst_data` or `myfirst_room`) instead of the `wmesg` (`myfrd`). `dtrace` can attach to specific cvs. Throughput is slightly higher because per-event signalling avoids waking unrelated waiters.

12.14.2 Stage 2: bounded-read

Adds a `read_timeout_ms` sysctl that bounds blocking reads via `cv_timedwait_sig`. A symmetric `write_timeout_ms` is also possible.

What changes: the read path can now return `EAGAIN` after a configurable timeout. The default of zero preserves the indefinite-wait behaviour from Stage 1.

What you can verify: `timeout_tester` reports `EAGAIN` after approximately the configured timeout. Setting the timeout to zero restores indefinite waits. Ctrl-C still works either way.

12.14.3 Stage 3: sx-config

Adds a `cfg` struct to the `softc`, protected by an `sx_lock` (`cfg_sx`). Three configuration fields (`debug_level`, `soft_byte_limit`, `nickname`) are exposed as sysctls. The data path consults `debug_level` for log emission and `soft_byte_limit` for write rejection.

What changes: the driver gains a configuration interface. The `MYFIRST_DBG` macro consults the current debug level. Writes that would exceed the soft limit return `EAGAIN`.

What you can verify: `sysctl -w dev.myfirst.0.debug_level=2` produces visible debug messages. Setting `soft_byte_limit` causes writes to start failing once the buffer reaches the limit. `WITNESS` reports the lock order (mtx first, sx second) and is silent under stress.

12.14.4 Stage 4: final

The combined version with all three primitives, plus a `LOCKING.md` update, the version bump to `0.6-sync`, and the new `myfirst_sysctl_reset` that exercises both locks together.

What changes: integration. No new primitives.

What you can verify: the regression suite passes; the composite stress workload runs cleanly for at least 30 minutes; `clang --analyze` is silent.

This four-stage progression is the canonical Chapter 12 driver. The companion examples mirror the stages exactly so a reader can compile and load any one of them.

12.15 Reference: Migrating From `mtx_sleep` to `cv`

If you are working on an existing driver that uses the legacy `mtx_sleep/wakeup` channel mechanism, the migration to `cv(9)` is mechanical. A short recipe.

A note before starting: the legacy mechanism is not deprecated and is still widely used in the FreeBSD tree. Many drivers will keep `mtx_sleep` indefinitely and that is perfectly correct. The migration is worth doing when you have multiple distinct conditions sharing a single channel (the thundering-herd case), or when you want the `procstat` and `dtrace` visibility that named `cvs` provide. For a driver with a single condition and a single channel, the migration is purely cosmetic; do it for readability if you want, skip it if you do not.

12.15.1 Step 1: Identify Each Logical Wait Channel

Read the source. Find every `mtx_sleep` call. For each, ask: what is the condition this thread is waiting for?

In the Chapter 11 driver, there were two logical conditions both using `&sc->cb`:

- `myfirst_wait_data`: waiting for `cbuf_used > 0`.
- `myfirst_wait_room`: waiting for `cbuf_free > 0`.

Two conditions; one channel. The migration assigns each its own `cv`.

12.15.2 Step 2: Add `cv` Fields to the Softc

For each logical condition, add a `struct cv` field. Pick a descriptive name:

```
struct cv  data_cv;  
struct cv  room_cv;
```

Initialize in `attach (cv_init)` and destroy in `detach (cv_destroy)`.

12.15.3 Step 3: Replace `mtx_sleep` with `cv_wait_sig`

For each `mtx_sleep` call, replace with `cv_wait_sig` (or `cv_timedwait_sig`):

```
/* Before: */  
error = mtx_sleep(&sc->cb, &sc->mtx, PCATCH, "myfrd", 0);  
  
/* After: */  
error = cv_wait_sig(&sc->data_cv, &sc->mtx);
```

The `wmesg` argument is gone (the `cv`'s description string takes its place). The `PCATCH` is implicit in the `_sig` suffix. The interlock argument is the same.

12.15.4 Step 4: Replace wakeup with cv_signal or cv_broadcast

For each `wakeup(&channel)` call, decide whether one waiter or all waiters should be woken. Replace with `cv_signal` or `cv_broadcast`:

```
/* Before: */
wakeup(&sc->cb); /* both readers and writers were on this channel */

/* After: */
if (write_succeeded)
    cv_signal(&sc->data_cv); /* only readers care about new data */
if (read_succeeded)
    cv_signal(&sc->room_cv); /* only writers care about new room */
```

This is also the moment to add the per-event correspondence the cv API encourages: signal only when the state actually changed.

12.15.5 Step 5: Update the Detach Path

Detach was waking the channel before destroying state:

```
/* Before: */
sc->is_attached = 0;
wakeup(&sc->cb);

/* After: */
sc->is_attached = 0;
cv_broadcast(&sc->data_cv);
cv_broadcast(&sc->room_cv);
/* later, after all waiters have exited: */
cv_destroy(&sc->data_cv);
cv_destroy(&sc->room_cv);
```

`cv_broadcast` ensures every waiter wakes; the post-wait `is_attached` check returns `ENXIO` for each of them.

12.15.6 Step 6: Update LOCKING.md

Document each new cv: its name, its condition, its interlock, its signaller(s), its waiter(s). The Chapter 12 driver's `LOCKING.md` is the template.

12.15.7 Step 7: Re-run the Stress Kit

The migration should not change observable behaviour; only the internal mechanism. Run the existing tests; they should pass. Run them under `WITNESS`; no new warnings should appear.

The migration in our chapter is a few hundred lines of source; the recipe above scales to drivers of any size. The benefit is that every wait is now self-documenting and every signal is targeted.

12.15.8 When Migration Is and Is Not Worth It

The migration costs a few hours of refactor effort, a careful re-run of the test suite, and an update to the documentation. The benefits are:

- Each wait acquires a name visible in `procstat`, `dtrace`, and source.
- Wakeups become per-condition; the thundering herd shrinks.
- Wakeup-channel mismatches are easier to spot in the source.

For a small driver with a single waiting condition, the costs and benefits roughly cancel; the legacy mechanism is fine. For a driver with two or more distinct conditions, the migration almost always pays off. For a driver maintained by multiple developers, the readability win is large.

12.16 Reference: Pre-Production Audit Checklist

A short audit to perform before promoting a synchronization-heavy driver from development to production. Each item is a question; each item should be answerable with confidence.

12.16.1 Lock Inventory

- ☐ Have I listed every lock the driver owns in `LOCKING.md`?
- ☐ For each lock, have I named what it protects?
- ☐ For each lock, have I named the contexts in which it may be acquired?
- ☐ For each lock, have I documented its lifetime (created where, destroyed where)?

12.16.2 Lock Order

- ☐ Is the global lock order documented in `LOCKING.md`?
- ☐ Does every code path that holds two locks follow the global order?
- ☐ Have I run `WITNESS` for at least 30 minutes under stress and observed no order reversals?
- ☐ If the driver has more than one instance, have I confirmed that intra-instance ordering is consistent with inter-instance ordering?

12.16.3 cv Inventory

- ☐ Have I listed every cv the driver owns?
- ☐ For each cv, have I named the condition it represents?
- ☐ For each cv, have I named the interlock mutex?
- ☐ For each cv, have I confirmed at least one signaller and at least one waiter?
- ☐ For each cv, have I confirmed `cv_broadcast` is called in detach before `cv_destroy`?

12.16.4 Wait Helpers

- ☐ Is every `cv_wait` (or variant) inside a `while (!condition)` loop?
- ☐ Does every wait helper re-check `is_attached` after the wait?
- ☐ Does every wait helper return a sensible error (`ENXIO`, `EINTR`, `EAGAIN`)?

12.16.5 Signal Sites

- ☐ Does every state change that should wake waiters have a corresponding `cv_signal` or `cv_broadcast`?
- ☐ Is `cv_signal` used when only one waiter needs to wake; `cv_broadcast` only when all do?
- ☐ Are signal sites guarded by `if (state_changed)` so empty signals are skipped?

12.16.6 Detach Path

- ☐ Does detach refuse to proceed while `active_fhs > 0`?
- ☐ Does detach clear `is_attached` under the device mutex?
- ☐ Does detach broadcast every `cv` before destroying?
- ☐ Are primitives destroyed in reverse acquisition order (innermost lock destroyed first)?

12.16.7 Static Analysis

- ☐ Has `clang --analyze` been run; new warnings triaged?
- ☐ Has `WARNS=6` build produced no warnings?
- ☐ Has the regression suite been run on a `WITNESS` kernel; all tests pass?

12.16.8 Documentation

- ☐ Is `LOCKING.md` up to date with the code?
- ☐ Is the version string in the source bumped?
- ☐ Is the `CHANGELOG.md` updated?
- ☐ Does the `README.md` describe the new features and their sysctls?

A driver that passes this audit is a driver you can trust under load.

12.17 Reference: Sleep Channel Hygiene

Both the legacy `mtx_sleep/wakeup` channel mechanism and the modern `cv(9)` API rely on a *channel* that identifies which waiters a wakeup affects. The channel is a key into the kernel's sleep-queue hash table. Mistakes around channels are the source of several common bugs.

A few rules of hygiene.

12.17.1 One Channel Per Logical Condition

If your driver has two distinct conditions that block (say, “data available” and “room available”), use two distinct channels. Sharing a single channel forces every wakeup to wake all waiters; some of them will go back to sleep immediately because their condition is still false. The performance cost is real; the readability cost is also real.

In our chapter, this rule manifests as `data_cv` and `room_cv` being separate cvs. The Chapter 11 driver used a shared anonymous channel `&sc->cb` and paid the thundering-herd cost; Chapter 12’s split is the cure.

12.17.2 Channel Pointers Must Be Stable

A channel is an address. The kernel does not interpret it; it uses it as a hash key. The address must not change between the wait and the signal. This usually happens automatically (the address of a `softc` field is stable for the lifetime of the `softc`), but be careful about temporary buffers, stack-allocated structures, or freed memory.

If you see a wait that hangs after a particular code path, suspect a channel-pointer mismatch. The signaller and the waiter must be using the same address.

12.17.3 Channel Pointers Must Be Unique to Their Purpose

If the same address is used for two different purposes (say, the data-available channel and a “completion” channel), wakeups for one purpose may unintentionally wake waiters for the other. Use a different field of the `softc` as the channel for each purpose, or use a `cv` (which has a name and is a separate object).

12.17.4 Wakers Should Hold the Interlock When the State Could Change

Although `wakeup` and `cv_signal` are not strictly required to be called under the interlock, doing so closes a race window in which a waiter checks the condition (false), the state changes, the wakeup fires (no waiters in the queue), and the waiter then enqueues and sleeps forever. Holding the interlock while signalling is the safe default; relax only when you can prove the state cannot revert.

Our Chapter 12 design signals after dropping the mutex, which is safe because the `cv`’s own enqueue-under-interlock contract closes the race for `cv` (not for wakeup). For wakeup, signal under the mutex.

12.17.5 A Signal With No Waiter Is Free

`cv_signal` and `wakeup` on a channel with no waiters do nothing. There is no penalty for an unnecessary signal; the cost is essentially the cost of taking and releasing the `cv`-queue spin lock. Do not avoid signals out of optimization fear; signal when the state changes, even if it sometimes signals nothing.

12.17.6 A Wait With No Signaller Is a Bug

A wait that is never signalled is a hang. Ensure that every wait has at least one matching signal site, and that the matching site is reached in every code path that produces the awaited state change.

This is the most common `cv` bug. The audit checklist asks the question; the discipline of asking it during code review catches most cases.

12.18 Reference: Common cv Idioms

Quick-lookup collection for the cv patterns you will use most often.

12.18.1 Wait for a Condition

```
mtx_lock(&mtx);
while (!condition)
    cv_wait_sig(&cv, &mtx);
/* condition is true; do work */
mtx_unlock(&mtx);
```

The while loop is essential. Spurious wakeups are permitted; signals interrupt the wait; both look like a return from `cv_wait_sig`. Re-check the condition after every return.

12.18.2 Signal One Waiter

```
mtx_lock(&mtx);
/* change state */
mtx_unlock(&mtx);
cv_signal(&cv);
```

`cv_signal` after the unlock saves a context switch (the woken thread does not contend immediately for the mutex). Acceptable when the state change is unambiguous and no concurrent path can revert it.

12.18.3 Broadcast a State Change

```
mtx_lock(&mtx);
state_changed_globally = true;
cv_broadcast(&cv);
mtx_unlock(&mtx);
```

Use `cv_broadcast` when every waiter needs to know about the change. Detach paths and configuration resets are typical examples.

12.18.4 Wait With a Timeout

```
mtx_lock(&mtx);
while (!condition) {
    int ticks = (ms * hz + 999) / 1000;
    int err = cv_timedwait_sig(&cv, &mtx, ticks);
    if (err == EWOULDBLOCK) {
        mtx_unlock(&mtx);
        return (EAGAIN);
    }
    if (err != 0) {
        mtx_unlock(&mtx);
        return (err);
    }
}
/* do work */
mtx_unlock(&mtx);
```

Convert milliseconds to ticks, round up, handle the three return cases (timeout, signal, normal wakeup) explicitly.

12.18.5 Wait With Detach Awareness

```
while (!condition) {
    int err = cv_wait_sig(&cv, &mtx);
    if (err != 0)
        return (err);
    if (!sc->is_attached)
        return (ENXIO);
}
```

The post-sleep `is_attached` check ensures we exit cleanly if the device was detached while we slept. `cv_broadcast` in the detach path makes this work.

12.18.6 Drain Waiters Before Destroy

```
mtx_lock(&mtx);
sc->is_attached = 0;
cv_broadcast(&cv);
mtx_unlock(&mtx);
/* waiters wake, see !is_attached, return ENXIO, exit */
/* by the time active_fhs == 0, no waiters remain */
cv_destroy(&cv);
```

The combination of broadcast and the `is_attached` re-check guarantees no waiter remains in the cv at destroy time.

12.19 Reference: Common sx Idioms

12.19.1 Read-Mostly Field

```
sx_slock(&sx);  
value = field;  
sx_sunlock(&sx);
```

Cheap on a multi-core system; multiple readers do not contend.

12.19.2 Update With Validation

```
sx_slock(&sx);  
old = field;  
sx_sunlock(&sx);  
  
/* validate possibly-new value with sysctl_handle_*, etc. */  
  
sx_xlock(&sx);  
field = new;  
sx_xunlock(&sx);
```

Two acquire-release cycles. The shared lock for the read; the exclusive lock for the write. Drop between them so the validation does not hold either lock.

12.19.3 Snapshot-and-Apply Across Two Locks

```
sx_slock(&cfg_sx);  
local = cfg.value;  
sx_sunlock(&cfg_sx);  
  
mtx_lock(&data_mtx);  
/* use local without holding either lock together */  
mtx_unlock(&data_mtx);
```

Avoids holding both locks simultaneously; relaxes the lock-order constraint.

12.19.4 Try-Upgrade Pattern

```

sx_slock(&sx);
if (need_modify) {
    if (sx_try_upgrade(&sx)) {
        /* exclusive */
        modify();
        sx_downgrade(&sx);
    } else {
        /* drop, reacquire as exclusive, re-validate */
        sx_sunlock(&sx);
        sx_xlock(&sx);
        if (still_need_modify())
            modify();
        sx_downgrade(&sx);
    }
}
sx_sunlock(&sx);

```

Optimistic upgrade. The fallback path must re-validate, because the world changed during the unlock window.

12.19.5 Assert Held

```

sx_assert(&sx, SA_SLOCKED); /* shared */
sx_assert(&sx, SA_XLOCKED); /* exclusive */
sx_assert(&sx, SA_LOCKED);  /* either */

```

Use at the start of helpers that expect a particular lock state.

12.20 Reference: Decision Table for Synchronization Primitives

A compact lookup table.

If you need to...	Use
Update a single word atomically	<code>atomic(9)</code>
Update a per-CPU counter cheaply	<code>counter(9)</code>
Protect composite state in process context	<code>mtx(9)</code> (MTX_DEF)
Protect composite state in interrupt context	<code>mtx(9)</code> (MTX_SPIN)
Protect read-mostly state in process context	<code>sx(9)</code>

If you need to...	Use
Protect read-mostly state where sleep is forbidden	<code>rw(9)</code>
Wait for a specific condition to become true	<code>cv(9)</code> (paired with <code>mtx(9)</code> or <code>sx(9)</code>)
Wait until a deadline	<code>cv_timedwait_sig</code> , or <code>mtx_sleep</code> with <code>timo > 0</code>
Wait such that Ctrl-C can interrupt	The <code>_sig</code> variant of any wait primitive
Run code at a specific time in the future	<code>callout(9)</code> (Chapter 13)
Defer work to a worker thread	<code>taskqueue(9)</code> (Chapter 16)
Read concurrently with no synchronization at all	<code>epoch(9)</code> (later chapters)

If two primitives both fit, use the simpler one.

12.21 Reference: Reading `kern_condvar.c` and `kern_sx.c`

Two files in `/usr/src/sys/kern/` are worth opening once you have used the `cv` and `sx` APIs in your driver.

`/usr/src/sys/kern/kern_condvar.c` is the `cv` implementation. The functions worth seeing:

- `cv_init`: initialization. Trivial.
- `_cv_wait` and `_cv_wait_sig`: the core blocking primitives. Each takes the `cv`-queue spin lock, increments the waiter count, drops the interlock, hands the thread to the sleep queue, yields, and on return reacquires the interlock. The atomicity of “drop interlock, sleep” is provided by the sleep queue layer.
- `_cv_timedwait_sbt` and `_cv_timedwait_sig_sbt`: the timed variants. Same shape, with a callout that wakes the thread if the timeout fires first.
- `cv_signal`: takes the `cv`-queue spin lock, signals one waiter via `sleepq_signal`.
- `cv_broadcastpri`: signals all waiters at the given priority.

The whole file is about 400 lines. An afternoon of reading is more than enough to understand it end to end.

`/usr/src/sys/kern/kern_sx.c` is the `sx` implementation. Larger and denser, because the lock supports both shared and exclusive modes with full priority propagation. The functions worth seeing:

- `sx_init_flags`: initialization. Sets the initial state, registers with `WITNESS`.
- `_sx_xlock_hard` and `_sx_xunlock_hard`: the slow paths for exclusive operations. The fast paths inline in `sx.h`.
- `_sx_slock_int` and `_sx_sunlock_int`: the shared-mode operations. The shared count is incremented via atomic compare-and-swap; if the lock is held exclusively, the thread blocks.
- `sx_try_upgrade_int` and `sx_downgrade_int`: the mode-change operations.

Skim. The internals are intricate, but the public-facing API behaves as documented and the source confirms it.

12.22 Reference: Common Mistakes With cv and sx

Each new primitive comes with a set of mistakes that beginners make until they have been bitten. A short catalogue.

12.22.1 cv Mistakes

Using if instead of while around cv_wait. The condition may not be true on return because of a spurious wakeup. Always loop.

Forgetting to broadcast in detach. Waiters never wake, the cv has lingering waiters at destroy time, the kernel may panic. Always cv_broadcast before cv_destroy.

Signalling the wrong cv. Waking up readers when you meant writers (or vice versa). Easy mistake when refactoring. The cv's name is your defense; if cv_signal(&sc->room_cv) does not feel right at the call site, it probably is not right.

Signalling without the interlock when the state could revert. If two threads can both modify the state, one of them must hold the interlock when signalling, or a wakeup may be lost. Default to signalling under the interlock; relax only when you can prove the state cannot revert.

Missing the post-wait check for detach. A waiter that wakes up because of a cv_broadcast from detach must re-check is_attached and return ENXIO. If the check is missing, the waiter proceeds as if the device is still alive and crashes.

Calling cv_wait while holding multiple locks. Only the interlock is dropped during the sleep. Other locks remain held. If those locks are needed by the waker, you have a deadlock. Drop other locks first.

12.22.2 sx Mistakes

Holding the sx across a sleeping call. Drop before sysctl_handle_*, uiomove, or malloc(M_WAITOK). The sx is sleepable, so the kernel will not panic, but other waiters will be blocked for the duration.

Acquiring shared and then xlock without dropping shared. sx_xlock while holding the same sx in shared mode is a deadlock; the call will block forever waiting for itself. Use sx_try_upgrade or drop and reacquire.

Forgetting that sx is sleepable. Calling sx_xlock from a context where sleeping is illegal (interrupt context, inside a spin lock) panics. Use rw(9) for those contexts.

Holding the sx in shared mode across a long operation. Other readers can proceed, but the sx writer is blocked indefinitely. If the operation is long, drop the shared lock, do the work, and reacquire if you need to commit.

Releasing the wrong mode. sx_xunlock on a shared-mode lock is a bug; sx_sunlock on an exclusive-mode lock is a bug. Use sx_unlock (the polymorphic version) only when you do not know which mode you are in (rare).

12.22.3 Mistakes Specific to Combining Both

Acquiring in the wrong order. The Chapter 12 driver requires mtx first, sx second. Reverse order produces a WITNESS warning under load.

Releasing in the wrong order. Acquire `mtx`, acquire `sx`, release `mtx`, release `sx`. The release order *must* be the reverse of the acquisition order: release `sx` first, then release `mtx`. Otherwise an observer between the two releases sees an unexpected combination.

Snapshot-and-apply where staleness matters. The pattern is correct only when the snapshot can tolerate small staleness. For values that must be current (security flags, hard-quota limits), snapshot-and-apply is wrong; you must hold both locks atomically.

Forgetting to update `LOCKING.md`. Adding a lock or changing the order without updating the documentation produces drift. Three months later, no one remembers what the rule was. Update the document in the same commit.

12.23 Reference: Time Primitives

A brief tour of how the kernel expresses time. Useful when reading or writing the timed-wait variants.

The kernel has three commonly-used time representations:

- `int` ticks. The legacy unit. `hz` ticks equal one second. The default `hz` on FreeBSD 14.3 is 1000, so one tick is one millisecond. `mtx_sleep`, `cv_timedwait`, and `tsleep` all take their timeouts in ticks.
- `sbintime_t`. A 64-bit signed binary fixed-point representation: the upper 32 bits are seconds, the lower 32 bits are a fraction of a second. The unit constants are in `/usr/src/sys/sys/time.h`: `SBT_1S`, `SBT_1MS`, `SBT_1US`, `SBT_1NS`. The newer time API (`msleep_sbt`, `cv_timedwait_sbt`, `callout_reset_sbt`) uses `sbintime`.
- `struct timespec`. POSIX seconds-and-nanoseconds. Used at the user-space boundary; rarely needed in driver internals.

Conversion helpers in `time.h`:

- `tick_sbt`: a global variable holding $1 / \text{hz}$ as an `sbintime`, so `tick_sbt * timo_in_ticks` gives the equivalent `sbintime`.
- `nstosbt(ns)`, `ustosbt(us)`, `sbttous(sbt)`, `sbttons(sbt)`, `tstosbt(ts)`, `sbt tots(ts)`: explicit conversions between the various units.

The `_sbt` time API exists because `hz` granularity is too coarse for some uses. With `hz=1000`, the smallest expressible timeout is 1 ms, and timeouts are aligned to tick boundaries. With `sbintime`, you can express 100 microseconds and ask the kernel to schedule the wakeup as close to that as the hardware timer allows.

For Chapter 12, we use the tick-based API everywhere because the precision is sufficient. The reference is here so you know where to reach when sub-millisecond precision matters.

The `pr` argument to `_sbt` functions deserves a sentence. It is the *precision* the caller is willing to accept: how much wiggle the kernel may add for power-saving timer coalescing. A precision of `SBT_1S` means “I do not care if my 5-second timer fires up to 1 second late; if you can coalesce it with another timer to save power, please do”. A precision of `SBT_1NS` means “fire as close to the deadline as you can”. For driver code, 0 (no slop) or `SBT_1MS` (a millisecond of slop) are the typical values.

The `flags` argument controls how the timer is registered. `C_HARDCLOCK` is the most common: align to the system’s hardclock interrupt for predictable timing. `C_DIRECT_EXEC` runs the callout in the timer interrupt

rather than deferring it to a callout thread. `C_ABSOLUTE` interprets `sbt` as an absolute time rather than a relative timeout. We use `C_HARDCLOCK` everywhere in Chapter 12.

12.24 Reference: Common WITNESS Warnings, Decoded

WITNESS produces several kinds of warning. Each has a recognisable shape.

12.24.1 “lock order reversal”

The signature: two lines naming “1st” and “2nd” lock, plus an “established at” line. We have walked through the diagnosis in Section 6.

Common cause: a path that takes locks in an order that contradicts a previously-observed order. Fix by reordering or restructuring.

12.24.2 “duplicate lock of same name”

The signature: a warning about acquiring a lock with the same `lo_name` as one already held.

Common cause: two instances of the same driver, each with its own lock, both with the same name. WITNESS is conservative and assumes that two locks of the same type belong to the same class. Fix by initializing each lock with a unique name (e.g., include the unit number via `device_get_nameunit(dev)`), or by passing the appropriate per-class “duplicate-acquire OK” flag at init time: `MTX_DUPOK` for mutexes, `SX_DUPOK` for `sx`, `RW_DUPOK` for `rwlocks`. Each of those expands to the lock-object-level `LO_DUPOK` bit; you write the per-class name in driver code.

12.24.3 “sleeping thread (pid N) owns a non-sleepable lock”

The signature: a thread is in a sleeping primitive (`cv_wait`, `mtx_sleep`, `_sleep`) while holding a spin mutex or an `rw` lock.

Common cause: a function that takes a non-sleepable lock and then calls something that may sleep. Fix by dropping the non-sleepable lock first.

12.24.4 “exclusive sleep mutex foo not owned at”

The signature: a thread tried to release or assert a mutex it does not hold.

Common cause: the wrong mutex pointer, or an unlock without a matching lock on this code path. Fix by tracing the lock acquisition.

12.24.5 “lock list reversal”

The signature: similar to lock-order reversal but indicates a more complex inversion involving more than two locks.

Common cause: a chain of acquisitions that taken together violates the global order. Fix by simplifying the acquisition pattern; if the chain is truly necessary, consider whether the design should use fewer locks.

12.24.6 “sleepable acquired while holding non-sleepable”

The signature: a thread tried to acquire a sleepable lock (sx, mtx_def, lockmgr) while holding a non-sleepable one (mtx_spin, rw).

Common cause: confusion about the lock classes. Fix by switching the inner lock to a sleepable variant or by restructuring to avoid the nesting.

12.24.7 Acting on a Warning

When WITNESS fires, the temptation is to suppress the warning. Resist. The warning means the kernel has observed a real situation that violates a real rule. Suppression hides the bug; it does not fix it.

The right responses, in order of preference:

1. Fix the bug (reorder locks, drop a lock, restructure code).
2. Explain why the warning is incorrect for this case and use the appropriate `_DUPOK` flag with a comment in the source.
3. If you cannot do either, escalate. Ask on `freebsd-hackers` or open a PR. A WITNESS warning that nobody can explain is a real bug somewhere.

12.25 Reference: Lock Class Quick Reference

A compact lookup for the differences between the lock classes you have seen so far.

Property	mtx_def	mtx_spin	sx	rw	rmlock	lockmgr
Sleeps when contended	Yes	No (spins)	Yes	No (spins)	No (mostly)	Yes
Multiple holders	No	No	Yes (shared)	Yes (read)	Yes (read)	Yes (shared)
Holder may sleep	Yes	No	Yes	No	No (read)	Yes
Priority propagation	Yes	n/a	No	Yes	n/a	Yes
Signal interruptible	n/a	n/a	_sig	No	No	Yes
Recursion supported	Optional	Yes	Optional	No	No	Yes

Property	mtx_def	mtx_spin	sx	rw	rmlock	lockmgr
WITNESS-tracked	Yes	Yes	Yes	Yes	Yes	Yes
Best driver use	Default	Interrupt context	Read-mostly	Hot read paths	Very hot reads	Filesystems

`rmlock(9)` and `lockmgr(9)` are listed for completeness; this book covers `mtx`, `cv`, `sx`, and `rw` in depth, and treats the others as “known to exist, look up the manual page if needed”.

12.26 Reference: Multi-Primitive Driver Design Patterns

Three patterns recur in drivers that combine several synchronization primitives. Each is worth a sentence so you recognize them in the wild.

12.26.1 Pattern: One Mutex, One Configuration `sx`

The `myfirst` driver of Chapter 12 is this pattern. The mutex protects the data path and a `sx` protects the configuration. The lock order is mutex first, `sx` second. Most simple drivers fit this pattern.

When to use: the data path is process-context, has a composite invariant, and reads configuration occasionally. The configuration is read frequently and written rarely.

When not to use: when the data path runs in interrupt context (mutex must be `MTX_SPIN`, configuration must be `rw`), or when the data path itself has sub-paths that benefit from different locks.

12.26.2 Pattern: Per-Queue Lock With a Configuration Lock

A driver with multiple queues (one per CPU, one per consumer, one per stream) gives each queue its own lock and uses a separate `sx` for configuration. The lock order is per-queue lock first, configuration `sx` second. Lock-order between queues is not defined (you should never hold two queues at once).

When to use: high core counts, the workload partitions naturally per queue.

When not to use: the workload is symmetric and the per-queue locks would not help, or the data crosses queues frequently and would force order rules.

12.26.3 Pattern: Per-Object Lock With a Container Lock

A driver that maintains a list of objects (devices, sessions, descriptors) gives each object its own lock and uses a container lock to protect the list of objects. Walking the list takes the container lock; modifying an object takes that object’s lock; both can be held in the order container first, object second.

When to use: list operations and per-object operations both need protection, with different lifetimes.

When not to use: a single mutex would be enough (small lists, infrequent operations).

The `myfirst` driver does not need this pattern yet; future drivers in the book will.

12.26.4 Pattern: Per-CPU Counters With Mutex-Protected Tail

This is the Chapter 11 pattern, which Chapter 12 inherits. Hot counters (`bytes_read`, `bytes_written`) use `counter(9)` per-CPU storage. The `cbuf`, with its composite invariant, uses a single mutex. The two are independent; updates to the counters do not need the mutex; updates to the `cbuf` still do.

When to use: a high-frequency counter sits next to a structure with a composite invariant.

When not to use: the counter updates need to be consistent with the structure updates (then both need the same lock).

12.26.5 Pattern: Snapshot-and-Apply Across Two Lock Classes

Any time a path needs both lock classes, the snapshot-and-apply pattern reduces the lock-order constraint to a single direction. Read from one lock, drop, then take the other. The snapshot may be slightly stale; for advisory values, that is acceptable.

When to use: the value being snapshot is not strictly current-required; staleness on the order of microseconds is acceptable.

When not to use: the value is a security flag, a hard-budget limit, or anything where staleness could violate a contract.

The `myfirst_write` path uses this for the soft byte limit: snapshot the limit under the `cfg sx`, drop it, take the data mutex, check the limit against the current `cb_used`. The combined operation is not atomic, but it is correct in the sense that any race causes the wrong answer to be a tolerable wrong answer (refuse a write that would have fit, or accept a write that just barely overflows; both are recoverable).

12.27 Reference: Pre-Conditions for Each Primitive

Each primitive has rules about when and how it may be used. Violating a rule is a bug; the rules are listed here for quick reference.

12.27.1 `mtx(9)` (`MTX_DEF`)

Pre-conditions for `mtx_init`: - Memory for the struct `mtx` exists and is not aliased. - The mutex is not already initialized.

Pre-conditions for `mtx_lock`: - Mutex is initialized. - Calling thread is in process context, kernel-thread context, or callout-mpsafe context. - Calling thread does not already hold the mutex (unless `MTX_RECURSE`). - Calling thread does not hold any spin mutex.

Pre-conditions for `mtx_unlock`: - Calling thread holds the mutex.

Pre-conditions for `mtx_destroy`: - Mutex is initialized. - No thread holds the mutex. - No thread is blocked on the mutex.

12.27.2 cv(9)

Pre-conditions for `cv_init`: - Memory for the struct `cv` exists. - The `cv` is not already initialized.

Pre-conditions for `cv_wait` and `cv_wait_sig`: - The interlock mutex is held by the calling thread. - Calling thread is in a context where sleeping is legal.

Pre-conditions for `cv_signal` and `cv_broadcast`: - The `cv` is initialized. - Convention: the interlock mutex is held by the calling thread (not strictly required by the API, but defensive).

Pre-conditions for `cv_destroy`: - The `cv` is initialized. - No thread is blocked on the `cv` (the wait queue must be empty).

12.27.3 sx(9)

Pre-conditions for `sx_init`: - Memory for the struct `sx` exists. - The `sx` is not already initialized (unless `SX_NEW` is used).

Pre-conditions for `sx_xlock` and `sx_xlock_sig`: - The `sx` is initialized. - Calling thread does not already hold the `sx` exclusively (unless `SX_RECURSE`). - Calling thread is in a context where sleeping is legal. - Calling thread does not hold any non-sleepable lock (no spin mutex, no rw lock).

Pre-conditions for `sx_slock` and `sx_slock_sig`: - Same as `sx_xlock` except recursion check applies to shared mode.

Pre-conditions for `sx_xunlock` and `sx_sunlock`: - Calling thread holds the `sx` in the corresponding mode.

Pre-conditions for `sx_destroy`: - The `sx` is initialized. - No thread holds the `sx` in any mode. - No thread is blocked on the `sx`.

12.27.4 rw(9)

Pre-conditions for `rw_init`, `rw_destroy`: same shape as `sx_init`, `sx_destroy`.

Pre-conditions for `rw_wlock` and `rw_rlock`: - The `rw` is initialized. - Calling thread does not currently hold the `rw` in a conflicting mode. - Calling thread is *not* required to be in a sleepable context. The `rw` lock itself does not sleep; however, the calling thread *must not* call any function that may sleep while the `rw` is held.

Pre-conditions for `rw_wunlock` and `rw_runlock`: - Calling thread holds the `rw` in the corresponding mode.

Following these pre-conditions is the difference between a driver that runs cleanly under WITNESS for years and one that produces an unexpected panic on the first uncommon code path.

12.28 Reference: A Chapter 12 Self-Assessment

Use this rubric to confirm you have internalised the Chapter 12 material before turning to Chapter 13. Every question should be answerable without re-reading the chapter.

12.28.1 Conceptual Questions

1. **Name the three primary forms of synchronization.** Mutual exclusion, shared access with restricted writes, coordinated waiting.
2. **Why is a condition variable preferable to an anonymous wakeup channel?** Each cv represents one logical condition; signals do not wake unrelated waiters; the cv has a name visible in procstat and dtrace; the API enforces the atomic drop-and-sleep contract through its types.
3. **What is the difference between cv_signal and cv_broadcast?** cv_signal wakes one waiter (highest priority, FIFO among equal); cv_broadcast wakes all waiters. Use signal for per-event state changes; use broadcast for global changes (detach, reset).
4. **What does cv_wait_sig return when interrupted by a signal?** Either EINTR or ERESTART, depending on the signal's restart disposition. The driver passes the value through unchanged.
5. **What is the difference between sx and rw locks?** sx(9) is sleepable; rw(9) is not. Use sx in process context where the critical section may include sleeping calls; use rw when the critical section may run in interrupt context or must not sleep.
6. **Why does sx_try_upgrade exist instead of an unconditional sx_upgrade?** Because two simultaneous holders both attempting an unconditional upgrade would deadlock. The try variant returns failure when another shared holder is present, letting the caller back off cleanly.
7. **What is the snapshot-and-apply pattern and why is it useful?** Acquire one lock, read needed values into local variables, release; then acquire a different lock and use the local values. Avoids holding two locks simultaneously, relaxing lock-order constraints. Acceptable when the snapshot can tolerate small staleness.
8. **What is the canonical lock order in the Chapter 12 driver?** sc->mtx before sc->cfg_sx. Documented in LOCKING.md; enforced by WITNESS.

12.28.2 Code Reading Questions

Open your Chapter 12 driver source and verify:

1. Every cv_wait_sig is inside a while (!condition) loop.
2. Every cv has at least one signaller and one broadcast caller (broadcast in detach is acceptable).
3. Every sx_xlock has a matching sx_xunlock on every code path, including error returns.
4. The detach path broadcasts each cv before destroying any primitive.
5. The cfg sx is dropped before any potentially-sleeping call (sysctl_handle_*, uiomove, malloc(M_WAITOK)).
6. The lock order rule (mtx first, sx second) is followed in every path that holds both.

12.28.3 Hands-On Questions

1. Load the Chapter 12 driver on a WITNESS kernel and run the composite stress for 30 minutes. Are there any warnings? If yes, investigate.

2. Set `read_timeout_ms` to 100 and run a `read(2)` against an idle device. What does the call return? After how long?
3. Toggle `debug_level` between 0 and 3 with `sysctl -w` while `mp_stress` is running. Does the level take effect promptly? Does anything break?
4. Use `lockstat(1)` to measure the contention on the `sx` lock under a config-writer-heavy workload. What is the wait time?
5. Open the `kern_condvar.c` source and find the function `cv_signal`. Read it. Can you describe what it does in two sentences?

If all five hands-on questions pass and the conceptual questions are easy, your Chapter 12 work is solid.

12.29 Reference: Further Reading on Synchronization

For readers who want to go deeper than this chapter covers:

12.29.1 Manual Pages

- `mutex(9)`: the mutex API (covered fully in Chapter 11; reference here for completeness).
- `condvar(9)`: the condition variable API.
- `sx(9)`: the shared/exclusive lock API.
- `rwlock(9)`: the reader/writer lock API.
- `rmlock(9)`: the read-mostly lock API (advanced).
- `sema(9)`: the counting semaphore API (advanced).
- `epoch(9)`: the deferred-reclamation read-mostly framework (advanced; relevant for network drivers).
- `locking(9)`: an overview of FreeBSD's locking primitives.
- `lock(9)`: the common lock-object infrastructure.
- `witness(4)`: the WITNESS lock-order checker (covered in Chapter 11; revisited in this chapter).
- `lockstat(1)`: the lock-profiling user-space tool.
- `dtrace(1)`: the dynamic tracing framework, covered in more depth in Chapter 15.

12.29.2 Source Files

- `/usr/src/sys/kern/kern_condvar.c`: the `cv` implementation.
- `/usr/src/sys/kern/kern_sx.c`: the `sx` implementation.
- `/usr/src/sys/kern/kern_rwlock.c`: the `rw` implementation.
- `/usr/src/sys/kern/subr_sleepqueue.c`: the sleep-queue machinery underlying `cv` and other sleep primitives.
- `/usr/src/sys/kern/subr_turnstile.c`: the turnstile machinery underlying `rw` and other priority-propagating primitives.
- `/usr/src/sys/sys/condvar.h`, `/usr/src/sys/sys/sx.h`, `/usr/src/sys/sys/rwlock.h`: the public API headers.
- `/usr/src/sys/sys/_lock.h`, `/usr/src/sys/sys/lock.h`: the common lock-object structure and class registry.

12.29.3 External Material

For concurrency theory applicable to any operating system, *The Art of Multiprocessor Programming* by Herlihy and Shavit is excellent. For FreeBSD-specific kernel internals, *The Design and Implementation of the FreeBSD Operating System* by McKusick and others remains the canonical textbook; the chapters on locking and scheduling are particularly relevant.

Neither book is required for this chapter. Both are useful when the time comes for deeper study.

12.30 Looking Ahead: Bridge to Chapter 13

Chapter 13 is titled *Timers and Delayed Work*. Its scope is the kernel's time infrastructure as seen from a driver: how to schedule a callback for some time in the future, how to cancel one cleanly, how to handle the rules around callouts that may run concurrently with the driver's other code paths, and how to use timers for typical driver patterns like watchdogs, deferred work, and periodic polling.

Chapter 12 prepared the ground in three specific ways.

First, you already know how to wait with a timeout. Chapter 13's `callout(9)` mechanism is the same idea seen from the other side: instead of "wake me at time T", it is "run this function at time T". The synchronization rules around callouts (callouts run on a kernel thread, can race with your other code, must be drained before destruction) build on the discipline Chapter 12 established for `cvs` and `sxs`.

Second, you already know how to design a multi-primitive driver. Chapter 13's callouts add another execution context to the driver: the callout handler runs concurrently with `myfirst_read`, `myfirst_write`, and the `sysctl` handlers. That means callout handlers participate in the lock order. The `LOCKING.md` you wrote in Chapter 12 will absorb the addition with one new entry.

Third, you already know how to debug under load. Chapter 13 introduces a new bug class (callout races at unload time) that benefits from the same `WITNESS`, `lockstat`, and `dtrace` workflow Chapter 12 taught.

Specific topics Chapter 13 will cover include:

- The `callout(9)` API: `callout_init`, `callout_init_mtx`, `callout_reset`, `callout_stop`, `callout_drain`.
- The lock-aware callout (`callout_init_mtx`) and why it is the right default for driver code.
- Callout reuse: scheduling the same callout multiple times safely.
- The unload race: how a callout that fires after `kldunload` can crash the kernel, and how to prevent it with `callout_drain`.
- Periodic patterns: the watchdog, the heartbeat, the deferred reaper.
- The `tick_sbt` and `sbintime_t` time abstractions, useful for sub-millisecond timing.
- Comparison with `timeout(9)` (the older interface, deprecated for new code).

You do not need to read ahead. Chapter 12's material is sufficient preparation. Bring your Chapter 12 driver, your test kit, and your `WITNESS`-enabled kernel. Chapter 13 starts where Chapter 12 ended.

A small closing reflection. You started this chapter with one mutex, one anonymous channel, and a clear idea of what synchronization meant. You leave with three primitives, a documented lock order, a richer vocabulary, and the experience of debugging real coordination problems with real kernel tools. That progression is the heart

of Part 3 of this book. From here, Chapter 13 expands the driver's awareness of *time*, Chapter 14 expands its awareness of *interrupts*, and the remaining chapters of Part 3 prepare you for the hardware-touching chapters of Part 4.

Take a moment. The driver you started Part 3 with knew only how to handle one thread at a time. The driver you have now coordinates many threads across two lock classes, can be reconfigured at runtime without disrupting its data path, and respects the user's signals and deadlines. That is a real, qualitative leap. Then turn the page.

When you do open Chapter 13, the first thing you will see is `callout(9)`, the kernel's timed-callback infrastructure. The discipline you learned here for `cvs`, `sxs`, and the lock-order-aware design transfers directly. Callouts are simply another concurrent execution context that participates in the lock order; the patterns from Chapter 12 absorb them without growing brittle. The synchronization vocabulary is the same; the time vocabulary is what is new.

13 Timers and Delayed Work

13.1 Reader Guidance & Outcomes

So far, every line of driver code we have written has been *reactive*: the user calls `read(2)`, the kernel calls our handler, we do work, we return. Chapter 12’s blocking primitives extended that model with the ability to *wait* for something we did not initiate. But the driver itself never reached out to the world on its own. It had no way to say “in 100 milliseconds from now, please do this”. It had no way to count time at all, except as something it observed passing while it was already inside a syscall.

That changes here. Chapter 13 introduces *time* as a first-class concept in your driver. The kernel has an entire subsystem dedicated to running your code at a specific moment in the future, repeatedly if you ask, with precise lock-handling rules and clean teardown semantics. It is called `callout(9)`, and it is small, regular, and deeply useful. By the end of this chapter, your `myfirst` driver will have learned to schedule its own work, to act on the world without being prodded, and to give back its scheduled work safely when the device is unloaded.

The shape of the chapter mirrors Chapter 12’s. Each new primitive comes with a motivation, a precise API tour, a worked refactor of the running driver, a WITNESS-verified design, and a documented locking story in `LOCKING.md`. The chapter does not stop at “you can call `callout_reset`”; it walks you through every contract the callout subsystem cares about, so that the timers you write keep working when the rest of the driver evolves.

13.1.1 Why This Chapter Earns Its Own Place

You could try to fake timers. A kernel thread that sleeps in a loop, calling `cv_timedwait_sig` and doing work each time it wakes, is technically a timer. So is a user-space process that opens the device once a second and pokes a `sysctl`. Neither is wrong, but both are clumsy compared to what the kernel offers, and both create new resources (the kernel thread, the user-space process) that have their own lifetime to manage.

`callout(9)` is the right answer in nearly every case where you want a function to run “later”. It is built on the kernel’s hardware-clock infrastructure, costs essentially nothing at rest, scales to thousands of pending callouts per system, integrates with WITNESS and INVARIANTS, and provides clear rules for how to interact with locks and how to drain pending work at teardown. Most drivers in `/usr/src/sys/dev/` use it. Once you know it, the pattern transfers across every kind of driver you will meet: USB, network, storage, watchdog, sensor, anything whose physical world has a clock in it.

The cost of *not* knowing `callout(9)` is high. A driver that re-invents timing creates a private subsystem that nobody else knows how to debug. A driver that uses `callout(9)` correctly slots into the kernel’s existing observability tools (`procstat`, `dtrace`, `lockstat`, `ddb`) and behaves predictably at unload time. The chapter pays for itself the first time you have to extend a driver someone else wrote.

13.1.2 Where Chapter 12 Left the Driver

A brief recap of where you should stand, because Chapter 13 builds directly on the Chapter 12 deliverables. If any of the following is missing or feels uncertain, return to Chapter 12 before starting this chapter.

- Your `myfirst` driver compiles cleanly and is at version 0.6-sync.
- It uses `MYFIRST_LOCK(sc)` / `MYFIRST_UNLOCK(sc)` macros around `sc->mtx` (the data-path mutex).
- It uses `MYFIRST_CFG_SLOCK(sc)` / `MYFIRST_CFG_XLOCK(sc)` around `sc->cfg_sx` (the configuration sx).
- It uses two named condition variables (`sc->data_cv`, `sc->room_cv`) for blocking reads and writes.
- It supports timed reads via `cv_timedwait_sig` and the `read_timeout_ms` sysctl.
- The lock order `sc->mtx -> sc->cfg_sx` is documented in `LOCKING.md` and enforced by `WITNESS`.
- `INVARIANTS` and `WITNESS` are enabled in your test kernel; you have built and booted it.
- The Chapter 12 stress kit (Chapter 11 testers plus `timeout_tester` and `config_writer`) builds and runs cleanly.

That driver is what we extend in Chapter 13. We will add a periodic callout, then a watchdog callout, then a configurable tick-source, and finally consolidate them with a refactor pass and a documentation update. The driver's data path stays as it was; the new code lives next to the existing primitives.

13.1.3 What You Will Learn

By the time you move on to the next chapter, you will be able to:

- Explain when a callout is the right primitive for the job and when a kernel thread, a `cv_timedwait`, or a user-space helper would serve better.
- Initialize a callout with the appropriate lock-awareness using `callout_init`, `callout_init_mtx`, `callout_init_rw`, or `callout_init_rm`, and choose between the lock-managed and `mpsafe` variants for your driver's context.
- Schedule a one-shot timer with `callout_reset` (tick-based) or `callout_reset_sbt` (sub-tick precision), using the `tick_sbt`, `SBT_1S`, `SBT_1MS`, `SBT_1US` time constants where appropriate.
- Schedule a periodic timer by having the callback re-arm itself, with the right pattern that survives `callout_drain`.
- Choose between `callout_reset` and `callout_schedule` and understand when each is the right tool.
- Describe the lock contract `callout(9)` enforces when you initialize it with a lock pointer: the kernel acquires that lock before your function runs, releases it after (unless you set `CALLOUT_RETURNUNLOCKED`), and serialises the callout with respect to other lock holders.
- Read and interpret the `c_iflags` and `c_flags` fields of a callout, and use `callout_pending`, `callout_active`, and `callout_deactivate` correctly.
- Use `callout_stop` to cancel a pending callout in normal driver code, and `callout_drain` at teardown to wait for an in-flight callback to finish.
- Recognise the unload race (a callout fires after `kldunload` and crashes the kernel) and describe the standard cure: drain at detach, refuse detach until the device is quiet.
- Apply the `is_attached` pattern (which we built for `cv` waiters in Chapter 12) to callout callbacks, so a callback that fires during teardown returns cleanly without rescheduling.
- Build a watchdog timer that detects a stuck condition and acts on it.

- Build a debounce timer that ignores rapid repeated events.
- Build a periodic tick-source that injects synthetic data into the cbuf for testing.
- Verify the callout-enabled driver against WITNESS, lockstat(1), and a long-running stress test that includes timer activity.
- Extend LOCKING.md with a “Callouts” section that names every callout, its callback, its lock, and its lifetime.
- Refactor the driver into a shape where timer code is grouped, named, and obviously safe to maintain.

That is a substantial list. None of it is optional for a driver that uses time at all. All of it transfers directly to drivers that will appear in Part 4 and beyond, where real hardware brings its own clocks and demands its own watchdogs.

13.1.4 What This Chapter Does Not Cover

Several adjacent topics are deliberately deferred:

- **Taskqueues (taskqueue(9)).** Chapter 16 introduces the kernel’s general deferred-work framework. Taskqueues and callouts are complementary: callouts run a function at a specific time; taskqueues run a function as soon as a worker thread can pick it up. Many drivers use both: a callout fires at the right moment, the callout enqueues a task, the task runs the actual work in process context where sleeping is permitted. Chapter 13 stays inside the callout’s own callback for simplicity; the deferred-work pattern belongs to Chapter 16.
- **Hardware interrupt handlers.** Chapter 14 introduces interrupts. A real driver may install an interrupt handler that runs without process context. The callout(9) rules around lock classes are similar to the rules for interrupt handlers (you may not sleep), but the framing is different. We will revisit timer-and-interrupt interaction in Chapter 14.
- **epoch(9).** A read-mostly synchronization framework used by network drivers. Out of scope for Chapter 13.
- **High-resolution event scheduling.** The kernel exposes sbintime_t and the _sbt variants for sub-tick precision; we touch on the sbintime-based variants of the callout API briefly, but the full story of event timer drivers (/usr/src/sys/kern/kern_clocksource.c) belongs in a kernel-internals book, not a driver book.
- **Real-time and deadline scheduling.** Out of scope. We rely on the general scheduler.
- **Periodic workloads via the scheduler tick (hardclock).** The kernel itself uses hardclock(9) for system-wide periodic work; drivers do not interact with hardclock directly. We mention it for context.

Staying inside those lines keeps the chapter focused. The reader of Chapter 13 should finish with confident control of callout(9) and a working sense of when to reach for taskqueue(9) instead. Chapter 14 and Chapter 16 fill in the rest.

13.1.5 Estimated Time Investment

- **Reading only:** about three hours. The API surface is small but the lock and lifetime rules deserve careful attention.
- **Reading plus typing the worked examples:** six to eight hours over two sessions. The driver evolves in four small stages; each stage adds one timer pattern.

- **Reading plus all labs and challenges:** ten to fourteen hours over three or four sessions, including time for stress tests with timers active and lockstat measurements.

If you find yourself confused midway through Section 5 (the lock-context rules), that is normal. The interaction between callouts and locks is the most surprising part of the API, and even experienced kernel programmers occasionally get it wrong. Stop, re-read Section 5's worked example, and continue when the model has settled.

13.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 12 Stage 4 (`stage4-final`). The starting point assumes the cv channels, bounded reads, sx-protected configuration, and reset sysctl are all in place.
- Your lab machine is running FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- You read Chapter 12 carefully. The lock-order discipline, the cv pattern, and the snapshot-and-apply pattern are assumed knowledge here.
- You have run the Chapter 12 composite stress kit at least once and seen it pass cleanly.

If any of the above is shaky, fixing it now is a much better investment than pushing through Chapter 13 and trying to debug from a moving foundation.

13.1.7 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep `/usr/src/sys/kern/kern_timeout.c` and `/usr/src/sys/sys/callout.h` bookmarked. The header is short and contains the API the chapter teaches. The implementation file is long but well-commented; we will point at specific functions a few times during the chapter. Two minutes spent at each pointer pays off.

A note on line numbers. When this chapter names a specific function in `kern_timeout.c` or a macro in `callout.h`, treat the name as the fixed address and any line we happen to mention as scenery around it. `callout_init_mtx` and `callout_reset_sbt_on` will still carry those names in future FreeBSD 14.x revisions; the lines where they sit will have moved by the time your editor opens the file. Jump to the symbol and let your editor report the rest.

Second, run every code change you make under `WITNESS`. The callout subsystem has its own rules that `WITNESS` checks at runtime. The most common Chapter 13 mistake is to schedule a callout whose function tries to acquire a sleepable lock from a context where sleeping is illegal; `WITNESS` catches it immediately on a debug kernel and silently corrupts on a production kernel. Do not run Chapter 13 code on the production kernel until it passes the debug kernel.

Third, type the changes by hand. The companion source under `examples/part-03/ch13-timers-and-delayed-work/` is the canonical version, but the muscle memory of typing `callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)` once is worth more than reading it ten times. The chapter shows the changes incrementally; mirror that incremental pace in your own copy of the driver.

13.1.8 Roadmap Through the Chapter

The sections in order are:

1. Why use timers in a driver. Where time enters the picture in real driver work, and which patterns map onto `callout(9)` rather than something else.
2. Introduction to FreeBSD's `callout(9)` API. The structure, the lifecycle, the four initialization variants, and what each one buys you.
3. Scheduling one-shot and repeating events. `callout_reset`, `callout_reset_sbt`, `callout_schedule`, and the periodic-callback re-arm pattern.
4. Integrating timers into your driver. The first refactor: a heartbeat callout that periodically logs stats or fires a synthetic event.
5. Handling locking and context in timers. The lock-aware initialization, the `CALLOUT_RETURNUNLOCKED` and `CALLOUT_SHAREDLOCK` flags, the rules around what a callout function may and may not do.
6. Timer cleanup and resource management. The unload race, `callout_stop` versus `callout_drain`, the standard detach pattern with timers.
7. Use cases and extensions for timed work. Watchdogs, debouncing, periodic polling, delayed retries, statistics rollovers, all framed as small recipes you can lift into other drivers.
8. Refactoring and versioning. A clean `LOCKING.md` extension, a bumped version string, an updated changelog, and a regression run that includes timer-related testing.

Hands-on labs and challenge exercises follow, then a troubleshooting reference, a wrapping-up section, and a bridge to Chapter 14.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, the cleanup section (Section 6) and the refactoring section (Section 8) stand alone and make good single-sitting reads.

13.2 Section 1: Why Use Timers in a Driver?

Most of what a driver does is reactive. A user opens the device, the open handler runs. A user issues `read(2)`, the read handler runs. A signal arrives, a sleeper wakes. The kernel hands control to the driver in response to something the world did. Each invocation has a clear cause, and once the work is done, the driver returns and waits for the next cause.

Real hardware does not always cooperate with that model. A network card may need a heartbeat sent every few seconds even when nothing else is happening, just to convince the switch on the other end that the link is alive. A storage controller may need a watchdog reset every five hundred milliseconds, or it will assume the host has gone away and reset the channel. A USB hub poll has to happen on a timer because the USB bus does not interrupt for the kind of state change the driver wants to see. A button on a development board needs debouncing because the spring contacts produce many events in quick succession when the user only meant one. A driver that retries a transient failure should back off, not loop tightly.

All of those are reasons to schedule code for the future. The kernel has a single primitive for the job, `callout(9)`, and Chapter 13 teaches it from the ground up. Before we get to the API, this section sets the conceptual stage. We look at what “later” means in a driver, what shapes a “later” callback typically takes, and where `callout(9)` fits relative to the other ways a driver could express the idea of time.

13.2.1 The Three Shapes of “Later”

Driver code that wants to do something in the future falls into one of three shapes. Knowing which shape you are in is half of choosing the right primitive.

One-shot. “Do this once, X milliseconds from now, then forget about it.” Examples: schedule a watchdog timeout that fires only if no activity has been observed in the next second; debounce a button by ignoring all subsequent presses for fifty milliseconds; defer a teardown step until the current operation completes. The callback runs once and the driver does not re-arm it.

Periodic. “Do this every X milliseconds, until I tell you to stop.” Examples: poll a hardware register that does not interrupt; emit a heartbeat to a peer; refresh a cached value; sample a sensor; rotate a statistics window. The callback runs once, then re-arms itself for the next interval, and continues until the driver stops it.

Bounded wait. “Do this when condition Y becomes true, but give up if Y has not happened in X milliseconds.” Examples: wait for a hardware response with a timeout; wait for the buffer to drain or the deadline to fire; allow Ctrl-C to interrupt a wait. We met this shape in Chapter 12 with `cv_timedwait_sig`. The driver thread is the one that waits, not a callback.

`callout(9)` is the primitive for the first two shapes. The third uses `cv_timedwait_sig` (Chapter 12), `mtx_sleep` with a non-zero `timo`, or one of the `_sbt` variants for sub-tick precision. The two are complementary, not alternatives: many drivers use both. A bounded wait suspends the calling thread; a callout runs in a separate context after a delay.

13.2.2 Real-World Patterns

A short tour of patterns that recur across drivers in `/usr/src/sys/dev/`. Recognising them early gives you a vocabulary for the rest of the chapter.

The heartbeat. A periodic callout that fires every N milliseconds and emits some trivial state (a counter increment, a log line, a packet on the wire). Useful for debugging and for protocols that need a liveness signal.

The watchdog. A one-shot callout scheduled at the start of an operation. If the operation completes normally, the driver cancels the callout. If the operation hangs, the callout fires and the driver takes corrective action (reset the hardware, log a warning, kill a stuck request). Almost every storage and network driver has at least one watchdog.

The debounce. A one-shot callout scheduled when an event arrives. Subsequent identical events within the timeout are ignored. When the callout fires, the driver acts on the most recent event. Used for hardware events that bounce (mechanical switches, optical sensors).

The poll. A periodic callout that reads a hardware register and acts on the value. Used when the hardware does not produce interrupts for the events the driver cares about, or when interrupts are too noisy to be useful.

The retry-with-backoff. A one-shot callout scheduled with an increasing delay after each failed attempt. The first failure schedules a 10 ms retry; the second schedules a 20 ms retry; and so on. Bounds the rate at which the driver pesters the hardware after a failure.

The statistics rollover. A periodic callout that takes a snapshot of internal counters at regular intervals, computes a per-interval rate, and stores it in a circular buffer for later inspection.

The deferred reaper. A one-shot callout that completes a teardown after some grace period. Used when an object cannot be freed immediately because some other code path may still hold a reference; the callout waits long enough for those references to drain, then frees the object.

We will implement the first three (heartbeat, watchdog, deferred tick-source) in `myfirst` over the course of this chapter. The others are the same shape; once you know the pattern, the variations are mechanical.

13.2.3 Why Not Just Use a Kernel Thread?

A reasonable question for a beginner: why is `callout(9)` a separate API at all? Could the same effects be achieved by a kernel thread that loops, sleeps, and acts?

In principle, yes. In practice, no driver should reach for a kernel thread when a callout will do.

A kernel thread is a heavyweight resource. It has its own stack (typically 16 KB on amd64), its own scheduler entry, its own priority, its own state. Spinning one up for a periodic action that takes 10 microseconds every second is wasteful: 16 KB of memory plus scheduler overhead just to wake up, do trivial work, and sleep again. Multiplied across many drivers, the kernel ends up with hundreds of mostly-idle threads.

A callout is essentially free at rest. The data structure is a few pointers and integers (see `struct callout` in `/usr/src/sys/sys/_callout.h`). There is no thread, no stack, no scheduler entry. The kernel's hardware-clock interrupt walks a callout wheel and runs every callout that has come due, then returns. Thousands of pending callouts cost essentially nothing until they fire.

A callout also slots into the kernel's existing observability tools. `dtrace`, `lockstat`, and `procstat` all understand callouts. A custom kernel thread does not have any of that for free; you would have to instrument it yourself.

The exception, of course, is when the work the timer needs to do is genuinely long and would benefit from being in a sleepable thread context. A callout function may not sleep; if your work requires sleeping, the callout's job is to *enqueue* the work onto a taskqueue or wake a kernel thread that can do it safely. Chapter 16 covers that pattern. For Chapter 13, the work the callout does is short, non-sleeping, and lock-aware.

13.2.4 Why Not Just Use `cv_timedwait` In a Loop?

Another reasonable alternative: a kernel thread that loops on `cv_timedwait_sig` would also produce periodic behaviour. So would a user-space helper that polls a `sysctl`. Why callout?

The kernel-thread answer is the resource argument from the previous subsection: callouts are vastly cheaper than threads.

The user-space-helper answer is correctness: a driver whose timing depends on a user-space process is a driver that fails when that process crashes, gets paged out, or is denied CPU by an unrelated workload. A driver should be self-sufficient for its own correctness, even if user-space tooling provides additional features on top.

There is one situation where `cv_timedwait_sig` is the right answer: when the *calling thread itself* needs to wait. Chapter 12's `read_timeout_ms` `sysctl` uses `cv_timedwait_sig` because the reader is the one waiting; it has work to do as soon as data arrives or the deadline fires. A callout would be wrong because the reader's `syscall` thread cannot be the one running the callback (the callback runs in a different context).

Use `cv_timedwait_sig` when the syscall thread waits. Use `callout(9)` when something independent of any syscall thread must happen at a specific time. The two coexist comfortably in the same driver; Chapter 13 will end with a driver that uses both.

13.2.5 A Brief Note on Time Itself

The kernel exposes time through several units, each with its own conventions. We met them in Chapter 12; a recap helps before we wade into the API.

- **int ticks.** The legacy unit. `hz` ticks equal one second. The default `hz` on FreeBSD 14.3 is 1000, so one tick is one millisecond. `callout_reset` takes its delay in ticks.
- **sbintime_t.** A 64-bit signed binary fixed-point representation: upper 32 bits seconds, lower 32 bits a fraction of a second. The unit constants are in `/usr/src/sys/sys/time.h`: `SBT_1S`, `SBT_1MS`, `SBT_1US`, `SBT_1NS`. `callout_reset_sbt` takes its delay in sbintime.
- **tick_sbt.** A global variable holding `1 / hz` as an sbintime. Useful when you have a tick count and want the equivalent sbintime: `tick_sbt * tmo_in_ticks`.
- **The precision argument.** `callout_reset_sbt` takes an additional precision argument. It tells the kernel how much wiggle is acceptable when scheduling, which lets the callout subsystem coalesce nearby timers for power efficiency. A precision of zero means “fire as close to the deadline as possible”. A precision of `SBT_1MS` means “anywhere within a millisecond of the deadline is fine”.

For most driver work the tick-based API is the right level of precision. We use `callout_reset` (ticks) throughout the early sections of the chapter and reach for `callout_reset_sbt` only when sub-millisecond precision matters or when we want to tell the kernel about acceptable slop.

13.2.6 When a Callout Is the Wrong Tool

For completeness, three situations where `callout(9)` is *not* the right answer.

- **The work needs to sleep.** Callout functions run in a context that may not sleep. If the work involves `uiomove`, `copyin`, `malloc(M_WAITOK)`, or any other potentially-blocking call, the callout must enqueue a task on a taskqueue or wake a kernel thread that can do the work in process context. Chapter 16.
- **The work needs to run on a specific CPU for cache reasons.** `callout_reset_on` lets you bind a callout to a specific CPU, which is useful, but if the requirement is “run on the same CPU that submitted the request” the answer might be a per-CPU primitive instead. We touch on `callout_reset_on` briefly and defer the deeper CPU-affinity discussion.
- **The work is event-driven, not time-driven.** If the trigger is “data arrived” rather than “100 ms have elapsed”, you want a `cv` or a wakeup, not a callout. Mixing the two often leads to unnecessary complexity.

13.2.7 A Mental Model: The Callout Wheel

To make the cost argument from the previous subsections concrete, here is what the kernel actually does to manage callouts. You do not need this to use `callout(9)` correctly, but knowing it makes several later sections easier to follow.

The kernel maintains a *callout wheel* per CPU. Conceptually, the wheel is a circular array of buckets. Each bucket corresponds to a small range of time. When you call `callout_reset(co, ticks_in_future, fn, arg)`, the kernel computes which bucket “now plus ticks_in_future” lands in and adds the callout to that bucket’s list. The arithmetic is $(\text{current\_tick} + \text{ticks\_in\_future}) \bmod \text{wheel\_size}$.

A periodic timer interrupt (the hardware clock) fires at every tick. The interrupt handler increments a global tick counter, looks at the current bucket of every CPU’s wheel, and walks the list. For each callout that has reached its deadline, the kernel pulls it off the wheel and either runs the callback inline (for `C_DIRECT_EXEC` callouts) or hands it to a callout-processing thread.

Three properties of this mechanism matter for the chapter.

First, scheduling a callout is cheap: it is essentially “compute a bucket index and link the structure into a list”. A few atomic operations. No allocation. No context switch.

Second, an unscheduled callout costs nothing: it is just a `struct callout` somewhere in your softc. The kernel does not know about it until you call `callout_reset`. There is no per-callout overhead at rest.

Third, the granularity of the wheel is one tick. A 1.7-tick delay rounds up to 2 ticks. The `precision` argument to `callout_reset_sbt` lets you trade exactness for the kernel’s freedom to coalesce nearby firings, which is a power-saving optimization on systems with many concurrent timers. For driver work, the default precision is almost always fine.

There is a great deal more in the actual implementation: per-CPU wheels for cache locality, deferred migration when a callout is rescheduled to a different CPU, special handling for `C_DIRECT_EXEC` callouts that run in the timer interrupt itself, and so on. The implementation is in `/usr/src/sys/kern/kern_timeout.c` if you are curious. Reading it once is worthwhile; you do not need to memorize it.

13.2.8 What “Now” Means in the Kernel

A small but recurring confusion: there are several time bases in the kernel, and they measure different things.

`ticks` is a global variable that counts hardware-clock interrupts since boot. It increments by one every clock tick. It is fast to read (one memory load), wraps around every few weeks at typical `hz=1000`, and is the time base `callout_reset` uses. Always express callout deadlines as “now plus N ticks”, which is what `callout_reset(co, N, ...)` does.

`time_uptime` and `time_second` are `time_t` values that count seconds since boot or since the epoch (respectively). Less precise; useful for log timestamps and human-readable elapsed times.

`sbinuptime()` returns an `sbintime_t` representing seconds-and-fractions since boot. This is the time base `callout_reset_sbt` works in. It does not wrap (well, it would in some hundreds of years).

`getmicrouptime()` and `getnanouptime()` are coarse but fast accessors for “now”; they may be a tick or two old. `microuptime()` and `nanouptime()` are precise but more expensive (they read the hardware timer directly).

For a driver doing typical timer work, `ticks` (for tick-based callout work) and `getsbinuptime()` (for sbintime-based work) are the two that come up. We use them in the labs without commentary; if you wonder where they come from, this is the answer.

13.2.9 Wrapping Up Section 1

Time enters driver work in three shapes: one-shot, periodic, and bounded wait. The first two are exactly what `callout(9)` is for; the third is what Chapter 12's `cv_timedwait_sig` is for. Real-world patterns (heartbeat, watchdog, debounce, poll, retry, rollover, deferred reaper) are all instances of one-shot or periodic callouts; recognising them lets you reuse the same primitive across many situations.

Underneath the API, the kernel maintains a per-CPU callout wheel that costs essentially nothing at rest and very little to schedule. The granularity is one tick (one millisecond on a typical FreeBSD 14.3 system). The implementation handles thousands of pending callouts per CPU without breaking a sweat.

Section 2 introduces the API: the callout structure, the four initialization variants, and the lifecycle every callout follows.

13.3 Section 2: Introduction to FreeBSD's `callout(9)` API

`callout(9)` is, like most of the synchronization primitives, a small API on top of a careful implementation. The data structure is short, the lifecycle is regular (init, schedule, fire, stop or drain, destroy), and the rules are explicit enough that you can verify your usage by reading the source. This section walks through the structure, names the variants of init, and lays out the lifecycle stages so the rest of the chapter has a vocabulary to reuse.

13.3.1 The Callout Structure

The data structure lives in `/usr/src/sys/sys/_callout.h`:

```
struct callout {
    union {
        LIST_ENTRY(callout) le;
        SLIST_ENTRY(callout) sle;
        TAILQ_ENTRY(callout) tqe;
    } c_links;
    sbintime_t c_time;           /* ticks to the event */
    sbintime_t c_precision;     /* delta allowed wrt opt */
    void *c_arg;                /* function argument */
    callout_func_t *c_func;     /* function to call */
    struct lock_object *c_lock; /* lock to handle */
    short c_flags;              /* User State */
    short c_iflags;             /* Internal State */
    volatile int c_cpu;         /* CPU we're scheduled on */
};
```

It is one structure per callout, embedded in the softc or wherever else you need it. The fields you touch directly are: none. Every interaction goes through API calls. The fields you can read for diagnostic purposes are `c_flags` (via `callout_active / callout_pending`) and `c_arg` (rarely useful from outside).

The two flag fields deserve a sentence each.

`c_iflags` is internal. The kernel sets and clears bits in it under the callout subsystem's own lock. The bits encode whether the callout is on a wheel or processing list, whether it is pending, and a handful of internal book-keeping states. Driver code uses `callout_pending(c)` to read it; nothing else.

`c_flags` is external. The caller (your driver) is supposed to manage two bits in it: `CALLOUT_ACTIVE` and `CALLOUT_RETURNUNLOCKED`. The active bit is meant to track "I have asked this callout to be scheduled and have not cancelled it yet". The returnunlocked bit changes the lock-handling contract; we will get to that in Section 5. Driver code reads the active bit via `callout_active(c)` and clears it via `callout_deactivate(c)`.

The `c_lock` field deserves its own paragraph. When you initialize the callout with `callout_init_mtx`, `callout_init_rw`, or `callout_init_rm`, the kernel records the lock pointer here. Later, when the callout fires, the kernel acquires that lock before calling your callback function and releases it after the callback returns (unless you specifically asked otherwise). This means your callback runs as if the caller had acquired the lock for it. The lock-managed callout is almost always what you want for driver code; we will say more in Section 5.

13.3.2 The Callback Function Signature

A callout's callback function has a single argument: a `void *`. The kernel passes whatever you registered with `callout_reset` (or its variants). The function returns `void`. Its full signature, from `/usr/src/sys/sys/_callout.h`:

```
typedef void callout_func_t(void *);
```

Convention: pass a pointer to your `softc` (or to whatever per-instance state the callback needs). The first line of the callback casts the void pointer back to the struct pointer:

```
static void
myfirst_heartbeat(void *arg)
{
    struct myfirst_softc *sc = arg;
    /* ... do timer work ... */
}
```

The argument is fixed at registration time and does not change between firings. If you need to pass changing context to the callback, store it somewhere the callback can find via the `softc`.

13.3.3 The Four Initialization Variants

`callout(9)` offers four ways to initialize a callout, distinguished by what kind of lock (if any) the kernel will acquire for you before the callback runs.

```
void callout_init(struct callout *c, int mpsafe);

#define callout_init_mtx(c, mtx, flags) \
```

```
_callout_init_lock((c), &(mtx)->lock_object, (flags))
#define callout_init_rw(c, rw, flags) \
    _callout_init_lock((c), &(rw)->lock_object, (flags))
#define callout_init_rm(c, rm, flags) \
    _callout_init_lock((c), &(rm)->lock_object, (flags))
```

`callout_init(c, mpsafe)` is the legacy, lock-naive variant. The `mpsafe` argument is now badly named; it really means “may run without acquiring Giant for me”. Pass 1 for any modern driver code; pass 0 only if you genuinely want the kernel to acquire Giant before your callback (almost never, and only in very old code paths). New drivers should not use this variant. The chapter mentions it for completeness because you will see it in old code.

`callout_init_mtx(c, mtx, flags)` registers a sleep mutex (`MTX_DEF`) as the callout’s lock. Before each firing, the kernel acquires the mutex and releases it after the callback returns. This is the variant you will use for almost all driver code. It pairs naturally with the `MTX_DEF` mutex you already have on the data path.

`callout_init_rw(c, rw, flags)` registers an `rw(9)` reader/writer lock. The kernel takes the write lock unless you set `CALLOUT_SHAREDLOCK`, in which case it takes the read lock. Less common in driver code; useful when the callback needs to read a piece of read-mostly state and several callouts share the same lock.

`callout_init_rm(c, rm, flags)` registers an `rmlock(9)`. Specialized; used in network drivers with hot read paths that should not contend.

For the `myfirst` driver, every callout we add will use `callout_init_mtx(&sc->some_co, &sc->mtx, 0)`. The kernel acquires `sc->mtx` before the callback runs, the callback can manipulate the `cbuf` and other mutex-protected state without taking the lock itself, and the kernel releases `sc->mtx` after. The pattern is clean, the rules are explicit, and `WITNESS` will yell if you violate them.

13.3.4 The flags Argument

The flags argument to `_callout_init_lock` is one of two values for driver code:

- 0: the callout’s lock is acquired before the callback and released after. This is the default and the right answer almost every time.
- `CALLOUT_RETURNUNLOCKED`: the callout’s lock is acquired before the callback. The callback is responsible for releasing it (or it may have already been released by something the callback called). This is occasionally useful when the callback’s last action is to drop the lock and do something the lock cannot cover.
- `CALLOUT_SHAREDLOCK`: only valid for `callout_init_rw` and `callout_init_rm`. The lock is acquired in shared mode rather than exclusive.

For Chapter 13 we use 0 everywhere. `CALLOUT_RETURNUNLOCKED` is mentioned in Section 5 for completeness; the chapter does not need it.

13.3.5 The Five Lifecycle Stages

Every callout follows the same five-stage lifecycle. Knowing the stages by name will make the rest of the chapter much easier to read.

Stage 1: initialized. The struct `callout` has been initialized with one of the init variants. It has a lock association (or `mpsafe`). It has not been scheduled. Nothing will fire until you tell it to.

Stage 2: pending. You have called `callout_reset` or `callout_reset_sbt`. The kernel has placed the callout on its internal wheel and noted the time at which it should fire. `callout_pending(c)` returns true. The callback has not yet run. You can cancel by calling `callout_stop(c)`, which removes it from the wheel.

Stage 3: firing. The deadline has arrived and the kernel is now running the callback. If the callout has a registered lock, the kernel has acquired it. Your callback function is executing. During this stage `callout_active(c)` is true, `callout_pending(c)` may be false (it has been removed from the wheel). The callback is free to call `callout_reset` to re-arm itself (this is the periodic pattern).

Stage 4: completed. The callback has returned. If the callback re-armed via `callout_reset`, the callout is back in stage 2. Otherwise it is now idle: `callout_pending(c)` is false. If the kernel acquired a lock for the callback, it has released it.

Stage 5: destroyed. The callout's underlying memory is no longer needed. There is no `callout_destroy` function; instead, you must ensure that the callout is not pending and not firing, then free the containing structure. The standard tool for the “wait for the callout to be safely idle” job is `callout_drain`. Section 6 covers this in detail.

The cycle is: init once, alternate between pending and (firing + completed) any number of times, drain, free.

13.3.6 A First Look at the API

We have not yet scheduled anything. Let us read the four most important calls, with one-line summaries each:

```
int callout_reset(struct callout *c, int to_ticks,
                  void (*fn)(void *), void *arg);
int callout_reset_sbt(struct callout *c, sbintime_t sbt,
                      sbintime_t prec, void (*fn)(void *), void *arg, int flags);
int callout_stop(struct callout *c);
int callout_drain(struct callout *c);
```

`callout_reset` schedules the callout. The first argument is the callout to schedule. The second is the delay in ticks (multiply seconds by `hz` to convert; on FreeBSD 14.3, `hz=1000` typically, so a tick is a millisecond). The third is the callback function. The fourth is the argument to pass to the callback. Returns nonzero if the callout was previously pending and got cancelled (so the new schedule is replacing the old).

`callout_reset_sbt` is the same but takes the delay as `sbintime_t` and accepts a precision and flags. Used for sub-tick precision or when you want to tell the kernel about acceptable slop. Most drivers use `callout_reset` and reach for `_sbt` only when needed.

`callout_stop` cancels a pending callout. If the callout was pending, it is removed from the wheel and never fires. Returns nonzero if a pending callout was cancelled. If the callout was not pending (already fired, or never scheduled), the call is a no-op and returns zero. Critically: `callout_stop` does *not* wait for an in-flight callback to finish. If the callback is currently executing on another CPU, `callout_stop` returns before the callback returns.

`callout_drain` is the safe-for-teardown variant. It cancels the callout if pending, *and* waits for any currently-executing callback to return before itself returning. After `callout_drain` returns, the callout is guaranteed to be idle and not running anywhere. This is the function you call at detach time. Section 6 walks through why this matters.

13.3.7 Reading the Source

If you have ten minutes, open `/usr/src/sys/sys/callout.h` and `/usr/src/sys/kern/kern_timeout.c` and skim. Three things to look for:

The header defines the public API in less than 130 lines. Every function the chapter mentions is declared there. The macros that wrap `_callout_init_lock` are clearly visible.

The implementation file is long (around 1550 lines in FreeBSD 14.3), but the function names match the API. `callout_reset_sbt_on` is the core scheduling function; everything else is a wrapper. `_callout_stop_safe` is the unified stop-and-maybe-drain function; `callout_stop` and `callout_drain` are macros that call it with different flags. `callout_init` and `_callout_init_lock` sit near the bottom of the file.

The chapter cites FreeBSD functions and tables by name rather than line number, because line numbers drift between releases while the function and symbol names survive. If you need approximate line numbers for `kern_timeout.c` in FreeBSD 14.3: `callout_reset_sbt_on` near 936, `_callout_stop_safe` near 1085, `callout_init` near 1347. Open the file and jump to the symbol; the line is whatever your editor reports.

The KASSERTs scattered through the source are the rules in code form. For example, the assertion in `_callout_init_lock` that “you may not give me a sleepable lock” enforces the rule that callouts may not block on a lock that could sleep. Reading those assertions builds confidence that the API guarantees what it says.

13.3.8 A Worked Lifecycle Walkthrough

Putting the lifecycle stages on a timeline makes them concrete. Imagine a heartbeat callout that is initialized at attach, enabled at $t=0$, and disabled at $t=2.5$ seconds.

- **$t=-1s$ (attach time):** The driver calls `callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)`. The callout is now in stage 1 (initialized). `callout_pending(c)` returns false. The kernel knows about the callout’s lock association.
- **$t=0s$:** The user enables the heartbeat by writing the sysctl. The handler acquires `sc->mtx`, sets `interval_ms = 1000`, and calls `callout_reset(&sc->heartbeat_co, hz, myfirst_heartbeat, sc)`. The callout transitions to stage 2 (pending). `callout_pending(c)` returns true. The kernel has placed it on a wheel bucket corresponding to $t+1$ second.
- **$t=1s$:** The deadline arrives. The kernel pulls the callout off the wheel (`callout_pending(c)` becomes false). The kernel acquires `sc->mtx`. The kernel calls `myfirst_heartbeat(sc)`. The callout is now in stage 3 (firing). The callback runs, emits a log line, calls `callout_reset` to re-arm. The re-arm puts the callout back on a wheel bucket for $t+2$ seconds. `callout_pending(c)` is true again. The callback returns. The kernel releases `sc->mtx`. The callout is now in stage 2 (pending) again, waiting for its next firing.
- **$t=2s$:** Same sequence. The callback fires, re-arms, the callout is pending for $t+3$ seconds.

- **t=2.5s:** The user disables the heartbeat by writing the sysctl. The handler acquires `sc->mtx`, sets `interval_ms = 0`, and calls `callout_stop(&sc->heartbeat_co)`. The kernel removes the callout from the wheel. `callout_stop` returns 1 (it cancelled a pending callout). `callout_pending(c)` becomes false. The callout is now back in stage 1 (initialized but idle).
- **t=∞ (later, at detach time):** The detach path calls `callout_drain(&sc->heartbeat_co)`. The callout is already idle; `callout_drain` returns immediately. The driver may now safely free the surrounding state.

Notice three things about the timeline.

The cycle of pending → firing → pending repeats indefinitely as long as the callback re-arms. There is no hard limit on iterations.

A `callout_stop` can intercept the pending-firing-pending cycle at any point. If the callout is in stage 2 (pending), `callout_stop` cancels it. If the callout is in stage 3 (firing) on another CPU, `callout_stop` does *not* cancel it (the callback will run to completion); the next iteration of the cycle will not happen because the callback's re-arm condition (`interval_ms > 0`) is now false.

The `is_attached` check in the callback (which we will introduce in Section 4) provides a similar interception point during teardown. If the callback fires after detach has cleared `is_attached`, the callback exits without re-arming, and the next iteration does not happen.

This timeline is the entire shape of `callout(9)` use in driver code. Variations involve adding a one-shot pattern (no re-arm), a watchdog pattern (cancel on success), or a debounce pattern (only schedule if not already pending). The lifecycle stages are the same.

13.3.9 A Word About “active” Versus “pending”

Two related concepts that beginners sometimes conflate.

`callout_pending(c)` is set by the kernel when the callout is on the wheel waiting to fire. It is cleared by the kernel when the callout fires (the callback is about to run) or when `callout_stop` cancels it.

`callout_active(c)` is set by the kernel when `callout_reset` succeeds. It is cleared by `callout_deactivate` (a function you call) or by `callout_stop`. Crucially, the kernel does *not* clear `callout_active` when the callback fires. The active bit is a flag that says “I scheduled this callout and have not actively cancelled it”; whether the callback has fired since then is a separate question.

A callout can be in any of four states:

- not active and not pending: never scheduled, or cancelled via `callout_stop`, or deactivated via `callout_deactivate` after firing.
- active and pending: scheduled, on the wheel, waiting to fire.
- active and not pending: scheduled, fired (or about to fire), and the callback has not yet called `callout_deactivate`.
- not active and pending: rare, but possible if the driver calls `callout_deactivate` while the callout is still scheduled. Most drivers never reach this state because they call `callout_deactivate` only inside the callback, after the pending bit has already been cleared.

For most drivers you only need `callout_pending` (used in patterns like the debounce). The `active` flag matters more in code that wants to know “did we schedule a callout, even if it has already run?”. For Chapter 13, we use `pending` once and never use `active`.

13.3.10 Wrapping Up Section 2

Callouts are small structures with a small API and a regular lifecycle. The four initialization variants pick the kind of lock the kernel will acquire for you (or none). The four functions you will use most are `callout_reset`, `callout_reset_sbt`, `callout_stop`, and `callout_drain`. Section 3 puts them to work, scheduling one-shot and periodic timers and showing how the periodic re-arm pattern actually works.

13.4 Section 3: Scheduling One-shot and Repeating Events

A timer in `callout(9)` is always conceptually one-shot. There is no `callout_reset_periodic` function. Periodic behaviour is built by having the callback re-arm itself at the end of each firing. Both the one-shot and the periodic patterns use the same API call (`callout_reset`); the difference is whether the callback decides to schedule the next firing.

This section walks through both patterns with worked examples that compile and run. We will not yet integrate them into `myfirst`; that is Section 4. Here we focus on the timing primitives and the patterns you will use.

13.4.1 The One-Shot Pattern

The simplest possible callout: schedule a callback to fire once, in the future.

```
static void
my_oneshot(void *arg)
{
    device_printf((device_t)arg, "one-shot fired\n");
}

void
schedule_a_one_shot(device_t dev, struct callout *co)
{
    callout_reset(co, hz / 10, my_oneshot, dev);
}
```

`hz / 10` means “100 milliseconds from now” on a system with `hz=1000`. The callback receives the device pointer we registered. It runs once, prints, and returns. The callout is now idle. To run it again, you would call `callout_reset` again.

Three things to notice. First, the callback’s argument is whatever we passed to `callout_reset`, untyped, recovered with a cast. Second, the callback emits one log line and returns; it does not re-schedule. This is the one-shot pattern. Third, we used `hz / 10` rather than a hard-coded value. Always express callout delays in terms of `hz` so the code is portable across systems with different clock rates.

If you wanted a 250 ms delay, you would write `hz / 4` (or `hz * 250 / 1000` for clarity). For a 5 second delay, `hz * 5`. The arithmetic is integer; for fractional values, multiply before dividing to preserve precision.

13.4.2 The Periodic Pattern

For periodic behaviour, the callback re-arms itself at the end:

```
static void
my_periodic(void *arg)
{
    struct myfirst_softc *sc = arg;
    device_printf(sc->dev, "tick\n");
    callout_reset(&sc->heartbeat_co, hz, my_periodic, sc);
}

void
start_periodic(struct myfirst_softc *sc)
{
    callout_reset(&sc->heartbeat_co, hz, my_periodic, sc);
}
```

The first call to `callout_reset` (in `start_periodic`) arms the callout for one second from now. When it fires, `my_periodic` runs, emits a log line, and re-arms for one second after the present moment. The next firing happens, the cycle continues. To stop the periodic firing, call `callout_stop(&sc->heartbeat_co)` (or `callout_drain` at teardown). Once the callout has been stopped, `my_periodic` will not fire again until `start_periodic` is called again.

Three subtleties.

First, the re-arm happens at the *end* of the callback. If the callback's work takes a long time, the next firing is delayed by that work. The actual interval between firings is roughly `hz` ticks plus the time the callback took. For most driver use cases this is fine. If you need an exact period, use `callout_schedule` or `callout_reset_sbt` with a calculated absolute deadline.

Second, the callback is called with the callout's lock acquired (we will see why in Section 5). When the callback calls `callout_reset` to re-arm, the callout subsystem handles the re-arm correctly even though it is being called from inside the firing of the same callout. The kernel's internal bookkeeping is designed for exactly this pattern.

Third, if the driver is being torn down at the same moment the callback re-arms, you have a race: the re-arm puts the callout back on the wheel after the cancel/drain has run. Section 6 explains how to handle this. The short answer is: at detach time, set a "shutting down" flag in the `softc` under the mutex, then `callout_drain` the callout. The callback checks the flag at entry and returns without re-arming if it sees the flag set. The drain waits for the in-flight callback to return.

13.4.3 `callout_schedule` for Re-Arming Without Repeating Arguments

For periodic callouts, the callback re-arms with the same function and argument every time. `callout_reset` requires you to pass them again. `callout_schedule` is a convenience that uses the function and argument from the last `callout_reset`:

```
int callout_schedule(struct callout *c, int to_ticks);
```

Inside the periodic callback:

```
static void
my_periodic(void *arg)
{
    struct myfirst_softc *sc = arg;
    device_printf(sc->dev, "tick\n");
    callout_schedule(&sc->heartbeat_co, hz);
}
```

The kernel uses the function pointer and argument it remembers from the last `callout_reset` call. Less typing, and the code reads slightly cleaner. Both `callout_reset` and `callout_schedule` work for the periodic pattern; pick whichever you prefer.

13.4.4 Sub-Tick Precision With `callout_reset_sbt`

When you need precision finer than a tick, or you want to tell the kernel about acceptable slop, use the sbintime variant:

```
int callout_reset_sbt(struct callout *c, sbintime_t sbt,
                    sbintime_t prec,
                    void (*fn)(void *), void *arg, int flags);
```

Example: schedule a 250-microsecond timer:

```
sbintime_t sbt = 250 * SBT_1US;
callout_reset_sbt(&sc->fast_co, sbt, SBT_1US,
    my_callback, sc, C_HARDCLOCK);
```

The `prec` argument is the precision the caller is willing to accept. `SBT_1US` says “anywhere within one microsecond of the deadline is fine”; the kernel may coalesce this timer with other timers up to one microsecond apart. `0` means “fire as close to the deadline as possible”. The flags include `C_HARDCLOCK` (align to the system clock interrupt, default for most cases), `C_DIRECT_EXEC` (run in the timer interrupt context, only useful with a spin lock), `C_ABSOLUTE` (interpret `sbt` as absolute time rather than a relative delay), and `C_PRECALC` (used internally; don’t set it).

For the chapter, we use `callout_reset` (tick-based) almost everywhere. `callout_reset_sbt` is mentioned for completeness; the lab section has one exercise using it.

13.4.5 Cancellation: `callout_stop`

To cancel a pending callout, call `callout_stop`:

```
int callout_stop(struct callout *c);
```

If the callout is pending, the kernel removes it from the wheel and returns 1. If the callout is not pending (already fired, or never scheduled), the call is a no-op and returns 0.

Critically: `callout_stop` does *not* wait. If the callback is currently executing on another CPU when `callout_stop` is called, the call returns immediately. The callback continues to run on the other CPU and finishes when it finishes. If the callback re-arms itself, the callout is back on the wheel after `callout_stop` returns.

This means `callout_stop` is the right tool for normal operation (cancel a pending callout because the condition that motivated it has been resolved) but the *wrong* tool for teardown (where you must wait for any in-flight callback to finish before freeing the surrounding state). For teardown, use `callout_drain`. Section 6 covers this distinction in depth.

The standard pattern in normal operation:

```
/* Decided we don't need this watchdog any more */
if (callout_stop(&sc->watchdog_co)) {
    /* The callout was pending; we just cancelled it. */
    device_printf(sc->dev, "watchdog cancelled\n");
}
/* If callout_stop returned 0, the callout had already fired
   or was never scheduled; nothing to do. */
```

A small point of caution: between `callout_stop` returning 1 and the next statement running, no other thread can re-arm the callout because we hold the lock that protects the surrounding state. Without the lock, `callout_stop` would still cancel correctly, but the meaning of the return value would become racy.

13.4.6 Cancellation: `callout_drain`

`callout_drain` is the teardown-safe variant:

```
int callout_drain(struct callout *c);
```

Like `callout_stop`, it cancels a pending callout. *Unlike* `callout_stop`, if the callback is currently executing on another CPU, `callout_drain` waits for it to return before itself returning. After `callout_drain` returns, the callout is guaranteed to be idle: not pending, not firing, and (if the callback has not re-armed) it will not fire again.

Two important rules.

First, the caller of `callout_drain` *must not* hold the callout's lock. If the callout is currently executing (it has acquired the lock and is running the callback), `callout_drain` needs to wait for the callback to return, which

means the callback needs to release the lock, which means the caller of `callout_drain` cannot be holding it. Holding the lock would deadlock.

Second, `callout_drain` may sleep. The thread waits on a sleep queue for the callback to finish. Therefore `callout_drain` is only legal in contexts where sleeping is allowed (process context or kernel thread; not interrupt or spin-lock context).

The standard teardown pattern:

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* mark "going away" so a re-arming callback will not re-schedule */
    MYFIRST_LOCK(sc);
    sc->is_attached = 0;
    MYFIRST_UNLOCK(sc);

    /* drain the callout: cancel pending, wait for in-flight */
    callout_drain(&sc->heartbeat_co);
    callout_drain(&sc->watchdog_co);

    /* now safe to destroy other primitives and free state */
    /* ... */
}
```

Section 6 expands this pattern in detail.

13.4.7 `callout_pending` and `callout_active`

Two diagnostic accessors that are useful when you want to know what state a callout is in:

```
int callout_pending(const struct callout *c);
int callout_active(const struct callout *c);
void callout_deactivate(struct callout *c);
```

`callout_pending(c)` returns nonzero if the callout is currently scheduled and waiting to fire. False if the callout has already fired (or never been scheduled, or was cancelled).

`callout_active(c)` returns nonzero if `callout_reset` has been called on this callout since the last `callout_deactivate`. The “active” bit is something *you* manage. The kernel never sets or clears it on its own (with one small exception: a successful `callout_stop` clears it). The convention is that the callback clears the bit at the start, the rest of the driver sets it when scheduling, and code that wonders “do I have a pending or just-fired callout?” can check `callout_active`.

For most driver work you do not need either accessor. We mention them because real driver source uses them and you should recognize the pattern. The `myfirst` driver in Chapter 13 uses `callout_pending` once, in the watchdog cancellation path; the rest of the chapter does not need them.

13.4.8 A Worked Example: A Two-Stage Schedule

Putting the pieces together: a small worked example that schedules a callback to fire 100 ms from now, then re-schedules it for 500 ms after that, then runs it once and stops.

```
static int g_count = 0;
static struct callout g_co;
static struct mtx g_mtx;

static void
my_callback(void *arg)
{
    printf("callback fired (count=%d)\n", ++g_count);
    if (g_count == 1) {
        /* Reschedule for 500 ms later. */
        callout_reset(&g_co, hz / 2, my_callback, NULL);
    } else if (g_count == 2) {
        /* Done; do nothing, callout becomes idle. */
    }
}

void
start_test(void)
{
    mtx_init(&g_mtx, "test_co", NULL, MTX_DEF);
    callout_init_mtx(&g_co, &g_mtx, 0);
    callout_reset(&g_co, hz / 10, my_callback, NULL);
}

void
stop_test(void)
{
    callout_drain(&g_co);
    mtx_destroy(&g_mtx);
}
```

Ten lines of substance. The callback decides whether to re-arm based on the count. After two firings, it stops re-arming and the callout becomes idle. `stop_test` drains the callout (waiting if necessary for any in-flight firing), then destroys the mutex.

This pattern, with variations, is the entire shape of `callout(9)` use in driver code. Section 4 puts it inside `myfirst` and gives it real work to do.

13.4.9 Wrapping Up Section 3

Callouts are scheduled with `callout_reset` (tick-based) or `callout_reset_sbt` (sbintime-based). One-shot behaviour comes from a callback that does not re-arm; periodic behaviour comes from a callback that re-arms itself at the end. Cancellation is `callout_stop` for normal operation and `callout_drain` for teardown. The accessors `callout_pending`, `callout_active`, and `callout_deactivate` are for diagnostic inspection.

Section 4 takes the patterns of this section and integrates a real callout into the `myfirst` driver: a heartbeat that periodically logs a stat line.

13.5 Section 4: Integrating Timers into Your Driver

Theory is comfortable; integration is where the rough edges show up. This section walks through adding a heartbeat callout to `myfirst`. The heartbeat fires once per second, logs a short statistics line, and re-arms itself. We will see how the callout integrates with the existing mutex, how the lock-aware initialization removes a class of race, how the `is_attached` flag from Chapter 12 protects the callback during teardown, and how `WITNESS` confirms the design is correct.

Consider this Stage 1 of the chapter's driver evolution. By the end of this section, the `myfirst` driver has its first timer.

13.5.1 Adding a Heartbeat Callout

Add two fields to struct `myfirst_softc`:

```
struct myfirst_softc {
    /* ... existing fields ... */
    struct callout      heartbeat_co;
    int                 heartbeat_interval_ms; /* 0 = disabled */
    /* ... rest ... */
};
```

`heartbeat_co` is the callout itself. `heartbeat_interval_ms` is a sysctl-tunable that lets the user enable, disable, and adjust the heartbeat at runtime. A value of zero disables the heartbeat. A positive value is the interval in milliseconds.

Initialize the callout in `myfirst_attach`. Place the call after the mutex is initialized and before the `cdev` is created (so the callout is ready to schedule but no user can yet trigger anything):

```
static int
myfirst_attach(device_t dev)
{
```

```

    /* ... existing setup ... */

    mtx_init(&sc->mtx, device_get_nameunit(dev), "myfirst", MTX_DEF);
    cv_init(&sc->data_cv, "myfirst data");
    cv_init(&sc->room_cv, "myfirst room");
    sx_init(&sc->cfg_sx, "myfirst cfg");
    callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0);

    /* ... rest of attach ... */
}

```

`callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)` registers `sc->mtx` as the callout's lock. From this point on, any time the heartbeat callout fires, the kernel will acquire `sc->mtx` before calling our callback and release it after the callback returns. This is exactly the contract we want: the callback may freely manipulate `cbuf` state and per-softc fields without taking the lock itself.

Drain the callout in `myfirst_detach`, before destroying the primitives:

```

static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* ... refuse detach while active_fhs > 0 ... */
    /* ... clear is_attached and broadcast cvs under sc->mtx ... */

    seldrain(&sc->rsl);
    seldrain(&sc->wsl);

    callout_drain(&sc->heartbeat_co);

    if (sc->cdev_alias != NULL) { destroy_dev(sc->cdev_alias); /* ... */ }
    /* ... rest of detach as before ... */
}

```

The `callout_drain` call must come *after* `is_attached` is cleared and the cvs are broadcast (so a callback that fires during the drain sees the cleared flag), and *before* any primitive the callback might touch is destroyed. The cleared `is_attached` flag prevents the callback from rescheduling; the drain waits for any in-flight callback to finish. After `callout_drain` returns, no callback can be running and none is pending; the rest of detach can safely free state.

13.5.2 The Heartbeat Callback

Now the callback itself:

```

static void
myfirst_heartbeat(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t used;
    uint64_t br, bw;
    int interval;

    MYFIRST_ASSERT(sc);

    if (!sc->is_attached)
        return; /* device going away; do not re-arm */

    used = cbuf_used(&sc->cb);
    br = counter_u64_fetch(sc->bytes_read);
    bw = counter_u64_fetch(sc->bytes_written);
    device_printf(sc->dev,
        "heartbeat: cb_used=%zu, bytes_read=%ju, bytes_written=%ju\n",
        used, (uintmax_t)br, (uintmax_t)bw);

    interval = sc->heartbeat_interval_ms;
    if (interval > 0)
        callout_reset(&sc->heartbeat_co,
            (interval * hz + 999) / 1000,
            myfirst_heartbeat, sc);
}

```

Ten lines that capture the entire periodic-heartbeat pattern. Let us walk through them.

`MYFIRST_ASSERT(sc)` confirms that `sc->mtx` is held. The callout was initialized with `callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)`, so the kernel acquired `sc->mtx` before calling us; the assertion is a sanity check that catches the case where someone (perhaps a future maintainer) accidentally changes the init to `callout_init` without paying attention.

`if (!sc->is_attached) return;` is the teardown guard. If the detach path has cleared `is_attached`, we exit immediately without doing any work and without re-arming. The drain in `myfirst_detach` will see the callout idle and complete cleanly.

The `cbuf-used` and counter reads happen under the lock. We call `cbuf_used` (which expects `sc->mtx` held) and `counter_u64_fetch` (which is lockless and safe everywhere). The `device_printf` call is potentially expensive but is conventional for log lines; we tolerate the cost because it happens at most once per second.

The re-arm at the end uses the current value of `heartbeat_interval_ms`. If the user has set it to zero (disabled the heartbeat), we do not re-arm, and the callout becomes idle until something else schedules it. If the user has changed the interval, the next firing will use the new value. This is a small but significant feature: the heartbeat's frequency is dynamically configurable without restarting the driver.

The $(\text{interval} * \text{hz} + 999) / 1000$ arithmetic converts milliseconds to ticks, rounding up. Same formula as Chapter 12's bounded waits, for the same reason: never round below the requested duration.

13.5.3 Starting the Heartbeat From a Sysctl

The user enables the heartbeat by writing a non-zero value to `dev.myfirst.<unit>.heartbeat_interval_ms`. We need a sysctl handler that schedules the first firing:

```
static int
myfirst_sysctl_heartbeat_interval_ms(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, old, error;

    old = sc->heartbeat_interval_ms;
    new = old;
    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);

    if (new < 0)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    sc->heartbeat_interval_ms = new;
    if (new > 0 && old == 0) {
        /* Enabling: schedule the first firing. */
        callout_reset(&sc->heartbeat_co,
            (new * hz + 999) / 1000,
            myfirst_heartbeat, sc);
    } else if (new == 0 && old > 0) {
        /* Disabling: cancel any pending heartbeat. */
        callout_stop(&sc->heartbeat_co);
    }
    MYFIRST_UNLOCK(sc);
    return (0);
}
```

The handler:

1. Reads the current value (so a read-only query returns the current interval).
2. Lets `sysctl_handle_int` validate and update the local `new` variable.
3. Validates that the new value is non-negative.
4. Acquires `sc->mtx` to commit the change atomically against any racing callout activity.
5. If the heartbeat was disabled and is now enabled, schedules the first firing.

6. If the heartbeat was enabled and is now disabled, cancels the pending callout.
7. Drops the lock and returns.

Note the symmetric handling. If the user toggles the heartbeat off and on rapidly, the handler does the right thing each time. A re-arm in the callback would not fire a new heartbeat after the user disables it (the callback checks `heartbeat_interval_ms` before re-arming). A schedule from the sysctl would not double-schedule (the callback re-arms only if `interval_ms > 0`, and the sysctl only schedules if `old == 0`).

A subtle point: the callout is initialized with `sc->mtx` as its lock, and the sysctl handler acquires `sc->mtx` before calling `callout_reset`. The kernel acquires `sc->mtx` for callbacks too. This means the sysctl handler and any in-flight callback are serialized: the sysctl waits if a callback is currently running, and the callback cannot run while the sysctl holds the lock. The race “user disables the heartbeat just as the callback re-arms” is closed by the lock.

Register the sysctl in attach:

```
SYSCALL_ADD_PROC(&sc->sysctl_ctx,
    SYSCTL_CHILDREN(device_get_sysctl_tree(dev)),
    OID_AUTO, "heartbeat_interval_ms",
    CTLTYPE_INT | CTLFLAG_RW | CTLFLAG_MPSAFE,
    sc, 0, myfirst_sysctl_heartbeat_interval_ms, "I",
    "Heartbeat interval in milliseconds (0 = disabled)");
```

And initialize `heartbeat_interval_ms = 0` in attach so the heartbeat is disabled by default. A user opts in by setting the sysctl; the driver is silent until then.

13.5.4 Verifying the Refactor

Build the new driver and load it on a WITNESS kernel. Three tests:

Test 1: heartbeat off by default.

```
$ kldload ./myfirst.ko
$ dmesg | tail -3  # attach line shown; no heartbeat logs
$ sleep 5
$ dmesg | tail -3  # still no heartbeat logs
```

Expected: the attach line, then nothing. The heartbeat is disabled by default.

Test 2: heartbeat on.

```
$ sysctl -w dev.myfirst.0.heartbeat_interval_ms=1000
$ sleep 5
$ dmesg | tail -10
```

Expected: about five heartbeat lines, one per second:

```
myfirst0: heartbeat: cb_used=0, bytes_read=0, bytes_written=0
myfirst0: heartbeat: cb_used=0, bytes_read=0, bytes_written=0
myfirst0: heartbeat: cb_used=0, bytes_read=0, bytes_written=0
```

Test 3: heartbeat under load.

In one terminal:

```
$ ../../part-02/ch10-handling-io-efficiently/userland/producer_consumer
```

While that runs, observe dmesg in another terminal. The heartbeat lines should now show non-zero byte counts:

```
myfirst0: heartbeat: cb_used=0, bytes_read=1048576, bytes_written=1048576
```

Test 4: disable cleanly.

```
$ sysctl -w dev.myfirst.0.heartbeat_interval_ms=0
$ sleep 5
$ dmesg | tail -3  # nothing new
```

The heartbeat stops; no further lines are emitted.

Test 5: detach with heartbeat active.

```
$ sysctl -w dev.myfirst.0.heartbeat_interval_ms=1000
$ kldunload myfirst
```

Expected: detach succeeds. The drain in `myfirst_detach` cancels the pending callout and waits for any in-flight firing to complete. No WITNESS warnings, no panics.

If any of these tests fails, the most likely cause is either (a) the `is_attached` check is missing in the callback (so the callback re-arms during teardown and the `callout_drain` never returns) or (b) the lock initialization is wrong (so the callback runs without the expected mutex held and `MYFIRST_ASSERT` fires).

13.5.5 A Note on the Heartbeat's Overhead

A 1-second heartbeat is essentially free: one callout per second, three counter reads, one log line, one re-arm. Total CPU: microseconds per firing. Memory: zero beyond the struct `callout` already in the softc.

A 1-millisecond heartbeat is a different story. A thousand log lines per second will saturate the dmesg buffer in seconds and dominate the driver's CPU usage. Use short intervals only when the work is genuinely fast and the log is gated by a debug level.

For demonstration purposes, 1000 (one per second) is reasonable. For a real-world heartbeat the reasonable range is probably 100 ms to 10 s. The chapter does not enforce a minimum; the user's choice is their own.

13.5.6 A Mental Model: How a Heartbeat Plays Out

A step-by-step picture of what the kernel and the driver do during a single heartbeat firing. Useful for cementing the lifecycle vocabulary in concrete terms.

- **t=0:** User runs `sysctl -w dev.myfirst.0.heartbeat_interval_ms=1000`.
- **t=0+δ:** The `sysctl` handler runs. It reads the current value (0), validates the new value (1000), and acquires `sc->mtx`. Inside the lock: it sets `sc->heartbeat_interval_ms = 1000`. Detecting the 0 → non-zero transition, it calls `callout_reset(&sc->heartbeat_co, hz, myfirst_heartbeat, sc)`. The kernel computes the wheel bucket for “now plus 1000 ticks” and links the callout into that bucket. The handler releases `sc->mtx` and returns 0.
- **t=0 to t=1s:** The kernel does other work. The callout sits on the wheel.
- **t=1s:** The hardware-clock interrupt fires. The callout subsystem walks the current wheel bucket and finds `sc->heartbeat_co` waiting. The kernel removes it from the wheel and dispatches it.
- **t=1s+δ:** A callout-processing thread wakes (or, if the system is idle, the timer interrupt itself runs the callback). The kernel acquires `sc->mtx` (this may briefly block if another thread holds it; for our typical workload, the lock is free). Once `sc->mtx` is held, the kernel calls `myfirst_heartbeat(sc)`.
- **Inside the callback:** `MYFIRST_ASSERT(sc)` confirms the lock is held. The `is_attached` check passes. The callback reads `cbuf_used` (lock held; safe), reads the per-CPU counters (lockless; always safe), emits one `device_printf` line. It checks `sc->heartbeat_interval_ms` (1000); since it is positive, it calls `callout_reset(&sc->heartbeat_co, hz, myfirst_heartbeat, sc)` to schedule the next firing. The kernel re-links the callout into the wheel bucket for “now plus 1000 ticks”. The callback returns.
- **t=1s+ε:** The kernel releases `sc->mtx`. The callout is now back on the wheel, waiting for t=2s.
- **t=2s:** The cycle repeats.

Three observations.

First, the kernel manages the lock on your behalf. Your callback runs as if some unseen caller had acquired `sc->mtx` for it. There is no `mtx_lock/mtx_unlock` in the callback because the kernel handles them.

Second, the re-arm is just another `callout_reset` call. It is allowed because the callout’s lock is held; the kernel’s internal bookkeeping handles the case “this callout is currently firing, and is being re-armed inside its own callback”.

Third, the time between firings is approximately `hz` ticks, but is slightly more than that: the callback’s work time plus any scheduling latency adds to the interval. For a 1-second heartbeat the drift is microseconds; for a 1-millisecond heartbeat it could be measurable. If exact period matters, use `callout_reset_sbt` and compute the next deadline as “previous deadline + interval”, not “now + interval”.

13.5.7 Visualizing the Timer With `dtrace`

A useful sanity check: confirm the heartbeat fires at the rate you configured.

```
# dtrace -n 'fbt::myfirst_heartbeat:entry { @ = count(); } tick-1sec { printa(@);  
↵ trunc(@); }'
```

This dtrace one-liner counts how many times `myfirst_heartbeat` is entered each second. With `heartbeat_interval_ms=1000`, the count should be 1 per second. With `heartbeat_interval_ms=100`, the count should be 10. With `heartbeat_interval_ms=10`, the count should be 100.

If the count is wildly off from the expected value, the configuration did not take effect. Common causes: the `sysctl` handler did not commit the change (bug in the handler), the callback is exiting early due to `is_attached == 0` (bug in the teardown flow), or the system is so loaded that the callout is firing late and pile-up is occurring. In normal operation the count should be stable to within one count per second.

A more elaborate dtrace recipe: histogram of the time spent in the callback.

```
# dtrace -n '  
fbt::myfirst_heartbeat:entry { self->ts = timestamp; }  
fbt::myfirst_heartbeat:return /self->ts/ {  
    @ = quantize(timestamp - self->ts);  
    self->ts = 0;  
}  
tick-30sec { exit(0); }'
```

Each callback typically takes a few microseconds (the time to read counters and emit a log line). If the histogram shows callbacks taking milliseconds or more, something is wrong; investigate.

13.5.8 Wrapping Up Section 4

The driver has its first timer. The heartbeat callout fires periodically, logs a stat line, and re-arms. The `is_attached` flag (introduced in Chapter 12 for `cv` waiters) plays exactly the same role here: it lets the callback exit cleanly when the device is being torn down. The lock-aware initialization (`callout_init_mtx` with `sc->mtx`) means the callback runs with the data-path mutex held, and the kernel handles the lock acquisition for us.

Section 5 examines the lock contract more carefully. The contract is the most important rule in the callout API; getting it right makes the rest easy, and getting it wrong creates bugs that are hard to find.

13.6 Section 5: Handling Locking and Context in Timers

Section 4 used `callout_init_mtx` and trusted the kernel to acquire `sc->mtx` before each firing. This section opens that black box. We look at exactly what the kernel does with the lock pointer you registered, what guarantees you can assume inside the callback, and what you may and may not do during a firing.

The lock contract is the most important rule in `callout(9)`. A driver that respects it is correct by construction. A driver that violates it produces races that are hard to reproduce and even harder to diagnose. Spend the time on this section now; the rest of the chapter is easier when the model is solid.

13.6.1 What the Kernel Does Before Your Callback Runs

When a callout's deadline arrives, the kernel's callout-processing code (in `/usr/src/sys/kern/kern_timeout.c`) finds the callout on the wheel and prepares to fire it. The preparation depends on what lock

you registered:

- **No lock (`callout_init` with `mpsafe=1`).** The kernel sets `c_iflags`, marks the callout as no longer pending, and calls your function directly. Your function must do all its own locking.
- **A mutex (`callout_init_mtx` with an `MTX_DEF` mutex).** The kernel acquires the mutex with `mtx_lock`. If the mutex is contended, the firing thread blocks until it can acquire. Once the mutex is held, the kernel calls your function. After your function returns, the kernel releases the mutex with `mtx_unlock` (unless you set `CALLOUT_RETURNUNLOCKED`).
- **An rw lock (`callout_init_rw`).** Same as the mutex case, but with `rw_wlock` (or `rw_rlock` if you set `CALLOUT_SHAREDLOCK`).
- **An rmlock (`callout_init_rm`).** Same shape with rmlock primitives.
- **Giant (the default of `callout_init` with `mpsafe=0`).** The kernel acquires Giant. Avoid this for new code.

The lock is acquired in the firing thread's context. From your callback's point of view, the lock is just held: the same invariants apply as if any other thread had called `mtx_lock` and then called your function.

13.6.2 Why the Lock Is Acquired By the Kernel

A natural question: why doesn't the callback acquire the lock itself? The kernel-acquires-the-lock model has three subtle benefits.

It cooperates correctly with `callout_drain`. When `callout_drain` waits for an in-flight callback to finish, it must know whether a callback is currently running. The kernel's callout subsystem tracks exactly that, but only because it is the code that acquired the lock and began the callback. If the callback acquired its own lock, the subsystem would not know the difference between "callback is currently blocked trying to acquire the lock" and "callback has returned", and a clean drain would be impossible to implement without exposing kernel-private state. The kernel-acquires model keeps the subsystem firmly in control of the firing timeline.

It enforces the lock-class rule. The kernel checks at registration time that the lock you supply is not sleepable beyond what callouts can tolerate. A sleepable `sx` lock or `lockmgr` lock would let the callback call `cv_wait`, which in callout context is illegal. The init function (`_callout_init_lock` in `kern_timeout.c`) has the assertion: `KASSERT(lock == NULL || !(LOCK_CLASS(lock)->lc_flags & LC_SLEEPABLE), ...)` to catch this.

It serializes the callback against `callout_reset` and `callout_stop`. When the callback is firing, the lock is held. When you call `callout_reset` or `callout_stop` from your driver code, you must hold the same lock (the kernel checks). Therefore the cancel/reschedule and the firing are mutually exclusive: at any moment, either the callback is firing (lock held by the kernel-acquired path) or the driver code is reacting to a state change (lock held by the driver code). They never run concurrently.

This third property is what makes the heartbeat `sysctl` handler in Section 4 race-free. The handler acquires `sc->mtx`, decides to cancel or schedule, and the cancel/schedule completes atomically against any in-flight callback. No special precautions needed; the lock does the work.

13.6.3 What You May Do Inside a Callback

The callback runs with the registered lock held. The lock determines what is legal.

For an MTX_DEF mutex (our case), the rules are the same as any other code that holds a sleep mutex:

- You may read and write any state protected by the mutex.
- You may call `cbuf_*` helpers and other mutex-internal operations.
- You may call `cv_signal` and `cv_broadcast` (the `cv` API does not require the interlock to be dropped first).
- You may call `callout_reset`, `callout_stop`, or `callout_pending` on the same callout (re-arm, cancel, or check).
- You may call `callout_reset` on a *different* callout if you hold its lock too (or if it's mpsafe).

13.6.4 What You May Not Do Inside a Callback

The same rules: no sleeping while holding the mutex.

- You may **not** call `cv_wait`, `cv_wait_sig`, `mtx_sleep`, or any other sleeping primitive directly. (The mutex is held; sleeping with it held would be a sleep-with-mutex violation that WITNESS catches.)
- You may **not** call `uiomove`, `copyin`, or `copyout` (each may sleep).
- You may **not** call `malloc(..., M_WAITOK)`. Use `M_NOWAIT` instead, with proper error handling for the allocation failure case.
- You may **not** call `selwakeup` (it takes its own locks that may produce ordering violations).
- You may **not** call any function that may sleep.

The callback should be short. A few microseconds of work is typical. If you need to do something long-running, the callback should *enqueue* the work to a taskqueue or wake a kernel thread that can do it in process context. Chapter 16 covers the taskqueue pattern.

13.6.5 What If You Do Need To Sleep?

The standard answer: do not sleep in the callback. Defer the work. Two patterns are common.

Pattern 1: Set a flag, signal a kernel thread. The callback sets a flag in the softc and signals a `cv`. A kernel thread (created by `kproc_create` or `kthread_add`, both topics for later chapters) is waiting on the `cv`; it wakes, does the long-running work in process context, and goes back to waiting. The callback is short; the work is unconstrained.

Pattern 2: Enqueue a task on a taskqueue. The callback calls `taskqueue_enqueue` to defer the work to a taskqueue worker thread. The worker runs in process context and may sleep. Again, the callback is short; the work is unconstrained. Chapter 16 introduces this in depth.

For Chapter 13 we keep all our timer work short and lock-friendly; we do not yet need to defer. The pattern is mentioned so you know the option exists.

13.6.6 The `CALLOUT_RETURNUNLOCKED` Flag

`CALLOUT_RETURNUNLOCKED` changes the lock contract. Without it, the kernel acquires the lock before calling the callback and releases it after the callback returns. With it, the kernel acquires the lock before calling the callback and the *callback* is responsible for releasing it (or the callback may call something that drops the lock).

Why would you want this? Two reasons.

The callback drops the lock to do something that cannot be done under it. For example, the callback finishes its locked work, drops the lock, then enqueues a task on a taskqueue. The enqueue does not need the lock and could even violate ordering if held. Setting `CALLOUT_RETURNUNLOCKED` lets you write the drop in the natural place.

The callback hands the lock off to another function. If the callback calls a helper that takes ownership of the lock and is responsible for releasing it, `CALLOUT_RETURNUNLOCKED` documents the handoff to `WITNESS` so the assertion check passes.

Without `CALLOUT_RETURNUNLOCKED`, the kernel will assert that the lock is still held by the firing thread when the callback returns. The flag tells the assertion that the callback is allowed to leave the function with the lock dropped.

For Chapter 13 we do not need `CALLOUT_RETURNUNLOCKED`. All our callbacks acquire no additional locks, drop no locks, and return with the same lock state as on entry. The flag is mentioned so you recognize it in real-driver source.

13.6.7 The `CALLOUT_SHAREDLOCK` Flag

`CALLOUT_SHAREDLOCK` is only valid for `callout_init_rw` and `callout_init_rm`. It tells the kernel to acquire the lock in shared (read) mode rather than exclusive (write) mode before calling the callback.

Used when the callback only reads state and there are many callouts that share the same lock. With `CALLOUT_SHAREDLOCK`, multiple callbacks can run concurrently as long as no writer holds the lock.

For Chapter 13 we use `callout_init_mtx` with `MTX_DEF`, where shared mode does not exist. The flag is mentioned for completeness.

13.6.8 The “Direct Execution” Mode

The kernel offers a “direct” mode where the callout function runs in the timer interrupt context itself, rather than being deferred to a thread. The flag is `C_DIRECT_EXEC`, passed to `callout_reset_sbt`. It is documented in `/usr/src/sys/sys/callout.h` and only valid for callouts whose lock is a spin mutex (or no lock at all).

Direct execution is fast (no context switch, no thread wakeup) but the rules are stricter than ordinary callout context: no sleeping (already true), no acquiring sleep mutexes, no calling functions that might. The function runs in interrupt context, with all the constraints that implies (Chapter 14).

For Chapter 13 we never use `C_DIRECT_EXEC`. Our callouts are not time-critical to that degree. We mention it because you will see it in some hardware drivers (especially network drivers with hot RX paths).

13.6.9 A Worked Example: Lock Contract in the Heartbeat

Recall the heartbeat callback from Section 4:

```
static void
myfirst_heartbeat(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t used;
    uint64_t br, bw;
    int interval;

    MYFIRST_ASSERT(sc);

    if (!sc->is_attached)
        return;

    used = cbuf_used(&sc->cb);
    br = counter_u64_fetch(sc->bytes_read);
    bw = counter_u64_fetch(sc->bytes_written);
    device_printf(sc->dev,
        "heartbeat: cb_used=%zu, bytes_read=%ju, bytes_written=%ju\n",
        used, (uintmax_t)br, (uintmax_t)bw);

    interval = sc->heartbeat_interval_ms;
    if (interval > 0)
        callout_reset(&sc->heartbeat_co,
            (interval * hz + 999) / 1000,
            myfirst_heartbeat, sc);
}
```

Walk through the lock contract:

- The callout was initialized with `callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)`. The kernel holds `sc->mtx` before calling us.
- The `MYFIRST_ASSERT(sc)` confirms `sc->mtx` is held. Sanity check.
- `sc->is_attached` is read under the lock. Safe.
- `cbuf_used(&sc->cb)` is called. The `cbuf` helper expects `sc->mtx` held; we have it.
- `counter_u64_fetch(sc->bytes_read)` is called. `counter(9)` is lockless and safe everywhere.
- `device_printf` is called. `device_printf` does not take any of our locks; it's safe under our mutex.
- `sc->heartbeat_interval_ms` is read under the lock. Safe.
- `callout_reset` is called to re-arm. The callout API requires the callout's lock to be held when calling `callout_reset`; we have it.

Every operation in the callback respects the lock contract. The kernel will release `sc->mtx` after the callback returns.

A specific check: the callback does *not* call anything that may sleep. `device_printf` does not sleep. `cbuf_used` does not sleep. `counter_u64_fetch` does not sleep. `callout_reset` does not sleep. The callback respects the mutex's no-sleep convention.

If we accidentally added a sleep, WITNESS would catch it on a debug kernel: “sleeping thread (pid X) owns a non-sleepable lock” or similar. The lesson: trust the kernel to enforce the rules; just keep the callback short.

13.6.10 What Happens If Two Callouts Share a Lock

A single lock can be the interlock for many callouts. Consider:

```
callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0);
callout_init_mtx(&sc->watchdog_co, &sc->mtx, 0);
callout_init_mtx(&sc->tick_source_co, &sc->mtx, 0);
```

Three callouts, all using `sc->mtx`. When any one of them fires, the kernel acquires `sc->mtx` and runs the callback. While that callback is running, the lock is held; no other callback (or other thread acquiring `sc->mtx`) can proceed.

This is the right pattern: the data-path mutex protects all per-softc state, and any callout that needs to read or modify that state shares the same lock. The serialization is automatic and free.

The downside: if the heartbeat callback is slow, it delays the watchdog callback. Keep callbacks short.

13.6.11 What If the Callback Is Currently Firing When You Call `callout_reset`?

A subtle but important question: what happens if the callback is in the middle of executing on one CPU, and you call `callout_reset` on another CPU to reschedule it?

The kernel handles this case correctly. Let us walk through it.

The callback is firing on CPU 0. It holds `sc->mtx` (the kernel acquired it before calling). On CPU 1, you call `callout_reset(&sc->heartbeat_co, hz, fn, arg)` (perhaps because the user changed the interval). The callout API requires the caller to hold the same lock the callout uses; you do, on CPU 1.

But CPU 0 is already inside the callback, holding `sc->mtx`. Therefore CPU 1 cannot have just acquired it. Either CPU 1 acquired the lock long before CPU 0 got it (in which case CPU 0 is currently blocked waiting for the lock and is not in the callback), or CPU 1 is somehow about to acquire the lock and CPU 0 is about to release it.

The kernel handles the case correctly via the same mechanism it uses for ordinary `mtx_lock` synchronization. There is exactly one holder of `sc->mtx` at any given instant. If CPU 0 is firing, CPU 1's `callout_reset` is blocked waiting for the lock. When CPU 0's callback finishes and the kernel releases the lock, CPU 1 acquires the lock and proceeds with the reschedule. The callout is now scheduled for the new deadline.

If the callback re-armed itself before CPU 0 released the lock (the periodic pattern), the callout is currently pending. CPU 1's `callout_reset` cancels the pending and replaces with the new schedule. The return value is 1 (cancelled).

If the callback did not re-arm (one-shot, or interval was 0), the callout is idle. CPU 1's `callout_reset` schedules it. The return value is 0 (no previous schedule cancelled).

Either way, the result is correct: after `callout_reset` returns, the callout is scheduled for the new deadline, with the new function and argument.

13.6.12 What If the Callback Is Currently Firing When You Call `callout_stop`?

Similar question: callback firing on CPU 0, caller on CPU 1 wants to cancel.

CPU 1 calls `callout_stop`. It needs to hold the callout's lock; it does. CPU 0 is firing the callback while holding the same lock; CPU 1's lock acquisition blocks. When CPU 0's callback returns and releases the lock, CPU 1 acquires it.

At this point, the callback may have re-armed (if it was a periodic). `callout_stop` cancels the pending schedule. Return value is 1.

If the callback did not re-arm, the callout is idle. `callout_stop` is a no-op. Return value is 0.

After `callout_stop` returns, the callout will not fire again unless something else schedules it. Importantly, the callback that was running on CPU 0 has *already finished* by the time `callout_stop` returns; the lock was held through the duration. So `callout_stop` does effectively wait for the in-flight callback, but only because of the lock-acquisition wait, not because of any explicit waiting in the callout subsystem.

This is why `callout_stop` is safe to use in normal driver operation when you hold the lock, and why `callout_drain` is needed only when you are about to free the surrounding state (where you cannot hold the lock during the wait).

13.6.13 `callout_stop` From a Context Without the Lock

What if you call `callout_stop` without holding the callout's lock? The kernel's `_callout_stop_safe` function will detect the missing lock and assert (under INVARIANTS). On a non-INVARIANTS kernel, the call may produce incorrect results or race conditions.

The rule: when calling `callout_stop` or `callout_reset`, you must hold the same lock the callout was initialized with. The kernel enforces this; a violation is a WITNESS warning or an INVARIANTS panic.

For Chapter 13 we always hold `sc->mtx` when calling `callout_reset` or `callout_stop` from `sysctl` handlers. The detach path is the exception: it drops the lock before calling `callout_drain`. `callout_drain` does not require the lock to be held; in fact it requires it to *not* be held.

13.6.14 A Pattern: Conditional Re-Arm

A useful pattern for periodic callouts: only re-arm if some condition is true. In our heartbeat:

```
interval = sc->heartbeat_interval_ms;
if (interval > 0)
    callout_reset(&sc->heartbeat_co, ..., myfirst_heartbeat, sc);
```

The conditional re-arm gives the user fine control over the periodic firing. A user who sets `interval_ms = 0` disables the heartbeat at the next firing. The callback exits without re-arming; the callout becomes idle.

A more elaborate version: re-arm at variable intervals based on activity. A heartbeat that fires more often when the buffer is busy and less often when it is idle:

```
if (cbuf_used(&sc->cb) > 0)
    interval = sc->heartbeat_busy_interval_ms; /* short */
else
    interval = sc->heartbeat_idle_interval_ms; /* long */

if (interval > 0)
    callout_reset(&sc->heartbeat_co, ..., myfirst_heartbeat, sc);
```

The variable interval lets the heartbeat sample the device adaptively. When activity is high, it fires often (catching state changes quickly); when activity is low, it fires rarely (saving CPU and log space).

13.6.15 Wrapping Up Section 5

The lock contract is the heart of `callout(9)`. The kernel acquires the registered lock before each firing, runs your callback, and releases the lock after. This serializes the callback against other holders of the lock and eliminates a class of race that would otherwise require explicit handling. The rules inside the callback are the same as the lock's normal rules: for an `MTX_DEF` mutex, no sleeping, no `uiomove`, no `malloc(M_WAITOK)`. The callback should be short; if it needs to do long work, defer to a taskqueue (Chapter 16) or a kernel thread.

Reschedule and stop work correctly even when the callback is firing on another CPU; the lock-acquisition mechanism ensures atomicity. The conditional re-arm pattern (re-arm only if some condition is true) is the natural way to give a periodic callout a graceful disable path.

Section 6 deals with the corollary of all this: at unload time, you must not free the surrounding state while a callback is in progress or pending. `callout_drain` is the tool, and the unload race is the problem it solves.

13.7 Section 6: Timer Cleanup and Resource Management

Every callout has a destruction problem. Between the moment you decide to remove the driver and the moment the surrounding memory is freed, you have to make sure no callback is running and no callback is scheduled to run. If a callback fires after the memory is freed, the kernel crashes. If a callback is running when you free the memory, the kernel crashes. The crash is reliable, immediate, and fatal; it is the kind of bug that hangs the test machine and is hard to debug because the backtrace points at code that has already been freed.

`callout(9)` provides the tools to solve this cleanly: `callout_stop` for normal cancellation, `callout_drain` for teardown, and `callout_async_drain` for the rare cases where you want to schedule cleanup without blocking. This section walks through each, names the unload race precisely, and presents the standard pattern for safe driver detach.

13.7.1 The Unload Race

Imagine the driver as Stage 1 of Chapter 13 (heartbeat enabled, `kldunload` called). Without `callout_drain`, the sequence might be:

1. User runs `kldunload myfirst`.
2. The kernel calls `myfirst_detach`.
3. `myfirst_detach` clears `is_attached`, broadcasts `cvs`, drops the mutex, and calls `mtx_destroy(&sc->mtx)`.
4. The driver module is unloaded; the memory containing `sc->mtx`, `sc->heartbeat_co`, and `myfirst_heartbeat`'s code is freed.
5. The hardware-clock interrupt fires, the callout subsystem walks the wheel, finds `sc->heartbeat_co` (still on the wheel because we never cancelled it), and calls `myfirst_heartbeat` with `sc` as the argument.
6. `myfirst_heartbeat` is no longer in memory. The kernel jumps to a now-invalid address. Panic.

The race is not theoretical. Even if step 5 happens microseconds after step 4, the kernel still crashes. The window is small but non-zero.

The cure is to ensure that by step 4, no callout is pending and no callback is in flight. Two actions:

- **Cancel pending callouts.** If the callout is on the wheel, remove it. `callout_stop` does this.
- **Wait for in-flight callbacks.** If a callback is currently running on another CPU, wait for it to return. `callout_drain` does this.

`callout_drain` does both: it cancels pending and waits for in-flight. It is what you call at detach time.

13.7.2 `callout_stop` vs `callout_drain`

The distinction is whether the call waits.

`callout_stop`: cancels pending, returns immediately. Does not wait for an in-flight callback. Returns 1 if the callout was pending and got cancelled; 0 otherwise.

`callout_drain`: cancels pending, *and* waits for any in-flight callback to return before itself returning. Returns 1 if the callout was pending and got cancelled; 0 otherwise. After `callout_drain` returns, the callout is guaranteed to be idle.

Use `callout_stop` in normal driver operation when you want to cancel the timer because the condition that motivated it has been resolved. The watchdog use case: schedule a watchdog at the start of an operation; cancel it (with `callout_stop`) when the operation completes successfully. If the watchdog is already firing on another CPU, `callout_stop` returns and the watchdog will run to completion; that is fine because the watchdog handler will see the operation has completed and do nothing (or take some recovery action that is now unnecessary but harmless).

Use `callout_drain` at detach time, where waiting is required to prevent the unload race. Do not use `callout_stop` at detach time; the callback might be running on another CPU and the surrounding memory could be freed before it returns.

13.7.3 Two Critical Rules for `callout_drain`

`callout_drain` has two rules that are easy to violate.

Rule 1: do not hold the callout's lock when calling `callout_drain`. If the callout is currently executing, the callback is holding the lock (the kernel acquired it for the callback). `callout_drain` waits for the callback to return; the callback returns when its work is done; the work includes the lock being released. If the caller of `callout_drain` is *also* holding the lock, the caller would block waiting for itself to release it. Deadlock.

Rule 2: `callout_drain` may sleep. It waits on a sleep queue for the in-flight callback to finish. Therefore `callout_drain` is only legal in contexts where sleeping is allowed: process context (typical detach path) or kernel-thread context. Not interrupt context. Not while holding a spin lock. Not while holding any other non-sleepable lock.

These rules together imply that the standard detach path drops `sc->mtx` (and any other non-sleepable lock) before calling `callout_drain`. The chapter's detach pattern follows this:

```
MYFIRST_LOCK(sc);
sc->is_attached = 0;
cv_broadcast(&sc->data_cv);
cv_broadcast(&sc->room_cv);
MYFIRST_UNLOCK(sc);    /* drop the mutex before draining */

seldrain(&sc->rsl);
seldrain(&sc->wsl);

callout_drain(&sc->heartbeat_co);    /* now safe to call */
```

The mutex is dropped after clearing `is_attached`. The `callout_drain` runs without the mutex held; it is free to wait on a sleep queue. Any callback that fires during the drain sees `is_attached == 0` and exits without re-arming. After the drain, the callout is idle.

13.7.4 The `is_attached` Pattern, Revisited

In Chapter 12 we used `is_attached` as a signal to cv waiters: “the device is going away; return `ENXIO`”. In Chapter 13 we use it for the same purpose with callouts: “the device is going away; do not re-arm”.

The pattern is identical:

```
static void
myfirst_some_callback(void *arg)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_ASSERT(sc);

    if (!sc->is_attached)
```

```

        return; /* device going away; do not re-arm */

/* ... do the work ... */

/* re-arm if periodic */
if (some_condition)
    callout_reset(&sc->some_co, ticks, myfirst_some_callback, sc);
}

```

The check is at the top, before any work. If `is_attached == 0`, the callback exits immediately without doing work and without re-arming. The drain in detach will see the callout idle (no pending firing) and complete cleanly.

A subtle point: the check happens *under the lock* (the kernel acquired it for us). The detach path clears `is_attached` *under the lock*. So the callback always sees the current value of `is_attached`; there is no race. This is the same property we relied on in Chapter 12 for cv waiters.

13.7.5 Why Not `callout_stop` Instead?

A natural question: instead of `callout_drain`, why not `callout_stop` followed by some manual wait?

The implementation of `callout_drain` (in `_callout_stop_safe` in `/usr/src/sys/kern/kern_timeout.c`) does exactly that, but inside the kernel where it can use internal sleep queues without exposing them. Trying to do the same thing in driver code is fragile: you would need to know whether the callback is currently running, which you cannot tell from outside without inspecting kernel-private fields.

Just call `callout_drain`. It is what the API is for.

13.7.6 `callout_async_drain`

For the rare case where you want to drain without blocking, the kernel offers `callout_async_drain`:

```
#define callout_async_drain(c, d) _callout_stop_safe(c, 0, d)
```

It cancels pending and arranges for a “drain done” callback (the `d` function pointer) to be called when the in-flight callback finishes. The caller does not block; control returns immediately. Useful in contexts where you cannot sleep but need to know when the drain has completed.

For the chapter’s purposes, `callout_async_drain` is overkill. We do detach in process context where blocking is fine. We mention it because you will see it in some real-driver source.

13.7.7 The Standard Detach Pattern with Timers

Putting it all together, the canonical detach pattern for a driver with one or more callouts:

Reading this example. The listing below is a composite view of the canonical `callout(9)` teardown sequence, distilled from real drivers such as `/usr/src/sys/dev/re/if_re.c` (where `callout_drain(&sc->rl_stat_callout)` runs at detach time) and `/usr/src/sys/dev/watchdog/watchdog.c` (where two callouts are drained in sequence). We have kept the phase ordering, the mandatory `callout_drain()` calls, and the lock discipline intact; a production driver adds per-device bookkeeping that the real detach function interleaves with each step. Every symbol the listing names, from `callout_drain` to `seldrain` to `mtx_destroy`, is a real FreeBSD API; the `myfirst_softc` fields are this chapter's evolving driver.

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* 1. Refuse detach if the device is in use. */
    MYFIRST_LOCK(sc);
    if (sc->active_fhs > 0) {
        MYFIRST_UNLOCK(sc);
        return (EBUSY);
    }

    /* 2. Mark the device as going away. */
    sc->is_attached = 0;
    cv_broadcast(&sc->data_cv);
    cv_broadcast(&sc->room_cv);
    MYFIRST_UNLOCK(sc);

    /* 3. Drain the selinfo readiness machinery. */
    seldrain(&sc->rsel);
    seldrain(&sc->wsel);

    /* 4. Drain every callout. Each takes its own line. */
    callout_drain(&sc->heartbeat_co);
    callout_drain(&sc->watchdog_co);
    callout_drain(&sc->tick_source_co);

    /* 5. Destroy cdevs (no new opens after this). */
    if (sc->cdev_alias != NULL) {
        destroy_dev(sc->cdev_alias);
        sc->cdev_alias = NULL;
    }
    if (sc->cdev != NULL) {
        destroy_dev(sc->cdev);
        sc->cdev = NULL;
    }
}
```

```

    }

    /* 6. Free other resources. */
    sysctl_ctx_free(&sc->sysctl_ctx);
    cbuf_destroy(&sc->cb);
    counter_u64_free(sc->bytes_read);
    counter_u64_free(sc->bytes_written);

    /* 7. Destroy primitives in reverse acquisition order:
     *   cvs first, then sx, then mutex. */
    cv_destroy(&sc->data_cv);
    cv_destroy(&sc->room_cv);
    sx_destroy(&sc->cfg_sx);
    mtx_destroy(&sc->mtx);

    return (0);
}

```

Seven phases. Each one is a hard requirement. Let us walk through them.

Phase 1: refuse detach while the device is in use (`active_fhs > 0`). Without this, a user with the device open could close their descriptor in the middle of detach, hitting code paths that no longer have valid state.

Phase 2: mark the device as going away. The `is_attached` flag is the signal to every blocked or future code path that the device is being removed. The cv broadcasts wake any cv waiters; they re-check `is_attached` and exit with `ENXIO`. The lock is held during this phase to make the change atomic against any thread that just entered a handler.

Phase 3: drain `selinfo`. This ensures that `selrecord(9)` and `selwakeup(9)` callers no longer reference the device's `selinfo` structures.

Phase 4: drain every callout. Each `callout_drain` cancels pending and waits for in-flight. The mutex is dropped before the first drain (it was dropped at the end of phase 2). After phase 4, no callout can be running.

Phase 5: destroy cdevs. After this, no new `open(2)` can reach the driver. (The ones that snuck in just before would have already been refused in phase 1, but that's the safety net.)

Phase 6: free auxiliary resources (sysctl context, cbuf, counters).

Phase 7: destroy primitives in reverse order. The order matters for the same reason discussed in Chapter 12: cvs use the mutex as their interlock; if we destroy the mutex first, a callback in the middle of releasing the mutex would crash.

This is a lot. It is also what every driver has to do if it has callouts and primitives. The companion source for Chapter 13 (`stage4-final/myfirst.c`) follows this pattern exactly.

13.7.8 A Note on Kernel-Module Unload

`kldunload myfirst` triggers the detach path through the kernel's module-event handling. The `MOD_UNLOAD` event causes the kernel to call the driver's detach function. If the detach function returns an error (typically

EBUSY), the unload fails and the module remains loaded.

The standard pattern we just walked through returns EBUSY if `active_fhs > 0`. A user who wants to unload the driver must first close every open descriptor. From a shell:

```
# List processes holding the device open.
$ fstat | grep myfirst
USER      CMD          PID    FD      ... NAME
root      cat           12345   3       ... /dev/myfirst
$ kill 12345
$ kldunload myfirst
```

This is conventional UNIX behavior; the user is expected to close descriptors before unloading. The driver enforces it.

13.7.9 Initializing After Drain

A subtle point: after `callout_drain`, the callout is idle but is *not* in the same state as a freshly-initialized callout. The `c_func` and `c_arg` fields still point at the last callback and argument, in case a later `callout_schedule` wants to reuse them. The internal flags are cleared.

If you wanted to reuse the same `struct callout` for a different purpose (different lock, different callback signature), you would need to call `callout_init_mtx` (or one of the variants) again to re-initialize. In the detach path, we never re-init; the surrounding memory is about to be freed. The state at drain time is sufficient.

13.7.10 A Worked Walkthrough: Catching the Unload Race in DDB

To make the unload race visceral, walk through what happens when a careless driver omits `callout_drain` and the next callout firing crashes the kernel.

Imagine a buggy driver that disables the heartbeat sysctl in detach but does not call `callout_drain`. The detach path looks like this:

```
static int
buggy_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    MYFIRST_LOCK(sc);
    sc->is_attached = 0;
    sc->heartbeat_interval_ms = 0; /* hope the callback won't re-arm */
    MYFIRST_UNLOCK(sc);

    /* No callout_drain here! */

    destroy_dev(sc->cdev);
}
```

```
    mtx_destroy(&sc->mtx);  
    return (0);  
}
```

The `is_attached = 0` and `heartbeat_interval_ms = 0` are intended to make the callback exit without re-arming. But:

- The callback might be already in the middle of executing when detach starts. The lock is held by the kernel-acquired path. The detach path's `MYFIRST_LOCK(sc)` blocks until the callback releases the lock. Once the lock is acquired by detach, `is_attached` and `heartbeat_interval_ms` are set. The detach drops the lock. So far so good.
- *But:* the callback that was just running has already entered the re-arm path before checking `interval_ms`. It calls `callout_reset` to schedule the next firing, with the just-cleared `interval_ms` value of 0... no, wait, the callback re-reads `sc->heartbeat_interval_ms`, sees 0, and does not re-arm. OK, that case is safe.
- *Or:* the callback completed cleanly with no re-arm. The callout is now idle. The detach path proceeds. It destroys `sc->mtx` and the surrounding state. Everything seems fine.
- *Then:* a different invocation of the callback starts firing. The callout was not on the wheel (no re-arm), so this should not happen, right?

It can happen if there was a concurrent firing on a different CPU. Imagine: the callout fires on CPU 0 and CPU 1 in close succession. CPU 0 starts the callback (acquires the lock). CPU 1 enters the firing path, tries to acquire the lock, blocks. CPU 0 finishes the callback and re-arms (puts the callout back on the wheel for the next firing). CPU 0 releases the lock. CPU 1 acquires the lock and runs the callback. The callback re-arms. CPU 1 releases the lock.

Now suppose the detach path runs between the CPU-0 release and the CPU-1 acquisition. The detach takes the lock (which is now free), clears the flags, drops the lock. CPU 1 acquires the lock and calls the callback. The callback re-reads the flags, sees the cleared values, and exits without re-arming. OK, still safe.

But now consider: the detach path has destroyed the mutex. CPU 1's callback execution is done. The kernel releases the now-destroyed mutex. The release operation operates on freed memory. Panic.

This is the unload race. The fix is straightforward but absolutely required: call `callout_drain(&sc->heartbeat_co)` after dropping the mutex and before destroying primitives. The drain waits for all in-flight callbacks (on any CPU) to return before it itself returns.

Walk through with the drain in place:

- Detach acquires the lock, clears flags, drops the lock.
- Detach calls `callout_drain(&sc->heartbeat_co)`. The drain notices any in-flight callback and waits.
- All callbacks that were firing return cleanly (they re-read the flags, exit without re-arming).
- The drain returns.
- Detach destroys the `cdev`, then destroys the mutex.
- No callback can be running at this point. No callback can fire later because the wheel does not have the callout.

The drain is the safety net. Skipping it produces a panic that may not happen on every unload, but will happen eventually under load. The drain is mandatory.

13.7.11 What Happens If You Forget Drain on a Production Kernel

A production kernel without `INVARIENTS` or `WITNESS` does not catch the unload race in advance. The first time a callout fires after the freed module's memory has been reused, the kernel reads garbage instructions, jumps to a random location, and crashes with whatever pattern the random bytes happen to produce. The crash backtrace points at code that was never the bug; the actual bug is several seconds in the past, in the detach path that did not drain.

This is exactly why the standard advice is “test on a debug kernel before promoting to production”. `WITNESS` catches some forms of the race (it warns about callbacks being called with non-sleepable locks held in unexpected ways); `INVARIENTS` catches some others (the `mtx_destroy` of a destroyed mutex). The production kernel sees only the panic and the wrong backtrace.

13.7.12 What `callout_drain` Returns

`callout_drain` returns the same value as `callout_stop`: 1 if a pending callout was cancelled, 0 if not. Callers usually do not look at the return value; the function is called for its side effect (waiting for in-flight callbacks to finish).

If you want to be sure that the callout is fully idle after a particular code path completed, the discipline is: call `callout_drain` and ignore the return value. Whether the callout was pending or not, after the drain it is idle.

13.7.13 Detach Order with Multiple Callouts

If your driver has three callouts (heartbeat, watchdog, tick source) and you `callout_drain` each in turn, the total wait time is at most the longest of any single in-flight callback (not the sum). The drains are independent: each waits for its own callback. They can effectively run in parallel because each only blocks on its specific callout.

For the chapter's pseudo-device, callbacks are short (microseconds). The drain time is dominated by the cost of the wakeup on the sleep queue, not by the callback work. In total, all three drains complete in much less than a millisecond, even under load.

For drivers with longer callback work, the wait time can be longer. A watchdog callback that takes 10 ms means the worst-case drain is 10 ms (if you happened to call `callout_drain` while it was firing). Most of the time the callout is idle and the drain is instant. Either way, the drain is bounded; it does not loop indefinitely.

13.7.14 The Same Bug, Different Primitive: A Taskqueue Sketch

The “callback ran after detach” bug is not unique to callouts. Every kernel deferred-work primitive has the same pitfall, and the standard answer is always a drain routine that waits for in-flight callbacks to finish. A brief sibling walkthrough drives the point home without pulling Chapter 13 off-topic.

Suppose a driver enqueues work on a taskqueue instead of using a callout. The softc holds a `struct task` and a `struct taskqueue *`, and something in the driver calls `taskqueue_enqueue(sc->tq, &sc->work)` when work is needed. Now imagine a buggy detach that clears `is_attached` and tears down the softc but forgets to drain the task:

```
static int
buggy_tq_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    MYFIRST_LOCK(sc);
    sc->is_attached = 0;
    MYFIRST_UNLOCK(sc);

    /* No taskqueue_drain here! */

    destroy_dev(sc->cdev);
    free(sc->buf, M_MYFIRST);
    mtx_destroy(&sc->mtx);
    return (0);
}
```

The outcome is the same shape as the callout case. If the task was pending when detach ran, the worker thread pops it after detach has freed `sc->buf` and destroyed `sc->mtx`. The task handler dereferences `sc`, finds stale memory, and either reads garbage or panics on the first locked operation. If the task was already running on another CPU, the worker thread is still inside the handler when detach frees the memory underneath it, with the same ending.

The fix is structurally identical to `callout_drain`:

```
taskqueue_drain(sc->tq, &sc->work);
```

`taskqueue_drain(9)` waits until the specified task is neither pending nor currently executing on any worker thread. After it returns, that task cannot fire again unless something re-enqueues it, which is exactly what detach is trying to prevent by clearing `is_attached` first. For drivers that use many tasks on the same queue, `taskqueue_drain_all(9)` waits for every task currently queued or running on that taskqueue, which is the usual call in a module-unload path where nothing on the queue will be re-enqueued.

The takeaway is not a new rule but a wider one: any deferred-work primitive in the kernel, whether `callout(9)`, `taskqueue(9)`, or the network-stack epoch callbacks you will meet in Part 6, needs a corresponding drain before the memory it reads is freed. Chapter 16 walks through `taskqueue(9)` in depth, including how drain interacts with task enqueue ordering; for now, remember that the mental model is identical. Clear the flag, drop the lock, drain the primitive, destroy the storage. The word changes with the primitive, but the shape of the pattern does not.

13.7.15 Wrapping Up Section 6

The unload race is real. `callout_drain` is the cure. The standard detach pattern is: refuse if busy, clear `is_attached` under the lock, broadcast cvs, drop the lock, drain selinfo, drain every callout, destroy cdevs, free auxiliary resources, destroy primitives in reverse order. Every phase is necessary; skipping any of them creates a race that crashes the kernel under load.

Section 7 puts the framework to work on real timer use cases: watchdogs, debouncing, periodic tick sources.

13.8 Section 7: Use Cases and Extensions for Timed Work

Sections 4 through 6 introduced the heartbeat callout: periodic, lock-aware, drained at teardown. The same pattern handles a wide range of real driver problems with small variations. This section walks through three more callouts that we add to `myfirst`: a watchdog that detects buffer staleness, a tick source that injects synthetic events, and (briefly) a debounce shape used in many hardware drivers. Together with the heartbeat, the four cover the bulk of what driver timers are used for in practice.

Treat this section as a recipe collection. Each subsection is a self-contained pattern that you can lift into other drivers.

13.8.1 Pattern 1: A Watchdog Timer

A watchdog detects a stuck condition and acts on it. The classic shape: schedule a callout at the start of an operation; if the operation completes successfully, cancel the callout; if the callout fires, the operation is presumed stuck and the driver takes recovery action.

For `myfirst`, a useful watchdog is “the buffer has not made progress for too long”. If `cb_used > 0` and the value has not changed for `N` seconds, no reader is draining the buffer. This is unusual; we will log a warning.

Add fields to the `softc`:

```
struct callout      watchdog_co;
int                 watchdog_interval_ms; /* 0 = disabled */
size_t              watchdog_last_used;
```

`watchdog_interval_ms` is a sysctl tunable. `watchdog_last_used` records the value of `cbuf_used` from the previous tick; the next tick compares.

Initialize in `attach`:

```
callout_init_mtx(&sc->watchdog_co, &sc->mtx, 0);
sc->watchdog_interval_ms = 0;
sc->watchdog_last_used = 0;
```

Drain in `detach`:

```
callout_drain(&sc->watchdog_co);
```

The callback:

```
static void
myfirst_watchdog(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t used;
    int interval;

    MYFIRST_ASSERT(sc);

    if (!sc->is_attached)
        return;

    used = cbuf_used(&sc->cb);
    if (used > 0 && used == sc->watchdog_last_used) {
        device_printf(sc->dev,
            "watchdog: buffer has %zu bytes, no progress in last "
            "interval; reader stuck?\n", used);
    }
    sc->watchdog_last_used = used;

    interval = sc->watchdog_interval_ms;
    if (interval > 0)
        callout_reset(&sc->watchdog_co,
            (interval * hz + 999) / 1000,
            myfirst_watchdog, sc);
}
```

The structure mirrors the heartbeat: assert, check `is_attached`, do work, re-arm if interval is non-zero. The work this time is the staleness check: compare current `cbuf_used` to last recorded; if they match and are non-zero, no progress has been made.

The sysctl handler is symmetric to the heartbeat's:

```
static int
myfirst_sysctl_watchdog_interval_ms(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, old, error;

    old = sc->watchdog_interval_ms;
```

```

    new = old;
    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    if (new < 0)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    sc->watchdog_interval_ms = new;
    if (new > 0 && old == 0) {
        sc->watchdog_last_used = cbuf_used(&sc->cb);
        callout_reset(&sc->watchdog_co,
            (new * hz + 999) / 1000,
            myfirst_watchdog, sc);
    } else if (new == 0 && old > 0) {
        callout_stop(&sc->watchdog_co);
    }
    MYFIRST_UNLOCK(sc);
    return (0);
}

```

The only addition: when enabling, we initialize `watchdog_last_used` to the current `cbuf_used`, so the first comparison has a sensible baseline.

To test: enable the watchdog with a 2-second interval, write some bytes into the buffer, and do not read them. After two seconds, `dmesg` should show the watchdog warning.

```

$ sysctl -w dev.myfirst.0.watchdog_interval_ms=2000
$ printf 'hello' > /dev/myfirst
$ sleep 5
$ dmesg | tail
myfirst0: watchdog: buffer has 5 bytes, no progress in last interval; reader stuck?
myfirst0: watchdog: buffer has 5 bytes, no progress in last interval; reader stuck?

```

Now drain the buffer:

```

$ cat /dev/myfirst
hello

```

The watchdog stops warning because `cbuf_used` is now zero (the comparison used `> 0` fails).

This is a contrived watchdog. Real watchdogs do more: reset a hardware engine, kill a stuck request, log to the kernel ringbuffer with a specific format that monitoring tools can grep. The shape is the same: detect, act, re-arm.

13.8.2 Pattern 2: A Tick Source for Synthetic Events

A tick source is a callout that periodically generates events as if the hardware did. Useful for drivers that simulate something or that want a stable test workload independent of user-space activity.

For myfirst, a tick source can periodically write a single byte into the cbuf. With the heartbeat enabled, the byte counts will rise visibly without any external producer.

Add fields:

```
struct callout      tick_source_co;
int                 tick_source_interval_ms; /* 0 = disabled */
char                tick_source_byte;        /* the byte to write */
```

Initialize in attach:

```
callout_init_mtx(&sc->tick_source_co, &sc->mtx, 0);
sc->tick_source_interval_ms = 0;
sc->tick_source_byte = 't';
```

Drain in detach:

```
callout_drain(&sc->tick_source_co);
```

The callback:

```
static void
myfirst_tick_source(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t put;
    int interval;

    MYFIRST_ASSERT(sc);

    if (!sc->is_attached)
        return;

    if (cbuf_free(&sc->cb) > 0) {
        put = cbuf_write(&sc->cb, &sc->tick_source_byte, 1);
        if (put > 0) {
            counter_u64_add(sc->bytes_written, put);
            cv_signal(&sc->data_cv);
            /* selwakeup omitted on purpose: it may sleep
             * and we are inside a callout context with the
```

```

        * mutex held. Defer to a taskqueue if real-time
        * poll(2) wakeups are needed. */
    }

}

interval = sc->tick_source_interval_ms;
if (interval > 0)
    callout_reset(&sc->tick_source_co,
        (interval * hz + 999) / 1000,
        myfirst_tick_source, sc);
}

```

The structure is the same as the heartbeat. The work is different: write one byte to the cbuf, increment the counter, signal data_cv so any reader wakes.

Note the deliberate omission of `se wakeup` from the callback. `se wakeup` may sleep and may take other locks, which is illegal under our mutex. Calling it from a callout context with the mutex held would be a WITNESS violation. The `cv_signal` is enough to wake blocking readers; `poll(2)` waiters will not be woken in real time, but they will pick up the next state change at their normal poll interval. For a real driver that needs immediate `poll(2)` wakeups from a callout, the answer is to defer the `se wakeup` to a taskqueue (Chapter 16). For Chapter 13, omitting it is acceptable.

A sysctl handler enables and disables, mirroring the others:

```

static int
myfirst_sysctl_tick_source_interval_ms(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, old, error;

    old = sc->tick_source_interval_ms;
    new = old;
    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    if (new < 0)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    sc->tick_source_interval_ms = new;
    if (new > 0 && old == 0)
        callout_reset(&sc->tick_source_co,
            (new * hz + 999) / 1000,
            myfirst_tick_source, sc);
    else if (new == 0 && old > 0)

```

```
        callout_stop(&sc->tick_source_co);
    MYFIRST_UNLOCK(sc);
    return (0);
}
```

To test:

```
$ sysctl -w dev.myfirst.0.tick_source_interval_ms=100
$ cat /dev/myfirst
ttttttttttttttttttttttttttttttttt      # ten 't's per second
^C
$ sysctl -w dev.myfirst.0.tick_source_interval_ms=0
```

The tick source produces ten ‘t’ characters per second, which cat reads and prints. Disable by setting the sysctl back to zero.

13.8.3 Pattern 3: A Debounce Shape

A debounce ignores rapid repeated events. The shape: when an event arrives, check whether a “debounce timer” is already pending; if so, ignore the event; if not, schedule a debounce timer for N milliseconds, and act on the event when the timer fires.

For myfirst, we do not have a hardware event source, so we will not implement a full debounce. The shape, in pseudo-code:

```
static void
some_event_callback(struct myfirst_softc *sc)
{
    MYFIRST_LOCK(sc);
    sc->latest_event_time = ticks;
    if (!callout_pending(&sc->debounce_co)) {
        callout_reset(&sc->debounce_co,
                      DEBOUNCE_DURATION_TICKS,
                      myfirst_debounce_handler, sc);
    }
    MYFIRST_UNLOCK(sc);
}
```

```
static void
myfirst_debounce_handler(void *arg)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_ASSERT(sc);
}
```

```

    if (!sc->is_attached)
        return;

    /* Act on the latest event seen. */
    process_event(sc, sc->latest_event_time);
    /* Do not re-arm; one-shot. */
}

```

When the first event arrives, the debounce timer is scheduled. Subsequent events update the recorded “latest event time” but do not re-schedule the timer (because it is still pending). When the debounce timer fires, the handler processes the most recent event. After the handler returns, the timer is no longer pending; the next event will reschedule.

This is a one-shot pattern, not periodic. The callback does not re-arm. The `callout_pending` check in `some_event_callback` is the gate.

Lab 13.5 walks through implementing a similar debounce as a stretch exercise. The chapter does not add it to `myfirst` because we have no hardware event to debounce, but the shape is one to remember.

13.8.4 Pattern 4: A Retry With Exponential Backoff

A retry-with-backoff shape: an operation fails; schedule a retry after N milliseconds; if the retry also fails, schedule the next retry after $2N$ milliseconds; and so on, capped at some maximum.

For `myfirst`, no operations fail in a way that demands retry. The shape:

```

struct callout      retry_co;
int                 retry_attempt;           /* 0, 1, 2, ... */
int                 retry_base_ms;          /* base interval */
int                 retry_max_attempts;     /* cap */

static void
some_operation_failed(struct myfirst_softc *sc)
{
    int next_delay_ms;

    MYFIRST_LOCK(sc);
    if (sc->retry_attempt < sc->retry_max_attempts) {
        next_delay_ms = sc->retry_base_ms * (1 << sc->retry_attempt);
        callout_reset(&sc->retry_co,
            (next_delay_ms * hz + 999) / 1000,
            myfirst_retry, sc);
        sc->retry_attempt++;
    } else {
        /* Give up. */
    }
}

```

```

        device_printf(sc->dev, "retry: exhausted attempts; failing\n");
        some_failure_action(sc);
    }
    MYFIRST_UNLOCK(sc);
}

static void
myfirst_retry(void *arg)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    if (some_operation(sc)) {
        /* success */
        sc->retry_attempt = 0;
    } else {
        /* failure: schedule next retry */
        some_operation_failed(sc);
    }
}

```

The callback retries the operation. Success resets the attempt counter. Failure schedules the next retry with an exponentially-increasing delay, capped at `retry_max_attempts`.

This pattern is in many real drivers, particularly storage and network drivers handling transient hardware errors. Chapter 13 does not add it to `myfirst` because we have no failures to retry. The shape is in your toolbox.

13.8.5 Pattern 5: A Deferred Reaper

A deferred reaper is a one-shot callout that frees something after a grace period. Used when an object cannot be freed immediately because some other code path may still hold a reference, but we know that after some time has passed, all references will have drained.

The shape, sketched as pseudo-code (the `some_object` type stands in for whatever deferred-free object your driver actually uses):

```

struct some_object {
    TAILQ_ENTRY(some_object) link;
    /* ... per-object fields ... */
};

TAILQ_HEAD(some_object_list, some_object);

```

```

struct myfirst_softc {
    /* ... existing fields ... */
    struct callout      reaper_co;
    struct some_object_list pending_free;
    /* ... */
};

static void
schedule_free(struct myfirst_softc *sc, struct some_object *obj)
{
    MYFIRST_LOCK(sc);
    TAILQ_INSERT_TAIL(&sc->pending_free, obj, link);
    if (!callout_pending(&sc->reaper_co))
        callout_reset(&sc->reaper_co, hz, myfirst_reaper, sc);
    MYFIRST_UNLOCK(sc);
}

static void
myfirst_reaper(void *arg)
{
    struct myfirst_softc *sc = arg;
    struct some_object *obj, *tmp;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    TAILQ_FOREACH_SAFE(obj, &sc->pending_free, link, tmp) {
        TAILQ_REMOVE(&sc->pending_free, obj, link);
        free(obj, M_DEVBUF);
    }

    /* Do not re-arm; new objects scheduled later will re-arm us. */
}

```

The reaper runs once a second (or whatever interval makes sense), frees everything on the pending list, and stops. New scheduling adds to the list and re-arms only if the reaper is not currently pending.

Used in network drivers where receive buffers cannot be freed immediately because the network layer still has references; the buffer is queued for the reaper, which frees it after a grace period.

myfirst does not need this pattern. It is in the toolbox.

13.8.6 Pattern 6: A Polling Loop Replacement

Some hardware does not interrupt for events the driver cares about. A typical example: a sensor that has a status register the driver must check every few milliseconds to learn about new readings. Without callouts, the driver would either spin (waste CPU) or run a kernel thread that sleeps and polls (waste a thread). With callouts, the polling loop is a periodic callback that reads the register, takes appropriate action, and re-arms.

```
static void
myfirst_poll(void *arg)
{
    struct myfirst_softc *sc = arg;
    uint32_t status;
    int interval;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    status = bus_read_4(sc->res, REG_STATUS);  /* hypothetical */
    if (status & STATUS_DATA_READY) {
        /* Pull data from the device into the cbuf. */
        myfirst_drain_hardware(sc);
    }
    if (status & STATUS_ERROR) {
        /* Recover from the error. */
        myfirst_handle_error(sc);
    }

    interval = sc->poll_interval_ms;
    if (interval > 0)
        callout_reset(&sc->poll_co,
            (interval * hz + 999) / 1000,
            myfirst_poll, sc);
}
```

The callback reads a hardware register (not implemented in our pseudo-device, but the shape is clear), checks bits, acts, and re-arms. The interval determines how often the driver checks; shorter means more responsive but more CPU. Real polling drivers typically use 1-10 ms intervals when active; longer when idle.

The code comment about `bus_read_4` is a forward reference to Chapter 19, which introduces bus space access. For Chapter 13, treat it as pseudo-code that demonstrates the pattern; the polling logic is what matters.

13.8.7 Pattern 7: A Statistics Window

A periodic callout that takes a snapshot of internal counters at regular intervals and computes per-interval rates. Useful for monitoring; the driver can answer “how many bytes per second am I currently moving?” without the

user having to sample manually.

```

struct myfirst_stats_window {
    uint64_t      last_bytes_read;
    uint64_t      last_bytes_written;
    uint64_t      rate_bytes_read;      /* bytes/sec, latest interval */
    uint64_t      rate_bytes_written;
};

struct myfirst_softc {
    /* ... existing fields ... */
    struct callout      stats_window_co;
    int                stats_window_interval_ms;
    struct myfirst_stats_window      stats_window;
    /* ... */
};

static void
myfirst_stats_window(void *arg)
{
    struct myfirst_softc *sc = arg;
    uint64_t cur_br, cur_bw;
    int interval;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    cur_br = counter_u64_fetch(sc->bytes_read);
    cur_bw = counter_u64_fetch(sc->bytes_written);
    interval = sc->stats_window_interval_ms;

    if (interval > 0) {
        /* bytes-per-second over this interval */
        sc->stats_window.rate_bytes_read = (cur_br -
            sc->stats_window.last_bytes_read) * 1000 / interval;
        sc->stats_window.rate_bytes_written = (cur_bw -
            sc->stats_window.last_bytes_written) * 1000 / interval;
    }

    sc->stats_window.last_bytes_read = cur_br;
    sc->stats_window.last_bytes_written = cur_bw;

    if (interval > 0)
        callout_reset(&sc->stats_window_co,

```

```
        (interval * hz + 999) / 1000,  
        myfirst_stats_window, sc);  
}
```

Expose the rates as sysctls. A user can `sysctl dev.myfirst.0.stats.rate_bytes_read` and see the per-interval rate, computed live without having to manually sample and difference.

This pattern is in many monitoring-friendly drivers. The granularity (the interval) is configurable; longer intervals smooth out short bursts; shorter intervals respond more quickly. Choose to match what the user wants to measure.

13.8.8 Pattern 8: A Timed Status Refresh

A periodic callout that refreshes a cached value the rest of the driver reads. Useful when the underlying value is expensive to compute every time but acceptable to be slightly stale.

For our `myfirst`, we do not have an expensive computation to cache. The shape, in pseudo-code:

```
static void  
myfirst_refresh_status(void *arg)  
{  
    struct myfirst_softc *sc = arg;  
  
    MYFIRST_ASSERT(sc);  
    if (!sc->is_attached)  
        return;  
  
    sc->cached_status = expensive_compute(sc);  
    callout_reset(&sc->refresh_co, hz, myfirst_refresh_status, sc);  
}  
  
/* Other code reads sc->cached_status freely; it may be up to 1s stale. */
```

Used in drivers where the computation is expensive (parsing a hardware status table, communicating with a remote subsystem) but the consumer can tolerate stale values. The callback runs periodically and refreshes; the consumer gets the cached value.

`myfirst` does not need this pattern. It is in your toolbox.

13.8.9 Pattern 9: A Periodic Reset

Some hardware needs a periodic reset (a write to a specific register) to keep an internal watchdog from triggering. The pattern:

```
static void
myfirst_periodic_reset(void *arg)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    bus_write_4(sc->res, REG_KEEPLIVE, KEEPALIVE_VALUE);
    callout_reset(&sc->keepalive_co, hz / 2,
        myfirst_periodic_reset, sc);
}
```

The hardware expects the keepalive write at least every second; we send it every 500 ms to have margin. If we miss a few writes (system load, reschedule), the hardware does not panic.

Used in storage controllers, network controllers, and embedded systems where the device has a per-side watchdog the host driver must satisfy.

13.8.10 Combining Patterns

A driver typically uses several callouts at once. `myfirst` (Stage 4 of this chapter) uses three: heartbeat, watchdog, tick source. Each has its own callout and its own sysctl tunable. They share the same lock (`sc->mtx`), which means only one fires at a time; serialization is automatic.

In a more complex driver, you might have ten or twenty callouts, each for a specific purpose. The pattern scales: each callout has its own struct callout, its own callback, its own sysctl (if user-facing), and its own line in the detach callout_drain block. The disciplines from this chapter (lock-aware init, `is_attached` check, drain at detach) apply to every one of them.

13.8.11 Wrapping Up Section 7

Nine patterns cover most of what driver timers do: heartbeat, watchdog, debounce, retry-with-backoff, deferred reaper, statistics rollover, polling loop, statistics window, timed status refresh, and periodic reset. Each is a small variation on the periodic or one-shot shape. The disciplines from Sections 4 through 6 (lock-aware initialization, `is_attached` check, drain at detach) apply uniformly. A driver that adds new timers follows the same recipe; the surface area expands without the maintenance burden growing.

Section 8 closes the chapter with the housekeeping pass: documentation, version bump, regression test, pre-commit checklist.

13.9 Section 8: Refactoring and Versioning Your Timer-Enhanced Driver

The driver now has three callouts (heartbeat, watchdog, tick source), four sysctls (the three intervals plus the existing config), and a detach path that drains every callout safely. The remaining work is the housekeeping pass: tidying the source for clarity, updating the documentation, bumping the version, running static analysis, and verifying the regression suite passes.

This section follows the same shape as the equivalent sections in Chapters 11 and 12. None of it is glamorous. All of it is what makes the difference between a driver delivered once and a driver that keeps working as it grows.

13.9.1 Cleaning Up the Source

After this chapter's focused additions, three small reorganizations are worth doing.

Group callout-related code. Move all the callout callbacks (myfirst_heartbeat, myfirst_watchdog, myfirst_tick_source) into a single section of the source file, after the wait helpers and before the cdevsw handlers. Move the corresponding sysctl handlers next to them. The compiler does not care about ordering; the reader does.

Standardise macro vocabulary. Add a small set of macros to make callout operations consistent across the driver. The existing pattern with MYFIRST_LOCK and MYFIRST_CFG_* extends naturally:

```
#define MYFIRST_CO_INIT(sc, co)  callout_init_mtx((co), &(sc)->mtx, 0)
#define MYFIRST_CO_DRAIN(co)    callout_drain((co))
```

The MYFIRST_CO_INIT macro takes sc explicitly so it works in any function, not just those where a local variable named sc happens to be in scope. MYFIRST_CO_DRAIN only needs the callout itself, because draining does not require the softc.

The macros are thin, but they document the convention: every callout in the driver uses sc->mtx as its lock and is drained at detach. A future maintainer who adds a callout sees the macro and knows the rule.

Comment the detach order. The detach function is short on its own but the order of operations is critical. Add comments at each phase:

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Phase 1: refuse if in use. */
    MYFIRST_LOCK(sc);
    if (sc->active_fhs > 0) {
        MYFIRST_UNLOCK(sc);
        return (EBUSY);
    }
}
```

```
/* Phase 2: signal "going away" to all waiters and callbacks. */
sc->is_attached = 0;
cv_broadcast(&sc->data_cv);
cv_broadcast(&sc->room_cv);
MYFIRST_UNLOCK(sc);

/* Phase 3: drain selinfo. */
seldrain(&sc->rsel);
seldrain(&sc->wsel);

/* Phase 4: drain every callout (no lock held; safe to sleep). */
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
MYFIRST_CO_DRAIN(&sc->tick_source_co);

/* Phase 5: destroy cdevs (no new opens after this). */
if (sc->cdev_alias != NULL) {
    destroy_dev(sc->cdev_alias);
    sc->cdev_alias = NULL;
}
if (sc->cdev != NULL) {
    destroy_dev(sc->cdev);
    sc->cdev = NULL;
}

/* Phase 6: free auxiliary resources. */
sysctl_ctx_free(&sc->sysctl_ctx);
cbuf_destroy(&sc->cb);
counter_u64_free(sc->bytes_read);
counter_u64_free(sc->bytes_written);

/* Phase 7: destroy primitives in reverse order. */
cv_destroy(&sc->data_cv);
cv_destroy(&sc->room_cv);
sx_destroy(&sc->cfg_sx);
mtx_destroy(&sc->mtx);

return (0);
}
```

In attach, the matching initialization uses the two-argument form so that `sc` is passed explicitly:

```
MYFIRST_CO_INIT(sc, &sc->heartbeat_co);
MYFIRST_CO_INIT(sc, &sc->watchdog_co);
MYFIRST_CO_INIT(sc, &sc->tick_source_co);
```

The comments turn the function from a sequence of seemingly-arbitrary calls into a documented checklist.

13.9.2 Updating LOCKING.md

The Chapter 12 LOCKING.md documented three primitives, two lock classes, and one lock order. Chapter 13 adds three callouts. The new sections to add:

Callouts Owned by This Driver

sc->heartbeat_co (callout(9), MYFIRST_CO_INIT)

Lock: sc->mtx (registered via callout_init_mtx).
 Callback: myfirst_heartbeat.
 Behaviour: periodic; re-arms itself at the end of each firing if
 sc->heartbeat_interval_ms > 0.
 Started by: the heartbeat sysctl handler (transition 0 -> non-zero).
 Stopped by: the heartbeat sysctl handler (transition non-zero -> 0)
 via callout_stop, and by myfirst_detach via callout_drain.
 Lifetime: initialised in attach via MYFIRST_CO_INIT; drained in detach
 via MYFIRST_CO_DRAIN.

sc->watchdog_co (callout(9), MYFIRST_CO_INIT)

Lock: sc->mtx.
 Callback: myfirst_watchdog.
 Behaviour: periodic; emits a warning if cb_used has not changed and
 is non-zero between firings.
 Started/stopped: via the watchdog sysctl handler and detach, parallel
 to the heartbeat.

sc->tick_source_co (callout(9), MYFIRST_CO_INIT)

Lock: sc->mtx.
 Callback: myfirst_tick_source.
 Behaviour: periodic; injects a single byte into the cbuf each firing
 if there is room.
 Started/stopped: via the tick_source sysctl handler and detach,
 parallel to the heartbeat.

Callout Discipline

1. Every callout uses `sc->mtx` as its lock via `callout_init_mtx`.
2. Every callout callback asserts `MYFIRST_ASSERT(sc)` at entry.
3. Every callout callback checks `!sc->is_attached` at entry and returns early without re-arming.
4. The detach path clears `sc->is_attached` under `sc->mtx`, broadcasts both cvs, drops the mutex, and then calls `callout_drain` on every callout.
5. `callout_stop` is used to cancel pending callouts in normal driver operation (sysctl handlers); `callout_drain` is used at detach.
6. NEVER call `selwakeup`, `uiomove`, `copyin`, `copyout`, `malloc(M_WAITOK)`, or any sleeping primitive from a callout callback. The mutex is held during the callback, and these calls would violate the sleep-with-mutex rule.

History (extended)

- 0.7-timers (Chapter 13): added heartbeat, watchdog, and tick-source callouts; documented callout discipline; standardised callout detach pattern.
- 0.6-sync (Chapter 12, Stage 4): combined version with cv channels, bounded reads, sx-protected configuration, reset sysctl.
- ... (earlier history as before) ...

Add this to the existing `LOCKING.md` rather than replacing the existing content. The new sections sit alongside the existing “Locks Owned by This Driver”, “Lock Order”, “Locking Discipline”, and so on.

13.9.3 Bumping the Version

Update the version string:

```
#define MYFIRST_VERSION "0.7-timers"
```

Update the changelog entry:

0.7-timers (Chapter 13)

- Added struct `callout heartbeat_co`, `watchdog_co`, `tick_source_co` to the softc.
- Added sysctls `dev.myfirst.<unit>.heartbeat_interval_ms`, `watchdog_interval_ms`, `tick_source_interval_ms`.
- Added callbacks `myfirst_heartbeat`, `myfirst_watchdog`, `myfirst_tick_source`, each lock-aware via `callout_init_mtx`.

- Updated detach to drain every callout under the documented seven-phase pattern.
- Added MYFIRST_CO_INIT and MYFIRST_CO_DRAIN macros for callout init and teardown.
- Updated LOCKING.md with a Callouts section and callout discipline rules.
- Updated regression script to include callout tests.

13.9.4 Updating the README

Two new features in the README:

Features (additions)

- Callout-based heartbeat that periodically logs cbuf usage and byte counts.
- Callout-based watchdog that detects stalled buffer drainage.
- Callout-based tick source that injects synthetic data for testing.

Configuration (additions)

- dev.myfirst.<unit>.heartbeat_interval_ms: periodic heartbeat in milliseconds (0 = disabled).
- dev.myfirst.<unit>.watchdog_interval_ms: watchdog interval in milliseconds (0 = disabled).
- dev.myfirst.<unit>.tick_source_interval_ms: tick-source interval in milliseconds (0 = disabled).

13.9.5 Running Static Analysis

Run `clang --analyze` against the new code. The exact flags depend on your kernel configuration; the same recipe the Chapter 11 regression section used still works, with the added knowledge that callout init macros expand into function calls that `clang` can now see through:

```
$ make WARNS=6 clean all
$ clang --analyze -D_KERNEL -DKLD_MODULE \
  -I/usr/src/sys -I/usr/src/sys/contrib/ck/include \
  -fno-builtin -nostdinc myfirst.c
```

Triage the output as before. A few false positives may appear around the callout init macros (the analyser does not always track the lock association embedded in `_callout_init_lock`); document each so the next maintainer does not re-triage them.

13.9.6 Running the Regression Suite

The Chapter 12 regression script extends naturally. Two design points are worth noting before the script: each subtest clears the kernel message buffer with `dmesg -c` so that `grep -c` only counts lines produced *during* that subtest; and reads use `dd` with a fixed count= rather than `cat`, so an unexpectedly empty buffer cannot make the script hang.

```
#!/bin/sh
# regression.sh: full Chapter 13 regression.

set -eu

die() { echo "FAIL: $" ">&2; exit 1; }
ok()  { echo "PASS: $*"; }

[ $(id -u) -eq 0 ] || die "must run as root"
kldstat | grep -q myfirst && kldunload myfirst
[ -f ./myfirst.ko ] || die "myfirst.ko not built; run make first"

# Clear any stale dmesg contents so per-subtest greps are scoped.
dmesg -c >/dev/null

kldload ./myfirst.ko
trap 'kldunload myfirst 2>/dev/null || true' EXIT

sleep 1
[ -c /dev/myfirst ] || die "device node not created"
ok "load"

# Chapter 7-12 tests (abbreviated; see prior chapters' scripts).
printf 'hello' > /dev/myfirst || die "write failed"
# dd with bs and count avoids blocking if the buffer is shorter
# than expected; if the read returns short, the test still proceeds.
ROUND=$(dd if=/dev/myfirst bs=5 count=1 2>/dev/null)
[ "$ROUND" = "hello" ] || die "round-trip mismatch (got '$ROUND')"
ok "round-trip"

# Chapter 13-specific tests. Each subtest clears dmesg first so the
# subsequent grep counts only the lines produced during that test.

# Heartbeat enable/disable.
dmesg -c >/dev/null
sysctl -w dev.myfirst.0.heartbeat_interval_ms=100 >/dev/null
sleep 1
HB_LINES=$(dmesg | grep -c "heartbeat:" || true)
```

```

[ "$HB_LINES" -ge 5 ] || die "expected >=5 heartbeat lines, got $HB_LINES"
sysctl -w dev.myfirst.0.heartbeat_interval_ms=0 >/dev/null
ok "heartbeat enable/disable"

# Watchdog: enable, write, wait, expect warning, then drain via dd
# (not cat, which would block once the 7 bytes are gone).
dmesg -c >/dev/null
sysctl -w dev.myfirst.0.watchdog_interval_ms=500 >/dev/null
printf 'wd_test' > /dev/myfirst
sleep 2
WD_LINES=$(dmesg | grep -c "watchdog:" || true)
[ "$WD_LINES" -ge 1 ] || die "expected >=1 watchdog line, got $WD_LINES"
sysctl -w dev.myfirst.0.watchdog_interval_ms=0 >/dev/null
dd if=/dev/myfirst bs=7 count=1 of=/dev/null 2>/dev/null # drain
ok "watchdog warns on stuck buffer"

# Tick source: enable, read, expect synthetic bytes.
dmesg -c >/dev/null
sysctl -w dev.myfirst.0.tick_source_interval_ms=50 >/dev/null
TS_BYTES=$(dd if=/dev/myfirst bs=1 count=10 2>/dev/null | wc -c | tr -d ' ')
[ "$TS_BYTES" -eq 10 ] || die "expected 10 tick bytes, got $TS_BYTES"
sysctl -w dev.myfirst.0.tick_source_interval_ms=0 >/dev/null
ok "tick source produces bytes"

# Detach with callouts active. The trap will not fire after the
# explicit unload because the unload succeeds.
sysctl -w dev.myfirst.0.heartbeat_interval_ms=100 >/dev/null
sysctl -w dev.myfirst.0.tick_source_interval_ms=100 >/dev/null
sleep 1 # allow each callout to fire at least a few times
dmesg -c >/dev/null
kldunload myfirst
trap - EXIT # the driver is now unloaded
ok "detach with active callouts"

# WITNESS check. Confined to events since the unload above.
WITNESS_HITS=$(dmesg | grep -ci "witness\|lor" || true)
if [ "$WITNESS_HITS" -gt 0 ]; then
    die "WITNESS warnings detected ($WITNESS_HITS lines)"
fi
ok "witness clean"

echo "ALL TESTS PASSED"

```

A few notes on portability and robustness.

The `dmesg -c` calls flush the kernel message buffer between subtests; on FreeBSD `dmesg -c` is documented to clear the buffer after printing it. Without these, a test that runs after the heartbeat subtest could see heartbeat lines from earlier in the run and miscount.

`dd` is used in place of `cat` for the round-trip and watchdog-drain reads. `cat` blocks until EOF, which a character device never returns; `dd` exits after `count=` blocks have been read. The driver is blocking-by-default, so an over-eager `cat` on an empty buffer would simply hang and break the script.

The detach step does not call `kldload` again at the end, because the only later test (`witness clean`) does not need the driver loaded. The trap is cleared after the successful unload so `EXIT` does not try to unload an already-unloaded module.

A green run after each commit is the minimum bar. A green run on a WITNESS kernel after the long-duration composite stress (Chapter 12 plus the Chapter 13 callouts active) is the higher bar.

13.9.7 Pre-Commit Checklist

The Chapter 12 checklist gets three new items for Chapter 13:

1. Have I updated `LOCKING.md` with any new callouts, intervals, or detach changes?
2. Have I run the full regression suite on a WITNESS kernel?
3. Have I run the long-duration composite stress for at least 30 minutes with all timers enabled?
4. Have I run `clang --analyze` and triaged every new warning?
5. Have I added a `MYFIRST_ASSERT(sc)` and `if (!sc->is_attached) return;` to every new callout callback?
6. Have I bumped the version string and updated `CHANGELOG.md`?
7. Have I verified that the test kit builds and runs?
8. Have I checked that every `cv` has both a signaller and a documented condition?
9. Have I checked that every `sx_xlock` has a paired `sx_xunlock` on every code path?
10. **(New)** Have I added a `MYFIRST_CO_DRAIN` for every new callout in the detach path?
11. **(New)** Have I confirmed no callout callback calls `se wakeup`, `uiomove`, or any sleeping primitive?
12. **(New)** Have I verified that disabling a callout via its `sysctl` actually stops the periodic firing?

The new items capture the most common Chapter 13 mistakes. A callout that is initialised but never drained is a `kldunload` crash waiting to happen. A callback that calls a sleeping function is a WITNESS warning waiting to happen. A `sysctl` that fails to stop a callout is a confusing user experience.

13.9.8 A Note on Backward Compatibility

A reasonable concern: the Chapter 13 driver adds three new `sysctls`. Will existing scripts that interact with `myfirst` (perhaps the Chapter 12 stress kit) break?

The answer is no, for two reasons.

First, the new `sysctls` all default to disabled (`interval = 0`). The driver's behaviour is unchanged unless the user enables one of them.

Second, the Chapter 12 `sysctls` (`debug_level`, `soft_byte_limit`, `nickname`, `read_timeout_ms`, `write_timeout_ms`) and stats (`cb_used`, `cb_free`, `bytes_read`, `bytes_written`) are unchanged. Existing scripts read and write the same values. The Chapter 13 additions are purely additive.

This is the discipline of *non-breaking changes*: when you add a feature, do not change the meaning of existing features. The cost is small (think about the change before making it); the benefit is that existing users see no regression.

For Chapter 13, the heartbeat, watchdog, and tick source are all opt-in. A user who does not know about Chapter 13 sees the same driver as before. A user who reads the chapter and enables one of the timers gets the new behaviour. Both groups are happy.

13.9.9 A Note on Sysctl Naming

The chapter uses sysctl names like `dev.myfirst.0.heartbeat_interval_ms`. The `_ms` suffix is intentional: it documents the unit. A user who sees `heartbeat_interval` could reasonably guess seconds, milliseconds, or microseconds; the suffix removes the ambiguity.

Other conventions:

- `_count` for counters (always non-negative).
- `_max`, `_min` for bounds.
- `_threshold` for switches.
- `_ratio` for percentages or fractions.

Following these conventions makes the sysctl tree self-describing. A user inspecting `sysctl dev.myfirst.0` can guess the meaning of every entry from its name and unit.

13.9.10 Wrapping Up Section 8

The driver is now version `0.7-timers`. It has:

- A documented callout discipline in `LOCKING.md`.
- A standardised macro pair (`MYFIRST_CO_INIT`, `MYFIRST_CO_DRAIN`) for callout lifecycle.
- A seven-phase detach pattern documented in code comments.
- A regression script that exercises every callout.
- A pre-commit checklist that catches the Chapter 13-specific failure modes.
- Three new sysctls with self-describing names and a default-disabled posture.

That is the close of the chapter's main teaching arc. The labs and challenges follow.

13.10 Hands-on Labs

These labs consolidate the Chapter 13 concepts through direct hands-on experience. They are ordered from least to most demanding.

13.10.1 Pre-Lab Setup Checklist

Before starting any lab, confirm:

1. **Debug kernel running.** `sysctl kern.ident` reports the kernel with `INVARIANTS` and `WITNESS`.

2. **WITNESS active.** `sysctl debug.witness.watch` returns a non-zero value.
3. **Driver source matches Chapter 12 Stage 4.** The Chapter 13 examples build on top of this.
4. **A clean dmesg.** `dmesg -c >/dev/null` once before the first lab.
5. **Companion userland built.** From `examples/part-03/ch12-synchronization-mechanisms/userland/`, the `timeout/config` testers should be present.
6. **Backup of Stage 4.** Copy your Chapter 12 Stage 4 driver to a safe location before starting any lab that modifies the source.

13.10.2 Lab 13.1: Add a Heartbeat Callout

Goal. Convert your Chapter 12 Stage 4 driver into a Chapter 13 Stage 1 driver by adding the heartbeat callout.

Steps.

1. Copy your Stage 4 driver into `examples/part-03/ch13-timers-and-delayed-work/stage1-heartbeat/`.
2. Add `struct callout heartbeat_co` and `int heartbeat_interval_ms` to `struct myfirst_softc`.
3. In `myfirst_attach`, call `callout_init_mtx(&sc->heartbeat_co, &sc->mtx, 0)` and initialize `heartbeat_interval_ms = 0`.
4. In `myfirst_detach`, drop the mutex and add `callout_drain(&sc->heartbeat_co)`; before destroying primitives.
5. Implement `myfirst_heartbeat` callback as shown in Section 4.
6. Implement `myfirst_sysctl_heartbeat_interval_ms` and register it.
7. Build and load on a WITNESS kernel.
8. Verify by setting the `sysctl`: `sysctl -w dev.myfirst.0.heartbeat_interval_ms=1000` and watching `dmesg` for heartbeat lines.

Verification. Heartbeat lines appear once per second when enabled. They stop when the `sysctl` is set to 0. Detach succeeds even with the heartbeat enabled. No WITNESS warnings.

Stretch goal. Use `dtrace` to count heartbeat callbacks per second:

```
# dtrace -n 'fbt::myfirst_heartbeat:entry { @ = count(); } tick-1sec { printa(@);  
↵  trunc(@); }'
```

The count should match the configured interval (1 per second for 1000 ms).

13.10.3 Lab 13.2: Add a Watchdog Callout

Goal. Add the watchdog callout that detects stalled buffer drainage.

Steps.

1. Copy Lab 13.1 into `stage2-watchdog/`.
2. Add `struct callout watchdog_co`, `int watchdog_interval_ms`, `size_t watchdog_last_used` to the `softc`.
3. Initialize and drain in `attach/detach` as for the heartbeat.

4. Implement `myfirst_watchdog` and the corresponding `sysctl` handler from Section 7.
5. Build and load.
6. Test: enable a 1-second watchdog, write some bytes, do not drain, observe warning.

Verification. The watchdog warning appears every second while the buffer has unconsumed bytes. The warning stops when the buffer is drained.

Stretch goal. Make the watchdog log the time since the last change in the warning message: “no progress for X.Y seconds”.

13.10.4 Lab 13.3: Add a Tick Source

Goal. Add the tick source callout that injects synthetic bytes into the `cbuf`.

Steps.

1. Copy Lab 13.2 into `stage3-tick-source/`.
2. Add struct callout `tick_source_co`, `int tick_source_interval_ms`, `char tick_source_byte` to the `softc`.
3. Initialize and drain as before.
4. Implement `myfirst_tick_source` as shown in Section 7. Note the deliberate omission of `selwakeup` from the callback.
5. Implement the `sysctl` handler.
6. Build and load.
7. Enable a 100 ms tick source, read with `cat`, observe the synthetic bytes.

Verification. `cat /dev/myfirst` produces approximately 10 bytes per second of the configured tick byte (default `'t'`).

Stretch goal. Add a `sysctl` that lets the user change the tick byte at runtime. Verify that changing the byte takes effect immediately on the next firing.

13.10.5 Lab 13.4: Verify Detach With Active Callouts

Goal. Confirm that detach works correctly even when all three callouts are firing.

Steps.

1. Load the Stage 3 (tick source) driver.
2. Enable all three callouts:

```
sysctl -w dev.myfirst.0.heartbeat_interval_ms=500
sysctl -w dev.myfirst.0.watchdog_interval_ms=500
sysctl -w dev.myfirst.0.tick_source_interval_ms=100
```

3. Confirm activity in `dmesg`.
4. Run `kldunload myfirst`.
5. Verify no panic, no WITNESS warning, no hang.

Verification. The unload completes within a few hundred milliseconds. `dmesg` shows no warnings related to the unload.

Stretch goal. Time the unload with `time kldunload myfirst`. The drain should be the dominant contributor to the time; expect a few hundred milliseconds depending on the intervals.

13.10.6 Lab 13.5: Build a Debounce Timer

Goal. Implement a debounce shape (not used by `myfirst`, but a useful exercise).

Steps.

1. Create a scratch directory for an experimental driver.
2. Implement a `sysctl dev.myfirst.0.event_count` that increments by 1 each time it is written. (The user write triggers the “event”.)
3. Add a debounce callout that fires 100 ms after the most recent event and prints the total count of events seen during the window.
4. Test: write the `sysctl` rapidly five times. Observe that one debounce log line appears 100 ms after the last write, reporting the count.

Verification. Multiple rapid events produce only one log line, with a count equal to the number of events.

13.10.7 Lab 13.6: Detect a Deliberate Race

Goal. Introduce a deliberate bug (a callout callback that calls something sleepable) and observe `WITNESS` catching it.

Steps.

1. In a scratch directory, modify the heartbeat callback to call something that may sleep, such as `pause("test", hz / 100)`.
2. Build and load on a `WITNESS` kernel.
3. Enable the heartbeat with a 1-second interval.
4. Observe `dmesg` for the warning: “Sleeping on ”test” with the following non-sleepable locks held: ...” or similar.
5. Revert the change.

Verification. `WITNESS` produces a warning that names the sleeping operation and the held mutex. The warning includes the source line.

13.10.8 Lab 13.7: Long-Running Composite Stress with Timers

Goal. Run the Chapter 12 composite stress kit for 30 minutes with the new Chapter 13 callouts enabled.

Steps.

1. Load the Stage 4 driver.
2. Enable all three callouts at 100 ms intervals.
3. Run the Chapter 12 composite stress script for 30 minutes.

4. After completion, check:

- `dmesg | grep -ci witness` returns 0.
- All loop iterations completed.
- `vmstat -m | grep cbuf` shows the expected static allocation.

Verification. All criteria met; no warnings, no panics, no memory growth.

13.10.9 Lab 13.8: Profile Callout Activity With `dtrace`

Goal. Use `dtrace` to observe callout firing patterns.

Steps.

1. Load the Stage 4 driver.
2. Enable all three callouts at 100 ms intervals.
3. Run a `dtrace` one-liner to count callout firings per callback per second:

```
# dtrace -n '
fbt::myfirst_heartbeat:entry,
fbt::myfirst_watchdog:entry,
fbt::myfirst_tick_source:entry { @[probefunc] = count(); }
tick-1sec { printa(@); trunc(@); }'
```

4. Observe the per-second counts.

Verification. Each callback fires approximately 10 times per second (1000 ms / 100 ms).

Stretch goal. Modify the `dtrace` script to report the time spent inside each callback (using `quantize` and `timestamp`).

13.10.10 Lab 13.9: Cancel a Watchdog Inline

Goal. Make the watchdog a one-shot timer that the read path cancels on success, demonstrating the cancel-on-progress pattern.

Steps.

1. Copy Lab 13.4 (stage3-tick-source plus heartbeat/watchdog) into a scratch directory.
2. Modify `myfirst_watchdog` to be one-shot: do not re-arm at the end.
3. Schedule the watchdog from `myfirst_write` after each successful write.
4. Cancel the watchdog (using `callout_stop`) from `myfirst_read` after a successful drain.
5. Test: write some bytes; do not read; observe the watchdog warning fire once.
6. Test: write some bytes; read them; observe no warning (because the read cancelled the watchdog).

Verification. The watchdog warning fires only when the buffer is left undrained. Successful drains cancel the pending watchdog.

Stretch goal. Add a counter that tracks how often the watchdog fired versus how often it was cancelled. Expose as a `sysctl`. The ratio is a quality metric for buffer drainage.

13.10.11 Lab 13.10: Schedule From Inside a Sysctl Handler

Goal. Verify that scheduling a callout from a sysctl handler produces correct timing.

Steps.

1. Add a sysctl `dev.myfirst.0.schedule_one-shot_ms` to the Stage 4 driver. Writing N to it schedules a one-shot callback to fire N milliseconds later.
2. The callback simply logs “one-shot fired”.
3. Test: write 100 to the sysctl. Observe the log line about 100 ms later.
4. Test: write 1000 to the sysctl. Observe about 1 second later.
5. Test: write 1 to the sysctl five times in quick succession. Observe how the kernel handles the rapid rescheduling.

Verification. Each write produces one log line at approximately the configured interval. Rapid writes either schedule new firings (cancelling the previous) or are coalesced; observe which.

Stretch goal. Use `dtrace` to measure the delta between the sysctl write and the actual firing. The histogram should be tight around the configured interval.

13.11 Challenge Exercises

The challenges extend Chapter 13 beyond the baseline labs. Each is optional; each is designed to deepen your understanding.

13.11.1 Challenge 1: Sub-Millisecond Tick Source

Modify the tick source callout to use `callout_reset_sbt` with a sub-millisecond interval (say, 250 microseconds). Test it. What happens to the heartbeat output (which logs counters)? What does `lockstat` show for the data mutex?

13.11.2 Challenge 2: Watchdog with Adaptive Intervals

Make the watchdog reduce its interval each time it fires (signal of trouble), and increase its interval when it sees forward progress. Cap both ends at reasonable values.

13.11.3 Challenge 3: Defer the Selwakeup to a Taskqueue

The tick source omits `selwakeup` because it cannot be called from the callout context. Read `taskqueue(9)` (Chapter 16 will introduce this in depth) and use a taskqueue to defer the `selwakeup` to a worker thread. Verify that `poll(2)` waiters now wake correctly.

13.11.4 Challenge 4: Multi-CPU Callout Distribution

By default, callouts run on a single CPU. Use `callout_reset_on` to bind each of the three callouts to a different CPU. Use `dtrace` to verify the binding. Discuss the trade-offs.

13.11.5 Challenge 5: Bound the Maximum Interval

Add validation to each interval sysctl to enforce a minimum (say, 10 ms) and a maximum (say, 60000 ms). Below the minimum, refuse with `EINVAL`. Above the maximum, also refuse. Document the choice.

13.11.6 Challenge 6: Callout-Based Read Timeout

Replace the Chapter 12 `cv_timedwait_sig`-based read timeout with a callout-based mechanism: schedule a one-shot callout when the reader starts blocking; the callout fires `cv_signal` on the data `cv` to wake the reader. Compare the two approaches.

13.11.7 Challenge 7: A Statistics Rollover

Add a callout that takes a snapshot of `bytes_read` and `bytes_written` every 5 seconds and stores the per-interval rates in a circular buffer (separate from the `cbuf`). Expose the most recent rates via a sysctl.

13.11.8 Challenge 8: Drain Without Hold

Verify experimentally that calling `callout_drain` while holding the callout's lock deadlocks. Write a small driver variant that does this deliberately, observe the deadlock with DDB, and document the symptom.

13.11.9 Challenge 9: Reuse a Callout Structure

Use the same `struct callout` for two different callbacks at different times: schedule with callback A, wait for it to fire, schedule with callback B. What happens if A is still pending when you call `callout_reset` with B's function? Write a test to verify the kernel's behaviour.

13.11.10 Challenge 10: Callout-Based Hello-World Module

Write a minimal module (no `myfirst` involved) that does nothing except install a single callout that prints "tick" every second. Use this as a sanity check for the callout subsystem on your test machine.

13.11.11 Challenge 11: Verify Lock Serialization

Demonstrate that two callouts sharing the same lock are serialized. Write a driver with two callouts; have each callback sleep briefly (with `DELAY()` if you must, since `DELAY()` does not sleep but spins). Confirm via `dt race` that the callbacks never overlap.

13.11.12 Challenge 12: Coalesce Latency

Use `callout_reset_sbt` with various precision values (0, `SBT_1MS`, `SBT_1S`) for a 1-second timer. Use `dt race` to measure the actual firing times. How much does the kernel coalesce when given more slop? When does coalescing reduce CPU usage?

13.11.13 Challenge 13: Callout Wheel Inspection

The kernel exposes the callout wheel state through `kern.callout_stat` and `kern.callout_*` sysctls. Read them on a busy system. Can you identify the callouts your driver has scheduled?

13.11.14 Challenge 14: Callout Function Pointer Replacement

Schedule a callout with one function. Before it fires, schedule it again with a different function. What happens? Does the second function replace the first? Document the behaviour with a small experiment.

13.11.15 Challenge 15: Adaptive Heartbeat

Make the heartbeat fire faster when there is recent activity (writes in the last second) and slower when idle. The interval should range from 100 ms (active) to 5 seconds (idle). Test it under a stress workload to verify it adapts as expected.

13.12 Troubleshooting

This reference catalogues the bugs you are most likely to encounter while working through Chapter 13.

13.12.1 Symptom: Callout never fires

Cause. Either the interval is zero (callout was disabled), or the sysctl handler did not actually call `callout_reset`.

Fix. Check the sysctl handler logic. Confirm that the transition from 0 to non-zero is detected. Add a `device_printf` at the call site to verify.

13.12.2 Symptom: kldunload panics shortly after

Cause. A callout was not drained at detach. The callout fired after the module was unloaded.

Fix. Add `callout_drain` for every callout in the detach path. Confirm the order: drain *after* clearing `is_attached`, *before* destroying primitives.

13.12.3 Symptom: WITNESS warns “sleeping thread (pid X) owns a non-sleepable lock”

Cause. A callout callback called something that sleeps (`uiomove`, `copyin`, `malloc(M_WAITOK)`, `pause`, or any `cv_wait` variant) while holding the kernel-acquired mutex.

Fix. Remove the sleeping operation from the callback. If the work requires sleeping, defer to a taskqueue or kernel thread.

13.12.4 Symptom: Heartbeat fires once and then never again

Cause. The callback re-arm code is missing or guarded by a condition that becomes false.

Fix. Check the re-arm at the end of the callback. Confirm that `interval_ms > 0` and that the call to `callout_reset` actually executes.

13.12.5 Symptom: Callout fires more often than the configured interval

Cause. Two paths are scheduling the same callout. Either the `sysctl` handler and the callback are both calling `callout_reset`, or two callbacks share a callout struct.

Fix. Audit the call sites. The `sysctl` handler should `callout_reset` only on the 0 -> non-zero transition; the callback re-arms only at its own end.

13.12.6 Symptom: Detach hangs

Cause. A callout callback re-armed itself between the `is_attached = 0` and the `callout_drain`. The drain is now waiting for the callback to finish; the callback (which checked `is_attached` before the assignment took effect) is not exiting.

Fix. Confirm that the `is_attached = 0` happens under the same lock as the callout's lock. Confirm that the drain happens after the assignment, not before. The check inside the callback must see the cleared flag.

13.12.7 Symptom: WITNESS warns about lock-order issues with the callout's lock

Cause. The callout lock is being acquired in conflicting orders by different paths.

Fix. The callout's lock is `sc->mtx`. Confirm that every path that acquires `sc->mtx` follows the canonical order (mtx first, then any other lock). The callback runs with `sc->mtx` already held; the callback must not acquire any lock that should be acquired before `sc->mtx`.

13.12.8 Symptom: Callout-Drain Sleeps Forever

Cause. `callout_drain` was called with the callout's lock held. Deadlock: the drain waits for the callback to release the lock, the callback is waiting because the drain is the lock holder.

Fix. Drop the lock before calling `callout_drain`. The standard detach pattern does this.

13.12.9 Symptom: Callback runs but data is stale

Cause. The callback is using cached values from before the firing. Either it stored data in a local variable that became stale, or it dereferenced a structure that was modified.

Fix. The callback runs with the lock held. Re-read fields each time the callback fires; do not cache across firings.

13.12.10 Symptom: `procstat -kk` shows no thread waiting on the callout

Cause. Callouts do not have associated threads. The callback runs in a kernel thread context (the callout subsystem manages a small pool), but no specific thread is “the callout’s thread” the way a kernel thread might own a wait condition.

Fix. None needed; this is by design. To see callout activity, use `dtrace` or `lockstat` instead.

13.12.11 Symptom: `callout_reset` returns 1 unexpectedly

Cause. The callout was previously pending and got cancelled by this `callout_reset`. The return value is informational, not an error.

Fix. None needed; this is normal. Use the return value if you care whether the previous schedule was overwritten.

13.12.12 Symptom: Sysctl handler reports `EINVAL` for valid input

Cause. The handler’s validation rejects the value. Common cause: the user passed a negative number that the validation correctly rejects, or the handler has a too-strict bound.

Fix. Inspect the validation code. Confirm the user’s input meets the documented constraints.

13.12.13 Symptom: Two callbacks for different callouts run concurrently and deadlock

Cause. Both callouts are bound to the same lock, so they cannot run concurrently. If they appear to deadlock, check whether either callback acquires another lock that the other path already holds.

Fix. Audit the lock acquisition order. The callback-running thread holds `sc->mtx`; if it tries to acquire `sc->cfg_sx`, the order must be `mtx-then-sx` (which our canonical order is).

13.12.14 Symptom: `tick_source` produces the wrong byte

Cause. The callback reads `tick_source_byte` at firing time. If a sysctl just changed it, the callback may see either the old or the new value depending on timing.

Fix. This is correct behaviour; the byte change takes effect on the next firing. If immediate effect is required, use the snapshot-and-apply pattern from Chapter 12.

13.12.15 Symptom: `lockstat` shows the data mutex held for unusually long during heartbeats

Cause. The heartbeat callback is doing too much work while the lock is held.

Fix. The heartbeat does only counter reads and one log line; if the hold time is long, it is probably the `device_printf` (which acquires global locks for the message buffer). For low-overhead heartbeats, gate the log line behind a debug level.

13.12.16 Symptom: Heartbeat continues after sysctl is set to 0

Cause. The `callout_stop` did not actually cancel because the callback was already running. The callback re-armed before checking the new value.

Fix. The race is closed if the sysctl handler holds `sc->mtx` while updating `interval_ms` and calling `callout_stop`. The callback runs under the same lock; it cannot run between the update and the stop. Verify the lock is held in the right places.

13.12.17 Symptom: WITNESS warns about acquiring the callout's lock during init

Cause. Some earlier path in `attach` has not yet established the lock order rules. Adding a callout's lock association makes WITNESS notice the inconsistency.

Fix. Move the `callout_init_mtx` to after the mutex is initialized. The order must be: `mtx_init`, then `callout_init_mtx`.

13.12.18 Symptom: A single fast callout causes high CPU usage

Cause. A 1 ms callout that does even a small amount of work fires 1000 times per second. If each firing takes 100 microseconds, that is 10% of one CPU.

Fix. Increase the interval. Sub-second intervals should be used only when truly required.

13.12.19 Symptom: dtrace cannot find the callback function

Cause. `dtrace`'s `fbt` provider needs the function to be present in the kernel's symbol table. If the function was inlined or optimized away, the probe is not available.

Fix. Confirm the function is not declared `static inline` or wrapped in a way that prevents external linkage. The standard `static void myfirst_heartbeat(void *arg)` is fine; `dtrace` can probe it.

13.12.20 Symptom: heartbeat_interval_ms reads back as 0 after setting it

Cause. The sysctl handler updates a local copy and never commits to the `softc` field, or the field is overwritten elsewhere.

Fix. Confirm the handler assigns `sc->heartbeat_interval_ms = new` after validation, before returning.

13.12.21 Symptom: WITNESS warns "callout_init: lock has sleepable lock_class"

Cause. You called `callout_init_mtx` with an `sx` lock or other sleepable primitive instead of an `MTX_DEF` mutex. Sleepable locks are forbidden as callout interlocks because callouts run in a context where sleeping is illegal.

Fix. Use `callout_init_mtx` with an `MTX_DEF` mutex, or `callout_init_rw` with an `rw(9)` lock, or `callout_init_rm` with an `rmlock(9)`. Do not use `sx`, `lockmgr`, or any other sleepable lock.

13.12.22 Symptom: Detach takes seconds even when callouts seem idle

Cause. A callout has a long interval (say, 30 seconds) and is currently pending. `callout_drain` waits for the next firing or for the explicit cancellation. If the deadline is far in the future, the wait can be long.

Fix. `callout_drain` actually does not wait for the deadline; it cancels the pending and returns once any in-flight callback completes. If your detach takes seconds, something else is wrong (a callback is genuinely taking that long, or a different sleep is involved). Use `dtrace` on `_callout_stop_safe` to investigate.

13.12.23 Symptom: `callout_pending` returns true after `callout_stop`

Cause. Race: another path scheduled the callout between the `callout_stop` and your check of `callout_pending`. Or: the callout was previously firing on another CPU and has just re-armed.

Fix. Always hold the callout's lock when calling `callout_stop` and checking `callout_pending`. The lock makes the operations atomic.

13.12.24 Symptom: A callout function appears in `dmesg` long after the driver was unloaded

Cause. The unload race. The callout fired after detach destroyed state. If the kernel did not panic immediately, the printed line is from the freed callback's code, executing in a kernel that has lost track of the original module.

Fix. This should not happen if you called `callout_drain` correctly. If it does, your detach path is broken; review every callout to confirm each is drained.

13.12.25 Symptom: Multiple callouts fire all at once after a long pause

Cause. The system was under load (a long-running interrupt, a stuck callout-processing thread) and could not service the callout wheel. When it recovers, it processes all the deferred callouts in quick succession.

Fix. This is normal under unusual load. If it happens routinely, investigate why the system could not service callouts on time. `dtrace -n 'callout-end'` (using the `callout` provider, if your kernel exposes it) shows actual firing times.

13.12.26 Symptom: A periodic callout drifts: each firing is slightly later than the previous

Cause. The re-arm is `callout_reset(&co, hz, ..., ...)`, which schedules "1 second from now". Each firing's "now" is slightly later than the previous firing's deadline, so the actual interval grows by the callback's execution time.

Fix. For exact periodicity, compute the next deadline as "previous deadline + interval", not "now + interval". Use `callout_reset_sbt` with `C_ABSOLUTE` and an absolute sbintime computed from the original schedule.

13.12.27 Symptom: Callout never fires even though `callout_pending` returns true

Cause. Either the callout is stuck on a CPU that is offline (rare, but possible during CPU hot-unplug), or the system's clock interrupt is not firing on that CPU.

Fix. Check `kern.hz` and `kern.eventtimer` sysctls. The default `hz=1000` should produce regular firings. If a CPU is offline, the callout subsystem migrates pending callouts to a working CPU, but there is a window. For most drivers, this is not a real concern.

13.12.28 Symptom: Stress test causes intermittent panic in `callout_process`

Cause. Almost certainly the unload race or an incorrect lock association on a callout. The callout subsystem itself is well-tested; bugs at this level are usually in the calling code.

Fix. Audit every callout's init and drain. Check that the lock association is correct (no sleepable locks). Run with `INVARIANTS` to catch invariant violations.

13.12.29 Symptom: `kern.callout.busy` counter grows under load

Cause. The callout subsystem detected callbacks taking too long. Each "busy" event is a callback that did not complete within an expected window.

Fix. Inspect the slow callbacks with `dtrace`. Long callbacks indicate either too much work (split into multiple callouts or defer to a taskqueue) or a lock-contention issue (the callback is waiting for the lock to become available).

13.12.30 Symptom: Driver logs show "callout_drain detected migration" or similar

Cause. A callout was bound to a specific CPU (via `callout_reset_on`) and the binding migration overlapped with the drain. The kernel resolves this internally; the log message is informational.

Fix. None usually needed. If the message is frequent, consider whether per-CPU binding is necessary at all.

13.12.31 Symptom: `callout_reset_sbt` gives unexpected timing

Cause. The precision argument is too loose: the kernel coalesced your callout with others into a window much wider than expected.

Fix. Set precision to a smaller value (or 0 for "fire as close to deadline as possible"). The default is `tick_sbt` (one tick of slop), which is fine for most timer work.

13.12.32 Symptom: A callout that was working stops firing after a power-management event

Cause. The system's clock interrupt may have been reconfigured (transition between event-timer modes during sleep/wake). The callout subsystem reschedules pending callouts after such transitions, but the timing may be slightly off.

Fix. Verify with `dtrace` that the callout's callback is being invoked. If not, the callout has been migrated or discarded; reschedule from a known-good code path.

13.12.33 Symptom: All callouts in the driver fire on the same CPU

Cause. This is the default. Callouts are bound to the CPU that scheduled them; if all your `callout_reset` calls run on CPU 0 (because the user's syscall was dispatched there), all the callouts fire on CPU 0.

Fix. This is correct for most drivers. If you want load distribution, use `callout_reset_on` to bind explicitly to different CPUs. Most drivers do not need this; the per-CPU wheels naturally balance over time as different syscalls hit different CPUs.

13.12.34 Symptom: `callout_drain` returns but the next syscall sees stale state

Cause. The callback completed and returned, but a subsequent code path observed state that the callback had set. This is correct behaviour, not a bug.

Fix. None. The drain only guarantees the callback is no longer running; any state changes the callback made are still in effect. If the changes are unwanted, the callback should not have made them.

13.12.35 Symptom: Re-arm in callback fails silently

Cause. The condition `interval > 0` is false because the user just disabled the timer. The callback exits without re-arming; the callout becomes idle.

Fix. This is correct behaviour. If you want to know when the callback declined to re-arm, add a counter or log line.

13.12.36 Symptom: Callout fires but `device_printf` is silent

Cause. The driver's `dev` field is NULL or the device has been detached and the `cdev` destroyed. `device_printf` may suppress output in those states.

Fix. Add an explicit `printf("%s: ...\n", device_get_nameunit(dev), ...)` to bypass the wrapper. Or confirm that `sc->dev` is valid via `KASSERT`.

13.13 Reference: The Driver's Stage Progression

Chapter 13 evolves the `myfirst` driver in four discrete stages, each of which is its own directory under `examples/part-03/ch13-timers-and-delayed-work/`. The progression mirrors the chapter's narrative; it lets a reader build the driver one timer at a time and see what each addition contributes.

13.13.1 Stage 1: heartbeat

Adds the heartbeat callout that periodically logs `cbuf` usage and byte counts. The new `sysctl dev.myfirst.<unit>.heartbeat` enables, disables, and adjusts the heartbeat at runtime.

What changes: one new callout, one new callback, one new `sysctl`, and the corresponding `init/drain` in `attach/detach`.

What you can verify: setting the sysctl to a positive value produces periodic log lines; setting it to 0 stops them; detach succeeds even with the heartbeat enabled.

13.13.2 Stage 2: watchdog

Adds the watchdog callout that detects stalled buffer drainage. The new sysctl `dev.myfirst.<unit>.watchdog_interval` enables, disables, and adjusts the interval.

What changes: one new callout, one new callback, one new sysctl, and the corresponding init/drain.

What you can verify: enabling the watchdog and writing bytes (without reading them) produces warning lines; reading the buffer stops the warnings.

13.13.3 Stage 3: tick-source

Adds the tick source callout that injects synthetic bytes into the cbuf. The new sysctl `dev.myfirst.<unit>.tick_source_interval` enables, disables, and adjusts the interval.

What changes: one new callout, one new callback, one new sysctl, and the corresponding init/drain.

What you can verify: enabling the tick source and reading from `/dev/myfirst` produces bytes at the configured rate.

13.13.4 Stage 4: final

The combined driver with all three callouts, plus a `LOCKING.md` extension, the version bump to `0.7-timers`, and the standardised `MYFIRST_CO_INIT` and `MYFIRST_CO_DRAIN` macros.

What changes: integration. No new primitives.

What you can verify: the regression suite passes; the long-duration stress test with all callouts active runs cleanly; `WITNESS` is silent.

This four-stage progression is the canonical Chapter 13 driver. The companion examples mirror the stages exactly so a reader can compile and load any one of them.

13.14 Reference: Anatomy of a Real Watchdog

A real production watchdog does more than the chapter's example. A short tour of what real watchdogs typically include, useful when you write or read driver source.

13.14.1 Per-Request Tracking

Real I/O watchdogs track each pending request individually. The watchdog callback walks a list of pending requests, finds those that have been outstanding too long, and acts on each.

```
struct myfirst_request {
    TAILQ_ENTRY(myfirst_request) link;
    sbintime_t    submitted_sbt;
    int           op;
    /* ... other request state ... */
};

TAILQ_HEAD(, myfirst_request) pending_requests;
```

The watchdog walks `pending_requests`, computes the age of each, and acts on the stale ones.

13.14.2 Threshold-Based Action

Different ages get different actions. Up to T1, ignore (the request is still working). T1 to T2, log a warning. T2 to T3, attempt soft recovery (send a reset to the request). Beyond T3, hard recovery (reset the channel, fail the request).

```
age_sbt = now - req->submitted_sbt;
if (age_sbt > sc->watchdog_hard_sbt) {
    /* hard recovery */
} else if (age_sbt > sc->watchdog_soft_sbt) {
    /* soft recovery */
} else if (age_sbt > sc->watchdog_warn_sbt) {
    /* log warning */
}
```

13.14.3 Statistics

A real watchdog tracks how often each threshold was hit, what percentage of requests exceeded each threshold, and so on. The statistics are exposed as sysctls for monitoring.

13.14.4 Configurable Thresholds

Each threshold (T1, T2, T3) is a sysctl. Different deployments need different bounds; hard-coding is wrong.

13.14.5 Recovery Logging

The recovery action logs to `dmesg` with a recognizable prefix that monitoring tools can `grep`. A detailed message with the request's identity, the action taken, and any kernel state that might help diagnose the underlying issue.

13.14.6 Coordination With Other Subsystems

A hard recovery often involves cooperation with other parts of the driver: the I/O layer must know that the channel is being reset, queued requests must be re-queued or failed, and the driver's "is operational" state must be updated.

For Chapter 13, our watchdog is much simpler. It detects one specific condition (no progress on the cbuf), logs a warning, and re-arms. This captures the essential pattern. Real-world watchdogs add the pieces above incrementally.

13.15 Reference: Periodic vs Event-Driven Driver Architecture

A small architectural digression. Some drivers are dominated by events (an interrupt arrives, the driver responds). Others are dominated by polling (the driver wakes periodically to check). Understanding which one your driver is helps choose primitives.

13.15.1 Event-Driven

In an event-driven design, the driver is mostly idle. Activity is triggered by:

- User syscalls (open, read, write, ioctl).
- Hardware interrupts (Chapter 14).
- Wake-ups from other subsystems (cv signals, taskqueue runs).

Callouts in an event-driven design are typically watchdogs (track an event, fire if it does not happen) and reapers (clean up after events).

The `myfirst` driver was originally event-driven (read/write triggered everything). Chapter 13 adds some polling-flavoured behaviour (heartbeat, tick source) for demonstration, but the underlying design is still event-driven.

13.15.2 Polling-Driven

In a polling-driven design, the driver wakes periodically to do work, regardless of whether anyone is asking. This is appropriate for hardware that does not interrupt for the events the driver cares about.

Callouts in a polling-driven design are the heartbeat of the driver: every firing, the callback checks the hardware and processes whatever it finds.

The polling-loop pattern (Section 7) is the basic shape. Real polling drivers extend it with adaptive intervals (poll faster when busy, slower when idle), error counting (give up after too many failed polls), and so on.

13.15.3 Hybrid

Most real drivers are hybrid: events drive most activity, but a periodic callout catches what events miss (timeouts, slow polling, statistics). The patterns from this chapter apply to either side; the choice of which to use where is a design decision.

For `myfirst`, our hybrid uses: - Event-driven syscall handlers for the main I/O. - A heartbeat callout for periodic logging. - A watchdog callout for stuck-state detection. - An optional tick source callout for synthetic event generation.

A real driver would have many more callouts, but the shape is the same.

13.16 Wrapping Up

Chapter 13 took the driver you built in Chapter 12 and gave it the ability to act on its own schedule. Three callouts now sit alongside the existing primitives: a heartbeat that periodically logs state, a watchdog that detects stalled drainage, and a tick source that injects synthetic bytes. Each is lock-aware, drained at detach, configurable through a `sysctl`, and documented in `LOCKING.md`. The driver's data path is unchanged; the new code is purely additive.

We learned that `callout(9)` is small, regular, and well-integrated with the rest of the kernel. The lifecycle is the same five stages every time: `init`, `schedule`, `fire`, `complete`, `drain`. The lock contract is the same model every time: the kernel acquires the registered lock before each firing and releases it after, serializing the callback against any other holder. The detach pattern is the same seven phases every time: `refuse if busy`, `mark going-away under the lock`, `drop the lock`, `drain selinfo`, `drain every callout`, `destroy cdevs`, `free state`, `destroy primitives in reverse order`.

We also learned a small handful of recipes that recur across drivers: heartbeat, watchdog, debounce, retry-with-backoff, deferred reaper, statistics rollover. Each is a small variation on the periodic or one-shot shape; once you know the patterns, the variations are mechanical.

Four closing reminders before moving on.

The first is to *drain every callout at detach*. The unload race is reliable, immediate, and fatal. The cure is mechanical: one `callout_drain` per callout, after `is_attached` is cleared and before primitives are destroyed. There is no excuse to skip this.

The second is to *keep callbacks short and lock-aware*. The callback runs with the registered lock held, in a context that may not sleep. Treat it like a hardware-interrupt handler: do the minimum, defer the rest. If the work needs to sleep, enqueue it on a taskqueue (Chapter 16) or wake a kernel thread.

The third is to *use sysctls to make timer behaviour configurable*. Hard-coding intervals is a maintenance burden. Letting users tune the heartbeat, the watchdog, or the tick source from `sysctl -w` makes the driver useful in environments you did not anticipate. The cost is small (one `sysctl` handler per knob) and the benefit is large.

The fourth is to *update `LOCKING.md` in the same commit as any code change*. A driver whose documentation drifts from the code accumulates subtle bugs because no one knows what the rules are supposed to be. The discipline is one minute per change; the benefit is years of clean maintenance.

These four disciplines together produce drivers that compose well with the rest of FreeBSD, that survive long-term maintenance, and that behave predictably under load. They are also the disciplines Chapter 14 will assume; the patterns from this chapter transfer directly to interrupt handlers.

13.16.1 What You Should Now Be Able to Do

A short self-checklist before turning to Chapter 14:

- Choose between `callout(9)` and `cv_timedwait_sig` for any “wait until X happens, or until Y time has passed” requirement.
- Initialize a callout with the appropriate lock variant for your driver’s needs.
- Schedule one-shot and periodic callouts using `callout_reset` (or `callout_reset_sbt` for sub-tick precision).
- Cancel callouts with `callout_stop` in normal operation; drain with `callout_drain` at detach.
- Write a callout callback that respects the lock contract and the no-sleeping rule.
- Use the `is_attached` pattern to make callbacks safe during teardown.
- Document every callout in `LOCKING.md`, including its lock, its callback, its lifecycle.
- Recognize the unload race and avoid it through the standard seven-phase detach pattern.
- Build watchdog, heartbeat, debounce, and tick-source patterns as needed.
- Use `dtrace` to verify callout firing rates, latency, and lifecycle behaviour.
- Read real-driver source (led, uart, network drivers) and recognize the patterns from this chapter at work.

If any of those feels uncertain, the labs in this chapter are the place to build the muscle memory. None requires more than an hour or two; together they cover every primitive and every pattern the chapter introduced.

13.16.2 A Note On the Companion Examples

The companion source under `examples/part-03/ch13-timers-and-delayed-work/` mirrors the chapter’s stages. Each stage builds on the previous one, so you can compile and load any stage to see exactly the driver state the chapter describes at that point.

If you prefer to type the changes by hand (recommended for the first read), use the chapter’s worked examples as your guide and the companion source as a reference. If you prefer to read finished code, the companion source is canonical.

A note on the `LOCKING.md` document: the chapter’s text explains what `LOCKING.md` should contain. The actual file is in the example tree alongside the source. Keep both in sync as you make changes; the discipline of updating `LOCKING.md` in the same commit as the code change is the most reliable way to keep the documentation accurate.

13.17 Reference: `callout(9)` Quick Reference

A compact API summary for everyday lookup.

13.17.1 Initialization

```
callout_init(&co, 1)                /* mpsafe; no lock */
callout_init_mtx(&co, &mtx, 0)      /* lock is mtx (default) */
callout_init_mtx(&co, &mtx, CALLOUT_RETURNUNLOCKED)
callout_init_rw(&co, &rw, 0)        /* lock is rw, exclusive */
callout_init_rw(&co, &rw, CALLOUT_SHAREDLOCK)
callout_init_rm(&co, &rm, 0)        /* lock is rmlock */
```

13.17.2 Scheduling

```
callout_reset(&co, ticks, fn, arg)           /* tick-based delay */
callout_reset_sbt(&co, sbt, prec, fn, arg, flags)
callout_reset_on(&co, ticks, fn, arg, cpu) /* bind to CPU */
callout_schedule(&co, ticks)                 /* re-use last fn/arg */
```

13.17.3 Cancellation

```
callout_stop(&co)                           /* cancel; do not wait */
callout_drain(&co)                          /* cancel + wait for in-flight */
callout_async_drain(&co, drain_fn)           /* drain async */
```

13.17.4 Inspection

```
callout_pending(&co)                        /* is the callout scheduled? */
callout_active(&co)                        /* user-managed active flag */
callout_deactivate(&co)                    /* clear the active flag */
```

13.17.5 Common Flags

```
CALLOUT_RETURNUNLOCKED /* callback releases the lock itself */
CALLOUT_SHAREDLOCK     /* acquire rw/rm in shared mode */
C_HARDCLOCK            /* align to hardclock() */
C_DIRECT_EXEC          /* run in timer interrupt context */
C_ABSOLUTE              /* sbt is absolute time */
```

13.18 Reference: Standard Detach Pattern

The seven-phase detach pattern for a driver with callouts:

```
static int
myfirst_detach(device_t dev)
{
    struct myfirst_softc *sc = device_get_softc(dev);

    /* Phase 1: refuse if in use. */
```

```
MYFIRST_LOCK(sc);
if (sc->active_fhs > 0) {
    MYFIRST_UNLOCK(sc);
    return (EBUSY);
}

/* Phase 2: mark going away; broadcast cvs. */
sc->is_attached = 0;
cv_broadcast(&sc->data_cv);
cv_broadcast(&sc->room_cv);
MYFIRST_UNLOCK(sc);

/* Phase 3: drain selinfo. */
seldrain(&sc->rsl);
seldrain(&sc->wsl);

/* Phase 4: drain every callout (no lock held). */
callout_drain(&sc->heartbeat_co);
callout_drain(&sc->watchdog_co);
callout_drain(&sc->tick_source_co);

/* Phase 5: destroy cdevs (no new opens). */
if (sc->cdev_alias != NULL) {
    destroy_dev(sc->cdev_alias);
    sc->cdev_alias = NULL;
}
if (sc->cdev != NULL) {
    destroy_dev(sc->cdev);
    sc->cdev = NULL;
}

/* Phase 6: free auxiliary resources. */
sysctl_ctx_free(&sc->sysctl_ctx);
cbuf_destroy(&sc->cb);
counter_u64_free(sc->bytes_read);
counter_u64_free(sc->bytes_written);

/* Phase 7: destroy primitives in reverse order. */
cv_destroy(&sc->data_cv);
cv_destroy(&sc->room_cv);
sx_destroy(&sc->cfg_sx);
mtx_destroy(&sc->mtx);

return (0);
```

}

Skipping any phase creates a class of bug that crashes the kernel under load.

13.19 Reference: When to Use Each Timing Primitive

A compact decision table.

Need	Primitive
One-shot callback at time T	<code>callout_reset</code>
Periodic callback every T ticks	<code>callout_reset</code> with re-arm
Sub-millisecond callback timing	<code>callout_reset_sbt</code>
Bind callback to a specific CPU	<code>callout_reset_on</code>
Run callback in timer-interrupt context	<code>callout_reset_sbt</code> with <code>C_DIRECT_EXEC</code>
Wait until a condition, with deadline	<code>cv_timedwait_sig</code> (Chapter 12)
Wait until a condition, no deadline	<code>cv_wait_sig</code> (Chapter 12)
Defer work to a worker thread	<code>taskqueue_enqueue</code> (Chapter 16)
Long-running periodic work	Kernel thread + <code>cv_timedwait</code>

The first four are `callout(9)` use cases; the others use other primitives.

13.20 Reference: Callout Mistakes to Avoid

A compact list of the most common mistakes:

- **Forgetting `callout_drain` at detach.** Causes a panic the next time the callout fires.
- **Calling `callout_drain` while holding the callout's lock.** Causes a deadlock.
- **Calling sleeping functions from the callback.** Causes a `WITNESS` warning or a panic.
- **Using `callout_init` (with `mpsafe=0`) for new code.** Acquires Giant; harms scalability.
- **Forgetting the `is_attached` check at the top of the callback.** Detach can race with re-arm and never complete.
- **Sharing a struct `callout` between two callbacks.** Confusing and rarely what you want; use two structs.
- **Hard-coding intervals in the callback.** No way for users to tune behaviour.
- **Failing to validate `sysctl` input.** Negative or absurd intervals create surprising behaviour.
- **Calling `selwakeup` from a callback.** Takes other locks; can produce ordering violations.
- **Using `callout_stop` at detach.** Does not wait for in-flight; causes the unload race.

13.21 Reference: Reading `kern_timeout.c`

Two functions in `/usr/src/sys/kern/kern_timeout.c` are worth opening once.

`callout_reset_sbt_on` is the core scheduling function. Every other variant of `callout_reset` is a wrapper that ends up here. The function handles the cases of “callout is currently running”, “callout is pending and being rescheduled”, “callout needs to be migrated to a different CPU”, and “callout is fresh”. The complexity is real; the public-facing behaviour is simple.

`_callout_stop_safe` is the unified stop-and-maybe-drain function. Both `callout_stop` and `callout_drain` are macros that call this function with different flags. The `CS_DRAIN` flag is the one that triggers the wait-for-in-flight behaviour. Reading this function once shows exactly how the drain interacts with the firing callback.

The file is around 1550 lines in FreeBSD 14.3. You do not need to read every line. Skim the function names, find the two functions above, and read each carefully. Twenty minutes of reading gives you a working sense of the implementation.

13.22 Reference: The `c_iflags` and `c_flags` Fields

A short look at the two flag fields, useful when you read real driver source that inspects them directly.

`c_iflags` (internal flags, set by the kernel):

- `CALLOUT_PENDING`: the callout is on the wheel waiting to fire. Read via `callout_pending(c)`.
- `CALLOUT_PROCESSED`: internal bookkeeping for which list the callout is on.
- `CALLOUT_DIRECT`: set if `C_DIRECT_EXEC` was used.
- `CALLOUT_DFRMIGRATION`: set during deferred migration to a different CPU.
- `CALLOUT_RETURNUNLOCKED`: set if the lock-handling contract was set up to expect the callback to release the lock.
- `CALLOUT_SHAREDLOCK`: set if the rw/rm lock is to be acquired in shared mode.

`c_flags` (external flags, managed by the caller):

- `CALLOUT_ACTIVE`: a user-managed bit. Set by the kernel during a successful `callout_reset`; cleared by `callout_deactivate` or by a successful `callout_stop`. Driver code reads via `callout_active(c)`.
- `CALLOUT_LOCAL_ALLOC`: deprecated; only used in legacy `timeout(9)` style.
- `CALLOUT_MPSAFE`: deprecated; use `callout_init_mtx` instead.

Driver code touches only `CALLOUT_ACTIVE` (via `callout_active` and `callout_deactivate`) and `CALLOUT_PENDING` (via `callout_pending`). Everything else is internal.

13.23 Reference: A Chapter 13 Self-Assessment

Before turning to Chapter 14, use this rubric. The format mirrors Chapter 11 and Chapter 12: conceptual questions, code-reading questions, and hands-on questions. If any item feels uncertain, the relevant section name is in parentheses.

The questions are not exhaustive; they sample the chapter's core ideas. A reader who can answer all of them confidently is ready for the next chapter. A reader who struggles on a particular item should re-read the relevant section before continuing.

13.23.1 Conceptual Questions

These questions sample the Chapter 13 vocabulary. A reader who can answer them all without re-checking the chapter has internalised the material.

1. **Why use `callout(9)` instead of a kernel thread for periodic work?** Callouts are essentially free at rest; threads have a 16 KB stack and scheduler overhead. For short periodic work, a callout is the right answer.
2. **What is the difference between `callout_stop` and `callout_drain`?** `callout_stop` cancels pending and returns immediately; `callout_drain` cancels pending and waits for any in-flight callback to finish. Use `callout_stop` in normal operation, `callout_drain` at detach.
3. **What does the lock argument to `callout_init_mtx` accomplish?** The kernel acquires that lock before each callback firing and releases it after. The callback runs with the lock held.
4. **What may a callout callback not do?** Anything that may sleep, including `cv_wait`, `mtx_sleep`, `uiomove`, `copyin`, `copyout`, `malloc(M_WAITOK)`, `selwakeup`.
5. **Why does the standard detach pattern call `callout_drain` after dropping the mutex?** `callout_drain` may sleep waiting for the in-flight callback. Sleeping with the mutex held is illegal. Dropping the mutex before draining is mandatory.
6. **What is the unload race?** A callout fires after `kldunload` has run, finding its function and surrounding state freed. The kernel jumps to invalid memory and panics.
7. **What is the periodic callback re-arm pattern?** The callback does its work and calls `callout_reset` at the end to schedule the next firing.
8. **Why does the callback check `is_attached` before doing work?** Detach clears `is_attached`; if the callback fires during the brief window between clearing and `callout_drain`, the check prevents the callback from doing work that depends on state being torn down.
9. **What happens if you call `callout_drain` while holding the callout's lock?** Deadlock: the drain waits for the callback to release the lock, but the callback cannot release the lock that the drainer is holding. Always drop the lock before calling `callout_drain`.
10. **What is the purpose of `MYFIRST_CO_INIT` and `MYFIRST_CO_DRAIN`?** They are macro wrappers around `callout_init_mtx` and `callout_drain` that document the convention: every callout uses `sc->mtx` and is drained at detach. Standardising via macros makes new callouts mechanical to add and easy to review.
11. **Why is `device_printf` safe to call from a callout callback while the mutex is held?** It does not acquire any of the driver's locks and it does not sleep; it writes to a global ringbuffer with its own internal locking. It is one of the few "safe to call from a callout context" output functions.
12. **What is the difference between scheduling a callout for hz ticks and scheduling it for `tick_sbt * hz`?** Conceptually nothing; both represent one second. The first uses `callout_reset` (tick-based API); the second uses `callout_reset_sbt` (sbintime-based API). Choose the API that matches the precision you need.

13.23.2 Code Reading Questions

Open your Chapter 13 driver source and verify:

1. Every `callout_init_mtx` is paired with a `callout_drain` in `detach`.
2. Every callback starts with `MYFIRST_ASSERT(sc)` and `if (!sc->is_attached) return;`.
3. No callback calls `selwakeup`, `uiomove`, `copyin`, `copyout`, `malloc(M_WAITOK)`, or `cv_wait`.
4. The `detach` path drops the mutex before calling `callout_drain`.
5. Every callout has a `sysctl` that allows the user to enable, disable, or change its interval.
6. Every callout's lifecycle (init in `attach`, drain in `detach`) is documented in `LOCKING.md`.
7. Every periodic callback re-arms only when its interval is positive.
8. Every `sysctl` handler holds the mutex when calling `callout_reset` or `callout_stop`.

13.23.3 Hands-On Questions

These should all be quick to run; if any fails, the relevant lab in this chapter walks through the setup.

1. Load the Chapter 13 driver. Enable the heartbeat with a 1-second interval. Confirm `dmesg` shows one log line per second.
2. Enable the watchdog with a 1-second interval. Write some bytes. Wait. Confirm the warning appears.
3. Enable the tick source with a 100 ms interval. Read with `cat`. Confirm 10 bytes per second.
4. Enable all three callouts. Run `kldunload myfirst`. Verify no panic, no warning.
5. Open `/usr/src/sys/kern/kern_timeout.c`. Find `callout_reset_sbt_on`. Read the first 50 lines. Can you describe what it does in two sentences?
6. Use `dttrace` to confirm that the heartbeat fires at the expected rate. With `heartbeat_interval_ms=200`, the rate should be 5 firings per second.
7. Modify the watchdog to log additional information (e.g., how many callbacks have fired since boot). Verify the new field appears in `dmesg`.
8. Open `/usr/src/sys/dev/led/led.c`. Find the calls to `callout_init_mtx`, `callout_reset`, and `callout_drain`. Compare to the patterns in this chapter. Are there differences?

If all eight hands-on questions pass and the conceptual questions are easy, your Chapter 13 work is solid. You are ready for Chapter 14.

A note on pacing: Part 3 of this book has been dense. Three chapters (11, 12, 13) on synchronization-related topics is a lot of new vocabulary to absorb. If the labs in this chapter felt easy, that is a good sign. If they felt hard, take a day or two before starting Chapter 14; the material will compound nicely after a short break, and starting Chapter 14 with fresh attention is better than pushing through tired.

A note on testing: the regression script in Section 8 covers the basic functionality. For long-term confidence, run the composite stress kit from Chapter 12 with all three Chapter 13 callouts active, on a `WITNESS` kernel, for at least 30 minutes. A clean run is the bar to clear before declaring the driver production-ready. Anything less risks the unload race or a subtle lock-order issue that the basic regression does not catch.

If the stress run finds problems, the troubleshooting reference earlier in this chapter is the first stop. Most issues fall into one of the symptom patterns there. If the symptom does not match anything in the reference, the next step is the in-kernel debugger; the DDB recipes in the troubleshooting section get you started.

When you have a clean stress run and a clean review, the chapter's work is done. The driver is now stage-4 final, version 0.7-timers, with a documented callout discipline and a regression suite that proves the discipline holds under load. Take a moment to appreciate that. Then proceed.

13.24 Reference: Callouts in Real FreeBSD Drivers

A short tour of how `callout(9)` is used in actual FreeBSD source. The patterns you have learned in this chapter map directly onto the patterns these drivers use.

13.24.1 `/usr/src/sys/dev/led/led.c`

A simple but instructive example. The `led(4)` driver lets user-space scripts blink LEDs on hardware that supports them. The driver schedules a callout every `hz / 10` (100 ms) to step through the blink pattern.

The key call inside `led_timeout` and `led_state` is:

```
callout_reset(&led_ch, hz / 10, led_timeout, p);
```

The callout is initialized in `led_drvinit`:

```
callout_init_mtx(&led_ch, &led_mtx, 0);
```

A periodic callout, lock-aware via the driver's mutex. Exactly the pattern this chapter teaches.

13.24.2 `/usr/src/sys/dev/uart/uart_core.c`

The serial-port (UART) driver uses a callout in some configurations to poll for input on hardware that does not interrupt for character receipt. The pattern is the same: `callout_init_mtx`, periodic callback, drain at detach.

13.24.3 Network Driver Watchdogs

Most network drivers (`ixgbe`, `em`, `mlx5`, etc.) install a watchdog callout at attach time. The watchdog fires every few seconds; it checks whether the hardware has produced an interrupt recently and resets the chip if not. The callback is short, lock-aware, and deferred to the rest of the driver if it needs to do something complex (typically by enqueueing a task on a taskqueue).

13.24.4 Storage Driver I/O Timeouts

ATA, NVMe, and SCSI drivers use callouts as I/O timeouts. When a request is sent to the hardware, the driver schedules a callout for some bounded time in the future. If the request completes normally, the driver cancels the callout. If the callout fires, the driver assumes the request is stuck and takes recovery action (reset the channel, retry, fail the request to the user).

This is the watchdog pattern (Section 7) applied to per-request operations rather than to the device as a whole.

13.24.5 USB Hub Polling

The USB hub driver polls hub status every few hundred milliseconds (configurable). The poll discovers attached/detached devices, port-status changes, and transfer completions that the hub does not interrupt for. The pattern is the polling-loop pattern (Section 7).

13.24.6 What These Drivers Do Differently

The drivers above use additional primitives beyond what Chapter 13 covers, especially taskqueues. Many of them schedule a callout that, instead of doing the actual work, enqueues a task on a taskqueue. The task runs in process context and may sleep. Chapter 16 introduces this pattern in depth.

For Chapter 13 we keep all the work inside the callout's callback, lock-aware and non-sleeping. Real drivers extend this pattern by deferring long work; the underlying timing infrastructure (callout) is the same.

13.25 Reference: Comparing callout to Other Time Primitives

A more detailed comparison than the decision table earlier in the chapter.

13.25.1 `callout(9)` vs `cv_timedwait_sig`

The same primitive at the syscall layer is `cv_timedwait_sig` (Chapter 12): “wait until condition X becomes true, but give up after T milliseconds”. The caller is the one waiting; the cv is the one that gets signalled.

Compare to `callout(9)`: a callback runs at time T, regardless of whether anyone is waiting for it. The callback is the one acting; it does its own work, possibly signalling other things.

The two differ in *who waits* and *who acts*. In `cv_timedwait_sig`, the syscall thread is both waiter and (after wakeup) actor. In `callout(9)`, the syscall thread is uninvolved; an independent context fires the callback.

Use `cv_timedwait_sig` when the syscall thread has work to do as soon as the wait completes. Use `callout(9)` when something independent must happen at a deadline.

13.25.2 `callout(9)` vs `taskqueue(9)`

`taskqueue(9)` runs a function “as soon as possible” by enqueueing it on a worker thread. There is no time delay; the work runs as soon as the worker can pick it up.

Compare to `callout(9)`: the function runs at a specific time in the future.

A common pattern is to combine the two: a callout fires at time *T*, decides that work is needed, and enqueues a task. The task runs in process context and does the actual work (which may include sleeping). Chapter 16 will cover this combination.

13.25.3 `callout(9)` vs Kernel Threads

A kernel thread can loop and call `cv_timedwait_sig` to produce periodic behaviour. The thread is heavyweight: 16 KB of stack, scheduler entry, priority assignment.

Compare to `callout(9)`: no thread; the kernel's timer interrupt mechanism handles the firing, and a small callout-processing pool runs the callbacks.

Use a kernel thread when the work is genuinely long-running (the worker thread waits, does substantial work, waits again). Use a callout when the work is short and you just need it to fire on a schedule.

13.25.4 `callout(9)` vs Periodic `SIGALRM` in User Space

A user-space process can install a `SIGALRM` handler and use `alarm(2)` for periodic behaviour. The signal handler runs in the process; it is short and constrained.

Compare to `callout(9)`: kernel-side, lock-aware, integrated with the rest of the driver.

User-space alarms are appropriate for user-space code. They have no role in driver work; the kernel does its own thing.

13.25.5 `callout(9)` vs Hardware Timers

Some hardware has its own timer registers (a “GP timer” or “watchdog timer” that the host driver programs). These hardware timers fire interrupts directly to the host. They are fast, precise, and bypass the kernel's callout subsystem.

Use the hardware timer when: - The hardware provides one and you have an interrupt handler. - The precision required exceeds what `callout_reset_sbt` can deliver.

Use `callout(9)` when: - The hardware does not have a usable timer for your purpose. - The precision the kernel can deliver (down to `tick_sbt` or sub-tick with `_sbt`) is sufficient.

For our pseudo-device, no hardware exists; `callout(9)` is the right and only choice.

13.26 Reference: Common Callout Vocabulary

A glossary of terms used in the chapter, useful when you encounter them in driver source.

Callout: an instance of `struct callout`; a scheduled-or-unscheduled timer.

Wheel: the kernel's per-CPU array of callout buckets, organized by deadline.

Bucket: one element of the wheel, holding a list of callouts that should fire in a small range of time.

Pending: state in which the callout is on the wheel waiting to fire.

Active: a user-managed bit indicating “I scheduled this callout and have not actively cancelled it”; not the same as pending.

Firing: state in which the callout’s callback is currently executing.

Idle: state in which the callout is initialized but not pending; either never scheduled or has fired and not re-armed.

Drain: the operation of waiting for an in-flight callback to complete (typically in detach); `callout_drain`.

Stop: the operation of cancelling a pending callout without waiting; `callout_stop`.

Direct execution: an optimization where the callback runs in the timer interrupt context itself, set with `C_DIRECT_EXEC`.

Migration: the kernel’s relocation of a callout to a different CPU (typically because the originally-bound CPU is offline).

Lock-aware: a callout initialized with one of the lock variants (`callout_init_mtx`, `_rw`, or `_rm`); the kernel acquires the lock for each firing.

Mpsafe: a legacy term for “may be called without acquiring Giant”; in modern use it appears as the `mpsafe` argument to `callout_init`.

Re-arm: the action a callback takes to schedule the next firing of the same callout.

13.27 Reference: Timer Anti-Patterns to Avoid

A short catalogue of patterns that look reasonable but are wrong.

Anti-pattern 1: Polling in a tight loop. Some drivers, especially ones written by beginners, busy-wait on a hardware register: `while (!(read_reg() & READY)) ; /* keep checking */`. This burns CPU and produces a system that is unresponsive under load. The callout-based polling pattern is the cure: schedule a callback that checks the register and re-arms.

Anti-pattern 2: Hard-coded intervals. A driver that hard-codes “wait 100 ms” everywhere is a driver that is hard to tune. Make the interval a `sysctl` or a `softc` field that the user can adjust.

Anti-pattern 3: Missing drain at detach. The most common Chapter 13 mistake. The unload race crashes the kernel. Always drain.

Anti-pattern 4: Sleeping in the callback. The callback runs with a non-sleepable lock held; sleeping is forbidden. If the work needs to sleep, defer to a kernel thread or taskqueue.

Anti-pattern 5: Using `callout_init` (the legacy variant) for new code. The lock-naive variant requires you to do all your own locking inside the callback, which is more error-prone than letting the kernel do it. Use `callout_init_mtx` for new code.

Anti-pattern 6: Sharing a `struct callout` between multiple callbacks. A `struct callout` is not a queue. If you need to fire two different callbacks, use two `struct callouts`.

Anti-pattern 7: Calling `callout_drain` while holding the callout’s lock. Causes a deadlock. Drop the lock first.

Anti-pattern 8: Setting the same lock as multiple unrelated subsystems' callout interlocks. The serialization can produce surprising lock contention. Each subsystem should generally have its own lock; share only when the work is genuinely related.

Anti-pattern 9: Re-using a struct callout after callout_drain without re-initializing. After drain, the callout's internal state is reset, but the function and argument from the last callout_reset are still there. If you callout_schedule next, you reuse those. This is subtle. For clarity, call callout_init_mtx again before reuse.

Anti-pattern 10: Forgetting that callout_stop does not wait. In normal operation this is correct; in detach it is wrong. Use callout_drain for detach.

These patterns recur often enough to be worth memorizing. A driver that avoids all ten will have a much easier time.

13.28 Reference: Tracing Callouts With dtrace

A short collection of dtrace recipes useful for inspecting callout behaviour. Each is one or two lines; together they cover most diagnostic needs.

13.28.1 Count Firings of a Specific Callback

```
# dtrace -n 'fbt::myfirst_heartbeat:entry { @ = count(); } tick-1sec { printa(@);
↪   trunc(@); }'
```

Per-second count of how many times the heartbeat callback ran. Useful for confirming the configured rate.

13.28.2 Histogram Time Spent In Callback

```
# dtrace -n '
fbt::myfirst_heartbeat:entry { self->ts = timestamp; }
fbt::myfirst_heartbeat:return /self->ts/ {
    @ = quantize(timestamp - self->ts);
    self->ts = 0;
}
tick-30sec { exit(0); }'
```

Distribution of callback durations, in nanoseconds. Useful for spotting unusually slow firings.

13.28.3 Trace All Callout Resets

```
# dtrace -n 'fbt::callout_reset_sbt_on:entry { printf("co=%p, fn=%p, arg=%p", arg0,  
↪ arg3, arg4); }'
```

Every `callout_reset` (and its variants) call. Useful for confirming what code paths are scheduling callouts.

13.28.4 Trace Callout Drains

```
# dtrace -n 'fbt::_callout_stop_safe:entry /arg1 == 1/ { printf("drain co=%p", arg0);  
↪ stack(); }'
```

Every call to the drain path (`flags == CS_DRAIN`). Useful for confirming detach calls drain on every callout.

13.28.5 Per-CPU Callout Activity

```
# dtrace -n 'fbt::callout_process:entry { @[cpu] = count(); } tick-1sec { printa(@);  
↪ trunc(@); }'
```

Per-second count of callout-processing invocations on each CPU. Tells you which CPUs are doing the timer work.

13.28.6 Identify Slow Callouts

```
# dtrace -n '  
fbt::callout_process:entry { self->ts = timestamp; }  
fbt::callout_process:return /self->ts/ {  
    @ = quantize(timestamp - self->ts);  
    self->ts = 0;  
}  
tick-30sec { exit(0); }'
```

Distribution of how long the callout-processing loop takes. Long durations indicate either many callouts firing at the same time or slow individual callbacks.

13.28.7 A Combined Diagnostic Script

For reading per-second:

```
# dtrace -n '
fbt::callout_reset_sbt_on:entry { @resets = count(); }
fbt::_callout_stop_safe:entry /arg1 == 1/ { @drains = count(); }
fbt::myfirst_heartbeat:entry { @hb = count(); }
fbt::myfirst_watchdog:entry { @wd = count(); }
fbt::myfirst_tick_source:entry { @ts = count(); }
tick-1sec {
    printa("resets=%@u drains=%@u hb=%@u wd=%@u ts=%@u\n",
        @resets, @drains, @hb, @wd, @ts);
    trunc(@resets); trunc(@drains);
    trunc(@hb); trunc(@wd); trunc(@ts);
}'
```

A condensed diagnostic line per second. Useful as a sanity check during development.

13.29 Reference: Inspecting Callout State From DDB

When a system hangs and you need to inspect callout state from the debugger, several DDB commands help.

13.29.1 show callout <addr>

If you know a callout's address, this shows its current state: pending or not, scheduled deadline, callback function pointer, argument. Useful when you know which callout to inspect.

13.29.2 show callout_stat

Dumps overall callout statistics: how many are scheduled, how many fired since boot, how many are pending. Useful for system-wide overview.

13.29.3 ps

The standard process listing. Threads inside callout-processing are typically named `clock` or similar. They are usually in `mi_switch` or in the callback being executed.

13.29.4 bt <thread>

Backtrace of a specific thread. If the thread is inside a callout callback, the backtrace shows the call chain: the kernel's callout subsystem at the bottom, the callback at the top. This tells you which callback is running.

13.29.5 show all locks

If a callout's callback is currently executing, the backtrace will show `mtx_lock` (the kernel acquiring the callout's lock). `show all locks` confirms which lock is held and by which thread.

13.29.6 Combined: Inspecting a Hung Callout

```
db> show all locks
... shows myfirst0 mutex held by thread 1234

db> ps
... 1234 is "myfirst_heartbeat" (or similar)

db> bt 1234
... backtrace shows _cv_wait or similar; the callback is sleeping (which it should not!)
```

If you see this, the callback is doing something illegal (sleeping with a non-sleepable lock held). The fix is to remove the sleeping operation from the callback.

13.30 Reference: Comparing Tick-Based and SBT-Based APIs

The two callout APIs (tick-based and sbintime-based) deserve a side-by-side comparison.

13.30.1 Tick-Based API

```
callout_reset(&co, ticks, fn, arg);
callout_schedule(&co, ticks);
```

The delay is in ticks: integer count of clock interrupts. On a 1000 Hz kernel, one tick is one millisecond. Multiply seconds by hz to convert; e.g., $5 * \text{hz}$ for five seconds, $\text{hz} / 10$ for 100 ms.

Pros: simple, well-known, fast (no sbintime arithmetic). Cons: precision limited to one tick (1 ms typical); cannot express sub-tick delays.

Use for: most callout work. Watchdogs at second-level intervals, heartbeats at hundred-millisecond intervals, periodic polling at tens-of-milliseconds intervals.

13.30.2 SBT-Based API

```
callout_reset_sbt(&co, sbt, prec, fn, arg, flags);
callout_schedule_sbt(&co, sbt, prec, flags);
```

The delay is an `sbintime_t`: high-precision binary fixed-point time. Use `SBT_1S`, `SBT_1MS`, `SBT_1US`, `SBT_1NS` constants to construct values.

Pros: sub-tick precision; explicit precision/coalescing argument; explicit flags for absolute vs relative time. Cons: more arithmetic; must understand `sbintime_t`.

Use for: callouts that need sub-millisecond precision (network protocols, hardware controllers with tight timing requirements). Most driver work does not need this.

13.30.3 Conversion Helpers

```
sbintime_t  ticks_to_sbt = tick_sbt * timo_in_ticks;  /* tick_sbt is global */
sbintime_t  ms_to_sbt  = ms_value * SBT_1MS;
sbintime_t  us_to_sbt  = us_value * SBT_1US;
```

The `tick_sbt` global gives you the sbintime equivalent of one tick; multiply by your tick count to convert.

13.31 Reference: Pre-Production Callout Audit

A short audit to perform before promoting a callout-using driver from development to production. Each item is a question; each item should be answerable with confidence.

13.31.1 Callout Inventory

- ☐ Have I listed every callout the driver owns in `LOCKING.md`?
- ☐ For each callout, have I named its callback function?
- ☐ For each callout, have I named the lock it uses (if any)?
- ☐ For each callout, have I documented its lifetime (init in `attach`, drain in `detach`)?
- ☐ For each callout, have I documented its trigger (what causes it to be scheduled)?
- ☐ For each callout, have I documented whether it re-arms (periodic) or fires once (one-shot)?

13.31.2 Initialization

- ☐ Does every callout init use `callout_init_mtx` (or `_rw/_rm`) rather than the bare `callout_init`?
- ☐ Is the init called after the lock it references is initialized?
- ☐ Is the lock kind correct (sleep mutex for sleepable contexts, etc.)?

13.31.3 Scheduling

- ☐ Does every `callout_reset` happen with the appropriate lock held?
- ☐ Is the interval reasonable for the work the callback does?
- ☐ Is the conversion from milliseconds to ticks correct ($(ms * hz + 999) / 1000$ for ceil)?
- ☐ If the callout is periodic, does the callback re-arm only under a documented condition?

13.31.4 Callback Hygiene

- ☐ Does every callback start with `MYFIRST_ASSERT(sc)` (or equivalent)?
- ☐ Does every callback check `is_attached` before doing work?
- ☐ Does every callback exit early if `is_attached == 0`?
- ☐ Does the callback avoid sleeping operations (`uiomove`, `cv_wait`, `mtx_sleep`, `malloc(M_WAITOK)`, `sel-wakeup`)?
- ☐ Is the callback's total work time bounded?

13.31.5 Cancellation

- ☐ Does the `sysctl` handler use `callout_stop` to disable the timer?
- ☐ Does the `sysctl` handler hold the lock when calling `callout_stop` and `callout_reset`?
- ☐ Are there any code paths that can race with the `sysctl` handler?

13.31.6 Detach

- ☐ Does the detach path drop the mutex before calling `callout_drain`?
- ☐ Does the detach path drain every callout?
- ☐ Are the callouts drained in the correct phase (after `is_attached` is cleared)?

13.31.7 Documentation

- ☐ Is every callout documented in `LOCKING.md`?
- ☐ Are the discipline rules (lock-aware, no-sleep, drain-at-detach) documented?
- ☐ Is the callout subsystem mentioned in the `README`?
- ☐ Are there `sysctls` exposed that let users tune the behaviour?

13.31.8 Testing

- ☐ Have I run the regression suite with `WITNESS` enabled?
- ☐ Have I tested detach with all callouts active?
- ☐ Have I run a long-duration stress test?
- ☐ Have I used `dt race` to verify the firing rates match the configured intervals?

A driver that passes this audit is a driver you can trust under load.

13.32 Reference: Standardising Timers Across a Driver

For a driver with several callouts, consistency matters more than cleverness. A short discipline.

13.32.1 One Naming Convention

Pick a convention and follow it. The chapter's convention:

- The callout struct is named `<purpose>_co` (e.g., `heartbeat_co`, `watchdog_co`, `tick_source_co`).
- The callback is named `myfirst_<purpose>` (e.g., `myfirst_heartbeat`, `myfirst_watchdog`, `myfirst_tick_source`).
- The interval sysctl is named `<purpose>_interval_ms` (e.g., `heartbeat_interval_ms`, `watchdog_interval_ms`, `tick_source_interval_ms`).
- The sysctl handler is named `myfirst_sysctl_<purpose>_interval_ms`.

A new maintainer can add a new callout following the convention without thinking about names. Conversely, a code review immediately catches deviations.

13.32.2 One Init/Drain Pattern

Every callout uses the same initialization and drain:

```
/* In attach: */
callout_init_mtx(&sc-><purpose>_co, &sc->mtx, 0);

/* In detach (after dropping the mutex): */
callout_drain(&sc-><purpose>_co);
```

Or, with the macros:

```
MYFIRST_CO_INIT(sc, &sc-><purpose>_co);
MYFIRST_CO_DRAIN(&sc-><purpose>_co);
```

The macros document the pattern in their definition; the call sites are short and uniform.

13.32.3 One Sysctl Handler Pattern

Every interval sysctl handler follows the same structure:

```
static int
myfirst_sysctl_<purpose>_interval_ms(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, old, error;

    old = sc-><purpose>_interval_ms;
    new = old;
    error = sysctl_handle_int(oidp, &new, 0, req);
```

```

    if (error || req->newptr == NULL)
        return (error);
    if (new < 0)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    sc-><purpose>_interval_ms = new;
    if (new > 0 && old == 0) {
        /* enabling */
        callout_reset(&sc-><purpose>_co,
            (new * hz + 999) / 1000,
            myfirst_<purpose>, sc);
    } else if (new == 0 && old > 0) {
        /* disabling */
        callout_stop(&sc-><purpose>_co);
    }
    MYFIRST_UNLOCK(sc);
    return (0);
}

```

The handler's shape is the same for every interval sysctl. A new sysctl is mechanical to add.

13.32.4 One Callback Pattern

Every periodic callback follows the same structure:

```

static void
myfirst_<purpose>(void *arg)
{
    struct myfirst_softc *sc = arg;
    int interval;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    /* ... do the per-firing work ... */

    interval = sc-><purpose>_interval_ms;
    if (interval > 0)
        callout_reset(&sc-><purpose>_co,
            (interval * hz + 999) / 1000,
            myfirst_<purpose>, sc);
}

```

Assert, check `is_attached`, do work, conditionally re-arm. Every callback in the driver has this shape; deviations stand out.

13.32.5 One Documentation Pattern

Every callout is documented in `LOCKING.md` with the same fields:

- Lock used.
- Callback function.
- Behaviour (periodic or one-shot).
- Started by (which code path schedules it).
- Stopped by (which code path stops it).
- Lifetime (init in attach, drain in detach).

A new callout's documentation is mechanical. A code review can verify the documentation against the code.

13.32.6 Why Standardise

Standardisation has costs: a new contributor must learn the conventions; deviations require a special reason. The benefits are larger:

- Reduced cognitive load. A reader who knows the pattern instantly understands every callout.
- Fewer mistakes. The standard pattern handles the common cases (lock acquisition, `is_attached` check, drain) correctly; a deviation is more likely to be wrong.
- Easier review. Reviewers can scan for shape rather than reading every line.
- Easier handoff. A maintainer who has not seen the driver can add a new callout following the existing template.

The cost of standardisation is paid once at design time. The benefits accrue forever. Always worth it.

13.33 Reference: Further Reading on Timers

For readers who want to go deeper:

13.33.1 Manual Pages

- `callout(9)`: the canonical API reference.
- `timeout(9)`: the legacy interface (deprecated; mentioned for historical reading).
- `microtime(9)`, `getmicrouptime(9)`, `getsbinuptime(9)`: time-reading primitives that callouts often use.
- `eventtimers(4)`: the event-timer subsystem that drives callouts.
- `kern.eventtimer`: the sysctl tree that exposes event-timer state.

13.33.2 Source Files

- `/usr/src/sys/kern/kern_timeout.c`: the callout implementation.
- `/usr/src/sys/kern/kern_clocksource.c`: the event-timer driver layer.
- `/usr/src/sys/sys/callout.h`, `/usr/src/sys/sys/_callout.h`: the public API and structure.
- `/usr/src/sys/sys/time.h`: the sbintime constants and conversion macros.
- `/usr/src/sys/dev/led/led.c`: a small driver that exemplifies the callout pattern.
- `/usr/src/sys/dev/uart/uart_core.c`: a more elaborate use, including a polling fallback for hardware that does not interrupt for input.

13.33.3 Manual Pages To Read in Order

For a reader new to FreeBSD's time subsystem, a sensible reading order:

1. `callout(9)`: the canonical API reference.
2. `time(9)`: units and primitives.
3. `eventtimers(4)`: the event-timer subsystem that drives callouts.
4. `kern.eventtimer` and `kern.hz sysctls`: runtime controls.
5. `microuptime(9)`, `getmicrouptime(9)`: time-reading primitives.
6. `kproc(9)`, `kthread(9)`: for when you genuinely need a kernel thread.

Each builds on the previous; reading in order takes a couple of hours and gives you a solid mental model of the kernel's time infrastructure.

13.33.4 External Material

The chapter on timers in *The Design and Implementation of the FreeBSD Operating System* (McKusick et al.) covers the historical evolution of timer subsystems and the reasoning behind the current design. Useful as context; not required.

The FreeBSD developers' mailing list (`freebsd-hackers@`) occasionally discusses callout improvements and edge cases. Searching the archive for "callout" returns relevant historical context for how the API has evolved.

For deeper understanding of how the kernel schedules events at the lowest level, the `eventtimers(4)` manual page and the source under `/usr/src/sys/kern/kern_clocksource.c` are worth a careful read. They are below the level of this chapter (we do not interact with event timers directly), but they explain why the callout subsystem can deliver the precision it does.

Finally, real driver source. Pick any driver in `/usr/src/sys/dev/` that uses callouts (most do), read its callout-related code, and compare it to the patterns in this chapter. The translation is direct; you will recognize the shapes immediately. That kind of reading turns the chapter's abstractions into working knowledge.

13.34 Reference: Callout Cost Analysis

A short discussion of what callouts actually cost, useful when deciding intervals or designing a high-frequency timer.

13.34.1 Cost At Rest

A `struct callout` that has not been scheduled costs nothing beyond the size of the structure (about 80 bytes on amd64). The kernel does not know about it. It sits in your softc, doing nothing.

A `struct callout` that has been scheduled but not yet fired costs slightly more: the kernel has linked it into a wheel bucket. The link entries cost a few bytes. The kernel does not poll the structure; it only looks at it when the relevant bucket comes due.

The hardware-clock interrupt (which drives the wheel) fires `hz` times per second (typically 1000). It is essentially zero-cost in the empty case (no callouts due) and proportional to the number of due callouts in the busy case.

13.34.2 Cost Per Firing

When a callout fires, the kernel does roughly:

1. Walk the wheel bucket; find the callout. Constant time per callout in the bucket.
2. Acquire the callout's lock (if any). Cost depends on contention; typically nanoseconds.
3. Call the callback function. Cost depends on the callback.
4. Release the lock. Microseconds.

For a typical short callback (a few microseconds of work), the per-firing cost is dominated by the callback itself plus the lock acquisition. The kernel's overhead is negligible.

13.34.3 Cost At Cancel/Drain

`callout_stop` is fast: linked-list removal plus an atomic flag update. Microseconds.

`callout_drain` is fast if the callout is idle (just like `callout_stop`). If the callback is currently firing, the drain waits via the sleep-queue mechanism; the wait time depends on how long the callback takes.

13.34.4 Practical Implications

Hundreds of pending callouts: no problem. The wheel handles them efficiently.

Thousands of pending callouts: still no problem in normal operation. Walking a wheel bucket of dozens of callouts is fast.

A single callout that fires at 1 Hz: essentially free. One hardware interrupt out of a thousand walks the bucket and finds the callout.

A single callout that fires at 1 kHz: starts to be measurable. One thousand callbacks per second adds up. If the callback takes 10 microseconds, that is 1% of one CPU. If the callback is heavier, more.

A callout at 10 kHz or faster: probably the wrong design. Reach for a busy-poll or a hardware timer or a specialised mechanism.

13.34.5 Comparison To Other Approaches

A kernel thread that loops on `cv_timedwait` and does work each wake costs:

- Memory: ~16 KB stack.
- Per wake: scheduler entry, context switch, callback, context switch back.

For a 1 Hz workload, the kernel-thread cost (one wake per second) is about the same as the callout cost. For a 1 kHz workload, both are similar. For a 10 kHz workload, both are getting expensive; consider whether you really need that frequency.

A user-space loop polling a `sysctl`:

- Memory: a whole user process (megabytes).
- Per poll: syscall round-trip, `sysctl` handler invocation, return to user space.

Always more expensive than a kernel callout. Only appropriate when the polling logic genuinely belongs in user space (a monitoring tool, an external probe).

13.34.6 When To Worry About Cost

Most drivers do not have to. Callouts are cheap; the kernel is well-tuned. Worry about cost only when:

- Profiling shows callouts dominate CPU usage. (Use `dtrace` to confirm.)
- You are writing a high-frequency driver (network or storage with tight latency requirements).
- The system has thousands of callouts active and you want to understand the load.

In all other cases, write the callout naturally and trust the kernel to handle the load.

13.35 Looking Ahead: Bridge to Chapter 14

Chapter 14 is titled *Taskqueues and Deferred Work*. Its scope is the kernel's deferred-work framework as seen from a driver: how to move work out of a context that cannot safely run it (a callout callback, an interrupt handler, an epoch section) and into a context that can.

Chapter 13 prepared the ground in three specific ways.

First, you already know that callout callbacks run under a strict context contract: no sleeping, no sleepable-lock acquisition, no `uiomove`, no `copyin`, no `copyout`, and no `selwakeup` with a driver mutex held. You saw that contract enforced at the line in `myfirst_tick_source` where `selwakeup` was deliberately omitted because the callout context could not legally make the call. Chapter 14 introduces `taskqueue(9)`, which is the primitive the kernel offers for exactly this kind of hand-off: the callout enqueues a task, and the task runs in thread context where the omitted call is legal.

Second, you already know the drain-at-detach discipline. `callout_drain` ensures no callback is running when detach proceeds. Tasks have a matching primitive: `taskqueue_drain` waits until a specific task is neither pending nor running. The mental model is the same; the ordering grows by one step (callouts first, tasks second, then everything they affect).

Third, you already know the shape of `LOCKING.md` as a living document. Chapter 14 extends it with a Tasks section that names every task, its callback, its lifetime, and its place in the detach order. The discipline is the same; the vocabulary is a little wider.

Specific topics Chapter 14 will cover:

- The `taskqueue(9)` API: `struct task`, `TASK_INIT`, `taskqueue_create`, `taskqueue_start_threads`, `taskqueue_enqueue`, `taskqueue_drain`, `taskqueue_free`.
- The predefined system taskqueues (`taskqueue_thread`, `taskqueue_swi`, `taskqueue_fast`, `taskqueue_bus`) and when a private taskqueue is preferable.
- The coalescing rule: what happens when a task is enqueued while it is already pending.
- `struct timeout_task` and `taskqueue_enqueue_timeout` for deferred-and-scheduled work.
- Patterns that recur in real FreeBSD drivers, and the debugging story for when they go wrong.

You do not need to read ahead. Chapter 13 is sufficient preparation. Bring your `myfirst` driver (Stage 4 of Chapter 13), your test kit, and your WITNESS-enabled kernel. Chapter 14 starts where Chapter 13 ended.

A small closing reflection. You started this chapter with a driver that could not act on its own: every line of work was triggered by something the user did. You leave with a driver that has internal time, that periodically logs its state, that detects stalled drainage, that injects synthetic events for testing, and that tears down all of that infrastructure cleanly when the module is unloaded. That is a real qualitative leap, and the patterns transfer directly to every kind of driver Part 4 will introduce.

Take a moment. The driver you started Part 3 with knew how to handle one thread at a time. The driver you have now coordinates many threads, supports configurable timed work, and tears down without a race. From here, Chapter 14 adds the *task*, which is the missing piece for any driver whose timer callbacks need to trigger work that callouts cannot safely perform. Then turn the page.

13.35.1 A Final Aside on Time

One last thought before Chapter 14. You have spent two chapters on synchronization (Chapter 12) and one chapter on time (Chapter 13). The two are deeply related: synchronization is, at its core, about *when* events happen relative to each other, and time is the explicit measure of that. Locks serialize accesses; cvs coordinate waits; callouts fire at deadlines. All three are different ways of slicing the same underlying question: how do independent execution streams agree on order?

Chapter 14 adds a fourth piece: *context*. A callout fires at a precise moment, but the context in which it fires (no sleeping, no sleepable locks, no user-space copy) is narrower than what most real work needs. Deferred work via `taskqueue(9)` is the bridge from that narrow context into a thread context where the full set of kernel operations is legal.

The patterns transfer. The lock-aware initialization that callouts use for their callbacks is the same shape you will apply when deciding which lock a task callback acquires. The drain pattern that callouts use at detach is the same shape that tasks use at teardown. The “do little here, defer the rest” discipline that callouts demand is the discipline that Chapter 14 gives you a concrete tool to follow.

So when you reach Chapter 14, the framework will already be familiar. You will be adding one more primitive to your driver’s toolkit. Its rules compose cleanly with the callout rules you now know. The tools you have built (`LOCKING.md`, the seven-phase detach, the assert-and-check-attached pattern) will absorb the new primitive without growing brittle.

That is what makes Part 3 of this book work as a unit. Each chapter adds one more dimension to the driver's awareness of the world (concurrency, synchronization, time, deferred work), and each builds on the previous chapter's infrastructure. By the end of Part 3, your driver will be ready for Part 4 and the real hardware that lies beyond.

14 Taskqueues and Deferred Work

14.1 Reader Guidance & Outcomes

At the end of Chapter 13 your `myfirst` driver gained a small but real sense of internal time. It could schedule periodic work with `callout(9)`, emit a heartbeat, notice stalled drainage with a watchdog, and inject synthetic bytes with a tick source. Every callback obeyed a strict discipline: acquire the registered mutex, check `is_attached`, do short bounded work, maybe re-arm, release the mutex. That discipline is what made the timers safe. It is also what made them narrow.

Chapter 14 confronts the narrowness directly. A callout callback runs in a context that cannot sleep. It cannot call `uiomove(9)`, it cannot call `copyin(9)`, it cannot acquire a sleepable `sx(9)` lock, it cannot allocate memory with `M_WAITOK`, it cannot call `selwakeup(9)` while the sleep mutex is held. If the work a timer wants to trigger needs any of those, the timer has to hand the work off. The same limitation applies to the interrupt handlers you will meet in Part 4, and to several other constrained contexts that appear throughout the kernel. The kernel exposes a single primitive for the hand-off: `taskqueue(9)`.

A taskqueue is, at its simplest, a queue of small work items paired with one or more kernel threads that consume the queue. Your constrained context enqueues a task; the taskqueue's thread wakes up and runs the task's callback in process context, where the ordinary kernel rules apply. The task can sleep, it can allocate freely, it can touch sleepable locks. The taskqueue subsystem also knows how to coalesce bursts of enqueues, cancel pending work, wait for in-flight work at teardown, and schedule a task for a specific future moment. All of that fits on a small API surface, and all of it is exactly what a callout-using or interrupt-using driver needs.

This chapter teaches `taskqueue(9)` with the same care Chapter 13 gave to `callout(9)`. We begin with the shape of the problem, walk through the API, then evolve the `myfirst` driver through four stages that add task-based deferral to the existing timer infrastructure. By the end the driver will use a private taskqueue to move every piece of work that cannot run in a callout or interrupt context out of those contexts, and it will tear the taskqueue down at detach without leaking a stale task, waking a dead thread, or corrupting anything.

14.1.1 Why This Chapter Earns Its Own Place

You could pretend taskqueues do not exist. Instead of enqueueing a task, your callout could try to do the deferred work inline, accept the consequences of panicking the kernel the first time `WITNESS` notices a sleep with a spin lock held, and hope nobody ever loads your driver on a debug kernel. That is not a real option, and we will not humor it. The purpose of this chapter is to give you the honest alternative, the one the rest of the kernel actually uses.

You could also roll your own deferred-work framework with `kproc_create(9)` and a custom condition variable. That is technically possible and occasionally unavoidable, but it is almost always the wrong first choice. A custom thread is a weightier resource than a task, and it misses the observability that comes for free when you

use the shared framework. `ps(1)`, `procstat(1)`, `dtrace(1)`, `ktr(4)`, `wchan` traces, and `ddb(4)` all understand taskqueue threads. They do not understand your one-off helper unless you instrument it yourself.

Taskqueues are the right answer in almost every case where a driver needs to move work out of a constrained context. The cost of not knowing them is higher than the cost of learning them, and the cost of learning them is modest: the API is smaller than `callout(9)`'s, the rules are regular, and the idioms transfer directly across drivers. Once the mental model clicks, you will start recognising the pattern in nearly every driver under `/usr/src/sys/dev/`.

14.1.2 Where Chapter 13 Left the Driver

A quick checkpoint before we go further. Chapter 14 extends the driver produced at the end of Chapter 13 Stage 4, not any earlier stage. If any of the items below feels uncertain, return to Chapter 13 before starting this chapter.

- Your `myfirst` driver compiles cleanly and identifies itself as version `0.7-timers`.
- It has three callouts declared in the `softc`: `heartbeat_co`, `watchdog_co`, and `tick_source_co`.
- Each callout is initialised with `callout_init_mtx(&co, &sc->mtx, 0)` in `myfirst_attach` and drained with `callout_drain` in `myfirst_detach` after `is_attached` has been cleared.
- Each callout has an interval `sysctl` (`heartbeat_interval_ms`, `watchdog_interval_ms`, `tick_source_interval_ms`) that defaults to zero (disabled) and reflects the enable/disable transitions in its handler.
- The detach path runs in the documented order: refuse on `active_fhs`, clear `is_attached`, broadcast both `cvs`, drain `selinfo`, drain all callouts, destroy devices, free `sysctls`, destroy `cbuf` and counters and `cvs` and the `sx` and the mutex.
- Your `LOCKING.md` has a Callouts section that names each callout, its callback, its lock, and its lifetime.
- The Chapter 13 stress kit (Chapter 12 testers plus the Chapter 13 timer exercisers) builds and runs cleanly with `WITNESS` and `INVARIANTS` enabled.

That driver is the shape we extend. Chapter 14 does not rework any of those structures. It adds a new column to the `softc`, a new initialisation call, a new teardown call, and small changes to the three callout callbacks and one or two other places where the driver would benefit from moving work out of a constrained context.

14.1.3 What You Will Learn

By the end of this chapter you will be able to:

- Explain why some work cannot be done inside a callout callback or an interrupt handler, and recognise the operations that force a hand-off to a different context.
- Describe the three things a taskqueue is: a queue of `struct task`, a thread (or small pool of threads) that consumes the queue, and an enqueue/dispatch policy that ties the two together.
- Initialise a task with `TASK_INIT(&sc->foo_task, 0, myfirst_foo_task, sc)`, understand what each argument means, and place the call in the correct stage of attach.
- Enqueue a task with `taskqueue_enqueue(tq, &sc->foo_task)` from a callout callback, from a `sysctl` handler, from a read or write path, or from any other driver code where deferral is the right answer.
- Choose between the predefined system taskqueues (`taskqueue_thread`, `taskqueue_swi`, `taskqueue_swi_giant`, `taskqueue_fast`, `taskqueue_bus`) and a private taskqueue you create with `taskqueue_create` and populate with `taskqueue_start_threads`.

- Understand the coalescing contract: when a task is enqueued while it is already pending, the kernel increments `ta_pending` instead of linking it twice, and the callback is handed the final pending count so it can batch.
- Use the struct `timeout_task` variant with `taskqueue_enqueue_timeout` to schedule a task for a specific future moment, and drain it correctly with `taskqueue_drain_timeout`.
- Block and unblock a taskqueue around delicate shutdown steps, and quiesce a taskqueue when you need a guarantee that no task is currently running anywhere in the queue.
- Drain every task a driver owns at detach, in the right order, without deadlocking against the callouts and cvs you already drain.
- Separate the concerns of timer code and task code inside your driver source, so a new reader can tell which work runs in which context just by looking at the file.
- Recognise and apply the network-driver pattern that uses `epoch(9)` and `grouptaskqueues` for lockless read paths, at the level of knowing when to reach for them and when not to.
- Debug a taskqueue-using driver with `procstat -t, ps ax, dtrace -l`, and `ktr(4)`, and interpret what each tool shows you.
- Tag the driver as version `0.8-taskqueues` and document the deferral policy in `LOCKING.md` so that the next person who inherits the driver can read it.

That is a long list. Most items build on each other, so the progression inside the chapter is the natural path.

14.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 14 stays focused.

- **Interrupt handlers as a primary topic.** Part 4 introduces `bus_setup_intr(9)` and the split between `FILTER` and `ITHREAD` handlers. Chapter 14 mentions interrupt context when it explains why deferred work matters, and the patterns it teaches transfer directly from callouts to real interrupt handlers, but the interrupt API itself is Part 4's job.
- **The full condition-variable and semaphore story.** Chapter 15 extends the synchronisation vocabulary with counting semaphores, signal-interruptible blocking, and cross-component handshakes that coordinate timers, tasks, and user threads. Chapter 14 uses the existing `cv` infrastructure as-is and does not add new synchronisation primitives beyond what taskqueues themselves bring.
- **Deep coverage of grouptaskqueues and iflib.** The `taskqgroup` family exists and this chapter explains when it is the right answer, but the complete story belongs to the network drivers in Part 6 (Chapter 28). The introduction here is intentionally light.
- **Hardware-driven DMA completion paths.** A taskqueue is the natural place to finish a DMA transfer after the hardware signalled completion via an interrupt, and we mention that pattern, but the mechanics of DMA buffer management wait until the bus-space and DMA chapters.
- **Workloops, kthreads for per-CPU polling, and the advanced scheduler hooks.** These are real parts of the kernel's deferred-work landscape, but they are specialised, and a driver hits them rarely. When they matter, the chapters that need them introduce them.

Staying inside those lines keeps the chapter's mental model coherent. Chapter 14 gives you one good tool, taught carefully. Later chapters give you the neighbouring tools and the real hardware contexts that justify using them.

14.1.5 Estimated Time Investment

- **Reading only:** about three hours. The API surface is smaller than `callout(9)`'s, but the interaction between a taskqueue and the rest of the driver's locking story takes a little time to settle.
- **Reading plus typing the worked examples:** six to eight hours over two sessions. The driver evolves in four stages; each stage changes roughly one concern.
- **Reading plus all labs and challenges:** ten to fourteen hours over three or four sessions, including the time needed to observe taskqueue threads under load with `procstat`, `dtrace`, and a stress workload.

If you find the ordering rules at the start of Section 4 disorienting, that is normal. The detach sequence with callouts, cvs, sel handlers, and now tasks has four pieces that must compose. We will walk through the order once, state it, justify it, and reuse it.

14.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 13 Stage 4 (`stage4-final`). The starting point assumes the three callouts, the three interval sysctls, the `is_attached` discipline in every callback, and the documented detach order.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel. Several of the source references in this chapter are things you should actually open and read.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- Chapter 13 feels comfortable. The lock-aware callout, the `is_attached` discipline in callbacks, and the detach ordering are assumed knowledge here.
- You have run the Chapter 13 stress kit at least once with every timer enabled and seen it pass cleanly.

If any of the above is shaky, fixing it now is a better investment than pushing through Chapter 14 and trying to debug from a moving foundation. The Chapter 14 patterns are specifically designed to compose with the Chapter 13 patterns; starting from a Chapter 13 driver that is not quite right makes every Chapter 14 step harder.

14.1.7 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep `/usr/src/sys/kern/subr_taskqueue.c` and `/usr/src/sys/sys/taskqueue.h` bookmarked. The header is short, about two hundred lines, and it is the canonical summary of the API. The implementation file is about a thousand lines, well commented, and reading `taskqueue_run_locked` carefully pays for itself the first time you have to reason about what a task's pending count actually means. Ten minutes with the header now buys ten hours of confidence later.

Second, run every code change under `WITNESS`. The taskqueue subsystem has its own lock (a spin mutex or a sleep mutex, depending on whether the queue was created with `taskqueue_create` or `taskqueue_create_fast`), and it interacts with your driver's locks in ways that `WITNESS` understands. A misplaced lock acquisition inside a task callback is exactly the kind of bug `WITNESS` catches instantly on

a debug kernel and corrupts silently on a production kernel. Do not run Chapter 14 code on the production kernel until it passes the debug kernel.

Third, type the changes by hand. The companion source under `examples/part-03/ch14-taskqueues-and-deferred-work/` is the canonical version, but muscle memory is worth more than reading. The chapter introduces small incremental edits; mirror that small-step rhythm in your own copy of the driver. When the test environment passes at one stage, commit that version and move on; when a step breaks, the previous commit is your recovery point.

14.1.8 Roadmap Through the Chapter

The sections in order are:

1. Why use deferred work in a driver. The shape of the problem: what cannot be done in callouts, interrupts, and other constrained contexts; the real-world cases that force the hand-off.
2. Introduction to taskqueue(9). The structures, the API, the predefined queues, and the comparison with callouts.
3. Deferring work from a timer or simulated interrupt. The first refactor, Stage 1: add a single task that a callout enqueues.
4. Taskqueue setup and cleanup. Stage 2: create a private taskqueue, wire the detach sequence, and audit the result against WITNESS.
5. Prioritisation and coalescing of work. Stage 3: use the `ta_pending` coalescing behaviour deliberately for batching, introduce `taskqueue_enqueue_timeout` for scheduled tasks, and discuss priorities.
6. Real-world patterns using taskqueues. A tour of patterns that recur in real FreeBSD drivers, presented as small recipes you can lift into your own code.
7. Debugging taskqueues. The tools, the common mistakes, and a guided break-and-fix on a realistic scenario.
8. Refactoring and versioning. Stage 4: consolidate the driver into a coherent whole, bump the version to `0.8-taskqueues`, and extend `LOCKING.md`.

After the eight main sections, we cover epoch(9), group taskqueues, and per-CPU taskqueues at a light, introductory level, then hands-on labs, challenge exercises, a troubleshooting reference, a wrapping-up section, and a bridge to Chapter 15.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 4, 6, and 8 stand alone and make good single-sitting reads.

14.2 Section 1: Why Use Deferred Work in a Driver?

Chapter 13 ended with a driver whose callouts did every job the callback could safely do. The heartbeat printed a one-line status report. The watchdog recorded a single count and optionally printed a warning. The tick source wrote a single byte to the circular buffer and signalled a condition variable. Each callback took microseconds, held the mutex for those microseconds, and returned. That is the callout contract at its best: small, predictable, lock-aware, and cheap.

Real driver work does not always fit inside that contract. Some tasks want to run at the same pace as the timer that notices the need for them, but they want to do things the timer cannot safely do. Other tasks are triggered

by a different constrained context (an interrupt handler, for example, or a filter routine in the network stack) but have the same “cannot do that here” problem. This section surveys the shape of the problem: what cannot be done in constrained contexts, what kinds of work drivers want to defer, and what options the kernel offers for getting the work to a place where it can actually run.

14.2.1 The Callout Contract, Re-Read

A short re-reading of the callout rule, because the taskqueue story is entirely about the things callouts cannot do.

A `callout(9)` callback runs in one of two modes. The default mode is `dispatch-from-callout-thread`: the kernel’s dedicated callout thread for that CPU wakes up on a hardware-clock boundary, walks the callout wheel, finds the callbacks whose deadlines have arrived, and calls them one by one. The alternative mode, `C_DIRECT_EXEC`, runs the callback directly inside the hardware-clock interrupt handler itself. Your driver rarely picks the alternative; the default is what almost all drivers use.

In both modes the callback runs with the callout’s registered lock held (for the `callout_init_mtx` family) and cannot cross certain context boundaries. It must not sleep. Sleeping means calling any primitive that can deschedule the thread and block for an indefinite period waiting for a condition. `mtx_sleep`, `cv_wait`, `msleep`, `sx_slock`, `malloc(..., M_WAITOK)`, `uiomove`, `copyin`, and `copyout` all sleep on their slow path. `selwakeup(9)` does not sleep per se, but it takes the per-selinfo mutex, which can be the wrong mutex for the context the callout is running in, and standard practice is to call it with no driver mutex held anyway. None of those calls belong inside a callout callback.

Those are hard rules at the kernel level. `INVARIANTS` and `WITNESS` catch many of the violations at runtime. A few of them corrupt the kernel silently, in ways that are hard to debug later. In all cases, a driver that wants the effect of one of those operations must make the call from a context that allows it. That context is the context a taskqueue provides.

The rest of this section expands on the same observation from different angles: what sort of work a driver wants to defer, why the constrained contexts deserve the constraints, and which FreeBSD facilities compete for the job.

14.2.2 Constrained Contexts, Not Just Callouts

The callout is the first constrained context a `myfirst`-style driver meets, but it is not the only one. Several other places in the kernel run code that cannot sleep or cannot do certain kinds of allocation. A driver that wants to take action from any of them faces the same “defer it” decision.

Hardware interrupt filters. When a real device raises an interrupt, the kernel runs a filter routine synchronously on the CPU that took the interrupt. Filters cannot sleep, cannot acquire sleep mutexes, and cannot call most of the kernel’s normal APIs. They are usually split into a tiny filter (read a status register, decide whether the interrupt is ours) that runs in hardware context, plus an associated `ithread` (interrupt thread) that runs the real work in a full thread context. We will meet the precise filter/`ithread` split when Part 4 introduces `bus_setup_intr(9)`, but the structural lesson is clear even now: interrupt filters are another place where work must be handed off somewhere else.

Network packet-input paths. Parts of the `ifnet(9)` reception path run under `epoch(9)` protection, which restricts the kind of lock acquisitions and sleeping operations that are safe. Network drivers frequently enqueue a task when they want to do non-trivial work that belongs in process context.

taskqueue_fast and taskqueue_swi callbacks. Even when you are already inside a task callback, if the task is running on a spin-mutex-backed queue (`taskqueue_fast`) or a software-interrupt queue (`taskqueue_swi`), the same no-sleeping rule applies as for the originating context. Task callbacks on the default `taskqueue_thread` have no such restriction; they run in full thread context and can sleep freely. That distinction matters and we will return to it in Section 2.

epoch(9) read sections. A code path bracketed by `epoch_enter()` and `epoch_exit()` cannot sleep. Network drivers use this pattern heavily to make read paths lock-free; write-side work is deferred to outside the epoch. Chapter 14 covers epoch at an introductory level in the later “Additional topics” part of the chapter.

The common thread across all those contexts is that something about the surrounding environment forbids thread-context operations. The “something” differs (a spin lock, a filter context, an epoch section, a software-interrupt dispatch), but the remedy is the same: enqueue a task to be run later by a thread that is not in the constrained context.

14.2.3 Real-World Reasons to Defer

Short tours of the kinds of work drivers push out of constrained contexts. Recognising the shapes now gives you vocabulary for the patterns Section 6 will develop.

Non-trivial selwakeup(9). `selwakeup` is the kernel’s notify-all-select/poll-waiters call. Traditional wisdom says to call it with no driver mutex held, and never from a context that has a spin lock held. A callout callback holds a mutex; an interrupt filter holds nothing, but is itself in a bad place. Drivers that want to notify pollers from those contexts typically enqueue a task whose only job is to call `selwakeup`.

copyin and copyout following a hardware event. After an interrupt signals that a DMA transfer has completed, the driver may want to copy data to or from a user-space buffer whose address was registered with a previous `ioctl`. Neither `copyin` nor `copyout` is legal in interrupt context. The driver schedules a task whose callback does the copy in process context.

Reconfiguration that requires a sleepable lock. The driver’s configuration is often protected by an `sx(9)` lock, which can sleep. A callout or interrupt cannot acquire a sleepable lock directly. If a timer-driven decision implies a configuration change, the timer enqueues a task; the task acquires the `sx` lock and performs the change.

Retrying a failed operation after a backoff. Hardware operations sometimes fail transiently. The sensible response is to wait some interval and retry. An interrupt handler cannot block; it enqueues a `timeout_task` with a delay equal to the backoff interval. The timeout task fires later in thread context, retries the operation, and if it fails again reschedules itself with a longer delay.

Logging a non-trivial event. Kernel `printf(9)` is surprisingly tolerant of weird contexts, but `log(9)` and its friends are not. A driver that wants to emit a multi-line diagnostic from an interrupt context writes the bare minimum in the handler (a flag, a counter increment) and schedules a task to do the real logging later.

Draining or reconfiguring a long hardware queue. A network driver that detects head-of-line blocking may want to walk its transmit ring, free completed descriptors, and reset per-descriptor state. The work is bounded but nontrivial. Doing it inline in the interrupt path monopolises a CPU in a bad context. Doing it in a task lets the interrupt return immediately and the real work happen on a thread.

Deferred teardown. When a driver detaches while some object still has outstanding references, the driver cannot free the object immediately. A common pattern: defer the free to a task that fires after the reference count is known to be zero, or after a grace period that is long enough for any in-flight references to drain.

All those cases share the structure: the constrained context detects a need, possibly records a small amount of state, and enqueues a task. The task runs later in thread context, does the real work, and optionally re-enqueues itself or schedules a follow-up.

14.2.4 Polling Versus Deferred Execution

A reasonable question at this point: if the constrained context cannot do the work, why not arrange for the work to happen somewhere entirely outside the constrained context? Why not have a single dedicated kernel thread that polls for “anything to do” and wakes up when it sees state that requires action?

That is, in effect, what a taskqueue does. A taskqueue thread sleeps until work is available and wakes up to process it. The difference between “a taskqueue” and “a hand-rolled polling thread” is that the taskqueue framework solves the surrounding logistics for you. Enqueue is a single atomic operation. The task structure holds the callback and context directly, so you do not have to design a “work queue entry” type. Coalescing of redundant enqueues is automatic. Draining a task is a single call. Teardown is a single call. Observability via the standard tools comes for free.

A hand-rolled polling thread can do the same work, and in extreme cases it is the right choice (if, for example, the work has hard real-time constraints, or if it is part of a subsystem that needs a dedicated priority). For ordinary driver work, reaching past `taskqueue(9)` is almost always a mistake.

A separate but related question: why not just spin up a new kernel thread for each deferred operation? That is extremely expensive: creating a thread takes time, allocates a full kernel stack, and hands the new thread to the scheduler. For work that happens repeatedly, the sensible design is to reuse a thread, which is exactly what a taskqueue provides. For work that happens once, you might `kproc_create(9)` and have the new thread exit when done, but even then a taskqueue with `taskqueue_drain` is usually simpler and nearly as cheap.

14.2.5 FreeBSD’s Solutions

The kernel offers a small family of facilities for deferred work. Chapter 14 focuses on one of them (`taskqueue(9)`) and mentions the others at the right level of detail for a driver writer to know when they are appropriate. A short tour now; the sections that follow expand on each one as it becomes relevant.

taskqueue(9). A queue of `struct task` entries and one or more kernel threads (or a software-interrupt context) that consume the queue. The dominant choice for deferred driver work. Covered in depth throughout this chapter.

epoch(9). A lockless read-synchronisation mechanism that network drivers use to allow readers to walk shared data structures without locks. Writers defer cleanup via `epoch_call` or `epoch_wait`. Not a general deferred-work mechanism for arbitrary drivers, but important enough to introduce later in this chapter so that you recognise it when you see it in network-driver code.

Grouptaskqueues. A scalable variation on taskqueues where a group of related tasks share a pool of per-CPU worker threads. Network drivers use this heavily; most other drivers do not. Introduced later in this chapter.

kproc_create(9) / kthread_add(9). Direct creation of a kernel thread. Useful when the deferred work is a long-running loop that does not fit the “short task” shape, and when the work deserves a dedicated priority or CPU affinity. Almost always overkill for simple deferral; a taskqueue is preferred.

Dedicated SWI (software interrupt) handlers via swi_add(9). A way to register a function that runs in a software-interrupt context. The system taskqueues (taskqueue_swi, taskqueue_swi_giant, taskqueue_fast) are built on top of this mechanism. Driver code rarely calls swi_add directly; the taskqueue layer is the right abstraction.

The callout itself, rescheduled for “zero-from-now”. A pattern that does not work: you cannot “escape” the callout context by scheduling another callout, because the next callout still runs in callout context. Recognising that this is a dead end is itself useful. Callouts schedule the moment; taskqueues provide the context.

For the rest of Chapter 14, unless we say otherwise, “defer to a task” or “enqueue a task” means “enqueue a struct task onto a struct taskqueue”.

14.2.6 When Deferral Is the Wrong Answer

Deferral is a tool, not a default. Several situations benefit from doing the work in place rather than deferring it.

The work is genuinely short and safe for the current context. Logging a one-line statistic with `device_printf(9)` from a callout is fine. So is incrementing a counter. So is signalling a cv. Deferring these trivialities to a task costs more than doing them. Only defer when the work actually does not belong in the current context.

Timing matters and the deferral introduces variance. A task does not run instantly. It runs when the taskqueue’s thread is next scheduled, which may be microseconds or milliseconds away depending on system load. If the work has tight timing requirements (acknowledging a hardware event within a deadline, for example), deferral may miss the deadline. For such work you need a faster mechanism (a hardware-level completion, a `C_DIRECT_EXEC` callout, or an SWI) or a different design.

The deferral would add a hop for no benefit. If your interrupt handler’s only work is already safe to do in interrupt context, adding a task round-trip doubles the latency without improving anything. Only defer the parts of the work that need to be deferred.

The work requires a specific thread. If the work needs to run as a specific user process (for example, to use that process’s file-descriptor table), a generic taskqueue thread is the wrong place. That situation is rare in drivers, but it exists.

For everything else, deferral via a taskqueue is the right answer, and the rest of the chapter is about how to do it well.

14.2.7 A Worked Example: Why the Tick Source Cannot Wake Pollers

A concrete example from the Chapter 13 driver, worth slowing down for because it is the first place Chapter 14 makes a real change.

The Chapter 13 `tick_source` callback, from `stage4-final/myfirst.c`, looks like this:

```

static void
myfirst_tick_source(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t put;
    int interval;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    if (cbuf_free(&sc->cb) > 0) {
        put = cbuf_write(&sc->cb, &sc->tick_source_byte, 1);
        if (put > 0) {
            counter_u64_add(sc->bytes_written, put);
            cv_signal(&sc->data_cv);
            /* selwakeup omitted: cannot be called from a
             * callout callback while sc->mtx is held. */
        }
    }
    ...
}

```

That comment at the bottom is not hypothetical. `selwakeup(9)` enters the per-selinfo mutex and may call into the kqueue subsystem, which is not safe to do inside a callout callback that holds a different driver mutex. A `select(2)/poll(2)` user program waiting on `/dev/myfirst` for readability therefore does not get notified when the tick source deposits a byte. The program only wakes when some other path calls `selwakeup`, for example when another thread's `write(2)` arrives.

That is a real bug in the Chapter 13 driver. We left it unfixed in Chapter 13 because fixing it required a primitive we had not yet introduced. Chapter 14 introduces that primitive and fixes the bug.

The fix is small. Add a `struct task` to the `_softc`. Initialise it in `attach`. Instead of omitting `selwakeup` from the `tick_source` callback, enqueue the task; the task runs in thread context, with no driver mutex held, and calls `selwakeup` safely. Drain the task in `detach` after `is_attached` has been cleared, before freeing the selinfo.

We will walk through every step of that change in Section 3. For now the point is that the change is mechanical, and its necessity is not contrived. Chapter 14's first real job is to give you the tool this kind of bug needs.

14.2.8 A Small Mental Model

A useful picture, offered once and referenced later.

Think of your driver as being made of two kinds of code. The first kind is the code that runs because somebody asked for it: the `read(2)` handler, the `write(2)` handler, the `ioctl(2)` handler, the `sysctl` handlers, the `open` and `close` handlers. That code runs in thread context, with ordinary rules, and it can sleep, allocate, and touch any lock. Call it “thread-context code”.

The second kind is the code that runs because time or the hardware said so: a callout callback, an interrupt filter, an epoch-protected read. That code runs in a constrained context, with a narrower set of rules, and it must keep its work short and non-sleeping. Call it “edge-context code”.

Most real work belongs in thread-context code. Most of what edge-context code actually needs to do is: notice the edge, record a tiny amount of state, and hand the work to thread-context code. A taskqueue is the hand-off. The task callback runs in thread-context code, because the taskqueue’s thread is in thread context. Everything the callback does follows the ordinary rules.

This mental model lets you read every subsequent section as variations on a single idea: edge-context code detects, thread-context code acts, and the taskqueue is the seam between them. Once you see the driver that way, the rest of the chapter is engineering details.

14.2.9 Wrapping Up Section 1

Some work must run in a constrained context (callouts, interrupt filters, epoch sections). The rules of those contexts forbid sleeping, heavy allocation, sleepable-lock acquisition, and several other common operations. Drivers with real responsibilities frequently need to do exactly those operations in response to events that arrive in constrained contexts. The remedy is to enqueue a task and let a worker thread do the real work in a context where the rules allow it.

The kernel exposes that pattern as `taskqueue(9)`. The API is small, the idioms are regular, and the tool composes cleanly with the callouts and synchronisation primitives you already know. Section 2 introduces the primitive.

14.3 Section 2: Introduction to `taskqueue(9)`

`taskqueue(9)` is, like most of the kernel’s well-aged subsystems, a small API on top of a careful implementation. The data structures are short, the lifecycle is regular (init, enqueue, run, drain, free), and the rules are explicit enough that you can verify your usage by reading the source. This section walks through the structures, names the API, lists the predefined queues the kernel provides for free, and compares taskqueues with the callouts from Chapter 13 so you can see when each is the right tool.

14.3.1 The Task Structure

The data structure is in `/usr/src/sys/sys/_task.h`:

```
typedef void task_fn_t(void *context, int pending);

struct task {
    STAILQ_ENTRY(task) ta_link;    /* (q) link for queue */
    uint16_t ta_pending;          /* (q) count times queued */
    uint8_t ta_priority;          /* (c) Priority */
    uint8_t ta_flags;             /* (c) Flags */
    task_fn_t *ta_func;           /* (c) task handler */
};
```

```
void      *ta_context;          /* (c) argument for handler */
};
```

The fields split into two groups. The (q) fields are managed by the taskqueue under its own internal lock; driver code does not touch them directly. The (c) fields are const-after-init; driver code sets them once via an initialiser and never modifies them again.

`ta_link` is the list linkage used when the task is enqueued. Unused when the task is idle.

`ta_pending` is the coalescing counter. When the task is first enqueued it goes from zero to one and the task is placed on the list. If it is enqueued again before the callback runs, the counter simply increments and the task stays on the list once. When the callback eventually runs, the final pending count is passed as the second argument to the callback, and the counter is reset to zero. The worst mistake you can make with `ta_pending` is to assume that a task will run *N* times if you enqueue it *N* times; it will not. It will run once and the callback will know it was enqueued *N* times. Section 5 covers the design implications in detail.

`ta_priority` orders tasks inside a single queue. Higher priority tasks run before lower priority tasks. For most drivers the value is zero (ordinary priority) and the queue is effectively FIFO.

`ta_flags` is a small bitfield. The kernel uses it to record whether the task is currently enqueued and, for network tasks, whether the task should be run inside the network epoch. Driver code does not touch it after `TASK_INIT` or `NET_TASK_INIT` has set it.

`ta_func` is the callback function. Its signature is `void (*)(void *context, int pending)`. The first argument is whatever you stored in `ta_context` at init time; the second is the coalescing count.

`ta_context` is the callback's argument. For a device-driver task this is almost always the softc pointer.

The structure is 32 bytes on amd64, plus or minus padding. You embed one per deferred-work pattern into your softc. A driver with three deferral paths has three `struct task` members.

14.3.2 Initialising a Task

The canonical macro is `TASK_INIT`, in `/usr/src/sys/sys/taskqueue.h`:

```
#define TASK_INIT_FLAGS(task, priority, func, context, flags) do {      \
    (task)->ta_pending = 0;                                           \
    (task)->ta_priority = (priority);                                \
    (task)->ta_flags = (flags);                                       \
    (task)->ta_func = (func);                                         \
    (task)->ta_context = (context);                                   \
} while (0)

#define TASK_INIT(t, p, f, c)    TASK_INIT_FLAGS(t, p, f, c, 0)
```

A typical call from a driver's attach routine looks like:

```
TASK_INIT(&sc->selwake_task, 0, myfirst_selwake_task, sc);
```

The arguments read as: “initialise this task, at ordinary priority zero, to run `myfirst_selwake_task(sc, pending)` when it fires”. That is the whole initialisation ritual. There is no corresponding “destroy” call; a task becomes idle again when its callback finishes, and goes out of scope when the surrounding softc is freed.

For network-path tasks there is a variant, `NET_TASK_INIT`, that sets the `TASK_NETWORK` flag so the taskqueue knows to run the callback inside the `net_epoch_preempt` epoch:

```
#define NET_TASK_INIT(t, p, f, c) TASK_INIT_FLAGS(t, p, f, c, TASK_NETWORK)
```

Unless you are writing a network driver, `TASK_INIT` is the one you use. Chapter 14 uses `TASK_INIT` throughout and returns to `NET_TASK_INIT` only in the “Additional topics” section.

14.3.3 The Taskqueue Structure, From a Driver’s Point of View

From a driver’s point of view, a taskqueue is a `struct taskqueue *`. The pointer is either a predefined global (`taskqueue_thread`, `taskqueue_swi`, `taskqueue_bus`, etc.) or one the driver created with `taskqueue_create` and stored in its softc. In both cases the pointer is opaque. All interactions go through API calls. The only internal we care about in the chapter is the fact that the taskqueue holds its own lock, which it acquires on enqueue and when its worker thread pulls tasks off the list.

For completeness, the definition (from `/usr/src/sys/kern/subr_taskqueue.c`):

```
struct taskqueue {
    STAILQ_HEAD(, task)    tq_queue;
    LIST_HEAD(, taskqueue_busy) tq_active;
    struct task            *tq_hint;
    u_int                  tq_seq;
    int                    tq_callouts;
    struct mtx_padalign    tq_mutex;
    taskqueue_enqueue_fn    tq_enqueue;
    void                   *tq_context;
    char                   *tq_name;
    struct thread          **tq_threads;
    int                    tq_tcount;
    int                    tq_spin;
    int                    tq_flags;
    ...
};
```

`tq_queue` is the pending-task list. `tq_active` records which tasks are currently running, which the drain logic uses to wait for completion. `tq_mutex` is the taskqueue’s own lock. `tq_threads` is the array of worker threads, of size `tq_tcount`. `tq_spin` records whether the mutex is a spin mutex (for taskqueues created with

`taskqueue_create_fast`) or a sleep mutex (for taskqueues created with `taskqueue_create`). `tq_flags` records shutdown state.

You do not touch any of those fields from driver code. They are shown here once so that the API calls in the rest of the section have a concrete referent. The rest of the chapter treats the taskqueue as opaque.

14.3.4 The API, One Function at a Time

The public functions are declared in `/usr/src/sys/sys/taskqueue.h`. A driver typically uses fewer than a dozen of them. We walk through the important ones now, grouped by purpose.

Creating and destroying a taskqueue.

```
struct taskqueue *taskqueue_create(const char *name, int mflags,
    taskqueue_enqueue_fn enqueue, void *context);

struct taskqueue *taskqueue_create_fast(const char *name, int mflags,
    taskqueue_enqueue_fn enqueue, void *context);

int taskqueue_start_threads(struct taskqueue **tqp, int count, int pri,
    const char *name, ...);

void taskqueue_free(struct taskqueue *queue);
```

`taskqueue_create` creates a taskqueue that uses a sleep mutex internally. Tasks enqueued on it run in a context where sleeping is legal (assuming they are dispatched via `taskqueue_thread_enqueue` and `taskqueue_start_threads`). This is the right choice for almost every driver taskqueue.

`taskqueue_create_fast` creates a taskqueue that uses a spin mutex internally. Required only if you intend to enqueue from a context where a sleep mutex would be wrong (for example, from inside a spin mutex or a filter interrupt). Driver code rarely needs this; the predefined `taskqueue_fast` exists for the cases that do.

The enqueue callback is called by the taskqueue layer when a task is added to an otherwise-empty queue, and is the way the layer “wakes” a consumer. For queues serviced by kernel threads the enqueue function is `taskqueue_thread_enqueue`, which the kernel provides. For software-interrupt-serviced queues the kernel provides `taskqueue_swi_enqueue`. Driver code almost always passes `taskqueue_thread_enqueue` here.

The context argument is passed back to the enqueue callback. When using `taskqueue_thread_enqueue` the convention is to pass `&your_taskqueue_pointer`, so the function can find the taskqueue it is waking. The Chapter 14 examples follow this convention literally.

`taskqueue_start_threads` creates count kernel threads that run the `taskqueue_thread_loop` dispatcher, each sleeping on the queue until a task arrives. The `pri` argument is the thread’s priority. `PWAIT` (defined in `/usr/src/sys/sys/priority.h`, numerically 76) is the ordinary choice for driver taskqueues; network drivers often pass `PI_NET` (numerically 4) to run at interrupt-adjacent priority. Chapter 14’s worker threads use `PWAIT`.

`taskqueue_free` shuts down the taskqueue. It drains all pending and running tasks, terminates the worker threads, and frees the internal state. It must be called with no tasks pending that have not yet been drained; after it returns, the `struct taskqueue *` is invalid and must not be used.

Initialising a task. TASK_INIT as shown above. There is no counterpart “destroy” because the task structure is caller-owned.

Enqueuing a task.

```
int taskqueue_enqueue(struct taskqueue *queue, struct task *task);
int taskqueue_enqueue_flags(struct taskqueue *queue, struct task *task,
    int flags);
int taskqueue_enqueue_timeout(struct taskqueue *queue,
    struct timeout_task *timeout_task, int ticks);
int taskqueue_enqueue_timeout_sbt(struct taskqueue *queue,
    struct timeout_task *timeout_task, sbintime_t sbt, sbintime_t pr,
    int flags);
```

taskqueue_enqueue is the workhorse. It links the task onto the queue and wakes the worker thread. If the task is already pending, it increments ta_pending and returns. Returns zero on success; rarely fails.

taskqueue_enqueue_flags is the same, with optional flags:

- TASKQUEUE_FAIL_IF_PENDING makes the enqueue return EEXIST instead of coalescing if the task is already pending.
- TASKQUEUE_FAIL_IF_CANCELING makes the enqueue return EAGAIN if the task is currently being cancelled.

The default taskqueue_enqueue silently coalesces; the flag variant lets you detect the situation when that matters.

taskqueue_enqueue_timeout schedules a struct timeout_task to fire after the given number of ticks. Behind the scenes it uses an internal callout whose callback enqueues the underlying task on the taskqueue when the delay elapses. The sbt variant takes sbintime for sub-tick precision.

Cancelling a task.

```
int taskqueue_cancel(struct taskqueue *queue, struct task *task,
    u_int *pendp);
int taskqueue_cancel_timeout(struct taskqueue *queue,
    struct timeout_task *timeout_task, u_int *pendp);
```

taskqueue_cancel removes a pending task from the queue if it has not yet started running, and writes the previous pending count to *pendp if that pointer is non-NULL. If the task is currently running, the function returns EBUSY and does not wait; you must follow up with taskqueue_drain if you need to wait.

taskqueue_cancel_timeout is the same for timeout tasks.

Draining a task.

```
void taskqueue_drain(struct taskqueue *queue, struct task *task);
void taskqueue_drain_timeout(struct taskqueue *queue,
    struct timeout_task *timeout_task);
void taskqueue_drain_all(struct taskqueue *queue);
```

`taskqueue_drain(tq, task)` blocks until the given task is no longer pending and no longer running. If the task was pending, the drain waits for it to run and complete. If the task was running, the drain waits for the current invocation to return. If the task was idle, the drain returns immediately. This is the call you use at detach for every task your driver owns.

`taskqueue_drain_timeout` is the same for timeout tasks.

`taskqueue_drain_all` drains every task and every timeout task in the taskqueue. Useful when you own a private taskqueue and want to be sure it is entirely quiet before freeing it. `taskqueue_free` itself does the equivalent work internally, so `taskqueue_drain_all` is not strictly required before `taskqueue_free`, but it is useful when you want to quiesce a taskqueue without destroying it.

Blocking and unblocking.

```
void taskqueue_block(struct taskqueue *queue);
void taskqueue_unblock(struct taskqueue *queue);
void taskqueue_quiesce(struct taskqueue *queue);
```

`taskqueue_block` stops the queue from running new tasks. Already-running tasks complete; newly enqueued tasks accumulate but do not run until `taskqueue_unblock` is called. The pair is useful for temporarily freezing a queue during a delicate transition without tearing it down.

`taskqueue_quiesce` waits for the currently running task (if any) to finish and for the queue to be empty of pending tasks. Equivalent to “drain everything, but do not destroy”. Safe to call with the queue running.

Membership check.

```
int taskqueue_member(struct taskqueue *queue, struct thread *td);
```

Returns true if the given thread is one of the taskqueue’s worker threads. Useful inside a task callback when you want to branch on “am I running on my own taskqueue”, though the more common idiom is to use `curthread` against a stored thread pointer.

That is the whole API a driver ordinarily uses. A handful of less-common functions exist (`taskqueue_set_callback` for init/shutdown hooks, `taskqueue_poll_is_busy` for polling-style checks) but most drivers never touch them.

14.3.5 The Predefined Taskqueues

The kernel provides a small set of preconfigured taskqueues for drivers that do not need a private one. They are declared in `/usr/src/sys/sys/taskqueue.h` with `TASKQUEUE_DECLARE`, which expands to an extern pointer. A driver uses them by name:

```
TASKQUEUE_DECLARE(thread);
TASKQUEUE_DECLARE(swi);
TASKQUEUE_DECLARE(swi_giant);
TASKQUEUE_DECLARE(fast);
TASKQUEUE_DECLARE(bus);
```

taskqueue_thread is the generic thread-context queue. One kernel thread, priority P`WAIT`. The thread's name shows up in `ps` as `thread taskq`. Safe for any task that wants a full thread context and does not need special properties. The easiest predefined queue to use; a very reasonable first choice if you are not sure which queue you need.

taskqueue_swi is dispatched by a software interrupt handler, not a kernel thread. Tasks on this queue run with no driver mutex held but in SWI context, which still has restrictions (no sleeping). Useful for short non-sleeping work that wants to run promptly after an enqueue without the scheduling latency of waking a kernel thread. Driver use is uncommon.

taskqueue_swi_giant is the same as `taskqueue_swi` but runs with the historical Giant lock held. Essentially never used in new code. Mentioned only for completeness.

taskqueue_fast is a spin-mutex-backed software-interrupt queue, used for tasks that must be enqueueable from contexts where a sleep mutex would be wrong (for example, from inside another spin mutex). The taskqueue itself uses a spin mutex for its internal list, so enqueue is legal from any context. The task callback, however, runs in SWI context, which still has the no-sleeping restriction. Driver use is rare; filter-interrupt contexts that need to enqueue work typically use `taskqueue_fast` or, more commonly today, a private `taskqueue_create_fast` queue.

taskqueue_bus is a dedicated queue for `newbus(9)` device events (hot-plug insertion, removal, child-bus notifications). Ordinary drivers do not enqueue onto this queue.

For a driver like `myfirst`, the realistic choices are `taskqueue_thread` (the shared queue) or a private taskqueue you own and tear down at detach. Section 4 discusses the trade-off; Stage 1 of the refactor uses `taskqueue_thread` for simplicity and Stage 2 moves to a private queue.

14.3.6 Comparing Taskqueues and Callouts

A short side-by-side comparison, because a new reader asks this question first.

Property	<code>callout(9)</code>	<code>taskqueue(9)</code>
Fires at	A specific time	As soon as a worker thread picks it up
Callback context	Callout thread (default) or hardclock IRQ (<code>C_DIRECT_EXEC</code>)	Kernel thread (for <code>taskqueue_thread</code> , private queues) or SWI (for <code>taskqueue_swi</code> , <code>taskqueue_fast</code>)
May sleep	No	Yes, for thread-backed queues; no, for SWI-backed queues
May acquire sleepable locks	No	Yes, for thread-backed queues
May call <code>uiomove</code> , <code>copyin</code> , <code>copyout</code>	No	Yes, for thread-backed queues

Property	<code>callout(9)</code>	<code>taskqueue(9)</code>
Coalesces redundant submissions	No, each reset replaces the previous deadline	Yes, <code>ta_pending</code> increments
Cancellable before firing	<code>callout_stop(co)</code>	<code>taskqueue_cancel(tq, task, &pendp)</code>
Waits for in-flight callback	<code>callout_drain(co)</code>	<code>taskqueue_drain(tq, task)</code>
Periodic	Callback reschedules itself	No; enqueue again from somewhere else, or use a callout to enqueue
Scheduled for the future	<code>callout_reset(co, ticks, ...)</code>	<code>taskqueue_enqueue_timeout(tq, tt, ticks)</code>
Cost per firing	Microseconds	Microseconds plus thread wake (can be larger under load)

The table illustrates the division. A callout is the right primitive when you need to fire at a particular moment and the work is safe for callout context. A taskqueue is the right primitive when you need thread-context work and are willing to accept whatever scheduling latency the taskqueue introduces. Many drivers use both together: a callout fires at the deadline, the callout enqueues a task, the task does the real work in thread context.

14.3.7 Comparing Taskqueues and a Private Kernel Thread

Another comparison the chapter owes you, because a reader asking “why not just make a kernel thread” deserves a straight answer.

A kernel thread created with `kproc_create(9)` is a full-fledged scheduled entity: its own stack (typically 16 KB on amd64), its own priority, its own proc entry, its own state. A driver that wants to run a loop “every second, do X” could create such a thread and have it `kproc_kthread_add` plus `cv_timedwait` its way through the loop. The code works, but it costs more than the job usually deserves. A taskqueue with one thread that sits idle most of the time and wakes on enqueue is cheaper per pending work item and easier to tear down.

There are legitimate cases for `kproc_create`. A long-running subsystem with its own tuning (priority, CPU affinity, process group) is one. A periodic job that genuinely needs a thread of its own for observability is another. A driver’s deferred-work pattern almost never is. Use a taskqueue until a specific requirement forces you to do something else.

14.3.8 The Enqueue-Already-Pending Rule

One rule worth calling out early, because it is the single most common source of surprise for newcomers to the API: a task cannot be pending twice. If you call `taskqueue_enqueue(tq, &sc->t)` while `sc->t` is already pending, the kernel increments `sc->t.ta_pending` and returns success without linking the task a second time.

This has two implications. First, your callback will run once, not twice, even if you enqueued twice. Second, the pending argument the callback receives is the number of times the task was enqueued before the callback got dispatched; your callback may use that count to batch accumulated work.

If you want to run the callback N times for N enqueues, a single task is the wrong model. Use N separate tasks, or enqueue a sentinel into a driver-owned queue and process each sentinel in the callback. Almost always the coalescing behaviour is what you want; Section 5 walks through how to exploit it deliberately.

14.3.9 A Minimal Example, End to End

A hello-world task, for concreteness. If you type this in a scratch module and load it, you will see the `device_printf` line in `dmesg`:

```
#include <sys/param.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/systm.h>
#include <sys/taskqueue.h>

static struct task example_task;

static void
example_task_fn(void *context, int pending)
{
    printf("example_task_fn: pending=%d\n", pending);
}

static int
example_modevent(module_t m, int event, void *arg)
{
    int error = 0;

    switch (event) {
    case MOD_LOAD:
        TASK_INIT(&example_task, 0, example_task_fn, NULL);
        taskqueue_enqueue(taskqueue_thread, &example_task);
        break;
    case MOD_UNLOAD:
        taskqueue_drain(taskqueue_thread, &example_task);
        break;
    default:
        error = EOPNOTSUPP;
        break;
    }
    return (error);
}
```

```
}

static moduledata_t example_mod = {
    "example_task", example_modevent, NULL
};
DECLARE_MODULE(example_task, example_mod, SI_SUB_DRIVERS, SI_ORDER_MIDDLE);
MODULE_VERSION(example_task, 1);
```

The module does five things, each a single line. At load, `TASK_INIT` prepares the task structure. `taskqueue_enqueue` asks the shared `taskqueue_thread` to run the callback. The callback prints a message. At unload, `taskqueue_drain` waits for the callback to finish if it has not already. The whole lifecycle is compact.

If you type this and load it, `dmesg` shows:

```
example_task_fn: pending=1
```

The `pending=1` reflects the fact that the task was enqueued once before the callback fired.

Now try a coalescing demonstration: change `MOD_LOAD` to enqueue the task five times in a row, then add a brief spin so the `taskqueue` thread gets a chance to wake up:

```
for (int i = 0; i < 5; i++)
    taskqueue_enqueue(taskqueue_thread, &example_task);
pause("example", hz / 10);
```

Run it again and `dmesg` shows:

```
example_task_fn: pending=5
```

One invocation, pending of five. That is the coalescing rule, live.

That is enough shape to make the worked refactors in the next sections meaningful. The rest of this chapter scales the same structure up to the real `myfirst` driver, replaces the scratch module with four integration stages, adds the teardown, adds a private `taskqueue`, and walks through the debugging story.

14.3.10 Wrapping Up Section 2

A `struct task` holds a callback and its context. A `struct taskqueue` manages a queue of such tasks and one or more threads (or an SWI context) that consume them. The API is small: create, start threads, enqueue (optionally with a delay), cancel, drain, free, block, unblock, quiesce. The kernel provides a handful of predefined queues that every driver can use without creating its own. The enqueue-already-pending rule folds redundant submissions into a coalesced invocation whose pending count is the final tally.

Section 3 takes those tools to the `myfirst` driver and deposits the first task in the code, under the `tick_source` callout that has been quietly skipping `selwakeup`. The fix is small; the mental model is the important part.

14.4 Section 3: Deferring Work from a Timer or Simulated Interrupt

Chapter 13 left the `myfirst` driver with three callouts that all obeyed the callout contract strictly. None of them tried to do anything that does not belong in a callout callback. The `tick_source` callback in particular omitted the `se wakeup` call that a real driver would want to make when new bytes appear in the buffer, and the file even carried a comment saying so. Chapter 14 removes that omission.

Section 3 is the first worked refactor. It introduces Stage 1 of the Chapter 14 driver: the driver gains one `struct task`, one task callback, an enqueue from `tick_source`, and a drain at detach. The private-taskqueue work is saved for Section 4; for Stage 1 we use the shared `taskqueue_thread`. Using the shared queue first keeps the first step small and isolates the change to the deferred-work pattern itself.

14.4.1 The Change in One Sentence

When `tick_source` has just deposited a byte into the circular buffer, instead of silently omitting `se wakeup`, enqueue a task whose callback runs `se wakeup` in thread context.

That is the whole change. Everything else is the surrounding setup.

14.4.2 The Softc Addition

Add two members to `struct myfirst_softc`:

```
struct task          selwake_task;
int                  selwake_pending_drops;
```

The `selwake_task` is the task we will enqueue. The `selwake_pending_drops` is a debug counter we will increment whenever the task coalesces two or more enqueues into one firing; the difference between “number of enqueue calls” and “number of callback invocations” tells us how often the tick source produced data faster than the taskqueue thread drained it. That is pure diagnostic; you can omit it if you prefer, but seeing a real coalescing count in action is valuable.

Add a read-only `sysctl` so we can observe the counter from userspace without a debug build:

```
SYSCALL_ADD_INT(&sc->sysctl_ctx, SYSCTL_CHILDREN(sc->sysctl_tree),
    OID_AUTO, "selwake_pending_drops", CTLFLAG_RD,
    &sc->selwake_pending_drops, 0,
    "Times selwake_task coalesced two or more enqueues into one firing");
```

Placement matters only in the sense that it must come after `sc->sysctl_tree` has been created and before the function returns success; the Chapter 13 attach sequence already has the right structure, so the addition slots in naturally alongside the other stats.

14.4.3 The Task Callback

Add a function:

```
static void
myfirst_selwake_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    if (pending > 1) {
        MYFIRST_LOCK(sc);
        sc->selwake_pending_drops++;
        MYFIRST_UNLOCK(sc);
    }

    /*
     * No driver mutex held. Safe to call selwakeup(9) here.
     */
    selwakeup(&sc->rsel);
}
```

Several things to notice.

The callback takes the `_softc` via the `arg` pointer, exactly like the callout callbacks do. It does not need `MYFIRST_ASSERT` at the top because the task callback does not run with any driver lock held; the taskqueue framework does not hold your lock for you. This is different from the callout lock-aware pattern from Chapter 13, and is worth pausing on. A callout initialised with `callout_init_mtx(&co, &sc->mtx, 0)` runs with `sc->mtx` held. A task never does. Inside the task callback, if you want to touch state that the mutex protects, you acquire the mutex yourself, do the work, release it, and continue.

The callback conditionally updates `selwake_pending_drops` under the mutex. The condition `pending > 1` means “this callback is handling at least two coalesced enqueues”. Incrementing a counter under the mutex is fast and safe; doing it unconditionally would make the common case (`pending == 1`, no coalescing) pay the lock cost needlessly.

The `selwakeup(&sc->rsel)` call itself is the reason we are here. It runs without any driver lock held, which is what `selwakeup` wants, and it runs in thread context, which is what `selwakeup` requires. The bug from Chapter 13 is fixed.

The callback does not check `is_attached`. It does not need to. The detach path drains the task before freeing the `selinfo`; by the time `is_attached` would be zero, the task callback is guaranteed not to be running, and `selwakeup` will see valid state. The drain ordering is what makes the omission safe, which is why we discuss the ordering so carefully in Section 4.

14.4.4 The `tick_source` Edit

Change the `tick_source` callback from:

```
static void
myfirst_tick_source(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t put;
    int interval;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    if (cbuf_free(&sc->cb) > 0) {
        put = cbuf_write(&sc->cb, &sc->tick_source_byte, 1);
        if (put > 0) {
            counter_u64_add(sc->bytes_written, put);
            cv_signal(&sc->data_cv);
            /* selwakeup omitted: cannot be called from a
             * callout callback while sc->mtx is held. */
        }
    }

    interval = sc->tick_source_interval_ms;
    if (interval > 0)
        callout_reset(&sc->tick_source_co,
            (interval * hz + 999) / 1000,
            myfirst_tick_source, sc);
}
```

To:

```
static void
myfirst_tick_source(void *arg)
{
    struct myfirst_softc *sc = arg;
    size_t put;
    int interval;
    bool wake_sel = false;

    MYFIRST_ASSERT(sc);
    if (!sc->is_attached)
        return;

    if (cbuf_free(&sc->cb) > 0) {
        put = cbuf_write(&sc->cb, &sc->tick_source_byte, 1);
```

```

        if (put > 0) {
            counter_u64_add(sc->bytes_written, put);
            cv_signal(&sc->data_cv);
            wake_sel = true;
        }
    }

    if (wake_sel)
        taskqueue_enqueue(taskqueue_thread, &sc->selwake_task);

    interval = sc->tick_source_interval_ms;
    if (interval > 0)
        callout_reset(&sc->tick_source_co,
            (interval * hz + 999) / 1000,
            myfirst_tick_source, sc);
}

```

Two edits. A local `wake_sel` flag records whether a byte was written; the `taskqueue_enqueue` call happens after the `cbuf` work. The comment about “selwakeupt omitted” becomes obsolete and is removed.

Why use a flag instead of calling `taskqueue_enqueue` inline in the `if (put > 0)` block? Because `taskqueue_enqueue` is safe to call while holding `sc->mtx` (it acquires its own internal mutex; there is no lock-order problem for the taskqueue’s own mutex because it is not ordered against `sc->mtx`), but it is good hygiene to keep mutex-held sections tight and to name the reason for the enqueue with a local variable. The version with the flag is easier to read and easier to extend if later stages add more conditions that should trigger the wake.

Is `taskqueue_enqueue` actually safe to call from a callout callback with `sc->mtx` held? Yes. The taskqueue uses its own internal mutex (`tq_mutex`) which is entirely separate from `sc->mtx`; no lock order between them is established, so `WITNESS` has nothing to complain about. We will verify this in the lab at the end of this section. For future reference, the relevant guarantee in `/usr/src/sys/kern/subr_taskqueue.c` is that `taskqueue_enqueue` acquires `TQ_LOCK(tq)` (a sleep mutex for `taskqueue_create`, a spin mutex for `taskqueue_create_fast`), performs the list manipulation, and releases the lock. No sleeping, no recursion into the caller’s lock, no cross-lock dependency.

14.4.5 The Attach Change

In `myfirst_attach`, add one line after the existing callout initialisations:

```
TASK_INIT(&sc->selwake_task, 0, myfirst_selwake_task, sc);
```

Place it alongside the callout init calls. The conceptual grouping (“here is where we prepare the driver’s deferred-work primitives”) makes the file easier to scan.

Initialise `selwake_pending_drops` to zero in the same block where other counters are zeroed:

```
sc->selwake_pending_drops = 0;
```

14.4.6 The Detach Change

This is the critical part of the stage. The Chapter 13 detach sequence, simplified, is:

1. Refuse detach if `active_fhs > 0`.
2. Clear `is_attached`.
3. Broadcast `data_cv` and `room_cv`.
4. Drain `rsl` and `wsl` via `seldrain`.
5. Drain the three callouts.
6. Destroy devices, free `sysctls`, destroy `cbuf`, free counters, destroy `cvs`, destroy `sx`, destroy `mtx`.

Chapter 14 Stage 1 adds one step: drain `selwake_task` between the callout drains (step 5) and the `seldrain` calls (step 4). Actually, the ordering subtlety is more careful than that. Let's think through it.

The `selwake_task` callback calls `selwakeup(&sc->rsl)`. If `sc->rsl` is being drained concurrently, the callback could race. The rule is: ensure the task callback is guaranteed not to be running before calling `seldrain`. That means `taskqueue_drain(taskqueue_thread, &sc->selwake_task)` must happen before `seldrain(&sc->rsl)`.

However, the task can still be enqueued by an in-flight callout callback until we have drained the callouts. If we drain the task first and then the callouts, an in-flight callout could re-enqueue the task after we drained it, and the re-enqueued task would then try to run after `seldrain`.

The only safe ordering is: drain callouts first (which guarantees no more enqueues will happen), then drain the task (which guarantees the last enqueue has completed), then call `seldrain`. But we also must clear `is_attached` before draining the callouts so an in-flight callback exits early instead of re-arming.

Putting it all together, the Stage 1 detach ordering is:

1. Refuse detach if `active_fhs > 0`.
2. Clear `is_attached` (under the mutex).
3. Broadcast `data_cv` and `room_cv` (release the mutex first).
4. Drain the three callouts (no mutex held; `callout_drain` may sleep).
5. Drain `selwake_task` (no mutex held; `taskqueue_drain` may sleep).
6. Drain `rsl` and `wsl` via `seldrain`.
7. Destroy devices, free `sysctls`, destroy `cbuf`, free counters, destroy `cvs`, destroy `sx`, destroy `mtx`.

Steps 4 and 5 are the new ordering constraint. Callouts first, tasks second, `sel` third. Violating that order on a debug kernel typically trips an assertion inside `seldrain`; on a production kernel it is a use-after-free waiting to happen.

The code in `myfirst_detach` becomes:

```
/* Chapter 13: drain every callout. No lock held; safe to sleep. */
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
```

```
MYFIRST_CO_DRAIN(&sc->tick_source_co);

/* Chapter 14: drain every task. No lock held; safe to sleep. */
taskqueue_drain(taskqueue_thread, &sc->selwake_task);

seldrain(&sc->rsel);
seldrain(&sc->wsel);
```

Two lines of code plus a comment. The ordering is visible in the source.

14.4.7 The Makefile

No change. `bsd.kmod.mk` picks up the taskqueue API headers from the system tree; no additional source files are needed for Stage 1.

14.4.8 Building and Loading

At this point your working copy should have:

- The two new softc members (`selwake_task`, `selwake_pending_drops`).
- The `myfirst_selwake_task` function.
- The edit to `myfirst_tick_source`.
- The `TASK_INIT` call and the counter zeroing in `attach`.
- The `taskqueue_drain` call in `detach`.
- The new `selwake_pending_drops` `sysctl`.

Build from the Stage 1 directory:

```
# cd /path/to/examples/part-03/ch14-taskqueues-and-deferred-work/stage1-first-task
# make clean && make
```

Load:

```
# kldload ./myfirst.ko
```

Verify:

```
# kldstat | grep myfirst
 7    1 0xffffffff82f30000    ... myfirst.ko
# sysctl dev.myfirst.0
dev.myfirst.0.stats.selwake_pending_drops: 0
...
```

14.4.9 Observing the Fix

To observe Stage 1 doing its job, start a `poll(2)` waiter on the device and have the tick source generate data. A simple poller lives under `examples/part-03/ch14-taskqueues-and-deferred-work/labs/poll_waiter.c`:

```
#include <stdio.h>
#include <unistd.h>
#include <fcntl.h>
#include <poll.h>
#include <err.h>

int
main(int argc, char **argv)
{
    int fd, n;
    struct pollfd pfd;
    char c;

    fd = open("/dev/myfirst", O_RDONLY);
    if (fd < 0)
        err(1, "open");
    pfd.fd = fd;
    pfd.events = POLLIN;

    for (;;) {
        n = poll(&pfd, 1, -1);
        if (n < 0) {
            if (errno == EINTR)
                continue;
            err(1, "poll");
        }
        if (pfd.revents & POLLIN) {
            n = read(fd, &c, 1);
            if (n > 0)
                write(STDOUT_FILENO, &c, 1);
        }
    }
}
```

Compile it with `cc poll_waiter.c -o poll_waiter` (no special libraries). Run it in one terminal:

```
# ./poll_waiter
```

In a second terminal, enable the tick source at a slow pace to make the output easy to watch:

```
# sysctl dev.myfirst.0.tick_source_interval_ms=500
```

The Chapter 13 driver, without the Stage 1 fix, would leave `poll_waiter` stuck. The reader byte would accumulate in the buffer, but `poll(2)` would never return because `selwakeup` was never called. You would see nothing.

The Stage 1 driver does call `selwakeup`, via the task. You should see `t` characters appearing in the `poll_waiter` terminal every half second. When you stop the test, `poll_waiter` exits cleanly via `Ctrl-C`.

Now speed up the tick source to stress the taskqueue:

```
# sysctl dev.myfirst.0.tick_source_interval_ms=1
```

You should see a continuous stream of `t` characters. Check the coalescing counter:

```
# sysctl dev.myfirst.0.stats.selwake_pending_drops
dev.myfirst.0.stats.selwake_pending_drops: <some number, growing slowly>
```

The number is the count of times the task callback handled a pending count greater than one. On a lightly loaded machine it may stay small (the taskqueue thread wakes quickly enough to handle each enqueue individually). Under contention the number grows, and you can watch the coalescing behaviour directly.

If the counter stays at zero even under load, the machine is fast enough that every enqueue drains before the next one arrives. That is not a bug; it is a sign that the coalescing is present but not triggered. Section 5 introduces a deliberate workload that forces coalescing.

14.4.10 Unloading

Stop the tick source:

```
# sysctl dev.myfirst.0.tick_source_interval_ms=0
```

Close the `poll_waiter` with `Ctrl-C`. Unload:

```
# kldunload myfirst
```

The unload should be clean. If it fails with `EBUSY`, you still have an open descriptor somewhere; the close and the next `kldunload` should succeed.

If the unload hangs, something in the detach path is blocked. The most likely cause is that the `taskqueue_drain` is waiting for a task that cannot complete. That would indicate a bug, and the debugging section (Section 7) shows how to identify it. For the normal flow, the unload completes in milliseconds.

14.4.11 What We Just Did

A short summary before Section 4 scales up.

Stage 1 added one task to the driver, initialised it in `attach`, enqueued it from a callout callback, drained it in `detach` in the correct order, and observed coalescing in action. The task runs on the shared `taskqueue_thread`; it shares that queue with every other driver in the system that also uses it. For a low-rate workload that is entirely fine. For a driver that will eventually do substantial work in its tasks, or that wants to isolate its task-processing latency from whatever else the system is doing, a private taskqueue is the right answer. Section 4 takes that step.

14.4.12 Common Mistakes to Avoid

A short list of mistakes that beginners make when writing their first task. Each has bitten real drivers; each has a simple rule that prevents it.

Forgetting to drain at detach. If you enqueue tasks but do not drain them, an in-flight task may run after the softc is freed, and the kernel crashes in the task callback with a dereference of freed memory. Always drain every task your driver owns before freeing anything the task touches.

Draining in the wrong order relative to the state the task uses. The task-then-sel ordering we discussed above is a specific case. The general rule: drain every producer of enqueues, then drain the task, then free the state the task uses. Violating the order is a race, even if the race is rare.

Assuming the task runs immediately after enqueue. It does not. The taskqueue thread wakes on enqueue and then the scheduler decides when to run it. Under load this can be milliseconds. Drivers that assume zero latency break under load.

Assuming the task runs once per enqueue. It does not. Coalescing folds redundant submissions. If you need “exactly once per event” semantics, you need per-event state inside the softc (a queue of work items, for example), not one task per event.

Acquiring a driver lock in the wrong order in the task callback. The task callback is ordinary thread-context code. It obeys your driver’s established lock order. If the driver’s order is `sc->mtx -> sc->cfg_sx`, the task callback must take the mutex before the sx. Violations of this order are WITNESS errors the same as they would be anywhere else.

Using `taskqueue_enqueue` from inside a filter-interrupt context without a fast taskqueue. `taskqueue_enqueue(taskq, ...)` acquires a sleep mutex on the taskqueue’s internal lock. That is illegal from a filter-interrupt context. Filter interrupts must enqueue onto `taskqueue_fast` or a `taskqueue_create_fast` queue. Callout callbacks do not hit this restriction because they run in thread context; the issue is specific to filter interrupts. Part 4 revisits this when it introduces `bus_setup_intr`.

Each of those mistakes can be caught by a review, by WITNESS, or by a carefully written stress test. The first two in particular are the kind of bug that looks fine until the first detach under load.

14.4.13 Wrapping Up Section 3

The `myfirst` driver now has one task. It uses the task to move `selwakeup` out of the callout callback and into thread context, fixing a real bug from Chapter 13. The task is initialised in `attach`, enqueued from the

`tick_source` callback, and drained in detach in the correct order relative to the callouts and the `selinfo` drain.

The shared `taskqueue_thread` is the first taskqueue we used because it was already there. For a driver that is going to grow more tasks and more responsibility, a private taskqueue gives better isolation and a cleaner teardown story. Section 4 creates that private taskqueue.

14.5 Section 4: Taskqueue Setup and Cleanup

Stage 1 used the shared `taskqueue_thread`. That choice kept the first change small: one task, one enqueue, one drain, and a detach ordering to respect. Stage 2 creates a private taskqueue owned by the driver. The change is small in code terms, but it buys a handful of properties that become important once the driver grows.

This section teaches Stage 2 of the refactor, walks through the setup and teardown of a private taskqueue, audits the detach ordering carefully, and finishes with a pre-production checklist you can reuse on every taskqueue-using driver you write.

14.5.1 Why a Private Taskqueue

Three reasons for a private taskqueue.

First, **isolation**. A private taskqueue's thread runs only your driver's tasks. If some other driver in the system misbehaves on `taskqueue_thread` (blocking for too long in its task callback, for example), your driver's tasks are not affected. Conversely, if your driver misbehaves, the misbehaviour is contained.

Second, **observability**. `procstat -t` and `ps ax` show each taskqueue thread with a distinct name. A private queue is easy to spot: it shows up with the name you gave it (`myfirst taskq` by convention). The shared `taskqueue_thread` shows up just as `thread taskq`, which is shared with every other driver.

Third, **teardown is self-contained**. When you detach, you drain and free your own taskqueue. You do not have to reason about whether some other driver has a pending task that your drain might wait for. (You would not actually wait for another driver's task on the shared queue, but the mental model of "we own our teardown" is easier to reason about.)

The cost is small. A taskqueue and one kernel thread, created at attach and torn down at detach. A few pages of memory and a couple of scheduler entries. Nothing measurable on any realistic system.

For a driver that will eventually have multiple tasks, a private taskqueue is the right default. For a driver with a single trivial task on a rare code path, the shared queue is fine. `myfirst` is the former: we already have one task, and the chapter will add more.

14.5.2 The Softc Addition

Add one member to `struct myfirst_softc`:

```
struct taskqueue      *tq;
```

No other `softc` changes for Stage 2.

14.5.3 Creating the Taskqueue in Attach

In `myfirst_attach`, between the `mutex / cv / sx` initialisations and the callout initialisations, add:

```
sc->tq = taskqueue_create("myfirst taskq", M_WAITOK,
    taskqueue_thread_enqueue, &sc->tq);
if (sc->tq == NULL) {
    error = ENOMEM;
    goto fail_sx;
}
error = taskqueue_start_threads(&sc->tq, 1, PWAIT,
    "%s taskq", device_get_nameunit(dev));
if (error != 0)
    goto fail_tq;
```

The call reads as: create a taskqueue called “myfirst taskq”, allocate with `M_WAITOK` so the allocation cannot fail (we are in attach, which is a sleepable context), use `taskqueue_thread_enqueue` as the dispatcher so the queue is serviced by kernel threads, and pass `&sc->tq` as the context so the dispatcher can find the queue.

The name “myfirst taskq” is the human-readable label that shows up in `procstat -t`. The convention in the Chapter 14 examples is “<driver> taskq” for a driver with a single private queue; drivers with multiple queues should use more specific names like “myfirst rx taskq” and “myfirst tx taskq”.

`taskqueue_start_threads` creates the worker threads. The first argument is `&sc->tq`, a double pointer so the function can find the taskqueue. The second argument is the thread count; we use one thread for `myfirst`. A driver with heavy, parallelisable work might use more. The third argument is the priority; `PWAIT` is the ordinary choice and equivalent to what the predefined `taskqueue_thread` uses. The variadic name is a format string for each thread’s name; `device_get_nameunit(dev)` gives a per-instance name so multiple `myfirst` instances have distinguishable threads.

The failure paths deserve attention. If `taskqueue_create` returns `NULL` (it normally does not with `M_WAITOK`, but be defensive), we jump to `fail_sx`. If `taskqueue_start_threads` fails, we jump to `fail_tq`, which must call `taskqueue_free` before continuing with the other cleanup. The Chapter 14 Stage 2 source (see the examples tree) has the labels in the right order.

14.5.4 Updating the Enqueue Call Sites

Every `taskqueue_enqueue(taskqueue_thread, ...)` call becomes `taskqueue_enqueue(sc->tq, ...)`. Same for drains: `taskqueue_drain(taskqueue_thread, ...)` becomes `taskqueue_drain(sc->tq, ...)`.

After Stage 1, the driver has two such call sites: the enqueue in `myfirst_tick_source` and the drain in `myfirst_detach`. Both change in a single search-and-replace pass.

14.5.5 The Teardown Sequence

The detach ordering grows by two lines. The full sequence for Stage 2 is:

1. Refuse detach if `active_fhs > 0`.
2. Clear `is_attached` under the mutex, broadcast both cvs, release the mutex.
3. Drain the three callouts.
4. Drain `selwake_task` on the private taskqueue.
5. Drain `rsel` and `wsel` via `seldrain`.
6. Free the private taskqueue with `taskqueue_free`.
7. Destroy devices, free `sysctls`, destroy `cbuf`, free counters, destroy cvs, destroy sx, destroy mtx.

The new steps are 4 (which already existed in Stage 1, now targeting `sc->tq`) and 6 (which is new in Stage 2).

A natural question: do we need the explicit `taskqueue_drain` at step 4 if step 6 is going to drain everything anyway? Technically no. `taskqueue_free` drains all pending tasks before destroying the queue. But keeping the explicit drain has two benefits. First, it makes the ordering explicit: you see that the task drain happens before `seldrain`, which is the ordering we care about. Second, it separates the “wait for this specific task to finish” question from the “tear down the whole queue” question. If later stages add more tasks on the same queue, each gets its own explicit drain, and the code tells the reader what is happening.

The relevant code in `myfirst_detach`:

```
/* Chapter 13: drain every callout. No lock held; safe to sleep. */
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
MYFIRST_CO_DRAIN(&sc->tick_source_co);

/* Chapter 14 Stage 1: drain every task. */
taskqueue_drain(sc->tq, &sc->selwake_task);

seldrain(&sc->rsel);
seldrain(&sc->wsel);

/* Chapter 14 Stage 2: destroy the private taskqueue. */
taskqueue_free(sc->tq);
sc->tq = NULL;
```

Setting `sc->tq` to `NULL` after freeing is defensive: a later bug that tries to use a pointer after free will dereference `NULL` and panic at the call site, rather than corrupt unrelated memory. It costs nothing and occasionally saves an afternoon of debugging.

14.5.6 The Attach Failure Path

Walk through the attach failure path carefully. The Chapter 13 attach had labels for the `cbuf` and mutex failure paths. Stage 2 adds taskqueue-related labels:

```

static int
myfirst_attach(device_t dev)
{
    struct myfirst_softc *sc;
    struct make_dev_args args;
    int error;

    sc = device_get_softc(dev);
    sc->dev = dev;
    sc->unit = device_get_unit(dev);

    mtx_init(&sc->mtx, device_get_nameunit(dev), "myfirst", MTX_DEF);
    cv_init(&sc->data_cv, "myfirst data");
    cv_init(&sc->room_cv, "myfirst room");
    sx_init(&sc->cfg_sx, "myfirst cfg");

    sc->tq = taskqueue_create("myfirst taskq", M_WAITOK,
        taskqueue_thread_enqueue, &sc->tq);
    if (sc->tq == NULL) {
        error = ENOMEM;
        goto fail_sx;
    }
    error = taskqueue_start_threads(&sc->tq, 1, PWAIT,
        "%s taskq", device_get_nameunit(dev));
    if (error != 0)
        goto fail_tq;

    MYFIRST_CO_INIT(sc, &sc->heartbeat_co);
    MYFIRST_CO_INIT(sc, &sc->watchdog_co);
    MYFIRST_CO_INIT(sc, &sc->tick_source_co);

    TASK_INIT(&sc->selwake_task, 0, myfirst_selwake_task, sc);

    /* ... rest of attach as in Chapter 13 ... */

    return (0);

fail_cb:
    cbuf_destroy(&sc->cb);
fail_tq:
    taskqueue_free(sc->tq);
fail_sx:
    cv_destroy(&sc->data_cv);
    cv_destroy(&sc->room_cv);

```

```
    sx_destroy(&sc->cfg_sx);
    mtx_destroy(&sc->mtx);
    sc->is_attached = 0;
    return (error);
}
```

The failure labels chain: `fail_cb` calls `cbuf_destroy` then falls through to `fail_tq` which calls `taskqueue_free` then falls through to `fail_sx` which destroys the cvs, the sx, and the mutex. Each label undoes everything up to the point the corresponding init call succeeded. If `taskqueue_start_threads` fails, we go straight to `fail_tq` (the taskqueue was allocated but has no threads; `taskqueue_free` still handles that correctly because a just-created-and-not-started taskqueue has zero threads to reap).

Note also: `TASK_INIT` does not have a failure mode (it is a macro that sets fields), and does not need a destroy counterpart. The task becomes idle once `taskqueue_drain` has been called on it, and the storage is simply reclaimed with the `softc`.

14.5.7 Thread Naming Conventions

`taskqueue_start_threads` takes a format string and a variable argument list, so each thread gets its own name. The naming convention has a real effect on debuggability, so a short paragraph about conventions is worth it.

The format string we use is `"%s taskq"` with `device_get_nameunit(dev)` as the argument. For a first myfirst instance the thread shows up as `myfirst0 taskq`. For a second instance it shows up as `myfirst1 taskq`. That makes the thread identifiable in `procstat -t` and `ps ax`.

A driver with multiple private queues should pick names that distinguish the queues:

```
taskqueue_start_threads(&sc->tx_tq, 1, PWAIT,
    "%s tx", device_get_nameunit(dev));
taskqueue_start_threads(&sc->rx_tq, 1, PWAIT,
    "%s rx", device_get_nameunit(dev));
```

Network drivers often name per-queue threads more specifically still (`"%s tx%d"` with the queue index) so that `procstat -t` shows every hardware queue's dedicated worker.

14.5.8 Choosing Thread Count

Most drivers create a single-threaded private taskqueue. One worker means tasks run sequentially, which simplifies the locking story: inside the task callback you can assume no other invocation of the same callback is running concurrently, without any explicit exclusion.

A driver with multiple hardware channels that need parallel processing might create multiple worker threads on the same taskqueue. The taskqueue guarantees that a single task is running on at most one thread at a time (that is what `tq_active` tracks), but different tasks on the same queue can run in parallel on different threads. For `myfirst` the single-threaded configuration is correct.

Multi-threaded taskqueues have implications for lock contention: two workers on the same queue, each running a different task, may contend for the same driver mutex. If the workload is naturally parallelisable, a multi-threaded queue speeds things up. If the workload is serialised anyway on the driver mutex, multiple threads add complexity without benefit. For a first taskqueue, single-threaded is the right default.

14.5.9 Choosing a Thread Priority

The `pri` argument to `taskqueue_start_threads` is the thread's scheduling priority. We use `PWAIT` in the Chapter 14 examples. The options in practice are:

- `PWAIT` (numerically 76): ordinary driver priority, equivalent to the priority of `taskqueue_thread`.
- `PI_NET` (numerically 4): network-adjacent priority, used by many ethernet drivers.
- `PI_DISK`: historical constant; `PRI_MIN_KERN` territory. Used by storage drivers.
- `PRI_MIN_KERN` (numerically 48): generic kernel-thread priority, used when the above constants do not fit.

For a driver whose task work is not latency-sensitive, `PWAIT` is fine. For a driver that must run its task callbacks promptly even under load, raising the priority closer to the interrupt threads is sometimes justified. `myfirst` uses `PWAIT`.

If you are writing a driver and are not sure what priority the convention expects, look at drivers of the same kind in `/usr/src/sys/dev/`. A storage driver that uses taskqueues probably uses `PRI_MIN_KERN` or `PI_DISK`; a network driver probably uses `PI_NET`. Pattern-matching on existing drivers is better than making up a priority.

14.5.10 A Worked Source Excerpt: `ale(4)`

A real driver using the exact pattern this section teaches. From `/usr/src/sys/dev/ale/if_ale.c`:

```
/* Create local taskq. */
sc->ale_tq = taskqueue_create_fast("ale_taskq", M_WAITOK,
    taskqueue_thread_enqueue, &sc->ale_tq);
taskqueue_start_threads(&sc->ale_tq, 1, PI_NET, "%s taskq",
    device_get_nameunit(sc->ale_dev));
```

The `ale` ethernet driver creates a fast taskqueue (`taskqueue_create_fast`) with a spin mutex, because it wants to be able to enqueue from its filter interrupt handler. It runs one thread at `PI_NET` priority, with the per-unit name convention. The shape is exactly what we use in `myfirst`, with the choice of fast vs. regular and the priority reflecting the driver's context.

From the same file, the matching teardown path:

```
taskqueue_drain(sc->ale_tq, &sc->ale_int_task);
/* ... */
taskqueue_free(sc->ale_tq);
```

taskqueue_drain on the specific task, then taskqueue_free on the queue. The same idiom we use.

Reading a `le(4)`'s setup and teardown once is worthwhile. It is a real driver, doing real work, using the pattern you are about to write in your own driver. Every driver under `/usr/src/sys/dev/` that uses taskqueues has very similar shape.

14.5.11 Regressing Chapter 13 Behaviour

Stage 2 must not break anything Chapter 13 established. Before proceeding, rerun the Chapter 13 stress kit with the Stage 2 driver loaded:

```
# cd /path/to/examples/part-03/ch13-timers-and-delayed-work/stage4-final
# ./test-all.sh
```

The test should pass exactly as it did at the end of Chapter 13. If it does not, the regression is in something Stage 2 changed; roll back to the pre-Stage-2 source and find the difference. The common cause is a missed enqueue-call-site update (an enqueue still targets `taskqueue_thread` instead of `sc->tq`). Those compile fine because the API is the same; they produce unrelated bugs at runtime.

14.5.12 Observing the Private Taskqueue

With the Stage 2 driver loaded, `procstat -t` shows the new thread:

```
# procstat -t | grep myfirst
<PID> <THREAD>      0 100 myfirst0 taskq      sleep  -      -      0:00
```

The name `myfirst0 taskq` is the per-instance thread name we asked for in `taskqueue_start_threads`. The state is `sleep` because the thread is blocked waiting for a task. The `wchan` is empty because the thread is sleeping on its own `cv`, which `procstat` may show differently across releases.

Enable the tick source and watch again:

```
# sysctl dev.myfirst.0.tick_source_interval_ms=100
# procstat -t | grep myfirst
<PID> <THREAD>      0 100 myfirst0 taskq      run    -      -      0:00
```

Briefly you may catch the thread in `run` state as it processes a task. Most of the time it sits in `sleep`. Both are expected.

`ps ax` shows the same thread:

```
# ps ax | grep 'myfirst.*taskq'
50  -  IL      0:00.00 [myfirst0 taskq]
```

The brackets indicate a kernel thread. The thread is always there while the driver is attached; it goes away at detach.

14.5.13 The Pre-Production Checklist for Stage 2

A short checklist to run through before declaring Stage 2 done. Each item is a question; each should be answerable with confidence.

- ☐ Does `attach` create the taskqueue before any code that might enqueue onto it?
- ☐ Does `attach` start at least one worker thread on the taskqueue before any code that expects a task to actually run?
- ☐ Does `attach` have failure labels that `taskqueue_free` the queue if a subsequent init fails?
- ☐ Does `detach` drain every task the driver owns before freeing any state those tasks touch?
- ☐ Does `detach` call `taskqueue_free` after every task drain and before destroying the mutex?
- ☐ Does `detach` set `sc->tq = NULL` after free, for defensive clarity?
- ☐ Is the taskqueue's thread priority chosen deliberately, with a rationale that matches the driver's kind?
- ☐ Is the taskqueue's thread name informative enough that `procstat -t` output is useful?
- ☐ Does every `taskqueue_enqueue` call target `sc->tq`, not `taskqueue_thread` (unless the enqueue is on a genuinely shared path for a specific reason)?
- ☐ Does every `taskqueue_drain` call match a `taskqueue_enqueue` on the same queue with the same task?

A driver that answers every item cleanly is a driver that handles its private taskqueue correctly. A driver that cannot is probably one step from a use-after-free at detach.

14.5.14 Common Mistakes in Stage 2

Three mistakes that beginners make when adding a private taskqueue. Each is preventable with a habit.

Creating the taskqueue after something that enqueues. If the enqueue happens before `taskqueue_create` has returned, the enqueue dereferences a NULL pointer. Always put `taskqueue_create` early in `attach`, before any code that can trigger an enqueue.

Forgetting `taskqueue_start_threads`. A taskqueue without worker threads is a queue that accepts enqueues but never runs the callbacks. Tasks pile up silently. If you think “my task never fires”, check that you called `taskqueue_start_threads`.

Calling `taskqueue_free` without first having cleared `is_attached`. If the taskqueue is freed while a callout callback is still running and could enqueue, the callout's enqueue will crash on the freed taskqueue. Always clear `is_attached`, drain callouts, drain the task, then free. The ordering is what makes it safe.

Section 7 will walk through each of these mistakes live, with a break-and-fix on a deliberately-misordered driver. For now the rule is: follow the ordering in this section, and the taskqueue lifecycle will be correct.

14.5.15 Wrapping Up Section 4

The driver now owns its own taskqueue. One thread, one name, one lifetime. Attach creates it and starts a worker; detach drains the task, frees the taskqueue, and unwinds. The ordering relative to callouts and `selinfo` is respected. `procstat -t` shows the thread by a recognisable name. The driver is self-contained in its deferred-work story.

Section 5 takes the next step: we exploit the coalescing behaviour deliberately for batching, introduce the `timeout_task` variant for scheduled tasks, and discuss how priority applies when a queue holds multiple task kinds.

14.6 Section 5: Prioritization and Coalescing of Work

Every task your driver owns enters a queue. The queue has a policy for deciding the order in which tasks run and what happens when the same task is enqueued twice. Section 5 makes that policy explicit, then shows how to use the coalescing contract deliberately to batch work, and finally introduces `timeout_task` as the taskqueue-side analogue of the callout.

This section is dense in ideas but short in code. The two driver changes for Stage 3 are a new task on the same taskqueue and a timeout task that drives a periodic batched write. The value is in the rules you internalise.

14.6.1 The Priority Ordering Rule

The `ta_priority` field in `struct task` orders tasks inside a single queue. Higher priority tasks run before lower priority tasks. A task with priority 5 that is enqueued after a task with priority 0 runs before the priority-0 task, even if the priority-0 task was enqueued first.

Priority is a small unsigned integer (`uint8_t`, so range 0-255). Most drivers use priority 0 for everything, in which case the queue is effectively FIFO. A driver with genuinely different urgencies for different tasks can assign different priorities and let the taskqueue reorder.

A quick example. Suppose a driver has two tasks: a `reset_task` that recovers from a hardware error, and a `stats_task` that rolls up accumulated statistics. If both are enqueued in a short window, the reset should run first. Giving `reset_task` priority 10 and `stats_task` priority 0 achieves that. The reset task runs first even if it was enqueued last.

Use priorities sparingly. A driver with ten different task kinds and ten different priorities is harder to reason about than a driver with ten task kinds that all run in enqueue order. Priorities exist for real differentiation, not for aesthetic ordering.

14.6.2 The Coalescing Rule, Restated

From Section 2, and worth saying again: if a task is enqueued while it is already pending, the kernel increments `ta_pending` and does not link the task a second time. The callback runs once, with the pending count in the second argument.

The precise code, from `/usr/src/sys/kern/subr_taskqueue.c`:

```
if (task->ta_pending) {
    if (__predict_false((flags & TASKQUEUE_FAIL_IF_PENDING) != 0)) {
        TQ_UNLOCK(queue);
        return (EEXIST);
    }
}
```

```

    if (task->ta_pending < USHRT_MAX)
        task->ta_pending++;
    TQ_UNLOCK(queue);
    return (0);
}

```

The counter saturates at `USHRT_MAX` (65535), which is a hard cap on how high the coalescing count can go. Past that, repeated enqueues are lost from the counter’s perspective, though they still return success. In practice nobody hits that cap, because a task that backs up 65535 times has deeper problems.

The coalescing rule has three consequences you design around.

First, **a task handles at most “one run per scheduler wakeup”**. If your work model needs “one callback per event”, a single task is wrong. You need per-event state.

Second, **the callback must be able to handle multiple events in one firing**. Writing the callback as if pending is always 1 is a bug that only shows up under load. Use the pending argument deliberately, or structure the callback so it processes whatever is in a driver-owned queue until the queue is empty.

Third, **you can exploit coalescing for batching**. If a producer enqueues a task once per event and the consumer drains a batch per firing, the system naturally converges on the rate the consumer can sustain. Under light load the coalescing never triggers (one event, one firing). Under heavy load the coalescing folds bursts into single firings with larger batches. The behaviour is self-tuning.

14.6.3 A Deliberate Batching Pattern: Stage 3

Stage 3 adds a second task to the driver: a `bulk_writer_task` that writes a fixed number of tick bytes to the buffer in a single firing, driven by a callout that enqueues the task periodically. The pattern is contrived (the real driver would just use a faster tick source), but it is the simplest demonstration of deliberate batching.

The softc addition:

```

struct task          bulk_writer_task;
int                  bulk_writer_batch;    /* bytes per firing */

```

The default `bulk_writer_batch` is zero (disabled). A `sysctl` exposes it for tuning.

The callback:

```

static void
myfirst_bulk_writer_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;
    int batch, written;
    char buf[64];

    MYFIRST_LOCK(sc);

```

```

    batch = sc->bulk_writer_batch;
    MYFIRST_UNLOCK(sc);

    if (batch <= 0)
        return;

    batch = MIN(batch, (int)sizeof(buf));
    memset(buf, 'B', batch);

    MYFIRST_LOCK(sc);
    written = (int)cbuf_write(&sc->cb, buf, batch);
    if (written > 0) {
        counter_u64_add(sc->bytes_written, written);
        cv_signal(&sc->data_cv);
    }
    MYFIRST_UNLOCK(sc);

    if (written > 0)
        selwakeup(&sc->rsel);
}

```

A few remarks.

The callback acquires `sc->mtx`, reads the batch size, releases. Acquiring and releasing twice is fine; the work in between (`memset`) does not need the lock. The second acquisition wraps the actual `cbuf` operation and the counter update. The `selwakeup` happens with no lock held, as always.

The pending argument is unused in this simple callback. For a different batching design, pending would tell the callback how many times the task was enqueued and therefore how much work accumulated. Here the batching policy is “always write exactly `bulk_writer_batch` bytes per firing, no matter how many times enqueued”, so pending does not come into it.

The callback does not check `is_attached`. It does not need to. The detach drains the task before freeing anything the task touches, and `sc->mtx` protects `sc->cb` until the drain completes.

14.6.4 The Coalescing in Action

To demonstrate coalescing deliberately, Stage 3 adds a `sysctl bulk_writer_flood` whose writer attempts to enqueue `bulk_writer_task` a thousand times in a tight loop:

```

static int
myfirst_sysctl_bulk_writer_flood(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int flood = 0;

```

```

    int error, i;

    error = sysctl_handle_int(oidp, &flood, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    if (flood < 1 || flood > 10000)
        return (EINVAL);

    for (i = 0; i < flood; i++)
        taskqueue_enqueue(sc->tq, &sc->bulk_writer_task);
    return (0);
}

```

Run it:

```

# sysctl dev.myfirst.0.bulk_writer_batch=32
# sysctl dev.myfirst.0.bulk_writer_flood=1000

```

Immediately after, observe the byte count. Without coalescing, a thousand enqueues at 32 bytes each would produce 32000 bytes. With coalescing, the actual number is one firing of 32 bytes, because the thousand enqueues collapsed into a single pending task. The driver's bytes_written counter should increase by 32, not 32000.

This is the coalescing contract working as designed. The producer asked for a thousand task runs; the taskqueue delivered one. The callback's single firing reflected all thousand requests but did the fixed amount of work the batching policy specified.

14.6.5 Using pending for Adaptive Batching

A more sophisticated pattern uses the pending argument to adapt batch size to queue depth. Suppose a driver wants to write pending bytes per firing: one byte per enqueue, folded into coalesced runs. The callback becomes:

```

static void
myfirst_adaptive_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;
    char buf[64];
    int n;

    n = MIN(pending, (int)sizeof(buf));
    memset(buf, 'A', n);

    MYFIRST_LOCK(sc);
}

```

```
(void)cbuf_write(&sc->cb, buf, n);
counter_u64_add(sc->bytes_written, n);
cv_signal(&sc->data_cv);
MYFIRST_UNLOCK(sc);

selwakeup(&sc->rsel);
}
```

The callback writes pending bytes (up to the buffer size). At low load, pending is 1 and the callback writes one byte. At high load, pending is the queue depth at the moment the callback started, and the callback writes that many bytes in a single pass. The batching naturally scales with load.

This design is useful when each enqueue corresponds to a real event that wants one unit of work, and the batching is a performance optimisation rather than a semantic change. A network driver’s “transmit completion” handler is a classic example: each transmitted packet generates an interrupt that enqueues a task; the task’s job is to reclaim completed descriptors; at high packet rates, many interrupts fold into a single task firing that reclaims many descriptors at once.

We will not add the adaptive-batching task to `myfirst` in Stage 3, because the fixed-batch version already demonstrates coalescing. The adaptive pattern is worth keeping in mind for real driver work; the real FreeBSD drivers you will read use it often.

14.6.6 The Enqueue Flags

`taskqueue_enqueue_flags` extends `taskqueue_enqueue` with two flag bits:

- `TASKQUEUE_FAIL_IF_PENDING`: if the task is already pending, return `EEXIST` instead of coalescing.
- `TASKQUEUE_FAIL_IF_CANCELING`: if the task is currently being cancelled, return `EAGAIN` instead of waiting.

`TASKQUEUE_FAIL_IF_PENDING` is useful when you want to know whether the enqueue actually produced a new pending state, for accounting or debugging. A driver that counts “how many times was this task enqueued” can use the flag, get `EEXIST` on the redundant calls, and count only the non-redundant enqueues.

`TASKQUEUE_FAIL_IF_CANCELING` is useful during shutdown. If you are tearing the driver down and some code path would enqueue a task, you can pass the flag and check for `EAGAIN` to avoid re-adding a task that is in the middle of being cancelled. Most drivers do not need this in practice; the `is_attached` check usually handles the equivalent condition.

Neither flag is used in `myfirst`. Both exist, and a driver with specific needs can reach for them. For ordinary work, the plain `taskqueue_enqueue` is correct.

14.6.7 The `timeout_task` Variant

Sometimes you want a task to fire after a specific delay. The callout would be the natural primitive for that, but if the work the delayed callback wants to do requires thread context, you need the task’s context, not the callout’s. The kernel offers `struct timeout_task` for exactly this case.

timeout_task is defined in /usr/src/sys/sys/_task.h:

```
struct timeout_task {
    struct taskqueue *q;
    struct task t;
    struct callout c;
    int f;
};
```

The structure wraps a struct task, a struct callout, and an internal flag. When you schedule a timeout task with taskqueue_enqueue_timeout, the kernel starts the callout; when the callout fires, its callback enqueues the underlying task on the taskqueue. The task then runs in thread context, with all the usual guarantees.

The initialisation uses TIMEOUT_TASK_INIT:

```
TIMEOUT_TASK_INIT(queue, timeout_task, priority, func, context);
```

The macro expands to a function call _timeout_task_init that initialises both the task and the callout with appropriate linkage. You must pass the taskqueue at init time because the callout is set up to enqueue on that specific queue.

Scheduling uses taskqueue_enqueue_timeout(tq, &tt, ticks):

```
int taskqueue_enqueue_timeout(struct taskqueue *queue,
    struct timeout_task *timeout_task, int ticks);
```

The ticks argument is the same convention as callout_reset: hz ticks equals one second.

Draining uses taskqueue_drain_timeout(tq, &tt), which waits for the callout to expire (or cancels it if still pending) and then waits for the underlying task to complete. The drain is a single call, but it handles both the callout and the task phases.

Cancelling uses taskqueue_cancel_timeout(tq, &tt, &pendp):

```
int taskqueue_cancel_timeout(struct taskqueue *queue,
    struct timeout_task *timeout_task, u_int *pendp);
```

Returns zero if the timeout was cancelled cleanly, or EBUSY if the task is currently running. In the EBUSY case you typically follow up with taskqueue_drain_timeout.

14.6.8 A Stage 3 Timeout Task: Delayed Reset

Stage 3 adds a timeout task to the driver: a delayed reset that fires reset_delay_ms milliseconds after the reset sysctl is written. The existing reset sysctl runs synchronously; the delayed variant schedules the reset for later. Useful for testing and for situations where the reset should not happen until after the current IO drains.

The softc addition:

```
struct timeout_task    reset_delayed_task;
int                    reset_delay_ms;
```

The initialisation in attach:

```
TIMEOUT_TASK_INIT(sc->taskqueue, &sc->reset_delayed_task, 0,
    myfirst_reset_delayed_task, sc);
sc->reset_delay_ms = 0;
```

TIMEOUT_TASK_INIT takes the taskqueue as its first argument because the callout inside the timeout_task needs to know which queue to enqueue onto when it fires.

The callback:

```
static void
myfirst_reset_delayed_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_LOCK(sc);
    MYFIRST_CFG_XLOCK(sc);

    cbuf_reset(&sc->cb);
    sc->cfg.debug_level = 0;
    counter_u64_zero(sc->bytes_read);
    counter_u64_zero(sc->bytes_written);

    MYFIRST_CFG_XUNLOCK(sc);
    MYFIRST_UNLOCK(sc);

    cv_broadcast(&sc->room_cv);
    device_printf(sc->dev, "delayed reset fired (pending=%d)\n", pending);
}
```

Same logic as the synchronous reset from Chapter 13, but in task context. It can acquire the sleepable cfg_sx without the complications a callout would face. The pending count is logged for diagnostic purposes.

The sysctl handler that arms the delayed reset:

```
static int
myfirst_sysctl_reset_delayed(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int ms = 0;
```

```

    int error;

    error = sysctl_handle_int(oidp, &ms, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    if (ms < 0)
        return (EINVAL);
    if (ms == 0) {
        (void)taskqueue_cancel_timeout(sc->tq,
            &sc->reset_delayed_task, NULL);
        return (0);
    }

    sc->reset_delay_ms = ms;
    taskqueue_enqueue_timeout(sc->tq, &sc->reset_delayed_task,
        (ms * hz + 999) / 1000);
    return (0);
}

```

A zero writes cancel the pending delayed reset. Any positive value schedules the task to fire after the given number of milliseconds. The tick conversion $(ms * hz + 999) / 1000$ is the same ceiling conversion we use for callouts.

The detach path drains the timeout task:

```
taskqueue_drain_timeout(sc->tq, &sc->reset_delayed_task);
```

Placement of the drain is the same as the plain task drain: after the callouts are drained, after `is_attached` is clear, before `sel drain` and before `taskqueue_free`.

14.6.9 Observing the Delayed Reset

With Stage 3 loaded, arm the delayed reset for three seconds in the future:

```
# sysctl dev.myfirst.0.reset_delayed=3000
```

Three seconds later `dmesg` shows:

```
myfirst0: delayed reset fired (pending=1)
```

The `pending=1` confirms that the timeout task fired once. Now arm it multiple times in rapid succession:

```
# sysctl dev.myfirst.0.reset_delayed=1000
# sysctl dev.myfirst.0.reset_delayed=1000
# sysctl dev.myfirst.0.reset_delayed=1000
```

One second later, only one reset fires. `dmesg` shows:

```
myfirst0: delayed reset fired (pending=1)
```

Why only one firing? Because `taskqueue_enqueue_timeout` behaves consistently with `callout_reset`: arming a pending timeout task replaces the previous deadline. The three successive arms produce one scheduled firing. The same behaviour would apply if we used `callout_reset` on a plain callout.

14.6.10 When to Use `timeout_task` vs. Callout Plus Task

A timeout task is the right primitive when you want a delayed action in thread context and the delay is the primary parameter. A plain callout with a task enqueue is the right primitive when you want a delayed action and the delay is an implementation detail: for example, when the delay is recomputed dynamically each time. Both work.

The two patterns have slightly different shapes in the source:

```
/* timeout_task pattern */
TIMEOUT_TASK_INIT(tq, &tt, 0, fn, ctx);
...
taskqueue_enqueue_timeout(tq, &tt, ticks);
...
taskqueue_drain_timeout(tq, &tt);
```

```
/* callout + task pattern */
callout_init_mtx(&co, &sc->mtx, 0);
TASK_INIT(&t, 0, fn, ctx);
...
callout_reset(&co, ticks, myfirst_co_fn, sc);
/* in the callout callback: taskqueue_enqueue(tq, &t); */
...
callout_drain(&co);
taskqueue_drain(tq, &t);
```

The `timeout_task` version is shorter because the kernel has bundled the pattern for you. The `callout+task` version is more flexible because the callout callback can decide dynamically whether to enqueue the task (for example, based on state conditions that do not exist at schedule time).

For `myfirst`'s delayed reset, the `timeout_task` is the right choice because the decision to fire is taken at schedule time (the `sysctl` writer requested it) and nothing in between changes that decision.

14.6.11 Priority Ordering Across Task Kinds

A driver with multiple tasks on the same taskqueue can use priorities to order them. For `myfirst` we do not need this; all tasks are equal-priority. But the pattern is worth understanding for when you do.

Suppose we had a `high_priority_reset_task` that must run ahead of any other pending tasks. We would initialise it with a priority greater than zero:

```
TASK_INIT(&sc->high_priority_reset_task, 10,  
         myfirst_high_priority_reset_task, sc);
```

And enqueue it normally:

```
taskqueue_enqueue(sc->tq, &sc->high_priority_reset_task);
```

If the queue has several tasks pending, including the new one and several priority-0 tasks, the new one runs first because of its higher priority. Priority is a property of the task (set at init), not of the enqueue (set at each call); if a task should sometimes be urgent and sometimes not, you need two task structures with two priorities, not one task you retune.

14.6.12 A Note on Fairness

A taskqueue with a single worker thread runs tasks strictly in priority order, with ties broken by enqueue order. A taskqueue with multiple worker threads can run several tasks in parallel; priority still orders the list, but the parallel workers may dispatch tasks out of strict order at the margin. For most drivers this does not matter.

If strict fairness or strict priority ordering is required, a single worker is the right choice. If throughput at the cost of occasional reordering is acceptable, multiple workers are fine. `myfirst` uses a single worker.

14.6.13 Wrapping Up Section 5

Stage 3 added a deliberate batching task and a timeout task. The batching task demonstrates coalescing by collapsing a thousand enqueues into a single firing; the timeout task demonstrates delayed execution in thread context. Both share the private taskqueue from Stage 2, both are drained at detach in the established order, and both obey the locking discipline the rest of the driver uses.

The priority and coalescing rules are now explicit. A task's priority orders it inside the queue; a task's `ta_pending` counter folds redundant enqueues into a single firing whose pending argument carries the tally.

Section 6 steps back from the `myfirst` refactor to survey the patterns that show up in real FreeBSD drivers. The mental models accumulate; the driver does not change again until Section 8.

14.7 Section 6: Real-World Patterns Using Taskqueues

Up to now Chapter 14 has developed a single driver through three stages. Real FreeBSD drivers use taskqueues in a handful of recurring shapes. This section catalogs the patterns, shows where each one appears in `/usr/src-`

c/sys/dev/, and explains when to reach for which. Recognising the patterns turns reading driver source from a puzzle into a vocabulary exercise.

Each pattern is presented as a short recipe: the problem, the taskqueue shape that solves it, a code sketch, and a real-driver reference you can read for the production version.

14.7.1 Pattern 1: Deferred Logging or Notification From an Edge Context

Problem. An edge-context callback (callout, interrupt filter, epoch section) detects a condition that should produce a log message or a notification to user-space. The logging call is too heavy for the edge context: `selwakeup`, `log(9)`, `kqueue_user_event`, or a multi-line `printf` that holds a lock the edge context cannot afford.

Solution. One `struct task` per condition, initialised in `attach` with a callback that performs the heavy call in thread context. The edge-context callback records the condition in softc state (a flag, a counter, a small piece of data), enqueues the task, and returns. The task runs in thread context, reads the condition from softc state, performs the call, clears the condition.

Code sketch.

```
struct my_softc {
    struct task log_task;
    int log_flags;
    struct mtx mtx;
    ...
};

#define MY_LOG_UNDERRUN 0x01
#define MY_LOG_OVERRUN 0x02

static void
my_log_task(void *arg, int pending)
{
    struct my_softc *sc = arg;
    int flags;

    mtx_lock(&sc->mtx);
    flags = sc->log_flags;
    sc->log_flags = 0;
    mtx_unlock(&sc->mtx);

    if (flags & MY_LOG_UNDERRUN)
        log(LOG_WARNING, "%s: buffer underrun\n",
            device_get_nameunit(sc->dev));
    if (flags & MY_LOG_OVERRUN)
        log(LOG_WARNING, "%s: buffer overrun\n",
```

```
        device_get_nameunit(sc->dev));
}

/* In an interrupt or callout callback: */
if (some_condition) {
    sc->log_flags |= MY_LOG_UNDERRUN;
    taskqueue_enqueue(sc->tq, &sc->log_task);
}
```

The flags field lets the edge context accumulate multiple distinct conditions before the task runs. When the task fires, it snapshots the flags, clears them, and emits one log line per condition. Coalescing folds repeated-same-condition enqueues into one callback invocation, which is what you want for log-spam prevention.

Real example. `/usr/src/sys/dev/ale/if_ale.c` uses an interrupt task (`sc->ale_int_task`) to handle deferred work from the filter interrupt, including conditions that want to log or notify.

14.7.2 Pattern 2: Delayed Reset or Reconfiguration

Problem. The driver detects a condition that calls for a hardware reset or a configuration change, but the reset should not happen immediately. Reasons for the delay include “give in-flight IO a chance to complete”, “batch multiple causes into one reset”, or “throttle resets to avoid a reset storm”.

Solution. A struct `timeout_task` (or a struct `callout` paired with a struct `task`). The detector enqueues the timeout task with the chosen delay. If the condition clears before the delay elapses, the detector cancels the timeout task. If the condition persists, the task fires in thread context and performs the reset.

Code sketch. Same shape as the `myfirst` Stage 3 delayed-reset task. The only variation is that the detector typically cancels the pending task whenever the “need to reset” state changes, so the reset happens only when the condition has persisted for the full delay.

Real example. Many storage and network drivers use this pattern for recovery. The `/usr/src/sys/dev/bge/if_bge.c` Broadcom driver uses timeout tasks for link-state re-evaluation after a physical-layer event.

14.7.3 Pattern 3: Post-Interrupt Processing (the Filter + Task Split)

Problem. A hardware interrupt arrives. The interrupt filter’s job is to decide “is this our interrupt and did the hardware really need attention”. The filter must run quickly and must not sleep. The actual processing (read registers, service completion queues, possibly copyout results to user-space) does not belong in the filter.

Solution. A two-level split. The filter handler runs synchronously, reads a status register, decides whether the interrupt belongs to us, and if so enqueues a task. The task runs in thread context and performs the real work. This is the standard filter-plus-ithread split that `bus_setup_intr(9)` supports natively, but the taskqueue variant is useful when the driver wants more control over the deferred context than `ithread` provides.

Code sketch.

```
static int
my_intr_filter(void *arg)
{
    struct my_softc *sc = arg;
    uint32_t status;

    status = CSR_READ_4(sc, STATUS_REG);
    if (status == 0)
        return (FILTER_STRAY);

    /* Mask further interrupts from the hardware. */
    CSR_WRITE_4(sc, INTR_MASK_REG, 0);

    taskqueue_enqueue(sc->tq, &sc->intr_task);
    return (FILTER_HANDLED);
}

static void
my_intr_task(void *arg, int pending)
{
    struct my_softc *sc = arg;

    mtx_lock(&sc->mtx);
    my_process_completions(sc);
    mtx_unlock(&sc->mtx);

    /* Unmask interrupts again. */
    CSR_WRITE_4(sc, INTR_MASK_REG, ALL_INTERRUPTS);
}
```

Several subtleties. The filter masks the interrupt at the hardware level before enqueueing the task, so the hardware does not keep firing while the task is pending. The task runs in thread context, processes completions, and re-enables interrupts at the end. Coalescing folds multiple interrupts into a single task firing; the masking prevents the hardware from firing unboundedly. Part 4 will walk through real interrupt setup; the pattern shown here is the shape the chapter prepares you for.

Real example. `/usr/src/sys/dev/ale/if_ale.c`, `/usr/src/sys/dev/age/if_age.c`, and most Ethernet drivers use this pattern or a close variant.

14.7.4 Pattern 4: Async copyin/copyout After Hardware Completion

Problem. The driver has a queued user-space request that supplied addresses for input or output data. Hardware completion arrives as an interrupt. The driver must copy the data between user-space and kernel buffers to finalise the request. `copyin` and `copyout` sleep on their slow path, so they cannot run in interrupt context.

Solution. The interrupt path records the request identifier and enqueues a task. The task runs in thread context, identifies the user-space addresses from the stored request state, performs the copyin or copyout, and wakes the waiting user thread.

Code sketch.

```
struct my_request {
    struct task finish_task;
    struct proc *proc;
    void *uaddr;
    void *kaddr;
    size_t len;
    int done;
    struct cv cv;
    /* ... */
};

static void
my_finish_task(void *arg, int pending)
{
    struct my_request *req = arg;

    (void)copyout(req->kaddr, req->uaddr, req->len);

    mtx_lock(&req->sc->mtx);
    req->done = 1;
    cv_broadcast(&req->cv);
    mtx_unlock(&req->sc->mtx);
}

/* In the interrupt task: */
taskqueue_enqueue(sc->tq, &req->finish_task);
```

The user-space thread waits on req->cv after submitting the request; it wakes when the task marks done and broadcasts.

Real example. Character-device drivers that implement ioctls with large data transfers sometimes use this pattern. USB bulk-transfer completion in `/usr/src/sys/dev/usb/` frequently defers the user-space data copy via tasks.

14.7.5 Pattern 5: Retry-With-Backoff After Transient Failure

Problem. A hardware operation failed, but the failure is known to be transient. The driver wants to retry after a backoff interval, with increasing backoff on repeated failures.

Solution. A struct `timeout_task` that is rearmed with increasing delay on each failure. The task callback performs the retry; on success the driver clears the backoff; on failure the task re-enqueues with a larger delay.

Code sketch.

```

struct my_softc {
    struct timeout_task retry_task;
    int retry_interval_ms;
    int retry_attempts;
    /* ... */
};

static void
my_retry_task(void *arg, int pending)
{
    struct my_softc *sc = arg;
    int err;

    err = my_attempt_operation(sc);
    if (err == 0) {
        sc->retry_attempts = 0;
        sc->retry_interval_ms = 10;
        return;
    }

    sc->retry_attempts++;
    if (sc->retry_attempts > MAX_RETRIES) {
        device_printf(sc->dev, "giving up after %d attempts\n",
            sc->retry_attempts);
        return;
    }

    sc->retry_interval_ms = MIN(sc->retry_interval_ms * 2, 5000);
    taskqueue_enqueue_timeout(sc->tq, &sc->retry_task,
        (sc->retry_interval_ms * hz + 999) / 1000);
}

```

The initial interval is 10 ms, doubling on each failure, capped at 5 seconds, with a maximum attempt count. The retry keeps firing until success or giveup. A separate code path can cancel the retry (with `taskqueue_cancel_timeout`) if the conditions that motivated it change.

Real example. `/usr/src/sys/dev/iwm/if_iwm.c` and other wireless drivers use timeout tasks for firmware-load retries and link recalibration.

14.7.6 Pattern 6: Deferred Teardown

Problem. An object inside the driver must be freed, but some other code path may still hold a reference. Freeing immediately would be a use-after-free. The driver needs to free later, after the references are known to be

gone.

Solution. A `struct task` whose callback frees the object. The code path that wants to free the object enqueues the task; the task runs in thread context, after any outstanding references have had a chance to complete.

In more elaborate forms, the pattern uses reference counting: the task decrements a reference count and frees the object only when the count reaches zero. In simpler forms, the taskqueue's FIFO ordering is enough: all earlier-enqueued tasks complete before the teardown task runs, so if references are always taken inside tasks, they are all gone by the time the teardown task fires.

Code sketch.

```
static void
my_free_task(void *arg, int pending)
{
    struct my_object *obj = arg;

    /* All earlier tasks on this queue have completed. */
    free(obj, M_DEVBUF);
}

/* When we want to free the object: */
static struct task free_task;
TASK_INIT(&free_task, 0, my_free_task, obj);
taskqueue_enqueue(sc->tq, &free_task);
```

Caveat: the `struct task` itself must live until the callback fires, which means either embedding it in the object (and freeing the containing structure) or allocating it separately.

Real example. `/usr/src/sys/dev/usb/usb_hub.c` uses deferred teardown when a USB device is removed while still being used by a driver further up the stack.

14.7.7 Pattern 7: Scheduled Statistics Rollover

Problem. The driver keeps accumulated statistics that must be rolled into a rate-per-interval at regular boundaries. The rollover involves snapshotting counters, computing the delta, and storing the result in a ring buffer. This can be done in a timer callback, but the computation touches data structures protected by a sleepable lock.

Solution. A periodic `timeout_task` that handles the rollover in thread context. The task re-enqueues itself at the end of each firing for the next interval.

This is, in effect, a “taskqueue-based callout”. It is slightly heavier than a plain callout because it rides a callout-plus-task combo, but it can do things a plain callout cannot. Useful only when the callout alone would not suffice.

Code sketch.

```
static void
my_stats_rollover_task(void *arg, int pending)
{
    struct my_softc *sc = arg;

    sx_xlock(&sc->stats_sx);
    my_rollover_stats(sc);
    sx_xunlock(&sc->stats_sx);

    taskqueue_enqueue_timeout(sc->tq, &sc->stats_task, hz);
}
```

The self-reenqueue at the end keeps the task firing once per second. A control path that wants to stop the rollover cancels the timeout task.

Real example. Several network drivers use this pattern for watchdog-adjacent timers whose work needs a sleepable lock.

14.7.8 Pattern 8: taskqueue_block During Delicate Configuration

Problem. The driver is performing a configuration change that must not be interrupted by task execution. A task firing in the middle of the configuration could observe inconsistent state.

Solution. `taskqueue_block(sc->tq)` before the configuration change; `taskqueue_unblock(sc->tq)` after. While blocked, new enqueues accumulate but no tasks are dispatched. The already-running task (if any) completes naturally before the block takes effect.

Code sketch.

```
taskqueue_block(sc->tq);
/* ... reconfigure ... */
taskqueue_unblock(sc->tq);
```

`taskqueue_block` is fast. It does not drain running tasks; it only prevents dispatch of new ones. For a guarantee that no task is currently running you combine it with `taskqueue_quiesce`:

```
taskqueue_block(sc->tq);
taskqueue_quiesce(sc->tq);
/* ... reconfigure ... */
taskqueue_unblock(sc->tq);
```

`taskqueue_quiesce` waits for the currently-running task to finish and for the pending queue to drain. Combined with `block`, you have a guarantee that no task is running and no task will start until you unblock.

Real example. Some Ethernet drivers use this pattern during interface state transitions (link up, link down, media change).

14.7.9 Pattern 9: `taskqueue_drain_all` at a Subsystem Boundary

Problem. A complex subsystem wants to be fully quiet at a specific point. All its pending tasks, including ones that may have been enqueued by other pending tasks, must complete before the subsystem proceeds.

Solution. `taskqueue_drain_all(tq)` drains every task on the queue, waits for every in-flight task to complete, and returns when the queue is quiet.

`taskqueue_drain_all` is not a substitute for per-task `taskqueue_drain` at detach (because the queue might have tasks from other paths that should not be drained), but it is useful for internal synchronisation points where you want “everything is done, full stop”.

Real example. `/usr/src/sys/dev/wg/if_wg.c` uses `taskqueue_drain_all` on its per-peer taskqueue during peer cleanup.

14.7.10 Pattern 10: Simulation-Grade Synthetic Event Generation

Problem. During testing, the driver wants to generate synthetic events that exercise the full event-processing path. A direct function call would bypass the scheduler, miss the race conditions, and not stress the taskqueue mechanism. A real hardware event is of course unavailable in a test rig.

Solution. A `sysctl` handler that enqueues a task. The task callback invokes the same driver routine a real event would have invoked. Because the task goes through the taskqueue, the synthetic event has the same execution shape as a real one: it runs in thread context, observes the same locking, and passes through the same coalescing.

This is exactly what `myfirst's bulk_writer_flood` `sysctl` does. The pattern transfers to any driver that wants to self-test its deferred-work paths without needing real hardware to generate the triggering event.

14.7.11 A Selection From Real Drivers

The patterns above are not invented for the chapter. A short tour of `/usr/src/sys/dev/` that you should explore for yourself, with a suggested order:

- `/usr/src/sys/dev/ale/if_ale.c`: A small, readable Ethernet driver that uses a private taskqueue, a filter-plus-task split, and a single interrupt task. Good first reading.
- `/usr/src/sys/dev/age/if_age.c`: Similar pattern, slightly different driver family. Reading both reinforces the pattern.
- `/usr/src/sys/dev/bge/if_bge.c`: A larger Ethernet driver with multiple tasks (interrupt task, link task, reset task). Shows how multiple tasks compose on one queue.
- `/usr/src/sys/dev/usb/usb_process.c`: USB's dedicated per-device process queue (`usb_proc_*`). Demonstrates how a subsystem wraps task-style deferred work for its own domain.
- `/usr/src/sys/dev/wg/if_wg.c`: WireGuard uses group taskqueues for per-peer encryption. Advanced reading, but useful once the basic patterns click.
- `/usr/src/sys/dev/iwm/if_iwm.c`: Wireless driver with multiple timeout tasks for calibration, scanning, and firmware management.
- `/usr/src/sys/kern/subr_taskqueue.c`: The implementation itself. Reading `taskqueue_run_locked` once makes everything else concrete.

Twenty minutes with any of those files is an hour of chapter explanations you can skip. The patterns are visible at a glance once you know what to look for.

14.7.12 Wrapping Up Section 6

The same small API composes into a large family of patterns. Deferred logging, filter-plus-task interrupts, async copyin/copyout, retry-with-backoff, deferred teardown, statistics rollover, block during reconfiguration, `drain_all` at subsystem boundaries, synthetic event generation: each pattern is a variation on “edge detects, task acts”, and each is productive whenever the driver you are writing or reading fits the shape.

Section 7 turns to the other side of the same coin: when the pattern goes wrong, how do you see it? What tools does FreeBSD provide for inspecting a taskqueue’s state, and what are the common bugs that those tools help you diagnose?

14.8 Section 7: Debugging Taskqueues

Most taskqueue code is short. The common bugs are not subtle: tasks that never fire, tasks that fire too often, tasks that fire after the softc is freed, deadlocks against the driver mutex, and draining at the wrong point in the detach sequence. This section names the bugs, shows how to observe them, and walks through a deliberate break-and-fix on `myfirst` so you can practise the debugging workflow with something in front of you.

14.8.1 The Tools

A short survey of the tools you will reach for.

procstat -t: lists every kernel thread with its name, priority, state, and wait-channel. A private taskqueue’s worker thread shows up as `<name> taskq`, where `<name>` is what you passed to `taskqueue_start_threads`. A thread stuck in a non-trivial wait channel is a clue: the name of the channel often tells you what the thread is waiting for.

ps ax: equivalent for most of what `procstat -t` shows, with a less taskqueue-specific output. The kernel thread name appears in brackets.

sysctl dev.<driver>: the driver’s own sysctl tree. If you added a counter like `selwake_pending_drops`, its value is visible here. Diagnostic sysctls are the cheapest form of observability; add them whenever the question “how often does this path fire” might matter later.

dtrace(1): the kernel tracing framework. Taskqueue activity is traceable via FBT (function boundary tracing) probes on `taskqueue_enqueue` and `taskqueue_run_locked`. A short D script can count enqueues, measure delays between enqueue and dispatch, and so on.

ktr(4): the kernel event tracer. Compile-time enabled in debug kernels, provides a ring buffer of kernel events that can be dumped after a crash or inspected live. Useful for post-mortem analysis.

ddb(4): the in-kernel debugger. Breakpoints, stack traces, memory inspection. Reachable via `kgdb` after a kernel panic, or interactively after a `sysctl debug.kdb.enter=1` if you built a kernel with KDB enabled.

INVARIANTS and WITNESS: compile-time assertions and lock-order checker. Not tools you invoke, but the first line of defence. A debug kernel catches most taskqueue bugs the first time you hit them.

The Chapter 14 labs exercise `procstat -t`, `sysctl`, and `dtrace` explicitly. `ktr` and `ddb` are mentioned for completeness.

14.8.2 Common Bug 1: The Task Never Runs

Symptoms. You enqueue a task from a `sysctl` handler or callout callback; the task callback's `device_printf` never appears; the driver otherwise seems to work.

Likely cause. `taskqueue_start_threads` was not called, or the taskqueue pointer you enqueued onto is `NULL`.

How to check.

```
# procstat -t | grep myfirst
```

If no `myfirst taskq` thread is listed, the taskqueue either does not exist or has no threads. Check the attach path: is `taskqueue_create` called? Is its return value stored? Is `taskqueue_start_threads` called after?

```
# dtrace -n 'fbt::taskqueue_enqueue:entry /arg0 != 0/ { @[stack()] = count(); }'
```

If the stack trace shows enqueues onto the driver's taskqueue, the task is being submitted. If nothing shows, the code path that should enqueue is not being reached. Trace back and find why.

14.8.3 Common Bug 2: The Task Runs Too Often

Symptoms. The task callback does more work than expected, or the driver logs a strange count.

Likely cause. The callback does not respect the pending argument, or the callback self-enqueues without a condition, so once started it loops forever.

How to check. Add a counter to the callback:

```
static void
myfirst_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;
    static int invocations;

    atomic_add_int(&invocations, 1);
    if ((invocations % 1000) == 0)
        device_printf(sc->dev, "task invocations=%d\n", invocations);
    /* ... */
}
```

If the counter grows faster than the expected trigger rate, the task is self-looping or coalescing is not happening. Inspect the enqueue call sites.

14.8.4 Common Bug 3: Use-After-Free In the Task Callback

Symptoms. Kernel panic with a stack trace ending in your task callback, at a location that accesses softc state. The panic may happen during or shortly after detach.

Likely cause. The detach path freed the softc (or something the task touches) before draining the task. A trailing enqueue from a callout or other edge context fired after the drain, and the task ran against freed state.

How to check. Review the detach path against the ordering from Section 4. Specifically:

1. `is_attached` must be cleared before callouts are drained, so callout callbacks exit without re-enqueueing.
2. Callouts must be drained before tasks are drained, so no more enqueues can happen after the task drain.
3. Tasks must be drained before the state they touch is freed.
4. `taskqueue_free` must be called after all tasks on the queue are drained.

A mismatch in any of those is a potential use-after-free.

The debug kernel catches many of these cases via INVARIANTS assertions in `cbuf_*`, `cv_*`, and `mtx_*` routines. Run the detach path under load with WITNESS enabled; a bug often surfaces immediately.

14.8.5 Common Bug 4: Deadlock Between Task and Driver Mutex

Symptoms. A `read(2)` or `write(2)` to the device hangs forever. The task callback sits in a lock wait. The driver mutex is held by a different thread.

Likely cause. The task callback tries to acquire a lock that the thread enqueueing the task already holds, creating a cycle. For example:

- Thread A holds `sc->mtx` and calls a function that enqueues a task.
- The task callback acquires `sc->mtx` before doing its work.
- The task cannot proceed because Thread A still holds the mutex.
- Thread A waits for the task to complete.

The “Thread A waits for the task to complete” part does not fit the `myfirst` architecture (the driver does not explicitly wait for tasks from inside mutex-held paths), but it is a common shape in other drivers. Avoid it by not draining tasks while holding a lock they need.

How to check.

```
# procstat -kk <pid of stuck read/write thread>
# procstat -kk <pid of taskqueue thread>
```

Compare the stack traces. If one shows `mtx_lock/sx_xlock` in the task callback and the other shows `msleep_sbt/sleepqueue` at a point that holds the same lock, you have a deadlock.

14.8.6 Common Bug 5: Drain Hangs Forever

Symptoms. Detach hangs, `kldunload` does not return. The taskqueue thread is stuck somewhere.

Likely cause. The task callback is waiting on a condition that cannot be satisfied because the drain path is blocking the producer. Or the task callback is waiting on a lock that the detach path holds.

How to check.

```
# procstat -kk <pid of kldunload>
# procstat -kk <pid of taskqueue thread>
```

The drain is in `taskqueue_drain`, which is in `msleep`. The task is in some wait. Identify the wait channel; the name often tells you what the task is blocked on. If the task is blocked on something the detach path is holding, the design has a cycle.

A common specific case: the task callback calls `seldrain`, the detach path also calls `seldrain`, and the two collide. Avoid by ensuring `seldrain` is called exactly once, in the detach path, after the task drain.

14.8.7 The Break-and-Fix Exercise

A deliberate bug-and-fix walkthrough. The Stage 1 driver is correct; we modify it to introduce each of the bugs above, observe the symptom, and fix it.

14.8.7.1 Broken variant 1: missing `taskqueue_start_threads`

Remove the `taskqueue_start_threads` call from `attach`. Rebuild, load, enable the tick source, and run the `poll_waiter`. You will observe: no data appears in `poll_waiter`, even though `sysctl dev.myfirst.0.tick_source_interval_ms` is set.

Check `procstat -t`:

```
# procstat -t | grep myfirst
```

No `myfirst taskq` thread appears. The taskqueue exists (you created it) but has no workers. The enqueued `selwake_task` sits on the queue forever.

Fix: put the `taskqueue_start_threads` call back. Rebuild. Confirm the thread appears in `procstat -t` and the `poll_waiter` sees data.

14.8.7.2 Broken variant 2: draining in the wrong order

Move the `taskqueue_drain` call in `detach` to happen before the callout drains:

```
/* WRONG ORDER: */
taskqueue_drain(sc->tq, &sc->selwake_task);
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
MYFIRST_CO_DRAIN(&sc->tick_source_co);
seldrain(&sc->rsl);
seldrain(&sc->wsl);
```

Rebuild, load, enable the tick source at a high rate, let data flow for a few seconds, then unload. Most times the unload works. Occasionally, the unload panics with a stack in `selwakeup` being called after `sel drain`. The race is rare but real.

The issue: `taskqueue_drain` returned, but then an in-flight `tick_source` callout fired (it had not been drained yet) and re-enqueued the task. The new task fired after `sel drain` had run, and tried to `selwakeup` on a drained `selinfo`.

Fix: restore the correct order (callouts first, then tasks, then `sel drain`). Rebuild, verify the race is gone under the same stress.

14.8.7.3 Broken variant 3: task callback holds the mutex too long

Change `myfirst_selwake_task` to hold the mutex across `selwakeup`:

```
static void
myfirst_selwake_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    MYFIRST_LOCK(sc);          /* WRONG: holds mutex across selwakeup */
    selwakeup(&sc->rsl);
    MYFIRST_UNLOCK(sc);
}
```

Rebuild. Load under a debug kernel. Enable the tick source. Within seconds the kernel panics with a WITNESS complaint about locking order (or in some configurations with an assertion failure in `selwakeup` itself).

The issue: `selwakeup` acquires a lock that is not in the driver's documented lock order. WITNESS notices and complains.

Fix: the correct `myfirst_selwake_task` calls `selwakeup` with no driver mutex held. Restore that, rebuild, verify no WITNESS warnings.

14.8.7.4 Broken variant 4: forget to drain the task in detach

Remove the `taskqueue_drain(sc->tq, &sc->selwake_task)` line from `detach`. Rebuild. Load, enable the tick source at a high rate, run the `poll_waiter`, and immediately unload the driver.

Most times the unload completes. Occasionally, a task that was in flight at unload time runs against a `softc` whose `selinfo` has been drained and freed. The symptom is usually a kernel panic or a memory corruption that shows up later as an unrelated crash.

Fix: restore the drain. Rebuild, verify that repeated load-and-unload under load is stable.

14.8.7.5 Broken variant 5: wrong taskqueue pointer

A subtle Stage-2 bug. After moving to the private taskqueue, forget to update the `taskqueue_drain` call in `detach`. It still targets `taskqueue_thread`:

```
/* WRONG: enqueue on sc->tq but drain on taskqueue_thread */
taskqueue_enqueue(sc->tq, &sc->selwake_task);
/* ... in detach ... */
taskqueue_drain(taskqueue_thread, &sc->selwake_task);
```

Rebuild. Load, enable the tick source, run the waiter, unload. The unload typically completes without error, but `taskqueue_drain(taskqueue_thread, ...)` does not actually wait for the task that is running on `sc->tq`. If the task is in flight when detach proceeds, use-after-free.

Fix: match enqueue and drain on the same taskqueue pointer. Rebuild, test.

14.8.8 A DTrace One-Liner

A useful one-liner for any taskqueue-using driver. It measures the time between enqueue and dispatch for every task on the system:

```
# dtrace -n '
  fbt::taskqueue_enqueue:entry { self->t = timestamp; }
  fbt::taskqueue_run_locked:entry /self->t/ {
    @[execname] = quantize(timestamp - self->t);
    self->t = 0;
  }
'
```

The output is a distribution of enqueue-to-dispatch latency per process. Run it while your driver is producing tasks, then hit Ctrl-C to see the quantised histogram. Typical results on a lightly-loaded machine: tens of microseconds. Under load: milliseconds. If you see seconds, something is wrong.

A second useful one-liner measures task callback duration:

```
# dtrace -n '
  fbt::taskqueue_run_locked:entry { self->t = timestamp; }
  fbt::taskqueue_run_locked:return /self->t/ {
    @[execname] = quantize(timestamp - self->t);
    self->t = 0;
  }
'
```

Same structure, different timing. Tells you how long each `taskqueue_run_locked` invocation takes (which is the callback duration plus a small constant overhead).

14.8.9 Diagnostic Sysctls to Add

Useful counters to add to any taskqueue-using driver, with minimal cost and high diagnostic value.

```

int enqueues;           /* Total enqueues attempted. */
int pending_drops;      /* Enqueues that coalesced. */
int callback_runs;      /* Total callback invocations. */
int largest_pending;    /* Peak pending count observed. */

```

Update the counters in the enqueue path and the callback:

```

static void
myfirst_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    sc->callback_runs++;
    if (pending > sc->largest_pending)
        sc->largest_pending = pending;
    if (pending > 1)
        sc->pending_drops += pending - 1;
    /* ... */
}

/* Enqueue site: */
sc->enqueues++;
taskqueue_enqueue(sc->tq, &sc->task);

```

Expose each as a read-only sysctl. Under normal load, `enqueues == callback_runs + pending_drops`. `largest_pending` tells you the worst coalescing moment; if it grows, the taskqueue is falling behind the producer.

These counters cost a few atomic adds per enqueue. On any realistic workload the cost is unmeasurable. The diagnostic value is substantial.

14.8.10 The Debug-Kernel Obligation

A reminder worth repeating: run every Chapter 14 change under a kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED`. Most taskqueue bugs that are hard to find on a production kernel are caught instantly on a debug kernel. The cost of running a debug kernel is a small performance hit and a slightly larger build; the cost of not running one is an afternoon of debugging whenever anything goes wrong.

14.8.11 Wrapping Up Section 7

Debugging taskqueues is a small skill that composes with the tools you already have for debugging callouts, mutexes, and cvs. `procstat -t` and `ps ax` show the thread. `sysctl` exposes diagnostic counters. `dtrace`

measures enqueue-to-dispatch latency and callback duration. WITNESS catches locking-order violations at run-time. The common bugs (task never runs, wrong drain order, wrong lock discipline in callback, forgotten drain) are each catchable with a checklist and a debug kernel.

Section 8 consolidates the Chapter 14 work into Stage 4, the final driver. We extend `LOCKING.md`, bump the version string, and audit the driver against a full stress pass.

14.9 Section 8: Refactoring and Versioning Your Taskqueue Driver

Stage 4 is the consolidation stage. It does not add new functionality beyond what Stage 3 established; it sharpens the organisation of the code, updates the documentation, bumps the version, and runs the full regression sweep. If Stages 1 through 3 are where you built the driver, Stage 4 is where you ship it.

This section walks through the consolidation. The driver source is unified into a single, well-structured file; `LOCKING.md` gains a Tasks section; the version string advances to `0.8-taskqueues`; and the final regression pass confirms that every Chapter 12 and Chapter 13 behaviour still works correctly alongside the new Chapter 14 additions.

14.9.1 File Organisation

The chapter does not split the driver into multiple `.c` files. `myfirst.c` stays as the single translation unit, with one added responsibility (the tasks) grouped next to the corresponding callouts. If the driver grew much larger, a natural split would be `myfirst_timers.c` for callout code and `myfirst_tasks.c` for task code, with shared declarations in `myfirst.h`. For the current size the single file is easier to read.

Inside `myfirst.c`, the Stage 4 organisation is:

1. Includes and global macros.
2. Softc structure.
3. File-handle structure.
4. `cdevsw` declaration.
5. Buffer helpers.
6. Condition-variable wait helpers.
7. Sysctl handlers, grouped:
 - Configuration sysctls (debug level, soft byte limit, nickname).
 - Timer interval sysctls (heartbeat, watchdog, tick source).
 - Task sysctls (reset delayed, bulk writer batch, bulk writer flood).
 - Read-only stats sysctls.
8. Callout callbacks.
9. Task callbacks.
10. Cdev handlers (open, close, read, write, poll, handle destructor).
11. Device methods (identify, probe, attach, detach).
12. Module glue (driver, `DRIVER_MODULE`, version).

A block comment at the top of the file lists the major sections, so a new reader can jump to the right area without grep. Inside each section, the order is established-first: heartbeat before watchdog before tick source, for the callouts that share that order in the outline.

14.9.2 The LOCKING.md Update

The Chapter 13 LOCKING.md had sections for the mutex, the cvs, the sx, and the callouts. Chapter 14 adds a Tasks section.

Tasks

The driver owns one private taskqueue (``sc->tq``) and three tasks:

- ``selwake_task`` (plain): calls ``selwakeup(&sc->rsl)``. Enqueued from ``myfirst_tick_source`` when a byte is written. Drained at detach after callouts are drained and before ``seldrain``.
- ``bulk_writer_task`` (plain): writes a configured number of bytes to the cbuf, signals ``data_cv``, calls ``selwakeup(&sc->rsl)``. Enqueued from sysctl handlers and from the tick_source callback when ``bulk_writer_batch`` is non-zero. Drained at detach after callouts.
- ``reset_delayed_task`` (timeout_task): performs a delayed reset of the cbuf, counters, and configuration. Enqueued by the ``reset_delayed`` sysctl. Drained at detach.

The taskqueue is created in ``myfirst_attach`` with ``taskqueue_create`` and one worker thread started at ``PWAIT`` priority via ``taskqueue_start_threads``. It is freed in ``myfirst_detach`` via ``taskqueue_free`` after every task has been drained.

All task callbacks run in thread context. Each callback acquires ``sc->mtx`` explicitly if it needs state protected by the mutex; the taskqueue framework does not acquire driver locks automatically.

All task callbacks call ``selwakeup(9)`` (when they call it at all) with no driver lock held. The rule is the same as for the ``myfirst_read`` / ``myfirst_write`` paths: drop the mutex before ``selwakeup``.

Detach Ordering

The detach sequence is:

1. Refuse detach if ``sc->active_fhs > 0`` (EBUSY).
2. Clear ``sc->is_attached`` under ``sc->mtx``.
3. Broadcast ``data_cv`` and ``room_cv``.
4. Release ``sc->mtx``.

5. Drain ``heartbeat_co`, `watchdog_co`, `tick_source_co``.
6. Drain ``selwake_task`, `bulk_writer_task`, `reset_delayed_task`` (the last via ``taskqueue_drain_timeout``).
7. ``seldrain(&sc->rsel)`, `seldrain(&sc->wsel)``.
8. ``taskqueue_free(sc->tq)``.
9. Destroy cdev and cdev alias.
10. Free sysctl context.
11. Destroy cbuf, free counters.
12. Destroy ``data_cv`, `room_cv`, `cfg_sx`, `mtx``.

Violating the order risks use-after-free in task callbacks, selinfo accesses after drain, or taskqueue teardown while a task is still running.

The update is explicit about the ordering because the ordering is the main thing that can go wrong. A reader who inherits the driver from you and wants to add a new task has the existing discipline spelled out.

14.9.3 The Version Bump

The version string in the source moves from 0.7-timers to 0.8-taskqueues:

```
#define MYFIRST_VERSION "0.8-taskqueues"
```

And the driver's probe string updates:

```
device_set_desc(dev, "My First FreeBSD Driver (Chapter 14 Stage 4)");
```

The version is visible via the `hw.myfirst.version` sysctl, which was established in Chapter 12.

14.9.4 The Final Regression Pass

Stage 4 must pass every test that Stages 1 through 3 passed, plus the Chapter 12 and Chapter 13 test suites. A compact pass order:

1. **Build cleanly** under the debug kernel (`make clean && make`).
2. **Load** with `kldload ./myfirst.ko`.
3. **Chapter 11 unit tests**: basic read, write, open, close, reset.
4. **Chapter 12 synchronisation tests**: bounded blocking reads, bounded blocking writes, timeout reads, sx-protected configuration, cv broadcasts at detach.
5. **Chapter 13 timer tests**: heartbeat fires at configured rate, watchdog detects stalled drainage, tick source injects bytes.
6. **Chapter 14 task tests**:
 - `poll_waiter` sees data when tick source is active.

- `selwake_pending_drops` counter grows under load.
 - `bulk_writer_flood` triggers coalescing into a single callback.
 - `reset_delayed` fires after the configured delay.
 - Re-arming `reset_delayed` replaces the deadline (only one fire).
7. **Detach under load:** tick source at 1 ms, `poll_waiter` running, `bulk_writer_flood` issuing floods, then immediate unload. Should be clean.
 8. **WITNESS pass:** every test above, with no WITNESS warnings in `dmesg`.
 9. **lockstat pass:** run the test suite under `lockstat -s 5` to measure lock contention. The taskqueue's internal mutex should show up only briefly.

Every test should pass. If any fails, the cause is almost certainly a regression introduced between Stage 3 and Stage 4, not a pre-existing issue; Stages 1-3 are each validated independently before Stage 4 starts.

14.9.5 Keeping Documentation in Sync

Three places where documentation should reflect Chapter 14:

- The top-of-file comment in `myfirst.c`. Update the “locking strategy” block to mention the taskqueue.
- `LOCKING.md`. Update per the earlier subsection.
- Any per-chapter `README.md` under `examples/part-03/ch14-taskqueues-and-deferred-work/`. Describe each stage's deliverables and how to build them.

Updating documentation feels like overhead. It is not. Next year's reader (often your future self) depends on the documentation to reconstruct the design. Writing it now, while the design is fresh, is an order of magnitude cheaper than writing it later.

14.9.6 A Final Audit

Before closing Stage 4, run through a short audit.

- ☐ Does every callout drain happen before every task drain in detach?
- ☐ Does every task drain happen before `seldrain`?
- ☐ Does `taskqueue_free` happen after all tasks are drained?
- ☐ Does the attach failure path `taskqueue_free` the queue if a subsequent init step fails?
- ☐ Is every enqueue call site targeting the right taskqueue pointer (private, not shared)?
- ☐ Is every drain call site matched with its enqueue call site (same taskqueue, same task)?
- ☐ Is every task callback free of assumptions that “I run exactly once per enqueue”?
- ☐ Is every task callback free of assumptions that “I hold a driver lock on entry”?
- ☐ Does `LOCKING.md` list every task and its callback, lifetime, and enqueue paths?
- ☐ Does the version string reflect the new stage?

A driver that passes this audit, plus Chapter 13's audit from Section 7 of that chapter, is a driver you can hand to another engineer with confidence.

14.9.7 Wrapping Up Section 8

Stage 4 is the consolidation. The driver code is organised. `LOCKING.md` is current. The version string reflects the new capability. The full regression suite passes under a debug kernel. The audit checklist is clean.

The `myfirst` driver has come a long way. It started Chapter 10 as a single-open character device that moved bytes through a circular buffer. Chapter 11 gave it concurrent access. Chapter 12 gave it bounded blocking, cv channels, and sx-protected configuration. Chapter 13 gave it callouts for periodic and watchdog work. Chapter 14 gives it deferred work, which is the bridge between edge contexts and thread context and the missing piece for a driver that will eventually face real hardware interrupts.

The rest of this chapter expands the view slightly. The additional topics section introduces `epoch(9)`, group-taskqueues, and per-CPU taskqueues at an introductory level. Hands-on labs consolidate the Section 3 through Section 8 material. Challenge exercises stretch the reader. A troubleshooting reference gathers the common issues into one place. Then the wrapping-up and the bridge to Chapter 15.

14.10 Additional Topics: `epoch(9)`, Group-taskqueues, and Per-CPU Taskqueues

The main body of Chapter 14 taught the `taskqueue(9)` patterns a typical driver needs. Three adjacent topics deserve a mention for readers who will eventually write or read network drivers, or whose drivers grow to a scale where the simple private taskqueue is not enough. Each topic is introduced at the “know when to reach for it” level. The full mechanics belong to later chapters, especially those covering network drivers in Part 6 (Chapter 28).

14.10.1 `epoch(9)` in One Page

`epoch(9)` is a lockless read-synchronisation mechanism. Its purpose is to allow many readers to walk a shared data structure concurrently, without acquiring any exclusive lock, while guaranteeing that the data structure will not disappear underneath them.

The shape is this. Code that reads shared data enters an “epoch section” with `epoch_enter(epoch)` and leaves it with `epoch_exit(epoch)`. Inside the section, readers can dereference pointers freely. Writers who want to change or free a shared object do not do so directly; instead, they either call `epoch_wait(epoch)` to block until every current reader has left the epoch section, or they register a callback via `epoch_call(epoch, cb, ctx)` that runs asynchronously after all current readers have left.

The benefit is scalability. Readers pay no atomic-operation cost; they simply record thread-local state on entry and exit. Writers pay the synchronisation cost, but writes are rare compared to reads, so the amortised cost is low. For data structures that are walked by many threads and changed only occasionally, `epoch(9)` beats reader-writer locks substantially.

The cost is discipline. Code inside an epoch section must not sleep, must not acquire sleepable locks, and must not call functions that might do either. Writers who use `epoch_wait` block until every current reader has left, which means the writer is waiting for potentially a lot of readers.

Network drivers use `epoch(9)` heavily. The `net_epoch_preempt` epoch protects reads of network state (ifnet lists, routing entries, interface flags). A packet-input path enters the epoch, walks the state, exits the epoch.

A writer who wants to remove an interface defers the free via `NET_EPOCH_CALL` and the free happens on a taskqueue-like mechanism once every reader has finished.

For the taskqueue connection: when a task is initialised with `NET_TASK_INIT` instead of `TASK_INIT`, the taskqueue runs the callback inside the `net_epoch_preempt` epoch. The task callback can therefore walk network state without entering the epoch explicitly. From the implementation in `/usr/src/sys/kern/subr_taskqueue.c`:

```
if (!in_net_epoch && TASK_IS_NET(task)) {
    in_net_epoch = true;
    NET_EPOCH_ENTER(et);
} else if (in_net_epoch && !TASK_IS_NET(task)) {
    NET_EPOCH_EXIT(et);
    in_net_epoch = false;
}
task->ta_func(task->ta_context, pending);
```

The taskqueue dispatcher notices the `TASK_NETWORK` flag and enters or exits the epoch around the callback as needed. Consecutive network tasks share a single epoch entry, which is a small optimisation the framework does for free.

For myfirst, this is not relevant. The driver does not touch network state. But if you later write a network driver or read network driver code, `NET_TASK_INIT` and `TASK_IS_NET` are the macros that tell you a task is epoch-aware.

14.10.2 Grouptaskqueues in One Page

A grouptaskqueue is a scalable generalisation of a taskqueue. The basic idea: instead of a single queue with a single (or small) pool of workers, distribute tasks across many per-CPU queues, each serviced by its own worker thread. A “grouptask” is a task that binds to one of those queues.

The header is `/usr/src/sys/sys/gtaskqueue.h`:

```
#define GROUPTASK_INIT(gtask, priority, func, context) \
    GTASK_INIT(&(gtask)->gt_task, 0, priority, func, context)

#define GROUPTASK_ENQUEUE(gtask) \
    grouptaskqueue_enqueue((gtask)->gt_taskqueue, &(gtask)->gt_task)

void    taskqgroup_attach(struct taskqgroup *qgroup,
                        struct grouptask *grptask, void *uniq, device_t dev,
                        struct resource *irq, const char *name);
int     taskqgroup_attach_cpu(struct taskqgroup *qgroup,
                        struct grouptask *grptask, void *uniq, int cpu, device_t dev,
                        struct resource *irq, const char *name);
void     taskqgroup_detach(struct taskqgroup *qgroup, struct grouptask *gtask);
```

A driver that uses grouptasks does the following at attach:

1. Initialise each grouptask with `GROUPTASK_INIT`.
2. Attach each grouptask to a taskqgroup with `taskqgroup_attach` or `taskqgroup_attach_cpu`. The attachment assigns the grouptask to a specific per-CPU queue and worker.
3. At event time, enqueue with `GROUPTASK_ENQUEUE`.
4. At detach, `taskqgroup_detach` disassociates the grouptask.

Why use grouptasks instead of plain tasks? Two reasons.

First, **scalability with CPU count**. A single-threaded taskqueue is a bottleneck when many producers on different CPUs enqueue concurrently. The taskqueue's internal mutex becomes contended. A grouptaskqueue with per-CPU queues lets each CPU enqueue onto its own queue with no cross-CPU contention.

Second, **cache locality**. When an interrupt fires on CPU N and enqueues a grouptask that is bound to CPU N, the task runs on the same CPU that saw the interrupt. The task's data is already in that CPU's caches. For high-rate network drivers this is a substantial performance win.

The cost is complexity. Grouptaskqueues require more setup, more teardown, and more thinking about which queue a task belongs to. For most drivers this cost is not justified. For a high-end Ethernet driver that processes millions of packets per second, the cost pays for itself.

`myfirst` does not use grouptasks. It would not benefit. We mention them so that when you read a driver like `/usr/src/sys/dev/wg/if_wg.c` or `/usr/src/sys/net/iflib.c`, the macros look familiar.

14.10.3 Per-CPU Taskqueues in One Page

A per-CPU taskqueue is the simple version of the grouptaskqueue idea: one taskqueue per CPU, each with its own worker thread. The driver creates N taskqueues (one per CPU), binds each to a specific CPU with `taskqueue_start_threads_cpuset`, and dispatches tasks to the appropriate queue based on whatever locality rule the driver wants.

The key primitive is `taskqueue_start_threads_cpuset`:

```
int taskqueue_start_threads_cpuset(struct taskqueue **tqp, int count,
    int pri, cpuset_t *mask, const char *name, ...);
```

It is like `taskqueue_start_threads` but with a `cpuset_t` describing which CPUs the threads may run on. For a single-CPU binding the mask has exactly one bit set. For multi-CPU flexibility the mask has multiple bits.

A driver that uses per-CPU taskqueues typically keeps an array of taskqueue pointers indexed by CPU:

```
struct my_softc {
    struct taskqueue *per_cpu_tq[MAXCPU];
    ...
};

for (int i = 0; i < mp_ncpus; i++) {
    CPU_SETOF(i, &mask);
```

```

    sc->per_cpu_tq[i] = taskqueue_create("per_cpu", M_WAITOK,
        taskqueue_thread_enqueue, &sc->per_cpu_tq[i]);
    taskqueue_start_threads_cpuset(&sc->per_cpu_tq[i], 1, PWAIT,
        &mask, "%s cpu%d", device_get_nameunit(sc->dev), i);
}

```

And at enqueue time, pick the queue corresponding to the current CPU:

```

int cpu = curcpu;
taskqueue_enqueue(sc->per_cpu_tq[cpu], &task);

```

The benefits are the same as grouptasks, without the grouptask framework: work stays on the CPU it was produced on, CPU-local contention is eliminated, caches stay warm. The cost is that the driver manages its own per-CPU data structure.

For `myfirst` this is overkill. For a driver whose event rate exceeds tens of thousands of events per second, per-CPU taskqueues are worth considering. Grouptaskqueues are more general and usually preferred when the scalability story matters; per-CPU taskqueues are the lighter-weight alternative.

14.10.4 When to Use Which

A short decision tree.

- **Low-rate, thread-context, shared-queue is fine:** use `taskqueue_thread`. Easiest.
- **Low-rate, thread-context, isolation matters:** private taskqueue with `taskqueue_create` and `taskqueue_start_threads`. What `myfirst` uses.
- **High-rate, contention is the bottleneck:** per-CPU taskqueues or grouptaskqueues. Start with per-CPU; reach for grouptasks if you need the extra scalability features.
- **Network-path data:** `NET_TASK_INIT` and grouptaskqueues, following the patterns in network drivers.
- **Filter-interrupt context, must enqueue without sleeping:** `taskqueue_create_fast` or `taskqueue_fast`, since filter interrupts cannot use a sleep mutex.

Most drivers you write or read will fit one of the first two lines. The remainder are specialised cases that their chapters will walk through.

14.10.5 Wrapping Up Additional Topics

`epoch(9)`, grouptaskqueues, and per-CPU taskqueues are the scaling story for taskqueues. They share the same mental model as the basic API: enqueue from a producer, dispatch on a worker, obey the lock discipline, drain at teardown. The differences are in how many queues there are and how tasks are dispatched across them. For most drivers the basic API is enough; these advanced variants exist for when it is not.

The chapter now moves to hands-on labs.

14.11 Hands-On Labs

The labs consolidate the chapter's material into four practical exercises. Each lab uses the driver you have been evolving through Stages 1 through 4, plus a few small userspace helpers provided under `examples/part-03/ch14-taskqueues-and-deferred-work/labs/`.

Allocate one session per lab. If time is limited, Labs 1 and 2 are the most important; Labs 3 and 4 are worthwhile but more involved.

14.11.1 Lab 1: Observing a Taskqueue Worker Thread

Objective. Confirm that your driver's private taskqueue has a worker thread, that the thread sleeps when there is no work, and that the thread wakes and runs the callback when work is enqueued.

Setup. Load the Stage 2 driver (or Stage 4, either works). Make sure no other taskqueue-using process is flooding the system; the quieter the system, the easier the observation.

Steps.

1. Run `procstat -t | grep myfirst`. Record the PID and TID shown. The thread should be in state `sleep`.
2. Run `sysctl dev.myfirst.0.heartbeat_interval_ms=1000`. Wait a few seconds.
3. Run `procstat -t | grep myfirst` again. The thread may briefly appear in `run` state during a heartbeat firing; most of the time it is still `sleep` because the heartbeat does not enqueue a task. Confirm this is what you see. Note that the heartbeat runs in the callout thread, not the driver's taskqueue thread.
4. Run `sysctl dev.myfirst.0.tick_source_interval_ms=100`. Wait a few seconds.
5. Run `procstat -t | grep myfirst` again. The thread should now oscillate between `sleep` and `run` because the tick source is enqueueing a task ten times per second.
6. Stop the tick source with `sysctl dev.myfirst.0.tick_source_interval_ms=0`. Confirm the thread returns to permanent `sleep`.
7. Stop the heartbeat. Unload the driver. Confirm the thread disappears from `procstat -t`.

Expected outcome. You have directly observed the thread's lifecycle: created at `attach`, sleeps when idle, runs when dispatched, destroyed at `detach`. The observation is worth more than the two pages of explanation that produced it.

14.11.2 Lab 2: Measuring Coalescing Under Load

Objective. Produce a workload that stresses the taskqueue enough to trigger coalescing, then measure the coalescing rate using the `selwake_pending_drops` `sysctl`.

Setup. Load the Stage 4 driver. Compile `poll_waiter` as in Section 3.

Steps.

1. Start the `poll_waiter` in one terminal: `./poll_waiter > /dev/null`. Redirecting to `/dev/null` prevents the terminal from becoming a bottleneck.
2. In a second terminal, set the tick source to a fast rate: `sysctl dev.myfirst.0.tick_source_interval_ms=1`.

3. Wait ten seconds.
4. Read `sysctl dev.myfirst.0.stats.selwake_pending_drops`. Record the value.
5. Wait ten more seconds and read again. Compute the per-second rate.
6. Increase the tick source rate to see if coalescing increases: the minimum tick source interval is 1 ms, but you can combine with the `bulk_writer_flood` `sysctl` to produce burstier load:

```
# for i in $(seq 1 100); do sysctl dev.myfirst.0.bulk_writer_flood=1000; done
```

7. Read `selwake_pending_drops` after the flood.

Expected outcome. The number grows over time, more under burstier load, less under steady load. If the number stays at zero even under aggressive load, the taskqueue thread is fast enough to keep up; this is a good state, not a bug.

Variation. Run the same workload with a debug kernel (WITNESS enabled) and observe whether `dmesg` shows any WITNESS warnings. It should not.

14.11.3 Lab 3: Verify the Detach Ordering

Objective. Confirm that the detach path correctly drains tasks before freeing the state those tasks touch. Deliberately introduce the Section 7 bug (task drain after `seldrain`) and observe the race.

Setup. Start from Stage 4. Make a working copy of `myfirst.c`.

Steps.

1. In your working copy, reorder the drains in `myfirst_detach` so `seldrain` comes before `taskqueue_drain`:

```
/* BROKEN ORDER: */
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
MYFIRST_CO_DRAIN(&sc->tick_source_co);
seldrain(&sc->rsl);
seldrain(&sc->wsl);
taskqueue_drain(sc->tq, &sc->selwake_task);
/* ... rest ... */
```

This is intentionally wrong.

2. Rebuild with the broken order.
3. Load the driver. Enable the tick source at 1 ms. Run the `poll_waiter`.
4. After a few seconds of data flow, unload the driver: `kldunload myfirst`.
5. Most often the unload succeeds. Occasionally, especially under load, the kernel panics. The panic stack typically includes `selwakeup` called from `myfirst_selwake_task`, after `seldrain` has run.
6. Restore the correct order. Rebuild. Run the same stress and repeat the unload many times.
7. Confirm that the correct order never panics.

Expected outcome. You have experienced the race directly. The takeaway is that “usually works” is not “works”. The correct order is an invariant you preserve even when the incorrect order seems to work on casual testing.

Note. On a production kernel the panic may not happen; the memory corruption can hide until something else crashes. Always run such experiments on a debug kernel with INVARIANTS and WITNESS enabled.

14.11.4 Lab 4: Coalescing vs. Adaptive Batching

Objective. Build a small modification that uses the pending argument to drive adaptive batching, and compare its behaviour to the fixed-batch `bulk_writer_task` from Stage 3.

Setup. Start from Stage 4.

Steps.

1. Add a new task to the driver: `adaptive_writer_task`. Its callback writes pending bytes (capped at 64) to the buffer. Use the pattern from Section 5.
2. Add a `sysctl` that enqueues `adaptive_writer_task` on demand:

```
static int
myfirst_sysctl_adaptive_enqueue(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int n = 0, i, error;

    error = sysctl_handle_int(oidp, &n, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    for (i = 0; i < n; i++)
        taskqueue_enqueue(sc->tq, &sc->adaptive_writer_task);
    return (0);
}
```

3. Initialise the task in `attach`, drain it in `detach`.
4. Rebuild, load.
5. Issue 1000 enqueues via the `sysctl`: `sysctl dev.myfirst.0.adaptive_enqueue=1000`.
6. Read `sysctl dev.myfirst.0.stats.bytes_written`. Observe how many bytes were written.
7. Compare to Stage 3’s `bulk_writer_flood` with `bulk_writer_batch=1`. The fixed batch would write 1 byte (coalesced into one firing). The adaptive batch writes whatever pending was, up to 64.

Expected outcome. The adaptive task writes more bytes under burst load because it uses the coalescing information the kernel has already computed. For workloads where the per-event work should scale with the event count, this pattern is preferable to a fixed batch size.

Variation. Add a counter that records the largest pending value ever seen. Expose it as a `sysctl`. Under stress, you will see the peak pending grow as load increases.

14.12 Challenge Exercises

The challenges are optional stretches. They push the patterns this chapter established into territory the main text did not cover. Take your time with them; they are meant to consolidate understanding, not to introduce new material.

14.12.1 Challenge 1: Per-File-Handle Task

Modify the driver so that each open file handle has its own task. The task's job, when enqueued, is to emit a log line identifying the handle. Write a sysctl that enqueues every handle's task simultaneously.

Hints: - The struct `myfirst_fh` allocated in `myfirst_open` is the natural home for the per-handle task. - Initialise the task in `myfirst_open` after `malloc`. - Drain the task in `myfirst_fh_dtor` before `free`. - Enqueuing "every handle's task" requires a list of open handles. `devfs_set_cdevpriv` does not maintain such a list; you will have to build one in the softc, protected by the mutex.

Expected outcome: a demonstration of task ownership at a granularity finer than the driver. The challenge tests your understanding of lifetime ordering.

14.12.2 Challenge 2: Two-Tier Task Pipeline

Add a pipeline of two tasks. Task A receives data from the `write(2)` handler, transforms it (for simplicity, uppercases each byte), and enqueues Task B. Task B writes the transformed data to a secondary buffer and notifies waiters.

Hints: - The transformation work happens in the task callback, in thread context. The `write(2)` handler should not block waiting for the transformation. - You will need a small queue of pending transformations, protected by the mutex. - Task A pulls from the queue, transforms, and enqueues Task B with per-item state. Alternatively, Task B runs once per enqueue of A and handles whatever is in the queue.

Expected outcome: a mental model of how taskqueues can form pipelines, with each stage running in its own invocation. This is how complex drivers split work.

14.12.3 Challenge 3: Priority-Driven Task Ordering

Add two tasks with different priorities to the driver. The `urgent_task` has priority 10 and prints "URGENT". The `normal_task` has priority 0 and prints "normal". Write a sysctl handler that enqueues both tasks, normal first, urgent second.

Expected outcome: the `dmesg` output shows URGENT before normal, confirming that priority overrides enqueue order inside the queue.

14.12.4 Challenge 4: Blocking Reconfiguration

Implement a reconfiguration path that uses `taskqueue_block` and `taskqueue_quiesce`. The path should:

1. Block the taskqueue.

2. Quiesce (wait for running tasks to finish).
3. Perform the reconfiguration (say, resize the circular buffer).
4. Unblock.

Verify with `dttrace` that no task runs during the reconfiguration window.

Expected outcome: experience with `taskqueue_block` and `taskqueue_quiesce`, and an understanding of when those primitives are appropriate.

14.12.5 Challenge 5: Multi-Threaded Taskqueue

Modify Stage 4 to use a multi-threaded private taskqueue (say, four worker threads instead of one). Run the Lab 2 coalescing test. Observe what changes.

Expected outcome: Under load, the coalescing rate decreases because multiple worker threads drain the queue faster. Under very light load, nothing visible changes. The challenge shows how taskqueue configuration trades off under different workloads.

14.12.6 Challenge 6: Implementing a Watchdog Using a Timeout Task

Reimplement the Chapter 13 watchdog using a `timeout_task` instead of a plain callout. Each watchdog firing re-enqueues itself with the configured interval. A “kick” operation (another `sysctl`, perhaps `watchdog_kick`) cancels and re-enqueues the timeout task to reset the timer.

Expected outcome: understanding how the `timeout_task` primitive can replace a callout for periodic work, and when each is preferable. (Answer: `timeout_task` when the work needs thread context; callout otherwise.)

14.12.7 Challenge 7: Load a Real Driver and Read Its Code

Pick one of the drivers listed in Section 6 (`/usr/src/sys/dev/ale/if_ale.c`, `/usr/src/sys/dev/age/if_age.c`, `/usr/src/sys/dev/bge/if_bge.c`, or `/usr/src/sys/dev/iwm/if_iwm.c`). Read through its taskqueue usage. Identify:

- Which tasks the driver owns.
- Where each task is initialised.
- Where each task is enqueued.
- Where each task is drained.
- Whether the driver uses `taskqueue_create` or `taskqueue_create_fast`.
- What thread priority the driver uses.

Write a short summary (a page or so) of how the driver uses the taskqueue API. Keep it as a reference.

Expected outcome: Real driver reading turns pattern recognition from abstract to concrete. After doing this once with one driver, reading the next one is dramatically faster.

14.13 Troubleshooting Reference

A flat reference list of symptoms and remedies, for the moment when a bug surfaces and you need the answer fast. Pair this reference with the common-mistakes lists inside each section; together they cover most real problems.

14.13.1 The task never runs

- **Did you call `taskqueue_start_threads` after `taskqueue_create`?** Without threads, the queue accepts enqueues but never dispatches them.
- **Is the `taskqueue` pointer `NULL` at enqueue time?** Check the attach path; `taskqueue_create` may have failed silently if you did not check its return value.
- **Is the driver's `is_attached` false when the enqueue fires?** Some code paths (like Chapter 13's callout callbacks) exit early if `is_attached` is false; if the exit happens before the enqueue, the task does not run.
- **Is the `taskqueue` blocked via `taskqueue_block`?** If so, it accepts enqueues but does not dispatch. Unblock it.

14.13.2 The task runs twice when you expected once

- **Is the task self-reenqueuing?** A task callback that calls `taskqueue_enqueue` on itself will loop indefinitely unless the callback exits early under some condition.
- **Is a different code path also enqueueing?** Check every `taskqueue_enqueue` call site for the task. Two sources enqueueing will produce the expected double-run under some timing.

14.13.3 The task runs once when you expected twice or more

- **Did your enqueues coalesce?** The enqueue-already-pending rule folds redundant submissions. If you need exactly-one-per-event semantics, use separate tasks or a per-event queue.
- **Is the pending argument reported as greater than one?** If so, the framework coalesced.

14.13.4 Kernel panic in the task callback

- **Is the callback accessing freed state?** The most common cause of a panic in a task callback is a use-after-free. Check the detach ordering: every producer of enqueues must be drained before the task is drained; the state the task touches must not be freed until the task is drained.
- **Is the callback holding a lock it should not?** `WITNESS` catches most of these. Run under a debug kernel and read `dmesg`.
- **Is the callback calling `selwakeup` with a driver mutex held?** Do not. `selwakeup` acquires its own lock and must not be called with unrelated driver locks held.

14.13.5 Detach hangs

- **Is `taskqueue_drain` waiting for a task that cannot complete?** Check with `procstat -kk` the state of the taskqueue worker. If it is in a wait that depends on something the detach path holds, the design has a cycle.
- **Is `taskqueue_free` waiting for tasks that are still being enqueued?** Check `is_attached`: if callouts are still running and still enqueueing, the drain will not terminate. Ensure callouts are drained first.

14.13.6 `kldunload` returns `EBUSY` immediately

- **Is a file descriptor still open?** The detach path in `myfirst_detach` rejects with `EBUSY` if `active_fhs > 0`. Close any open descriptors and retry.

14.13.7 Coalescing count stays at zero

- **Is the workload too light?** Coalescing happens only when the producer outruns the consumer. On a lightly-loaded machine this rarely happens.
- **Is your measurement correct?** Coalescing is counted in the callback, not in the enqueue path. Check your counter logic.
- **Is the taskqueue multi-threaded?** More threads mean faster consumption, less coalescing.

14.13.8 The private taskqueue's thread does not appear in `procstat -t`

- **Did `taskqueue_start_threads` return zero?** If it returned an error, the threads were not created. Check the return value.
- **Is the driver actually loaded?** `kldstat` confirms.
- **Is the thread's name different from what you expected?** The format string to `taskqueue_start_threads` controls the name; make sure you are grepping for the right thing.

14.13.9 Deadlock between task and driver mutex

- **Does the task callback acquire a lock that a different thread holds while waiting for the task?** That is the textbook deadlock shape. Break it by moving the task enqueue outside the lock-held section, or by restructuring the wait so it does not block on the task.

14.13.10 `taskqueue_enqueue` fails with `EEXIST`

- **You passed `TASKQUEUE_FAIL_IF_PENDING` and the task was already pending.** The failure is intentional; check whether the flag is what you want.

14.13.11 `taskqueue_enqueue_timeout` does not seem to fire

- **Is the taskqueue blocked?** Blocked queues do not dispatch timeout tasks either.

- **Is the tick count reasonable?** A tick count of zero fires immediately, but a non-integer millisecond-to-tick conversion can produce unexpectedly long delays. Use $(\text{ms} * \text{hz} + 999) / 1000$ for ceil.
- **Has the timeout task been cancelled by a `taskqueue_cancel_timeout`?** If so, re-enqueue.

14.13.12 Re-arming a `timeout_task` is not replacing the deadline

- **Each `taskqueue_enqueue_timeout` replaces the pending deadline.** If your driver calls it multiple times and only the first seems to take effect, you may have an ordering issue: are you sure the subsequent calls are happening?

14.13.13 WITNESS complains about a lock order involving `tq_mutex`

- **The taskqueue's internal mutex is entering your driver's lock order.** Usually because a task callback acquires a driver lock, and some other code path acquires that driver lock first and then enqueues.
- **The resolution is usually to enqueue before acquiring the driver lock, or to restructure the code so the two locks are never held in the same thread in the wrong order.**

14.13.14 `procstat -kk` shows the taskqueue thread sleeping on a lock

- **A task callback is blocked on a sleepable lock.** Identify the lock from the wait channel. Check whether the holder of that lock is also waiting for something; if so, you have a dependency chain.

14.13.15 Task callbacks are slow

- **Profile with `dtrace`.** The one-liner from Section 7 measures callback duration.
- **Is the callback holding a lock during long operations?** Move the long operation outside the lock.
- **Is the callback performing synchronous IO?** That belongs in `read(2)` / `write(2)` / `ioctl(2)` handlers, not in taskqueue callbacks, unless the IO is genuinely the point of the task.

14.13.16 Taskqueue deadlock during boot

- **Are you enqueueing tasks from an `SI_SUB` that runs before `SI_SUB_TASKQ`?** The predefined taskqueues are initialised at `SI_SUB_TASKQ`. Earlier `SI_SUB` handlers cannot enqueue onto them.

14.14 Wrapping Up

Chapter 14 taught one primitive in depth. The primitive is `taskqueue(9)`. Its purpose is to move work out of contexts that cannot do the work and into a context that can. Its API is small: initialise a task, enqueue it, drain it, free the queue when you are done. The mental model is equally small: edge contexts detect, thread-context tasks act.

The `myfirst` driver absorbed the new mechanism gracefully because every earlier chapter had prepared the scaffolding. Chapter 11 gave it concurrency. Chapter 12 gave it `cv` channels and `sx` configuration. Chapter 13

gave it callouts and the drain-at-detach discipline. Chapter 14 added tasks as a fifth primitive in the same shape: initialise in attach, drain in detach, obey the established locking rules, and compose with what came before. The driver is now version 0.8-taskqueues, with three tasks and one private taskqueue, and it tears down cleanly under load.

Underneath those concrete changes, the chapter made several larger points. A short recap of each.

Deferred work is the bridge between edge contexts and thread contexts. Callouts, interrupt filters, and epoch sections all face the same constraint: they cannot do work that requires sleeping or sleepable-lock acquisition. A taskqueue solves the problem uniformly by accepting a small submission from the edge context and running the real work on a thread.

The taskqueue framework handles the logistics so you do not have to. Allocation, locking of the internal queue, dispatch, coalescing, cancellation, drain: every one of those is handled by the framework. Your driver provides a callback and an enqueue site. The rest is a short setup in attach and a short teardown in detach.

Coalescing is a feature, not a bug. A task coalesces redundant enqueues into a single firing whose pending argument carries the tally. This lets bursts of events fold into a single callback invocation, which is almost always what you want for performance. A design that needs per-event invocation needs a per-event task or a per-event queue, not one task enqueued many times.

Detach ordering is the biggest new discipline the chapter added. Callouts first, tasks second, selinfo third, taskqueue_free last. Violating the order is a race that may not appear on quiet testing and will appear under load. The `LOCKING.md` document is where you write the order down; following it is where you avoid the race.

Real drivers all use the same handful of patterns. Deferred logging from edge context; filter-plus-task interrupt splits; async copyin/copyout; retry-with-backoff; deferred teardown; scheduled rollover; block-during-reconfiguration. Every one of them is a variation on the edge-detects, task-acts shape. Reading `/usr/src/sys/dev/` is the fastest way to absorb the patterns in depth.

The taskqueue story scales up. epoch(9), group taskqueues, and per-CPU taskqueues handle the scalability cases that a simple private taskqueue cannot. They share the mental model of the basic API; the differences are in the number of queues, the dispatch strategy, and the scaffolding around the workers. For most drivers the basic API is enough; for the high-end cases, the advanced variants are there when you need them.

14.14.1 A Reflection Before Chapter 15

You started Chapter 14 with a driver that could act on its own through time (callouts) but whose actions were constrained to what callouts allow. You leave with a driver that can act through time and also act through work handed off to a worker thread. Those two combine to cover almost every kind of deferred action a driver needs. The third piece is the synchronisation that coordinates the producers and consumers safely, and that piece is what Chapter 15 develops.

The mental model is cumulative. Chapter 12 introduced cvs, mutexes, and sx. Chapter 13 introduced callouts and the no-sleep context. Chapter 14 introduced tasks and the defer-to-thread context. Chapter 15 will introduce the advanced coordination primitives (semaphores, cv_timedwait_sig, cross-component handshakes) that compose the earlier pieces into richer patterns. Each chapter adds a small primitive and the discipline that goes with it.

The cumulative shape of the driver is visible in `LOCKING.md`. A Chapter 10 driver had no `LOCKING.md`. A Chapter 11 driver had a single paragraph. A Chapter 14 driver has a multi-page document with sections for the

mutex, the cvs, the sx, the callouts, and the tasks, plus a detach-ordering section that names every drain step in the correct order. That document is an artefact you carry forward into every future chapter. When Chapter 15 adds semaphores, `LOCKING.md` grows a Semaphores section. When Part 4 adds interrupts, it grows an Interrupts section. The driver's lifetime is its `LOCKING.md`.

14.14.2 A Second Reflection: The Discipline

One habit the chapter wants you to internalise above all others: every new primitive in your driver earns an entry in `LOCKING.md`, a destructor pair in attach/detach, and a place in the documented detach ordering. Skipping any of those creates a bug waiting to happen. The discipline pays for itself the first time you hand the driver to someone else.

The inverse is also true: every time you read someone else's driver, look at their `LOCKING.md` first. If it is missing, read the attach and detach functions to reconstruct the ordering from code. If you see a primitive in attach with no corresponding drain in detach, that is a bug. If you see a drain without a clear predecessor, that is probably an ordering error. The discipline is the same for writing and for reading.

14.14.3 A Short Note on Simplicity

Taskqueues look simple. They are. The API is small, the patterns are regular, and the idioms transfer across drivers. The simplicity is deliberate; it is what makes the API usable in practice. The same simplicity also makes the rules non-negotiable: a rule that is skipped produces a race that is hard to debug. Follow the discipline, and taskqueues will stay simple for you. Improvise, and they will not.

14.14.4 What to Do If You Are Stuck

If something in your driver is not behaving as expected, work the troubleshooting reference from Section 7 in order. Check the first item that matches your symptom. If no item matches, re-read Section 4 (setup and cleanup) and audit your detach ordering against `LOCKING.md`. If the ordering is correct, `dtrace` the enqueue path and see whether the expected events are happening.

If the driver panics, use `gdb` on the crash dump. A bt shows the stack. A stack that includes your task callback is a good place to start; compare it against the patterns in Section 7.

If all else fails, re-read the real driver you picked for Challenge 7 in the previous section. Sometimes the pattern that seems confusing in your own code reads naturally in a driver someone else wrote. The patterns are universal; the driver you are reading is not special.

14.15 Bridge to Chapter 15

Chapter 15 is titled *More Synchronization: Conditions, Semaphores, and Coordination*. Its scope is the advanced coordination primitives that compose the mutexes, cvs, sx locks, callouts, and tasks you now have into more sophisticated patterns.

Chapter 14 prepared the ground in four specific ways.

First, **you now have a working producer/consumer pair in the driver**. The `tick_source` callout (and the other Chapter 14 enqueue sites) is a producer; the taskqueue thread is a consumer. The cv channels from Chapter 12 are another producer/consumer pair: `write(2)` produces, `read(2)` consumes. Chapter 15 generalises the pattern and adds primitives (counting semaphores, interruptible cv waits) that handle more elaborate versions of the same shape.

Second, **you know the discipline of drain-at-detach**. Every primitive you have added so far has a matching drain. Chapter 15 introduces semaphores, which have their own “drain” pattern (release all waiters, then destroy), and the discipline transfers directly.

Third, **you know how to think about context boundaries**. The callout context, the task context, the syscall context: each has its own rules, and your driver’s design respects them. Chapter 15 adds signal-interruptible waits, which add user-interaction context to the mix. The habit of “which context am I in and what can I do here” transfers.

Fourth, **your `LOCKING.md` is in the rhythm of “one section per primitive, plus an ordering section at the end”**. Chapter 15 will add a Semaphores section and possibly a Coordination section. The structure is established; only the content changes.

Specific topics Chapter 15 will cover:

- Counting semaphores and binary semaphores via the `sema(9)` API.
- `cv_timedwait_sig` and signal-interruptible blocking.
- Readers-writers patterns via `sx(9)` in their fully-general form.
- Cross-component handshakes that coordinate timers, tasks, and user threads.
- State flags and memory barriers for lock-free coordination (at an introductory level).
- Testing harnesses for concurrency: stress scripts, fault-injection, replay of races.

You do not need to read ahead. Chapter 14 is sufficient preparation. Bring your `myfirst` driver at Stage 4 of Chapter 14, your `LOCKING.md`, your WITNESS-enabled kernel, and your test kit. Chapter 15 starts where Chapter 14 ended.

A small closing reflection. The driver you started Part 3 with understood one syscall at a time. The driver you have now has three callouts, three tasks, two cvs, two locks, and a full detach ordering. It handles concurrent readers and writers, timed events, deferred work across context boundaries, coalesced bursts of events, and clean teardown under load. It has a documented locking story and a validated regression suite. It is starting to look like a real FreeBSD driver.

Chapter 15 closes out Part 3 by adding the coordination primitives that let the pieces compose into richer patterns. Then Part 4 begins: hardware and platform-level integration. Real interrupts. Real memory-mapped registers. Real hardware that might fail, misbehave, or refuse to cooperate. The discipline you have built through Part 3 is what will carry you through.

Take a moment before moving on. The leap from Chapter 13 to Chapter 14 was a qualitative one: the driver gained the ability to defer work to a thread context, and the patterns you learned along the way (detach ordering, coalescing, the edge/thread mental model) are patterns you will reuse in every chapter that follows. From here, Chapter 15 consolidates the synchronisation story, and Part 4 begins the hardware story. The work you have done is not lost; it compounds.

14.15.1 A Final Aside on the Shape of the Kernel

One last thought before Chapter 15. You have now met five of the kernel's synchronisation-and-deferral primitives: the mutex, the condition variable, the sx lock, the callout, and the taskqueue. Each exists because earlier, simpler primitives could not address the same problem. A mutex cannot express “wait for a condition”; that is what cvs do. A sleep mutex cannot be held across a sleep; that is what sx locks allow. A callout cannot run work that needs to sleep; that is what taskqueues allow.

The pattern is recognisable across the kernel. Every synchronisation primitive exists because of a specific gap in the earlier ones. When you read kernel code, you can often guess why a particular primitive was chosen by asking what its neighbours cannot do. A file descriptor cannot suffer a use-after-free because the reference-count primitive prevents it. A network packet cannot be freed while a reader is walking the list because the epoch primitive prevents it. A task cannot run after detach because the drain primitive prevents it.

The kernel is a catalogue of these primitives, each deliberate, each a response to a specific class of problem. Your driver accumulates its own catalogue as it grows. Chapter 14 added one more item to the list. Chapter 15 adds several. Part 4 begins the hardware-facing catalogue. From here on the primitives multiply, but the shape of the discipline does not change. Define the problem, pick the primitive, initialise and tear down cleanly, document the ordering, verify under load.

That is the craft. The rest of the book walks you through it.

14.16 Reference: Pre-Production Taskqueue Audit

A short audit to perform before promoting a taskqueue-using driver from development to production. Each item is a question; each should be answerable with confidence.

14.16.1 Task Inventory

- ☐ Have I listed every task the driver owns in `LOCKING.md`?
- ☐ For each task, have I named its callback function?
- ☐ For each task, have I documented its lifetime (init in `attach`, drain in `detach`)?
- ☐ For each task, have I documented its trigger (what causes it to be enqueued)?
- ☐ For each task, have I documented whether it self-reenqueues or runs once per external trigger?
- ☐ For each timeout task, have I named the interval it is scheduled for and the cancellation path?

14.16.2 Taskqueue Inventory

- ☐ Is the taskqueue a private queue or a predefined one? Is the choice justified?
- ☐ If private, does `attach` call `taskqueue_create` (or `taskqueue_create_fast`) before any code that could enqueue?
- ☐ If private, does `attach` call `taskqueue_start_threads` before any code that expects a callback to fire?
- ☐ Is the worker thread count appropriate for the workload?
- ☐ Is the worker thread priority appropriate for the workload?
- ☐ Is the worker thread name informative enough that `procstat -t` output is useful?

14.16.3 Initialisation

- ☐ Does every `TASK_INIT` happen after the `softc` is zeroed and before the task can be enqueued?
- ☐ Does every `TIMEOUT_TASK_INIT` reference the correct taskqueue and a valid callback?
- ☐ Does `attach` handle `taskqueue_create` failure by unwinding earlier initialisations?
- ☐ Does `attach` handle `taskqueue_start_threads` failure by freeing the taskqueue?

14.16.4 Enqueue Sites

- ☐ Does every enqueue site target the right taskqueue pointer?
- ☐ Does every enqueue from an edge context (callout, interrupt filter) confirm the taskqueue exists before enqueueing?
- ☐ Is the enqueue call safe in the context it happens from (not inside a spin mutex if the taskqueue is `taskqueue_create`, for example)?
- ☐ Is the coalescing behaviour intentional at every enqueue site?

14.16.5 Callback Hygiene

- ☐ Does every callback have the correct signature (`void *context, int pending`)?
- ☐ Does every callback acquire driver locks explicitly where needed?
- ☐ Does every callback release driver locks before calling `selwakeup`, `log`, or other functions that acquire unrelated locks?
- ☐ Does every callback avoid `M_NOWAIT` allocations where `M_WAITOK` is safe?
- ☐ Is the callback's total work time bounded?

14.16.6 Cancellation

- ☐ Does every `taskqueue_cancel` / `taskqueue_cancel_timeout` call happen under the right mutex if the cancellation race matters?
- ☐ Are the cases where `cancel` returns `EBUSY` handled (usually by a follow-up drain)?

14.16.7 Detach

- ☐ Does `detach` clear `is_attached` before draining callouts?
- ☐ Does `detach` drain every callout before draining any task?
- ☐ Does `detach` drain every task before calling `sel drain`?
- ☐ Does `detach` call `sel drain` before `taskqueue_free`?
- ☐ Does `detach` call `taskqueue_free` before destroying the mutex?
- ☐ Does `detach` set `sc->tq = NULL` after free?

14.16.8 Documentation

- ☐ Is every task documented in `LOCKING.md`?
- ☐ Are the discipline rules (enqueue-safe, callback-lock, drain-order) documented?

- ☐ Is the taskqueue subsystem mentioned in the README?
- ☐ Are there sysctls exposed that let users observe the behaviour?

14.16.9 Testing

- ☐ Have I run the regression suite with WITNESS enabled?
- ☐ Have I tested detach with all tasks in flight?
- ☐ Have I run a long-duration stress test with high enqueue rates?
- ☐ Have I used dtrace to verify the enqueue-to-dispatch latency is within expectations?
- ☐ Have I used procstat -kk under load to confirm the taskqueue thread is not stuck?

A driver that passes this audit is a driver you can trust under load.

14.17 Reference: Standardising Tasks Across a Driver

For a driver with several tasks, consistency matters more than cleverness. A short discipline.

14.17.1 One Naming Convention

Pick a convention and follow it. The chapter's convention:

- The task struct is named `<purpose>_task` (e.g., `selwake_task`, `bulk_writer_task`).
- The timeout-task struct is named `<purpose>_delayed_task` (e.g., `reset_delayed_task`).
- The callback is named `myfirst_<purpose>_task` (e.g., `myfirst_selwake_task`, `myfirst_bulk_writer_task`).
- The sysctl that enqueues the task (if one exists) is named `<purpose>_enqueue` or `<purpose>_flood` for bulk variants.
- The sysctl that configures the task (if one exists) is named `<purpose>_<parameter>` (e.g., `bulk_writer_batch`).

A new maintainer can add a new task following the convention without thinking about names. Conversely, a code review immediately catches deviations.

14.17.2 One Init/Drain Pattern

Every task uses the same initialisation and drain:

```
/* In attach, after taskqueue_start_threads: */
TASK_INIT(&sc-><purpose>_task, 0, myfirst_<purpose>_task, sc);

/* In detach, after callout drains, before seldrain: */
taskqueue_drain(sc->tq, &sc-><purpose>_task);
```

For timeout tasks:

```

/* In attach: */
TIMEOUT_TASK_INIT(sc->tq, &sc-><purpose>_delayed_task, 0,
    myfirst_<purpose>_delayed_task, sc);

/* In detach: */
taskqueue_drain_timeout(sc->tq, &sc-><purpose>_delayed_task);

```

The call sites are short and uniform. A reviewer can scan for the pattern and flag deviations instantly.

14.17.3 One Callback Pattern

Every task callback follows the same structure:

```

static void
myfirst_<purpose>_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    /* Optional: record coalescing for diagnostics. */
    if (pending > 1) {
        MYFIRST_LOCK(sc);
        sc-><purpose>_drops += pending - 1;
        MYFIRST_UNLOCK(sc);
    }

    /* ... do the work, acquiring locks as needed ... */
}

```

The optional coalescing record makes the coalescing behaviour visible through sysctl. Drop it if the task rarely coalesces or if the counter would not be useful.

14.17.4 One Documentation Pattern

Every task is documented in `LOCKING.md` with the same fields:

- Task name and kind (plain or `timeout_task`).
- Callback function.
- Which code paths enqueue it.
- Which code paths cancel it (if any).
- Where it is drained at detach.
- What lock, if any, the callback acquires.
- Why this task is deferred (i.e., why it cannot run in the enqueue context).

A new task's documentation is mechanical. A code review can verify the documentation against the code.

14.17.5 Why Standardise

Standardisation has costs: a new contributor must learn the conventions; deviations require a special reason. The benefits are larger:

- Reduced cognitive load. A reader who knows the pattern instantly understands every task.
- Fewer mistakes. The standard pattern handles the common cases (init in attach, drain in detach, drop lock before selwakeup) correctly; a deviation is more likely to be wrong.
- Easier review. Reviewers can scan for shape rather than reading every line.
- Easier handoff. A maintainer who has not seen the driver can add a new task following the existing template.

The cost of standardisation is paid once at design time. The benefits accrue forever. Always worth it.

14.18 Reference: Further Reading on Taskqueues

For readers who want to go deeper.

14.18.1 Manual Pages

- `taskqueue(9)`: the canonical API reference.
- `epoch(9)`: the epoch synchronisation framework, relevant for network tasks.
- `callout(9)`: the companion primitive; `timeout_task` is built on top of it.
- `swi_add(9)`: the software-interrupt registration used by `taskqueue_swi` and friends.
- `kproc(9)`, `kthread(9)`: direct kernel-thread creation, for when a taskqueue is not enough.

14.18.2 Source Files

- `/usr/src/sys/kern/subr_taskqueue.c`: the taskqueue implementation. Read `taskqueue_run_locked` carefully; it is the heart of the subsystem.
- `/usr/src/sys/sys/taskqueue.h`, `/usr/src/sys/sys/_task.h`: the public API and structures.
- `/usr/src/sys/kern/subr_gtaskqueue.c`, `/usr/src/sys/sys/gtaskqueue.h`: the group taskqueue layer.
- `/usr/src/sys/sys/epoch.h`, `/usr/src/sys/kern/subr_epoch.c`: the epoch framework.
- `/usr/src/sys/dev/ale/if_ale.c`: a clean Ethernet driver using taskqueues.
- `/usr/src/sys/dev/bge/if_bge.c`: a larger Ethernet driver with multiple tasks.
- `/usr/src/sys/dev/wg/if_wg.c`: WireGuard's group taskqueue usage.
- `/usr/src/sys/dev/iwm/if_iwm.c`: a wireless driver with timeout tasks.
- `/usr/src/sys/dev/usb/usb_process.c`: USB's dedicated per-device process queue (`usb_proc_*`).

14.18.3 Manual Pages To Read in Order

For a reader new to FreeBSD's deferred-work subsystem:

1. `taskqueue(9)`: the canonical API.

2. `epoch(9)`: the lockless read-synchronisation framework.
3. `callout(9)`: the sibling timed-execution primitive.
4. `swi_add(9)`: the software-interrupt layer beneath some taskqueues.
5. `kthread(9)`: the direct-thread-creation alternative.

Each builds on the previous; reading in order takes a couple of hours and gives you a solid mental model of the kernel's deferred-work infrastructure.

14.18.4 External Material

The chapter on synchronization in *The Design and Implementation of the FreeBSD Operating System* (McKusick et al.) covers the historical evolution of deferred-work subsystems. Useful as context; not required.

The FreeBSD developers' mailing list (`freebsd-hackers@`) occasionally discusses taskqueue improvements and edge cases. Searching the archive for "taskqueue" returns relevant historical context.

For deeper understanding of the network stack's use of `epoch(9)` and group taskqueues, the `iflib(9)` framework documentation and the source under `/usr/src/sys/net/iflib.c` are worth a read. They are beyond the level of this chapter, but they explain why modern network drivers are structured the way they are.

Finally, real driver source. Pick any driver in `/usr/src/sys/dev/` that uses taskqueues (most do), read its taskqueue-related code, and compare it to the patterns in this chapter. The translation is direct; you will recognize the shapes immediately. That kind of reading turns the chapter's abstractions into working knowledge.

14.19 Reference: Taskqueue Cost Analysis

A short discussion of what taskqueues actually cost, useful when deciding whether to defer or whether to create a private queue.

14.19.1 Cost At Rest

A `struct task` that has not been enqueued costs nothing beyond the size of the structure (32 bytes on amd64). The kernel does not know about it. It sits in your softc, doing nothing.

A `struct taskqueue` allocated and idle costs: - The taskqueue structure itself (a few hundred bytes). - One or more worker threads (16 KB stack each on amd64, plus scheduler state). - No per-enqueue cost at rest.

14.19.2 Cost Per Enqueue

When you call `taskqueue_enqueue(tq, &task)`, the kernel does:

1. Acquire the taskqueue's internal mutex. Microseconds.
2. Check whether the task is already pending. Constant time.
3. If not pending, link into the list and wake the worker (via wakeup on the queue). Constant time plus a scheduler event.
4. If already pending, increment `ta_pending`. Single arithmetic.
5. Release the mutex.

The total cost is microseconds on an uncontended queue. Under contention the mutex acquisition can take longer, but the framework uses a padalign mutex to minimise false sharing, and the mutex is rarely held for more than a few instructions.

14.19.3 Cost Per Dispatch

When the worker thread wakes and runs `taskqueue_run_locked`, the per-task cost is:

1. Walk to the head of the queue. Constant time.
2. Pull the task off. Constant time.
3. Record the pending count, reset it. Constant time.
4. Drop the mutex.
5. Enter any required epoch (for network tasks).
6. Call the callback. Cost depends on the callback.
7. Exit epoch if entered.
8. Re-acquire the mutex for the next iteration.

For a typical short callback (microseconds of work), the per-dispatch overhead is dominated by the callback itself plus one mutex round-trip and one wakeup round-trip.

14.19.4 Cost At Cancel/Drain

`taskqueue_cancel` is fast: mutex acquisition, list removal if pending, mutex release. Microseconds.

`taskqueue_drain` is fast if the task is idle. If the task is pending, the drain waits for it to run and complete; duration depends on queue depth and callback duration. If the task is running, the drain waits for the current invocation to return.

`taskqueue_drain_all` is more expensive: it must wait for every task in the queue. Duration is proportional to the total work remaining.

`taskqueue_free` drains the queue, terminates the threads, and frees the state. The thread termination involves signalling each thread to exit and waiting for it to finish its current task. Microseconds to milliseconds depending on queue depth.

14.19.5 Practical Implications

A few practical notes.

Single-thread taskqueues are cheap. The per-instance cost is a few hundred bytes plus a 16-KB thread stack. On any realistic system, this is negligible.

Shared taskqueues are cheaper per driver but contended. `taskqueue_thread` is used by every driver that does not create its own. Under heavy load it becomes a serial bottleneck. For drivers with significant task traffic, a private queue avoids the contention.

Multi-thread taskqueues trade memory for parallelism. Four threads is four 16-KB stacks plus four scheduler entries. Worthwhile when the workload is naturally parallel; wasted when the workload serialises on a single driver mutex.

Coalescing is free performance. When enqueues come faster than the taskqueue can dispatch, coalescing folds the bursts into single firings. The driver pays one callback invocation for whatever work the pending count implies.

14.19.6 Comparison To Other Approaches

A kernel thread created with `kproc_create` and managed by the driver costs: - 16 KB stack plus scheduler entry (same as a taskqueue worker). - No built-in enqueue/dispatch framework: the driver rolls its own queue and wakeup. - No built-in coalescing or cancellation.

For work that fits the task model (enqueue, dispatch, drain), a taskqueue is always the right choice. For work that does not (a long-running loop with its own rhythm), a `kproc_create` thread may fit better.

A callout that enqueues a task combines the costs of both primitives. Worthwhile when the work needs both a specific deadline and thread context.

14.19.7 When To Worry About Cost

Most drivers do not have to. Taskqueues are cheap; the kernel is well-tuned. Worry about cost only when:

- Profiling shows taskqueue operations dominate CPU usage. (Use `dtrace` to confirm.)
- You are writing a high-rate driver (thousands of events per second or more) and the taskqueue is the serialisation point.
- The system has many drivers competing for `taskqueue_thread` and contention is measurable.

In all other cases, write the taskqueue naturally and trust the kernel to handle the load.

14.20 Reference: The Task Coalescing Semantics, Precisely

Coalescing is the feature that most often surprises newcomers. A precise statement of the semantics, with worked examples, is worth its own reference subsection.

14.20.1 The Rule

When `taskqueue_enqueue(tq, &task)` is called on a task that is already pending (`task->ta_pending > 0`), the kernel increments `task->ta_pending` and returns success. The task is not linked onto the queue a second time. When the callback eventually runs, it runs exactly once, with the accumulated `ta_pending` value passed as its second argument (and the field is reset to zero before the callback is called).

The rule has edge cases worth naming.

The cap. `ta_pending` is a `uint16_t`. It saturates at `USHRT_MAX` (65535). Enqueues past that point still return success but the counter does not grow further. In practice, reaching 65535 coalesced enqueues is a design problem, not a performance problem.

The `TASKQUEUE_FAIL_IF_PENDING` flag. If you pass this flag to `taskqueue_enqueue_flags`, the function returns `EEXIST` instead of coalescing. Useful when you want to know whether the enqueue produced a new pending state.

Timing. The coalescing happens at enqueue time. If enqueue A and enqueue B both happen while the task is pending, both coalesce. If enqueue A causes the task to start running, and enqueue B happens while the callback is executing, enqueue B makes the task pending again (`pending=1`) and the callback will be invoked again after the current invocation returns. The second invocation sees `pending=1` because only B has accumulated. Both the first and second invocations happen; no enqueue is lost.

Priority. If two different tasks are pending on the same queue and one has higher priority, the higher-priority one runs first regardless of enqueue order. Within a single task, priority is not a factor; all invocations of a given task run in sequence.

14.20.2 Worked Examples

Example 1: Simple single enqueue.

```
taskqueue_enqueue(tq, &task);  
/* Worker fires the callback. */  
/* Callback sees pending == 1. */
```

Example 2: Coalesced enqueue before dispatch.

```
taskqueue_enqueue(tq, &task);  
taskqueue_enqueue(tq, &task);  
taskqueue_enqueue(tq, &task);  
/* (Worker has not yet woken up.) */  
/* Worker fires the callback. */  
/* Callback sees pending == 3. */
```

Example 3: Enqueue during callback execution.

```
taskqueue_enqueue(tq, &task);  
/* Callback starts; pending is reset to 0. */  
/* While callback is running: */  
taskqueue_enqueue(tq, &task);  
/* Callback finishes its first invocation. */  
/* Worker notices pending == 1; fires callback again. */  
/* Second callback invocation sees pending == 1. */
```

Example 4: Cancel before dispatch.

```
taskqueue_enqueue(tq, &task);  
taskqueue_enqueue(tq, &task);  
/* Cancel: */  
taskqueue_cancel(tq, &task, &pendp);  
/* pendp == 2; callback does not run. */
```

Example 5: Cancel during execution.

```
taskqueue_enqueue(tq, &task);
/* Callback starts. */
/* During callback: */
taskqueue_cancel(tq, &task, &pendp);
/* Returns EBUSY; pending (if any future enqueues came in) may or may not be zeroed. */
/* The currently executing invocation completes; the cancellation affects only future
↳ runs. */
```

14.20.3 Design Implications

A few design implications follow from the rule.

Your callback must be idempotent over pending. Writing a callback that assumes `pending==1` breaks under load. Always use `pending` deliberately, either by looping `pending` times or by doing a single pass that handles whatever state has accumulated.

Do not use “number of callback invocations” as a count of events. Use `pending` from each invocation, summed. Or, better, use a per-event state structure (a queue inside the softc) that the callback drains.

Coalescing changes per-event work into per-burst work. A callback that does $O(1)$ work per invocation, with `pending` discarded, handles the same amount of work regardless of enqueue rate. That is usually fine for “notify waiters” kinds of work; it is wrong for “process each event” kinds of work.

Coalescing lets you enqueue freely from edge contexts. A callout that fires every millisecond can enqueue a task every millisecond; if the callback takes 10 ms to run, nine enqueues coalesce into one invocation per callback. The system converges naturally on the throughput the callback can sustain.

14.21 Reference: The Taskqueue State Diagram

A short state diagram for a single task, as an aid to reasoning about the lifecycle.

```

        | worker picks up
        v
+-----+
|  RUNNING  |
| (callback |
| executing)|
+-----+
        |
        | callback returns
        v
+-----+
|  IDLE     |
| pending=0 |
+-----+

```

A task is always in exactly one of three states: IDLE, PENDING, or RUNNING.

IDLE. Not on any queue. `ta_pending == 0`. Enqueue moves it to PENDING.

PENDING. On the taskqueue's pending list. `ta_pending >= 1`. Coalescing increments `ta_pending` without leaving PENDING. Cancellation moves it back to IDLE.

RUNNING. In `tq_active`, with the callback executing. `ta_pending` has been reset to zero, and the callback has received the previous value. New enqueues transition back to PENDING (so after the callback returns, the worker fires it again). Cancellation returns `EBUSY` in this state.

The state transitions are all serialised by `tq_mutex`. At any instant, the kernel can tell you which state a task is in, and the transitions are atomic.

`taskqueue_drain(tq, &task)` waits until the task is IDLE and no new enqueues arrive before returning. That is the precise guarantee the drain provides.

14.22 Reference: Observability Cheat Sheet

For quick reference during debugging.

14.22.1 List Every Taskqueue Thread

```
# procstat -t | grep taskq
```

14.22.2 List Every Task Submission Rate With DTrace

```
# dtrace -n 'fbt::taskqueue_enqueue:entry { @[caddr_t)arg1 = count(); }' -c 'sleep
↳ 10'
```

The script counts enqueues per task pointer over ten seconds. The task pointers map back to drivers via `addr2line` or `kgdb`.

14.22.3 Measure Dispatch Latency

```
# dtrace -n '
fbt::taskqueue_enqueue:entry { self->t = timestamp; }
fbt::taskqueue_run_locked:entry /self->t/ {
    @[execname] = quantize(timestamp - self->t);
    self->t = 0;
}
' -c 'sleep 10'
```

14.22.4 Measure Callback Duration

```
# dtrace -n '
fbt::taskqueue_run_locked:entry { self->t = timestamp; }
fbt::taskqueue_run_locked:return /self->t/ {
    @[execname] = quantize(timestamp - self->t);
    self->t = 0;
}
' -c 'sleep 10'
```

14.22.5 Stack Trace of the Taskqueue Thread When Stuck

```
# procstat -kk <pid>
```

14.22.6 Active Tasks Inside ddb

From the ddb prompt:

```
db> show taskqueues
```

Lists every taskqueue, its active task (if any), and the pending queue.

14.22.7 Sysctl Knobs Your Driver Should Provide

For every task the driver owns, consider exposing:

- `<purpose>_enqueues`: total enqueues attempted.
- `<purpose>_coalesced`: count of times coalescing fired.
- `<purpose>_runs`: total callback invocations.
- `<purpose>_largest_pending`: peak pending count.

Under normal conditions: `enqueues == runs + coalesced`. Under coalescing: `runs < enqueues`. Under no load: `largest_pending == 1`. Under heavy load: `largest_pending` grows.

These counters turn opaque driver behaviour into a readable sysctl display. The cost is a few atomic adds; the value is high.

14.23 Reference: A Minimal Working Task Template

For copy-and-adapt convenience. Every piece has been introduced in the chapter; the template assembles them into a ready-to-use skeleton.

```
#include <sys/param.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/system.h>
#include <sys/bus.h>
#include <sys/taskqueue.h>
#include <sys/mutex.h>
#include <sys/lock.h>

struct example_softc {
    device_t      dev;
    struct mtx    mtx;
    struct taskqueue *tq;
    struct task    work_task;
    int           is_attached;
};

static void
example_work_task(void *arg, int pending)
{
    struct example_softc *sc = arg;

    mtx_lock(&sc->mtx);
    /* ... do work under the mutex if state protection is needed ... */
    mtx_unlock(&sc->mtx);
}
```

```
        /* ... do lock-free work or calls like selwakeup here ... */
    }

static int
example_attach(device_t dev)
{
    struct example_softc *sc = device_get_softc(dev);
    int error;

    sc->dev = dev;
    mtx_init(&sc->mtx, device_get_nameunit(dev), "example", MTX_DEF);

    sc->tq = taskqueue_create("example taskq", M_WAITOK,
        taskqueue_thread_enqueue, &sc->tq);
    if (sc->tq == NULL) {
        error = ENOMEM;
        goto fail_mtx;
    }
    error = taskqueue_start_threads(&sc->tq, 1, PWAIT,
        "%s taskq", device_get_nameunit(dev));
    if (error != 0)
        goto fail_tq;

    TASK_INIT(&sc->work_task, 0, example_work_task, sc);
    sc->is_attached = 1;
    return (0);

fail_tq:
    taskqueue_free(sc->tq);
fail_mtx:
    mtx_destroy(&sc->mtx);
    return (error);
}

static int
example_detach(device_t dev)
{
    struct example_softc *sc = device_get_softc(dev);

    mtx_lock(&sc->mtx);
    sc->is_attached = 0;
    mtx_unlock(&sc->mtx);
}
```

```

        taskqueue_drain(sc->tq, &sc->work_task);
        taskqueue_free(sc->tq);
        mtx_destroy(&sc->mtx);
        return (0);
}

/* Elsewhere, a code path that wants to defer work: */
static void
example_trigger_work(struct example_softc *sc)
{
    if (sc->is_attached)
        taskqueue_enqueue(sc->tq, &sc->work_task);
}

```

Every element is essential. Dropping any of them reintroduces a bug this chapter warned against.

14.24 Reference: Comparison With Linux Workqueues

A short comparison for readers coming from Linux kernel work. Both systems solve the same problem; the differences are in naming, granularity, and defaults.

14.24.1 Naming

Concept	FreeBSD	Linux
Unit of deferred work	struct task	struct work_struct
Queue	struct taskqueue	struct workqueue_struct
Shared queue	taskqueue_thread	system_wq
Unbound queue	taskqueue_thread with many threads	system_unbound_wq
Create a queue	taskqueue_create	alloc_workqueue
Enqueue	taskqueue_enqueue	queue_work
Enqueue with delay	taskqueue_enqueue_timeout	queue_delayed_work
Wait for work to finish	taskqueue_drain	flush_work
Destroy a queue	taskqueue_free	destroy_workqueue
Priority	ta_priority	WQ_HIGHPRI flag
Coalescing behaviour	Automatic, pending count exposed	work_pending check, no count

14.24.2 Semantic Differences

Coalescing visibility. FreeBSD exposes the pending count to the callback; Linux does not. A Linux callback knows the work fired but not how many times it was requested.

Timeout task vs. delayed work. FreeBSD's `timeout_task` embeds a callout; Linux's `delayed_work` embeds a `timer_list`. Both behave the same from the user's point of view.

Group taskqueues vs. percpu workqueues. FreeBSD's `taskqgroup` is explicit and separate; Linux's `alloc_workqueue(..., WQ_UNBOUND | WQ_CPU_INTENSIVE)` has similar semantics with different knobs.

Epoch integration. FreeBSD has `NET_TASK_INIT` for tasks that run inside the network epoch; Linux does not have a direct analogue (the RCU framework is similar but not identical).

A driver ported from Linux to FreeBSD (or vice versa) can usually translate the deferred-work pattern nearly one-to-one. The structural differences are in the surrounding APIs (device registration, memory allocation, locking) more than in the taskqueue itself.

14.25 Reference: When Not To Use a Taskqueue

A short list of scenarios where another primitive is preferable.

The work has tight timing requirements. Taskqueues add scheduling latency. For microsecond-scale deadlines, a `C_DIRECT_EXEC` callout or a `taskqueue_swi` is faster. For nanosecond-scale deadlines, none of the deferred-work mechanisms is fast enough; the work needs to happen inline.

The work is a one-shot cleanup that has no producer to associate with. A simple `free` inside a teardown path does not need a taskqueue; just call it directly. Deferral for deferral's sake adds no value.

The work must run at a specific scheduler priority higher than `PWAIT`. If the work is genuinely high-priority (a real-time driver, an interrupt-threshold task), use `kthread_add` with an explicit priority rather than a generic taskqueue.

The work requires a specific thread context that a generic worker cannot provide. Tasks run in a kernel thread with no specific user-process context. Work that needs a specific user's credentials, file-descriptor table, or address space must happen inside that process, not in a task.

The driver has only one task and it runs rarely. A single `kthread_add` with a `cv_timedwait` loop may be clearer than the full taskqueue setup. Use judgment; for three or more tasks, taskqueues are almost always clearer.

For everything else, use a taskqueue. The default is "use `taskqueue(9)`"; the exceptions are narrow.

14.26 Reference: A Worked Reading of `subr_taskqueue.c`

One more reading exercise, because understanding the implementation makes the API's behaviour predictable.

The file is `/usr/src/sys/kern/subr_taskqueue.c`. The structure, briefly:

struct taskqueue. Defined near the top of the file. Holds the pending queue (`tq_queue`), the active task list (`tq_active`), the internal mutex (`tq_mutex`), the enqueue callback (`tq_enqueue`), the worker threads (`tq_threads`), and flags.

TQ_LOCK / TQ_UNLOCK macros. Just after the structure. Acquire the mutex (spin or sleep, depending on `tq_spin`).

taskqueue_create and _taskqueue_create. Allocate the structure, initialise the mutex (`MTX_DEF` or `MTX_SPIN`), return.

taskqueue_enqueue and taskqueue_enqueue_flags. Acquire the mutex, check `task->ta_pending`, coalesce or link, wake the worker (via the enqueue callback), release the mutex.

taskqueue_enqueue_timeout. Schedule the internal callout; the callout's callback will later call `taskqueue_enqueue` on the underlying task.

taskqueue_cancel and taskqueue_cancel_timeout. Remove from queue if pending; return `EBUSY` if running.

taskqueue_drain and variants. `msleep` on a condition that is set when the task is idle and not pending.

taskqueue_run_locked. The heart of the subsystem. In a loop: take a task from the pending queue, record `ta_pending`, clear it, move to active, drop the mutex, optionally enter the net epoch, call the callback, re-acquire the mutex, signal any drainers. Loop until the queue is empty.

taskqueue_thread_loop. The worker thread's main loop. Acquire the taskqueue mutex, wait for work (`msleep`) if the queue is empty, call `taskqueue_run_locked` when work arrives, loop.

taskqueue_free. Set the "draining" flag, wake every worker, wait for every worker to exit, drain any remaining tasks, free the structure.

This reading cites each function by name rather than by line number, because line numbers drift between FreeBSD releases while symbol names survive. If you want approximate coordinates for `subr_taskqueue.c` in FreeBSD 14.3, the main entry points live near these lines: `_taskqueue_create` 141, `taskqueue_create` 178, `taskqueue_free` 217, `taskqueue_enqueue_flags` 305, `taskqueue_enqueue` 317, `taskqueue_enqueue_timeout` 382, `taskqueue_run_locked` 485, `taskqueue_cancel` 579, `taskqueue_cancel_timeout` 591, `taskqueue_drain` 612, `taskqueue_thread_loop` 820. Treat those numbers as a scroll hint; open the file and jump to the symbol.

Reading these functions once is a good investment. Everything Chapter 14 taught about the API's behaviour is visible in the implementation.

14.27 A Final Tour: Five Common Shapes

Five shapes that account for most taskqueue usage in the FreeBSD tree. Recognising them turns reading driver source from parsing to pattern-matching.

14.27.1 Shape A: The Solo Task

One task, enqueued from one place, drained at detach. Simplest. Used by drivers that need to defer exactly one kind of work.

```
TASK_INIT(&sc->task, 0, sc_task, sc);
/* ... */
taskqueue_enqueue(sc->tq, &sc->task);
/* ... */
taskqueue_drain(sc->tq, &sc->task);
```

14.27.2 Shape B: The Filter-Plus-Task Split

Interrupt filter does the minimum, enqueues a task for the rest.

```
static int
sc_filter(void *arg)
{
    struct sc *sc = arg;
    taskqueue_enqueue(sc->tq, &sc->intr_task);
    return (FILTER_HANDLED);
}
```

14.27.3 Shape C: The Callout-Driven Periodic Task

Callout fires periodically, enqueues a task that does the work.

```
static void
sc_periodic_callout(void *arg)
{
    struct sc *sc = arg;
    taskqueue_enqueue(sc->tq, &sc->periodic_task);
    callout_reset(&sc->co, hz, sc_periodic_callout, sc);
}
```

14.27.4 Shape D: The Timeout Task

timeout_task for delayed work in thread context.

```
TIMEOUT_TASK_INIT(sc->tq, &sc->delayed, 0, sc_delayed, sc);
/* ... */
taskqueue_enqueue_timeout(sc->tq, &sc->delayed, delay_ticks);
/* ... */
taskqueue_drain_timeout(sc->tq, &sc->delayed);
```

14.27.5 Shape E: The Self-Re-Enqueueing Task

A task that schedules itself again from its own callback.

```
static void
sc_self(void *arg, int pending)
{
    struct sc *sc = arg;
    /* work */
    if (sc->keep_running)
        taskqueue_enqueue_timeout(sc->tq, &sc->self_tt, hz);
}
```

Every driver you read will use some combination of these five shapes. Once they are familiar, the rest is implementation detail.

14.28 Closing Summary: What The Chapter Delivered

A short inventory, for a reader who wants the compressed version after working through the full chapter.

Concepts introduced.

- Deferred work as the bridge from edge contexts to thread context.
- The `struct task` / `struct timeout_task` data structures and their lifecycle.
- Taskqueues as the queue + worker-thread pair.
- Private versus predefined taskqueues and when each is right.
- Coalescing via `ta_pending` and the `pending` argument.
- Priority ordering within a queue.
- The `block/unblock/quiesce/drain_all` primitives.
- Detach ordering with callouts, tasks, `selinfo`, and taskqueue teardown.
- Debugging via `procstat`, `dtrace`, `sysctl` counters, and `WITNESS`.
- Introductory exposure to `epoch(9)`, `grouptaskqueues`, and per-CPU taskqueues.

Driver changes.

- Stage 1: one task enqueued from `tick_source`, drained at detach.
- Stage 2: a private taskqueue owned by the driver.
- Stage 3: a bulk-writer task demonstrating deliberate coalescing, a `timeout_task` for delayed reset.
- Stage 4: consolidation, version bump to 0.8- taskqueues, full regression.

Documentation changes.

- A Tasks section in `LOCKING.md`.
- A detach-ordering section that enumerates every drain step.
- Per-task documentation listing callback, lifetime, enqueue paths, and cancellation paths.

Patterns catalogued.

- Deferred logging.
- Delayed reset.
- Filter-plus-task interrupt split.
- Async copyin/copyout.
- Retry-with-backoff.
- Deferred teardown.
- Statistics rollover.
- Block-during-reconfiguration.
- Drain-all at subsystem boundary.
- Synthetic event generation.

Debugging tools used.

- `procstat -t` for taskqueue thread state.
- `ps ax` for kernel thread inventory.
- `sysctl dev.<driver>` for driver-exposed counters.
- `dtrace` for enqueue latency and callback duration.
- `procstat -kk` for stuck-thread diagnosis.
- WITNESS and INVARIANTS as the debug-kernel safety net.

Deliverables.

- `content/chapters/part3/chapter-14.md` (this file).
- `examples/part-03/ch14-taskqueues-and-deferred-work/stage1-first-task/`.
- `examples/part-03/ch14-taskqueues-and-deferred-work/stage2-private-taskqueue/`.
- `examples/part-03/ch14-taskqueues-and-deferred-work/stage3-coalescing/`.
- `examples/part-03/ch14-taskqueues-and-deferred-work/stage4-final/`.
- `examples/part-03/ch14-taskqueues-and-deferred-work/labs/` with `poll_waiter.c` and small helper scripts.
- `examples/part-03/ch14-taskqueues-and-deferred-work/LOCKING.md` with the Tasks section.
- `examples/part-03/ch14-taskqueues-and-deferred-work/README.md` with per-stage build and test instructions.

That is the end of Chapter 14. Chapter 15 continues the synchronisation story.

14.29 Reference: Reading `taskqueue_run_locked` Line By Line

The heart of the taskqueue subsystem is a short loop inside `taskqueue_run_locked` in `/usr/src/sys/kern/-subr_taskqueue.c`. Reading it once, slowly, pays off whenever you need to reason about the subsystem's behaviour. A narrated pass follows.

The function is called from the worker thread's main loop, `taskqueue_thread_loop`, with the taskqueue mutex held. Its job is to process every pending task, release the mutex around the callback, and return with the mutex still held when the queue is empty.

```
static void
taskqueue_run_locked(struct taskqueue *queue)
{
    struct epoch_tracker et;
    struct taskqueue_busy tb;
    struct task *task;
    bool in_net_epoch;
    int pending;

    KASSERT(queue != NULL, ("tq is NULL"));
    TQ_ASSERT_LOCKED(queue);
    tb.tb_running = NULL;
    LIST_INSERT_HEAD(&queue->tq_active, &tb, tb_link);
    in_net_epoch = false;

```

The function starts by asserting the mutex is held and inserting a local `taskqueue_busy` structure into the active list. The `tb` structure represents this invocation of `taskqueue_run_locked`; later code uses it to track what this invocation is currently running. The `in_net_epoch` flag tracks whether we are currently inside the network epoch, so we do not enter it redundantly when consecutive tasks are all network-flagged.

```
while ((task = STAILQ_FIRST(&queue->tq_queue)) != NULL) {
    STAILQ_REMOVE_HEAD(&queue->tq_queue, ta_link);
    if (queue->tq_hint == task)
        queue->tq_hint = NULL;
    pending = task->ta_pending;
    task->ta_pending = 0;
    tb.tb_running = task;
    tb.tb_seq = ++queue->tq_seq;
    tb.tb_canceling = false;
    TQ_UNLOCK(queue);

```

The main loop. Pull the head off the pending queue. Snapshot the pending count into a local variable, reset the field to zero (so new enqueues that arrive during the callback increment from zero again). Record the task in the `tb` structure so drain callers can see what is running. Increment a sequence counter for stale-drain detection. Drop the mutex.

Notice that between here and the next `TQ_LOCK`, the mutex is not held. This is the window where the callback runs; the rest of the kernel can enqueue more tasks (which will coalesce or queue up), drain other tasks (which will see `tb.tb_running == task` and wait), or run its own business.

```
KASSERT(task->ta_func != NULL, ("task->ta_func is NULL"));
if (!in_net_epoch && TASK_IS_NET(task)) {
    in_net_epoch = true;
    NET_EPOCH_ENTER(et);

```

```

        } else if (in_net_epoch && !TASK_IS_NET(task)) {
            NET_EPOCH_EXIT(et);
            in_net_epoch = false;
        }
        task->ta_func(task->ta_context, pending);

        TQ_LOCK(queue);
        wakeup(task);
    }
    if (in_net_epoch)
        NET_EPOCH_EXIT(et);
    LIST_REMOVE(&tb, tb_link);
}

```

The epoch bookkeeping: enter the net epoch if this task is net-flagged and we are not already in it; exit the epoch if we entered it for an earlier task but this one is not net-flagged. This lets consecutive net tasks share a single epoch entry, which is an optimisation the framework does for free.

Call the callback with the context and pending count. Re-acquire the mutex. Wake up any drain caller who is waiting for this specific task. Loop.

After the loop, if we are still in the net epoch, exit it. Remove the tb structure from the active list.

Seven observations from reading this function.

Observation 1. The mutex is dropped for exactly as long as the callback runs. No taskqueue-internal code runs with the callback; if the callback takes milliseconds, the taskqueue mutex is free for milliseconds.

Observation 2. `ta_pending` is reset before the callback runs, not after. A new enqueue during the callback makes the task pending again (`pending=1`). After the callback returns, the loop sees the new pending, pulls it off, and runs the callback a second time with `pending=1`. No enqueue is lost.

Observation 3. The pending value passed to the callback is the count at the moment the task was pulled off the queue, not at the moment the enqueue calls happened. If enqueues arrive during the callback, they do not contribute to this invocation's pending; they contribute to the next invocation's pending.

Observation 4. The wakeup at the bottom of the loop wakes drain callers sleeping on the task's address. Drain uses `msleep(&task, &tq->mutex, ...)` and waits for the task to be off the queue and not currently running. The wakeup here is what makes the drain terminate.

Observation 5. The sequence counter `tq_seq` and the `tb.tb_seq` allow drain-all to detect whether new tasks have been added since the drain started. Without the sequence, drain-all would race with new enqueues.

Observation 6. `tb.tb_canceling` is a flag that `taskqueue_cancel` sets to tell a waiter "this task is currently being cancelled"; its purpose is to let concurrent cancel/drain calls coordinate. We have not discussed it in the main text because most drivers never see it.

Observation 7. Multiple worker threads can each be inside `taskqueue_run_locked` simultaneously, each dispatching a different task. The `tq_active` list holds all their `tb` structures. Different tasks on the same queue run in parallel; the same task cannot run in parallel with itself, because only one worker pulls it off at a time.

Those observations together describe exactly what the taskqueue guarantees and what it does not. Every behaviour the chapter described earlier is a consequence of this short loop.

14.30 Reference: A Walkthrough of `taskqueue_drain`

Equally illuminating, equally short. From `/usr/src/sys/kern/subr_taskqueue.c`, roughly:

```
void
taskqueue_drain(struct taskqueue *queue, struct task *task)
{
    if (!queue->tq_spin)
        WITNESS_WARN(WARN_GIANTOK | WARN_SLEEPOK, NULL, ...);

    TQ_LOCK(queue);
    while (task->ta_pending != 0 || task_is_running(queue, task))
        TQ_SLEEP(queue, task, "taskqueue_drain");
    TQ_UNLOCK(queue);
}
```

The function acquires the taskqueue mutex, then loops until the task is neither pending nor running. Each iteration sleeps on the task's address; each wakeup at the bottom of `taskqueue_run_locked` wakes the drainer to re-check.

`task_is_running(queue, task)` walks the active list (`tq_active`) and returns true if any `tb.tb_running == task`. It is $O(N)$ in the number of workers, but for most drivers N is 1 and this is $O(1)$.

The function does not hold the lock across the sleep; `TQ_SLEEP` (which expands to `msleep` or `msleep_spin`) drops the mutex during the sleep and re-acquires it on wakeup, which is the standard condition-variable pattern.

Observations from reading `taskqueue_drain`.

Observation 1. Drain is a condition-variable wait, using the task pointer as the wakeup channel. The wake comes from the `wakeup(task)` at the bottom of `taskqueue_run_locked`.

Observation 2. Drain does not stop new enqueues from happening. If the task is enqueued again while the drain is waiting, the drain will continue waiting until that new enqueue fires and completes. This is why detach discipline requires draining every producer (callouts, other tasks, interrupt handlers) before draining the victim task.

Observation 3. Drain on an idle task (never enqueued, or enqueued and completed) returns immediately. It is safe to call drain unconditionally in detach.

Observation 4. Drain holds the taskqueue mutex across the initial check and before the sleep, which means drain cannot race with enqueue in a way that misses a newly pending task. If an enqueue arrives between the check and the sleep, `ta_pending` becomes non-zero and the drain loop re-iterates.

Observation 5. The `WITNESS_WARN` at the top asserts that the caller is in a context where sleeping is legal. If you try to call `taskqueue_drain` from a context that cannot sleep (a callout callback, for example), `WITNESS` complains.

Two complementary functions are `taskqueue_cancel` (which removes the task from the queue if it is pending and returns `EBUSY` if it is running) and `taskqueue_drain_timeout` (which also cancels the embedded callout). Reading their implementations once is worthwhile; they are short.

14.31 Reference: The Lifecycle As Seen From the Softc

One more view, for completeness. The same information, organised around the `softc` instead of around the API.

At **attach time**, the `softc` gains:

- A taskqueue pointer (`sc->tq`), created by `taskqueue_create` and populated by `taskqueue_start_threads`.
- One or more task structures (`sc->foo_task`), initialised by `TASK_INIT` or `TIMEOUT_TASK_INIT`.
- Counters and flags for observability (optional but recommended).

At **runtime**, the `softc`'s taskqueue state is:

- `sc->tq` is an opaque pointer; drivers never read its fields.
- `sc->foo_task` may be `IDLE`, `PENDING`, or `RUNNING` at any instant.
- The taskqueue's worker threads sleep most of the time, wake on enqueue, run callbacks, sleep again.

At **detach time**, the `softc` is torn down in this order:

1. Clear `sc->is_attached` under the mutex, broadcast cvs, release mutex.
2. Drain every callout.
3. Drain every task.
4. Drain selinfo.
5. Free the taskqueue.
6. Destroy the `cdev` and its alias.
7. Free the `sysctl` context.
8. Destroy the `cbuf` and counters.
9. Destroy the `cvs`, `sx`, mutex.

After `taskqueue_free`, `sc->tq` becomes invalid. After the task drains, the `sc->foo_task` structures are idle and their storage can be reclaimed along with the `softc`.

The `softc`'s lifetime is determined by the device's attach/detach. Tasks cannot outlive their `softc`. The drain at detach is what guarantees that property.

14.32 Reference: A Glossary of Terms

For quick lookup.

Task. An instance of `struct task`; a callback-plus-context bundled for enqueue onto a taskqueue.

Taskqueue. An instance of `struct taskqueue`; a queue of pending tasks paired with one or more worker threads.

Timeout task. An instance of `struct timeout_task`; a task plus an internal callout, used for scheduled-in-the-future work.

Enqueue. To add a task to a taskqueue. If the task is already pending, increment its pending count instead.

Drain. To wait until a task is neither pending nor running.

Dispatch. The act of the taskqueue worker taking a task off the pending list and running its callback.

Coalesce. To fold redundant enqueues into a single pending-state increment rather than two list entries.

Pending count. The value of `ta_pending`, representing how many coalesced enqueues are accumulated on this task.

Idle task. A task that is not pending and not running. `ta_pending == 0` and no worker has it.

Worker thread. A kernel thread (usually one per taskqueue) whose job is to wait for work and run task callbacks.

Edge context. A constrained context (callout, interrupt filter, epoch section) where some operations are not permitted.

Thread context. An ordinary kernel thread context where sleeping, sleepable-lock acquisition, and all standard operations are permitted.

Detach ordering. The sequence in which primitives are drained and freed at device detach, such that no primitive is freed while something can still reference it.

Drain race. A bug where a primitive is freed while a callback or handler is still potentially running, caused by incorrect detach ordering.

Pending-drop counter. A diagnostic counter incremented when the callback's pending argument is greater than one, indicating coalescing occurred.

Private taskqueue. A taskqueue owned by the driver, created and freed with attach/detach, not shared with other drivers.

Shared taskqueue. A kernel-provided taskqueue (`taskqueue_thread`, `taskqueue_swi`, etc.) used by multiple drivers simultaneously.

Fast taskqueue. A taskqueue created with `taskqueue_create_fast` that uses a spin mutex internally, safe for enqueue from filter-interrupt context.

Grouptaskqueue. A scalable variation where tasks are distributed across per-CPU queues. Used by high-rate network drivers.

Epoch. A lockless read-synchronisation mechanism. The `net_epoch_preempt` epoch protects network state.

Chapter 14 ends here. The next chapter takes the synchronisation story further.

15 More Synchronization: Conditions, Semaphores, and Coordination

15.1 Reader Guidance & Outcomes

At the end of Chapter 14 your `myfirst` driver reached a qualitatively different state from where it started Part 3. It has a documented data-path mutex, two condition variables, a configuration `sx` lock, three callouts, a private taskqueue with three tasks, and a detach path that drains every primitive in the correct order. The driver is, for the first time in the book, more than a collection of handlers. It is a composition of synchronisation primitives that cooperate to deliver bounded, safe behaviour under load.

Chapter 15 is about pushing that composition further. Most real drivers eventually discover that mutexes and basic condition variables, even combined with `sx` locks and taskqueues, are not always the primitives that make a particular problem easy to express. A driver might need to cap the number of concurrent writers, enforce a bounded pool of reusable hardware slots, coordinate a handshake between a callout and a task, let a slow read wake up for a signal without losing the partial progress it made, or surface shutdown state across several subsystems in a way that every piece of code can check cheaply. Each of those shapes is solvable with what you already know, but each has a primitive or idiom that makes the solution direct and the code readable. This chapter teaches those primitives and idioms one at a time, applies them to the driver, and ties the result together with a small wrapper layer that turns scattered calls into a named vocabulary.

The chapter is also the last chapter of Part 3. After Chapter 15, Part 4 begins and the book turns to hardware. Every primitive Part 3 taught you, from the first `mtx_init` in Chapter 11 to the last `taskqueue_drain` in Chapter 14, stays with you into Part 4. The coordination patterns in this chapter are not a bonus topic. They are the closing piece of the synchronisation toolbox your driver carries forward into the hardware-facing chapters.

15.1.1 Why This Chapter Earns Its Own Place

You could skip this chapter. The driver as it stands at the end of Chapter 14 is functional, tested, and technically correct. Its mutex-and-cv discipline is sound. Its detach ordering works. Its taskqueue is clean.

What the driver lacks, and what Chapter 15 adds, is a small set of sharper tools for specific shapes of coordination that mutexes and basic condition variables express awkwardly. A counting semaphore is a few lines of code that says “at most *N* participants at once”; expressing the same invariant with a mutex and a counter and a cv requires more lines and hides the intent. A refined `sx` pattern with `sx_try_upgrade` lets a read path occasionally promote to a writer without releasing its slot and racing with other would-be writers; without the primitive, you write awkward retry loops. A proper `cv_timedwait_sig` usage distinguishes between `EINTR` and `ERESTART` and between “the caller was interrupted” and “the deadline fired”; a naive wait leaves the caller hanging or abandons partial work on any signal.

The payoff of learning these tools is not just that the current chapter's refactor will be cleaner. It is that when you read a production FreeBSD driver a year from now, you will recognise these shapes immediately. When `/usr/src/sys/dev/hyperv/storvsc/hv_storvsc_drv_freebsd.c` calls `sema_wait` on a per-request semaphore to block until hardware completion, you will know what the author was thinking. When a network driver reaches for `sx_try_upgrade` in a statistics-update path, you will know why that was the correct call. Without Chapter 15 those calls are opaque. With Chapter 15 they are obvious.

The other payoff is maintainability. A driver that scatters its synchronisation vocabulary across a hundred places is hard to change. A driver that encapsulates its synchronisation in a small named layer (even just a set of inline functions in a header) is easy to change. Section 6 walks through the encapsulation explicitly; by the end of the chapter, your driver will have a small `myfirst_sync.h` that names every coordination primitive it uses. Adding a new synchronised state later becomes an exercise in extending the header, not in spreading new `mtx_lock/mtx_unlock` calls across the file.

15.1.2 Where Chapter 14 Left the Driver

A few prerequisites to verify before starting. Chapter 15 extends the driver produced at the end of Chapter 14 Stage 4 (version 0.8-taskqueues). If any of the items below feels uncertain, return to Chapter 14 before starting this chapter.

- Your `myfirst` driver compiles cleanly and identifies itself as version 0.8-taskqueues.
- It uses `MYFIRST_LOCK/MYFIRST_UNLOCK` macros around `sc->mtx` (the data-path mutex).
- It uses `MYFIRST_CFG_SLOCK/MYFIRST_CFG_XLOCK` around `sc->cfg_sx` (the configuration `sx`).
- It uses two named condition variables (`sc->data_cv`, `sc->room_cv`) for blocking reads and writes.
- It supports timed reads via `cv_timedwait_sig` and the `read_timeout_ms` sysctl.
- It has three callouts (`heartbeat_co`, `watchdog_co`, `tick_source_co`) with their interval sysctls.
- It has a private taskqueue (`sc->tq`) with three tasks (`selwake_task`, `bulk_writer_task`, `reset_delayed_task`).
- The lock order `sc->mtx -> sc->cfg_sx` is documented in `LOCKING.md` and enforced by `WITNESS`.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel; you have built and booted it.
- The Chapter 14 stress kit runs cleanly under the debug kernel.

That driver is what we extend in Chapter 15. The additions are modest in volume but substantial in what they enable. The driver's data path is unchanged at the mechanical level; what changes is the vocabulary it uses to talk about concurrency.

15.1.3 What You Will Learn

After finishing this chapter you will be able to:

- Recognise when a mutex plus a condition variable is not the right primitive for a particular invariant, and name the alternative (a semaphore, an `sx` upgrade pattern, an atomic flag with a memory barrier, a per-cpu counter, or an encapsulated coordinator function).
- Explain what a counting semaphore is, how it differs from a mutex and from a binary semaphore, and why FreeBSD's `sema(9)` API is specifically a counting-semaphore API with no ownership concept.

- Use `sema_init`, `sema_wait`, `sema_post`, `sema_trywait`, `sema_timedwait`, `sema_value`, and `sema_destroy` correctly, including the lifetime contract that no waiters may be present when `sema_destroy` is called.
- Describe the known limitations of FreeBSD's kernel semaphore: no priority inheritance, no signal-interruptible wait, and the guidance in `/usr/src/sys/kern/kern_sema.c` about why they are not a general replacement for a mutex plus a condition variable.
- Refine the driver's `sx` usage with `sx_try_upgrade`, `sx_downgrade`, `sx_xlocked`, and `sx_slock` patterns that express read-mostly workloads cleanly.
- Distinguish `cv_wait`, `cv_wait_sig`, `cv_timedwait`, and `cv_timedwait_sig`, and know what each returns on timeout, signal, and normal wakeup.
- Handle the `EINTR` and `ERESTART` return values from signal-interruptible waits correctly, so that `read(2)` and `write(2)` on the driver respond sensibly to `SIGINT` and friends.
- Build cross-component handshakes between a callout, a task, and a user thread using a small state flag protected by the driver mutex.
- Introduce a `myfirst_sync.h` header that names every synchronisation primitive the driver uses, so future contributors can change the locking strategy in one place.
- Use the `atomic(9)` API correctly for small lock-free coordination steps, especially shutdown flags that need to be visible across contexts without a lock.
- Write stress tests that deliberately trigger race conditions in the driver's synchronisation and confirm the primitives handle them.
- Refactor the driver to version 0.9-coordination and update `LOCKING.md` with a Semaphores section and a Coordination section.

That is a long list. Each item in it is small; the value of the chapter is in the composition.

15.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 15 stays focused.

- **Hardware interrupt handlers and the full split between `FILTER` and `IThread` execution contexts.** Part 4 introduces `bus_setup_intr(9)` and the actual interrupt story. Chapter 15 mentions interrupt-adjacent contexts only when they illustrate a synchronisation pattern you might reuse.
- **Lock-free data structures at scale.** The `atomic(9)` family covers small coordination flags; it does not cover SMR, hazard pointers, RCU analogues, or full lock-free queues. Chapter 15 touches on atomic operations and epoch briefly; the deeper lock-free story belongs to a specialised kernel-internals discussion.
- **Detailed scheduler tuning.** Thread priorities, RT classes, priority inheritance, CPU affinity: out of scope. We pick sensible defaults and move on.
- **Userland POSIX semaphores and SysV IPC.** `sema(9)` in the kernel is a different beast. Chapter 15 focuses on the kernel primitive.
- **Performance micro-benchmarks.** Lockstat and DTrace lock profiling get a mention, not a full treatment. A dedicated performance chapter later in the book, when it exists, will carry that load.
- **Cross-process coordination primitives.** Some drivers need to coordinate with userland helpers; that problem is fundamentally different and belongs to a later chapter about ioctl-based protocols.

Staying inside those lines keeps the chapter's mental model coherent. Chapter 15 adds the coordination toolkit; Part 4 and later chapters apply the toolkit to hardware-facing scenarios.

15.1.5 Estimated Time Investment

- **Reading only:** about three to four hours. The API surface is small but the composition takes some thought.
- **Reading plus typing the worked examples:** seven to nine hours over two sessions. The driver evolves in four stages.
- **Reading plus all labs and challenges:** twelve to sixteen hours over three or four sessions, including time to run stress tests against race-prone code paths.

If you find Section 5 (cross-subsystem coordination) disorienting on first pass, that is normal. The material is conceptually simple but requires holding several parts of the driver in your head at once. Stop, re-read the worked handshake in Section 5, and continue when the diagram has settled.

15.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 14 Stage 4 (`stage4-final`). The starting point assumes every Chapter 14 primitive, every Chapter 13 callout, every Chapter 12 `cv` and `sx`, and the Chapter 11 concurrent-IO model.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- You understand the Chapter 14 detach ordering well enough to extend it without getting lost.
- You have a comfortable mental model of `cv_wait_sig` and `cv_timedwait_sig` from Chapters 12 and 13.

If any of the above is shaky, fix it now rather than pushing through Chapter 15 and trying to reason from a moving foundation. The Chapter 15 primitives are sharper than what came before, and they amplify whatever discipline (or lack of it) the driver already has.

15.1.7 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep `/usr/src/sys/kern/kern_sema.c` and `/usr/src/sys/sys/sema.h` bookmarked. The implementation is short, under two hundred lines, and it is the shortest path to understanding what a FreeBSD semaphore actually does. Read `_sema_wait`, `_sema_post`, and `_sema_timedwait` carefully once. Knowing that a semaphore is “a counter plus a mutex plus a `cv`, wrapped in an API” makes the rest of the chapter feel obvious.

A note on line numbers. Every pointer into the source in this chapter hangs on a function, macro, or structure name, not on a numeric line. `sema_init` and `_sema_wait` in `kern_sema.c`, and `sx_try_upgrade` in `/usr/src/sys/kern/kern_sx.c`, will remain findable by those names across FreeBSD 14.x point releases; the line each one occupies can drift as the surrounding code is revised. When in doubt, `grep` for the symbol.

Second, compare every new primitive to what you would have written with the old ones. The exercise “if I did not have `sema(9)`, how would I express this?” is instructive. Writing the alternative with `mtx` and `cv` is usually possible, but the semaphore version is often half as long and substantially clearer. Seeing the contrast is how the value of the primitive becomes concrete.

Third, type the changes by hand and run each stage under `WITNESS`. Advanced synchronisation bugs are almost always detected by `WITNESS` on first contact if you run a debug kernel; they are almost always silent on a production kernel until the first crash. The companion source under `examples/part-03/ch15-more-synchronization/` is the reference version, but the muscle memory of typing `sema_init(&sc->writers_sema, 4, "myfirst writers")` once is worth more than reading it ten times.

15.1.8 Roadmap Through the Chapter

The sections in order are:

1. **When mutexes and condition variables are not enough.** A survey of the shapes of problem that benefit from a different primitive.
2. **Using semaphores in the FreeBSD kernel.** The `sema(9)` API in depth, with the writer-cap refactor as Stage 1 of the Chapter 15 driver.
3. **Read-mostly scenarios and shared access.** Refined `sx(9)` patterns, including `sx_try_upgrade` and `sx_downgrade`, with a small statistics-cache refactor as Stage 2.
4. **Condition variables with timeout and interruption.** A careful treatment of `cv_timedwait_sig`, `EINTR` vs `ERESTART`, partial-progress handling, and the `sysctl` tuning that lets readers observe the behaviour. Stage 3 of the driver.
5. **Synchronisation between modules or subsystems.** Handshakes between callouts, tasks, and user threads via small state flags. Atomic operations and memory ordering at an introductory level. Stage 4 begins here.
6. **Synchronisation and modular design.** The `myfirst_sync.h` header, the naming discipline, and how the driver changes shape when synchronisation is encapsulated.
7. **Testing advanced synchronisation.** Stress kits, fault injection, and the observability `sysctls` that let you see the primitives working.
8. **Refactoring and versioning.** Stage 4 complete, version bump to 0.9-coordination, `LOCKING.md` extended, and the Part 3 closing regression pass.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Part 3, and a bridge to Chapter 16 that opens Part 4. The same reference-and-cheat-sheet material that Chapters 13 and 14 ended with returns here at the end.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 5 and 6 stand alone and make good single-sitting reads.

15.2 Section 1: When Mutexes and Condition Variables Are Not Enough

The Chapter 11 mutex and the Chapter 12 condition variable are the default primitives of FreeBSD driver synchronisation. Nearly every driver uses them. Many drivers use nothing else. For a large class of problems the combination is exactly right: a mutex protects shared state, a condition variable lets a waiter sleep until the

state matches a predicate, and the two together express “wait for state to become acceptable” and “tell others that state has changed” cleanly.

This section is about the problems where that default is awkward. Not because the mutex-and-cv combination cannot express the invariant, but because it expresses it more verbosely and more error-prone than a different primitive. Recognising those shapes is the first step toward using the right tool.

15.2.1 The Shape of the Mismatch

Every synchronisation primitive has an underlying model of what it protects. A mutex protects mutual exclusion: at most one thread executes inside the lock at a time. A condition variable protects a predicate: a waiter sleeps until the predicate becomes true, and the signaller asserts that the predicate has changed. The two compose because the condition variable’s wait drops and reacquires the mutex automatically, which lets the waiter observe the predicate under the lock, release the lock during the sleep, and regain the lock on wakeup.

The mismatch appears when the invariant you are protecting is not best described as “at most one” or “wait for a predicate”. A handful of common shapes recur.

Bounded admission. The invariant is “at most N of a thing at once”. For N equal to one, a mutex is natural. For N greater than one, the mutex-plus-cv-plus-counter version requires you to write an explicit counter, test it under the mutex, sleep on a cv if the counter is at N, decrement on entry, re-signal on exit, and rediscover the right wakeup policy. The semaphore primitive expresses the same invariant in three calls: `sema_init(&s, N, ...)`, `sema_wait(&s)` at entry, `sema_post(&s)` at exit.

Read-mostly state with occasional promotion. The invariant is “many readers concurrently, or one writer; when a reader detects a need to write, promote”. The `sx(9)` lock handles the many-readers-or-one-writer part natively. The promotion part (`sx_try_upgrade`) is a primitive that a mutex-plus-cv version has to simulate with a rwlock-like counter and retry logic.

Predicate that must survive signal interruption with partial-progress preservation. A `read(2)` that copied half its requested bytes and is now sleeping for more should, on a signal, return the copied bytes rather than `EINTR`. `cv_timedwait_sig` gives you the `EINTR` and `ERESTART` distinction; writing the equivalent with `raw_cv_wait` plus a periodic signal check is possible but error-prone.

Cross-component shutdown coordination. Several parts of the driver (callouts, tasks, user threads) need to observe “the driver is shutting down” consistently. A mutex-protected flag is an option. An atomic flag with a seq-cst fence on the writer and acquire loads on readers is often cheaper and clearer for this specific pattern, and the chapter will show when to pick which.

Rate-limited retries. “Do this at most once per 100 ms, skip if already in progress.” Expressible with a mutex and a timer, but a taskqueue plus a timeout task plus an atomic test-and-set on an “already scheduled” flag is often cleaner. This pattern came up at the end of Chapter 14; Chapter 15 refines it.

For each shape, Chapter 15 picks a primitive that fits and shows the refactor side by side. The purpose is not to argue that the semaphore or the `sx` upgrade or the atomic flag is “better”. The purpose is to let you pick the tool that matches the problem, so your driver reads cleanly to the next person who opens it.

15.2.2 A Concrete Motivating Example: Too Many Writers

A motivating example to make the mismatch concrete. Suppose the driver wants to limit the number of concurrent writers. “Concurrent writers” means user threads that are simultaneously inside the `myfirst_write` handler past the initial validation. The limit is a small integer, say four, exposed as a `sysctl` tuning knob.

The mutex-plus-counter version looks like this:

```
/* In the softc: */
int writers_active;
int writers_limit; /* Configurable via sysctl. */
struct cv writer_cv;

/* In myfirst_write, at entry: */
MYFIRST_LOCK(sc);
while (sc->writers_active >= sc->writers_limit) {
    int error = cv_wait_sig(&sc->writer_cv, &sc->mtx);
    if (error != 0) {
        MYFIRST_UNLOCK(sc);
        return (error);
    }
    if (!sc->is_attached) {
        MYFIRST_UNLOCK(sc);
        return (ENXIO);
    }
}
sc->writers_active++;
MYFIRST_UNLOCK(sc);

/* At exit: */
MYFIRST_LOCK(sc);
sc->writers_active--;
cv_signal(&sc->writer_cv);
MYFIRST_UNLOCK(sc);
```

Every line is necessary. The loop handles spurious wakeups and signal returns. The signal check preserves partial progress (if any). The `is_attached` check ensures we do not proceed after detach. The `cv_signal` wakes the next waiter. The caller must remember to decrement.

The semaphore version looks like this:

```
/* In the softc: */
struct sema writers_sema;

/* In attach: */
sema_init(&sc->writers_sema, 4, "myfirst writers");
```

```
/* In destroy: */
sema_destroy(&sc->writers_sema);

/* In myfirst_write, at entry: */
sema_wait(&sc->writers_sema);
if (!sc->is_attached) {
    sema_post(&sc->writers_sema);
    return (ENXIO);
}

/* At exit: */
sema_post(&sc->writers_sema);
```

Five lines of runtime logic, including the attached check. The primitive expresses the invariant directly. A reader who sees `sema_wait(&sc->writers_sema)` understands the intent in one glance.

Note what the semaphore version gives up. `sema_wait` is not signal-interruptible (as we will see in Section 2, FreeBSD's `sema_wait` uses `cv_wait` internally, not `cv_wait_sig`). If you need interruptibility, you fall back to the mutex-plus-cv version or combine `sema_trywait` with a separate interruptible wait. Every primitive has its trade-offs; Section 2 names them.

The broader point is that neither version is “wrong”. The mutex-plus-counter version is correct and has been used in drivers for decades. The semaphore version is correct and clearer for this specific invariant. Knowing both lets you pick the right one for the specific constraints at hand.

15.2.3 The Rest of the Section Previews the Chapter

Section 1 is deliberately short. The rest of the chapter unfolds each shape in its own section with its own refactor of the `myfirst` driver:

- Section 2 does the writer-cap semaphore refactor as Stage 1.
- Section 3 does the read-mostly `sx` refinement as Stage 2.
- Section 4 does the interruptible-wait refinement as Stage 3.
- Section 5 does the cross-component handshake as part of Stage 4.
- Section 6 extracts the synchronisation vocabulary into `myfirst_sync.h`.
- Section 7 writes the stress tests.
- Section 8 ties it all together and ships `0.9-coordination`.

Before diving in, one general observation. The Chapter 15 changes are small in lines of code. The whole chapter probably adds fewer than two hundred lines to the driver. What it adds in mental model is larger. Each primitive we introduce expresses an invariant that was implicit in the Chapter 14 driver; making it explicit is most of the value.

15.2.4 Wrapping Up Section 1

A mutex and a condition variable cover most driver synchronisation. When the invariant is “at most N”, “many readers or one writer with occasional promotion”, “interruptible wait with partial progress”, “cross-component shutdown”, or “rate-limited retries”, a different primitive expresses the intent more directly and leaves less room for bugs. Section 2 introduces the first of those primitives, the counting semaphore.

15.3 Section 2: Using Semaphores in the FreeBSD Kernel

A counting semaphore is a small primitive. Internally it is a counter, a mutex, and a condition variable; the API wraps those three into operations that expose the counter-and-wait-for-positive semantics as its main interface. FreeBSD’s kernel semaphore lives in `/usr/src/sys/sys/semaphore.h` and `/usr/src/sys/kern/kern_semaphore.c`. The whole implementation is under two hundred lines. Reading it once is the fastest way to understand what the API guarantees.

This section covers the API in depth, compares semaphores with mutexes and condition variables, walks through the writer-cap refactor as Stage 1 of the Chapter 15 driver, and names the trade-offs that come with the primitive.

15.3.1 The Counting Semaphore, Precisely

A counting semaphore holds a non-negative integer. The API exposes two core operations:

- `sem_post(&s)` increments the counter. If anyone was waiting because the counter was zero, one of them is woken up.
- `sem_wait(&s)` decrements the counter if it is positive. If the counter is zero, the caller sleeps until `sem_post` increments it, then decrements and returns.

Those two operations, composed, give you bounded admission. Initialise the semaphore with N. Each participant calls `sem_wait` on entry and `sem_post` on exit. The invariant “at most N participants are between their wait and their post” is preserved automatically.

The FreeBSD counting semaphore differs from a binary semaphore (which can only be 0 or 1) in that the counter can go higher than 1. A binary semaphore is effectively a mutex, with one important difference: a semaphore has no ownership concept. Any thread may call `sem_post`; any thread may call `sem_wait`. A mutex, by contrast, must be released by the same thread that acquired it. This lack of ownership is important for exactly the use cases semaphores are best at: a producer that posts and a consumer that waits, which might be different threads.

15.3.2 The Data Structure

The data structure, from `/usr/src/sys/sys/semaphore.h`:

```
struct sema {  
    struct mtx      sema_mtx;      /* General protection lock. */
```

```
    struct cv      sema_cv;      /* Waiters. */
    int            sema_waiters;  /* Number of waiters. */
    int            sema_value;    /* Semaphore value. */
};
```

Four fields. `sema_mtx` is the semaphore's own internal mutex. `sema_cv` is the condition variable that waiters block on. `sema_waiters` counts the number of currently-blocked waiters (for diagnostic purposes and to avoid unnecessary broadcasts). `sema_value` is the counter itself.

You never touch these fields directly. The API is the contract; the structure is shown here once so you can visualise what the primitive is.

15.3.3 The API

From `/usr/src/sys/sys/sema.h`:

```
void sema_init(struct sema *sema, int value, const char *description);
void sema_destroy(struct sema *sema);
void sema_post(struct sema *sema);
void sema_wait(struct sema *sema);
int  sema_timedwait(struct sema *sema, int timo);
int  sema_trywait(struct sema *sema);
int  sema_value(struct sema *sema);
```

sema_init: initialises the semaphore with the given initial value and human-readable description. The description is used by kernel tracing facilities. The value must be non-negative; `sema_init` asserts this with `KASSERT`.

sema_destroy: tears the semaphore down. You must ensure no waiters are present when you call `sema_destroy`; the implementation asserts this. Typically you guarantee it by design: the destroy happens in `detach`, after every path that could `sema_wait` has been quiesced.

sema_post: increments the counter. If there are waiters, wakes one of them. Always succeeds.

sema_wait: if the counter is positive, decrements it and returns. Otherwise sleeps on the internal cv until `sema_post` increments the counter, at which point it decrements and returns. **sema_wait is not signal-interruptible**; it uses `cv_wait` under the hood, not `cv_wait_sig`. A signal will not wake the waiter. If you need interruptibility, `sema_wait` is the wrong tool; use a mutex-plus-cv pattern directly.

sema_timedwait: same as `sema_wait` but bounded by `timo` ticks. Returns 0 on success (value was decremented), `EWOULDBLOCK` on timeout. Internally uses `cv_timedwait`, so also not signal-interruptible.

sema_trywait: non-blocking variant. Returns 1 if the value was successfully decremented, 0 if the value was already zero. Note the unusual convention: 1 means success, 0 means failure. Most FreeBSD kernel APIs return 0 on success; `sema_trywait` is an exception. Be careful when reading or writing code that uses it.

sema_value: returns the current counter value. Useful for diagnostics; not useful for making synchronisation decisions, because the value can change immediately after the call returns.

15.3.4 What a Semaphore Is Not

Three properties the FreeBSD kernel semaphore does not have. Each is important.

No priority inheritance. The comment at the top of `/usr/src/sys/kern/kern_sema.c` is explicit:

Priority propagation will not generally raise the priority of semaphore “owners” (a misnomer in the context of semaphores), so should not be relied upon in combination with semaphores.

If you are protecting a resource and a high-priority thread is waiting on a semaphore held by a low-priority thread, the low-priority thread does not inherit the high priority. This is a consequence of the no-ownership design: there is no “holder” to raise. For resources where priority inheritance matters, use a mutex or a `lockmgr(9)` lock instead.

Not signal-interruptible. `sema_wait` and `sema_timedwait` are not interrupted by signals. A `read(2)` or `write(2)` that blocks in `sema_wait` will not return `EINTR` or `ERESTART` when the user sends `SIGINT`. If your syscall needs to respond to signals, you cannot block in `sema_wait` unconditionally. The two usual workarounds: structure the wait as `sema_trywait` plus an interruptible sleep on a separate `cv`, or keep `sema_wait` but arrange for the producer (the code that `sema_posts`) to also post when shutdown is in progress.

No ownership. Any thread can post; any thread can wait. This is a feature, not a bug, for the producer-consumer shape where one thread signals completion and another waits for it. It is a surprise if you were expecting mutex-like ownership semantics.

Knowing what a primitive is not is as important as knowing what it is. The FreeBSD kernel semaphore is a small, focused tool. Use it where it fits; reach for different primitives where it does not.

15.3.5 A Real-World Example: Hyper-V storvsc

Before the driver refactor, a short look at a real FreeBSD driver that uses `sema(9)` heavily. The Hyper-V storage driver lives at `/usr/src/sys/dev/hyperv/storvsc/hv_storvsc_drv_freebsd.c`. It uses per-request semaphores to block a thread waiting for hardware completion. The pattern:

```
/* In the request submission path: */
sema_init(&request->synch_sema, 0, "stor_synch_sema");
/* ... send command to hypervisor ... */
sema_wait(&request->synch_sema);
/* At this point the completion handler has posted; work is done. */
sema_destroy(&request->synch_sema);
```

And in the completion callback (run from a different context):

```
sema_post(&request->synch_sema);
```

The semaphore is initialised to zero, so `sema_wait` blocks. When hardware completes and the driver’s completion handler runs, it posts, and the submitting thread unblocks. The ownership-free nature of the semaphore is

exactly what makes this pattern work: a different thread (the completion handler) does the post than the one that does the wait.

The same driver uses a second semaphore (`hs_drain_sema`) for drain coordination during shutdown. The shutdown path waits on the semaphore; the request-completion path posts when all outstanding requests have finished.

These patterns are not inventions. They are the canonical uses of `sema(9)` in the FreeBSD tree. The Chapter 15 refactor uses a variation for the “at most N writers” invariant. The underlying idea is the same.

15.3.6 The Writer-Cap Refactor: Stage 1

The first Chapter 15 change to the driver adds a counting semaphore that caps the number of concurrent `myfirst_write` callers. The cap is configurable via a `sysctl`, with a default of 4.

The change is not about performance. The driver can already handle many concurrent writers; the `cbuf` is protected by the mutex and writes serialise there anyway. The change is about expressing the invariant “at most N writers” as a first-class primitive. A real driver might use this pattern for more substantive reasons (a fixed-size DMA descriptor pool, a hardware command queue with bounded depth, a serial device with a transmit window); the refactor is a didactic vehicle for learning the primitive in a context you can run and observe.

15.3.7 The Softc Addition

Add three members to `struct myfirst_softc`:

```
struct sema    writers_sema;
int            writers_limit;           /* Current configured limit. */
int            writers_trywait_failures; /* Diagnostic counter. */
```

`writers_sema` is the semaphore itself. `writers_limit` records the current configured value so the `sysctl` handler can detect changes. `writers_trywait_failures` counts the number of times a writer tried to enter, could not, and returned `EAGAIN` (for `O_NONBLOCK` opens) or `EWOULDBLOCK` (for bounded waits).

15.3.8 Initialising and Destroying the Semaphore

In `myfirst_attach`, before any code that could call `sema_wait` (so typically alongside the other `sema_init/cv_init` calls early in `attach`):

```
sema_init(&sc->writers_sema, 4, "myfirst writers");
sc->writers_limit = 4;
sc->writers_trywait_failures = 0;
```

The initial value of 4 matches the default limit. If we later raise the limit dynamically, we will adjust the semaphore’s value to match; Section 2 shows how.

In `myfirst_detach`, after every path that could `sema_wait` has been quiesced (which, at Stage 1, means after `is_attached` is cleared and all user syscalls have returned or failed with `ENXIO`):

```
sema_destroy(&sc->writers_sema);
```

A subtle point here, and a genuinely tricky one worth slowing down for. `sema_destroy` asserts that no waiters are present; more importantly, it then calls `mtx_destroy` on the semaphore's internal mutex and `cv_destroy` on its internal cv. If any thread is still executing inside any `sema_*` function, that thread may be about to re-acquire the internal mutex when `mtx_destroy` races ahead and frees it. That is a use-after-free, not just an assertion failure.

The naive cure “just post `writers_limit` slots to wake blocked waiters, then destroy” is *almost* correct but has a real race. A woken thread returns from `cv_wait` with the internal `sema_mtx` held, then needs to execute `sema_waiters--` and the final `mtx_unlock`. If the detach thread runs `sema_destroy` before the woken thread reaches its final unlock, the internal mutex is destroyed underneath it.

In practice that window is short (the woken thread typically runs within microseconds of `cv_signal`), but correctness means we cannot rely on “usually works”. The cure is a small extension: track every thread that might currently be inside `sema_*` code and wait for that count to reach zero before calling `sema_destroy`.

We add `sc->writers_inflight`, an int the driver treats as atomic. The write path increments it before calling `sema_wait` and decrements it after calling the matching `sema_post`. The detach path, after posting the wake-up slots, waits for the counter to reach zero:

```
/* In the write path, early: */
atomic_add_int(&sc->writers_inflight, 1);
if (!sc->is_attached) {
    atomic_subtract_int(&sc->writers_inflight, 1);
    return (ENXIO);
}
... sema_wait / work / sema_post ...
atomic_subtract_int(&sc->writers_inflight, 1);

/* In detach, after the posts: */
while (atomic_load_acq_int(&sc->writers_inflight) > 0)
    pause("myfwrdr", 1);
sema_destroy(&sc->writers_sema);
```

Why this works: any thread that could possibly be using the `sema`'s internal state has been counted. Detach waits until every counted thread has finished its final `sema_post`, which by the time the decrement fires has already returned from every `sema_*` function. No thread is still holding or about to acquire the internal mutex when `sema_destroy` runs.

The pattern is worth remembering because it is general: any external primitive whose destroy races with in-flight callers can be drained the same way. `sema(9)` is the immediate example; you will see variants of this counter in real drivers whenever a primitive without a built-in drain needs to be torn down cleanly.

The chapter's Stage 1 through Stage 4 drivers all implement this pattern. Section 6 encapsulates the logic in `myfirst_sync_writer_enter/myfirst_sync_writer_leave` so the call sites read naturally; the inflight bookkeeping hides in the wrapper.

15.3.9 Using the Semaphore in the Write Path

Add `sema_wait/sema_post` around the body of `myfirst_write`:

```
static int
myfirst_write(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    struct myfirst_fh *fh;
    char bounce[MYFIRST_BOUNCE];
    size_t want, put, room;
    ssize_t nbefore;
    int error;

    error = devfs_get_cdevpriv((void **)&fh);
    if (error != 0)
        return (error);
    if (sc == NULL || !sc->is_attached)
        return (ENXIO);

    /* Chapter 15: enforce the writer cap. */
    if (ioflag & IO_NDELAY) {
        if (!sema_trywait(&sc->writers_sema)) {
            MYFIRST_LOCK(sc);
            sc->writers_trywait_failures++;
            MYFIRST_UNLOCK(sc);
            return (EAGAIN);
        }
    } else {
        sema_wait(&sc->writers_sema);
    }
    if (!sc->is_attached) {
        sema_post(&sc->writers_sema);
        return (ENXIO);
    }

    nbefore = uio->uio_resid;
    while (uio->uio_resid > 0) {
        /* ... same body as Chapter 14 ... */
    }

    sema_post(&sc->writers_sema);
    return (0);
}
```

Several things to notice.

The `IO_NDELAY` (non-blocking) case uses `sema_trywait`, which returns 1 on success and 0 on failure. Note the inverted convention: `if (!sema_trywait(...))` means “if we failed to acquire”. Beginners miss this regularly; read the return value with care every time.

On `sema_trywait` failure the non-blocking caller gets `EAGAIN`. A diagnostic counter is incremented under the mutex (brief mutex acquire/release, unrelated to the semaphore).

The blocking case uses `sema_wait`. It is not signal-interruptible, so a blocking `write(2)` waiting for the semaphore cannot be interrupted by `SIGINT`. This is an important property; users must know it. For the current driver the semaphore is rarely contended in practice (the default limit of 4 is generous), so the interruptibility concern is largely theoretical. If the limit were 1 and writers genuinely queued, you might want to revisit using a semaphore here and instead use an interruptible primitive. Section 4 returns to this trade-off.

After the wait returns we check `is_attached`. If detach happened while we were blocked, we must not proceed with the write; we post the semaphore (restoring the count) and return `ENXIO`.

The `sema_post` at the exit path runs on every successful path. A common mistake is to forget it on an early return (for example, if an intermediate validation fails). The usual discipline is to make the post unconditional via a cleanup pattern: acquire, then all subsequent exits go through one common cleanup.

15.3.10 The Sysctl Handler for the Limit

Users of the driver may want to adjust the writer cap at runtime. The sysctl handler:

```
static int
myfirst_sysctl_writers_limit(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    int new, old, error, delta;

    old = sc->writers_limit;
    new = old;
    error = sysctl_handle_int(oidp, &new, 0, req);
    if (error || req->newptr == NULL)
        return (error);
    if (new < 1 || new > 64)
        return (EINVAL);

    MYFIRST_LOCK(sc);
    delta = new - sc->writers_limit;
    sc->writers_limit = new;
    MYFIRST_UNLOCK(sc);

    if (delta > 0) {
        /* Raised the limit: post the extra slots. */
        int i;
```

```

        for (i = 0; i < delta; i++)
            sema_post(&sc->writers_sema);
    }
    /*
     * Lowering is best-effort: we cannot reclaim posted slots from
     * threads already in the write path. New entries will observe
     * the lower limit once the counter drains below the new cap.
     */
    return (0);
}

```

Interesting details.

Raising the limit requires posting extra slots to the semaphore. If the old limit was 4 and the new limit is 6, we need to post twice so two more writers can enter simultaneously.

Lowering the limit is harder. A semaphore has no way to “consume” excess slots back out of it. If the current counter is 4 and we want a limit of 2, we cannot reduce the counter except by waiting for writers to enter and not posting on their exit. That is complicated and rarely worth the code. Instead, the simple approach: lower the `writers_limit` field, and let the semaphore drain naturally to the new level as writers enter without replacement. The `sysctl` handler comment documents this behaviour.

The mutex is held only for the `writers_limit` read/write, not for the `sema_post` loop. Taking the mutex around `sema_post` would be incorrect anyway: `sema_post` acquires its own internal mutex, and we would be introducing a lock order `sc->mtx -> sc->writers_sema.sema_mtx` that nothing else uses. Since `writers_limit` is the only field we actually protect, the mutex window is small.

15.3.11 Observing the Effect

With Stage 1 loaded, a few experiments.

Start many concurrent writers using a small shell loop:

```

# for i in 1 2 3 4 5 6 7 8; do
    (yes "writer-$i" | dd of=/dev/myfirst bs=512 count=100 2>/dev/null) &
done

```

Eight writers start simultaneously. With `writers_limit=4` (the default), four enter the write loop and the other four block in `sema_wait`. As one finishes and calls `sema_post`, a blocked one wakes up. The throughput is slightly lower than unconstrained (because only four writers actively progress at any moment), but the `cbuf` never has more than four writers contending for the mutex.

Observe the semaphore value live:

```

# sysctl dev.myfirst.0.stats.writers_sema_value
dev.myfirst.0.stats.writers_sema_value: 0

```

During the stress test the value should be near zero. When no writers are present it should equal `writers_limit`.

Tune the limit dynamically:

```
# sysctl dev.myfirst.0.writers_limit=2
```

Rerun the eight-writer stress. Two writers progress; six block. Throughput drops accordingly.

Tune the limit back up:

```
# sysctl dev.myfirst.0.writers_limit=8
```

All eight writers proceed concurrently.

Check the trywait-failure counter by using non-blocking writers (via `open` with `O_NONBLOCK`):

```
# ./nonblock_writer_stress.sh
# sysctl dev.myfirst.0.stats.writers_trywait_failures
```

The count grows whenever a non-blocking writer is turned away because the semaphore was at zero.

15.3.12 Common Mistakes

A short list of mistakes beginners make with `sema(9)`. Each has bitten real drivers; each has a simple rule.

Forgetting to `sema_post` on an error path. If the write path has a `return (error)` that bypasses the `sema_post`, the semaphore leaks a slot. After enough leaks the semaphore is permanently at zero and all writers block. The fix is either to place the `sema_post` in a single cleanup block that all exits flow through, or to audit every `return` statement to confirm it posts.

`sema_wait` in a context that cannot sleep. `sema_wait` blocks. It cannot be called from a callout callback, an interrupt filter, or any other non-sleeping context. The WITNESS assertion catches this on a debug kernel; the production kernel may deadlock or panic silently.

Destroying a semaphore with waiters. `sema_destroy` asserts that no waiters exist. In a driver's detach, the careful thing to do is drain every path that could wait before destroying. If the detach ordering is wrong (destroying before the waiters have woken), the assertion fires on a debug kernel and the destroy silently corrupts on a production kernel.

Using `sema_wait` where signal interruptibility is needed. Users expect `read(2)` and `write(2)` to respond to `SIGINT`. If the syscall blocks in `sema_wait`, it does not. Either pick a different primitive or structure the code so `sema_wait` is short enough that signal latency is acceptable.

Confusing `sema_trywait`'s return value. Returns 1 on success, 0 on failure. Most FreeBSD kernel APIs return 0 on success. A misreading of the return value produces the opposite of the intended behaviour. Always double-check this one.

Assuming priority inheritance. If the invariant requires that a high-priority waiter raise the effective priority of the thread that will post, `sema(9)` will not do that. Use a mutex or a `lockmgr(9)` lock instead.

15.3.13 A Note on When Not to Use Semaphores

For completeness, a short list of situations where `sema(9)` is the wrong tool.

- **When the invariant is “exclusive ownership of a resource”.** That is a mutex. A semaphore initialised to 1 approximates it but loses ownership semantics and priority inheritance.
- **When the waiter must be signal-interruptible.** Use `cv_wait_sig` or `cv_timedwait_sig` with your own counter.
- **When the work is short and contention is high.** The semaphore’s internal mutex is a single point of serialisation. For very short critical sections, the overhead may dominate.
- **When priority inheritance is required.** Use a mutex or `lockmgr(9)`.
- **When you need more than counting.** If the invariant is “wait until this specific complex predicate holds”, a mutex and a `cv` that tests the predicate is the right tool.

For the driver’s writer-cap use case, none of these disqualifications apply. The semaphore is the right tool, the refactor is small, and the resulting code is readable. Stage 1 of the Chapter 15 driver keeps the new vocabulary and moves on.

15.3.14 Wrapping Up Section 2

A counting semaphore is a counter, a mutex, and a condition variable wrapped into a small API. `sema_init`, `sema_wait`, `sema_post`, `sema_trywait`, `sema_timedwait`, `sema_value`, and `sema_destroy` cover the whole surface. The primitive is ideal for bounded admission and for producer-consumer completion shapes where the producer and consumer are different threads. It lacks priority inheritance, signal interruptibility, and ownership, and those limitations are real. Stage 1 of the Chapter 15 driver applied a writer-cap semaphore; the next section applies a read-mostly `sx` refinement.

15.4 Section 3: Read-Mostly Scenarios and Shared Access

The `sx` lock from Chapter 12 is already in the driver. `sc->cfg_sx` protects the `myfirst_config` structure, and the configuration sysctls acquire it in shared mode for reads and exclusive mode for writes. That pattern is correct and, for the configuration use case, sufficient. This section refines the `sx` pattern to cover a slightly different shape: a read-mostly cache where readers occasionally notice that the cache needs updating and must promote to a writer briefly.

This section also introduces a small number of `sx` operations the driver has not used yet: `sx_try_upgrade`, `sx_downgrade`, `sx_xlocked`, and a few introspection macros. The Stage 2 driver refactor adds a tiny statistics cache protected by its own `sx` and uses the upgrade pattern to refresh the cache under light contention.

15.4.1 The Read-Mostly Cache Problem

A concrete motivating problem for the Stage 2 refactor. Suppose the driver wants to expose a computed statistic, “average bytes written per second over the last 10 seconds”. The statistic is expensive to compute (it requires a walk over a per-second history buffer) and is read often (every sysctl read, every heartbeat log line). A naive

implementation recomputes on every read. A better implementation caches the result and invalidates the cache periodically.

The cache has three properties:

1. Reads vastly outnumber writes. Any number of threads may read simultaneously; only the occasional cache refresh needs to write.
2. Readers sometimes detect that the cache is stale. When that happens, the reader wants to promote to a writer briefly, refresh the cache, and return to reading.
3. Refreshing the cache takes a few microseconds. A reader that promotes and refreshes still wants to release the exclusive lock quickly.

The `sx` lock handles properties 1 and 3 natively: many readers can hold `sx_s` lock simultaneously; a writer with `sx_x` lock excludes readers. Property 2 requires `sx_try_upgrade`.

15.4.2 `sx_try_upgrade` and `sx_downgrade`

Two operations on the `sx` lock that Chapter 12 did not introduce.

`sx_try_upgrade(&sx)` attempts to atomically promote a shared lock to an exclusive lock. Returns non-zero on success, zero on failure. A failure means another thread also holds the shared lock (exclusive-with-other-readers is not representable; the upgrade can only succeed if the calling thread is the sole shared holder). On success the shared lock is gone and the caller now holds the exclusive lock.

`sx_downgrade(&sx)` atomically demotes an exclusive lock to a shared lock. Always succeeds. The exclusive holder becomes a shared holder; other shared lockers can then join.

The pattern for read-with-occasional-upgrade:

```
sx_slock(&sx);
if (cache_stale(&cache)) {
    if (sx_try_upgrade(&sx)) {
        /* Promoted to exclusive. */
        refresh_cache(&cache);
        sx_downgrade(&sx);
    } else {
        /*
         * Upgrade failed: another reader holds the lock.
         * Release the shared lock, take the exclusive lock,
         * refresh, downgrade.
         */
        sx_sunlock(&sx);
        sx_xlock(&sx);
        if (cache_stale(&cache))
            refresh_cache(&cache);
        sx_downgrade(&sx);
    }
}
```

```
use_cache(&cache);  
sx_sunlock(&sx);
```

Three things to notice.

The happy path is the `sx_try_upgrade` success. The upgrade is atomic: at no point is the lock released and re-acquired, so no other writer can slip in between. For a read-mostly workload where readers rarely contend with each other, this path dominates.

The fallback path when `sx_try_upgrade` fails drops the shared lock entirely, acquires the exclusive lock from scratch, and re-checks the stale predicate. The re-check is essential: between dropping the shared lock and acquiring the exclusive lock, another thread may have refreshed the cache. Without the re-check you would refresh redundantly.

The final `sx_sunlock` after `sx_downgrade` is always correct because the downgraded state is shared.

This pattern is surprisingly common in the FreeBSD source tree. Search for `sx_try_upgrade` under `/usr/src/sys/` and you find it in several subsystems, including VFS and the routing table updates.

15.4.3 A Worked Application: Stage 2 Driver

Stage 2 of the Chapter 15 driver adds a small statistics cache protected by its own `sx` lock. The cache holds a single integer, “bytes_written in the last 10 seconds, as of the last refresh”, and a timestamp recording when the cache was last refreshed.

The softc addition:

```
struct sx      stats_cache_sx;  
uint64_t      stats_cache_bytes_10s;  
uint64_t      stats_cache_last_refresh_ticks;
```

The cache validity is based on a timestamp. If the current ticks differs from `stats_cache_last_refresh_ticks` by more than `hz` (one second’s worth), the cache is considered stale. Any `sysctl` read of the cached value triggers a staleness check; if stale, the reader promotes and refreshes.

15.4.4 The Cache Refresh Function

The refresh function is trivial for the didactic version: it just reads the current counter and records the current time.

```
static void  
myfirst_stats_cache_refresh(struct myfirst_softc *sc)  
{  
    KASSERT(sx_xlocked(&sc->stats_cache_sx),  
            ("stats cache not exclusively locked"));  
    sc->stats_cache_bytes_10s = counter_u64_fetch(sc->bytes_written);  
}
```

```

        sc->stats_cache_last_refresh_ticks = ticks;
    }

```

The KASSERT documents the contract: this function must be called with the sx held exclusively. A debug kernel catches violations at runtime.

15.4.5 The Sysctl Handler

The sysctl handler that reads the cached value:

```

static int
myfirst_sysctl_stats_cached(SYSCTL_HANDLER_ARGS)
{
    struct myfirst_softc *sc = arg1;
    uint64_t value;
    int stale;

    sx_slock(&sc->stats_cache_sx);
    stale = (ticks - sc->stats_cache_last_refresh_ticks) > hz;
    if (stale) {
        if (sx_try_upgrade(&sc->stats_cache_sx)) {
            myfirst_stats_cache_refresh(sc);
            sx_downgrade(&sc->stats_cache_sx);
        } else {
            sx_sunlock(&sc->stats_cache_sx);
            sx_xlock(&sc->stats_cache_sx);
            if ((ticks - sc->stats_cache_last_refresh_ticks) > hz)
                myfirst_stats_cache_refresh(sc);
            sx_downgrade(&sc->stats_cache_sx);
        }
    }
    value = sc->stats_cache_bytes_10s;
    sx_sunlock(&sc->stats_cache_sx);

    return (sysctl_handle_64(oidp, &value, 0, req));
}

```

The shape matches the pattern from the previous subsection. Worth reading once carefully. The staleness check happens twice in the fallback path: once to decide whether to take the exclusive lock at all, and once after acquisition to confirm the staleness still applies.

15.4.6 Attach and Detach

Initialise the sx in myfirst_attach, alongside the existing cfg_sx:

```
sx_init(&sc->stats_cache_sx, "myfirst stats cache");
sc->stats_cache_bytes_10s = 0;
sc->stats_cache_last_refresh_ticks = 0;
```

Destroy in `myfirst_detach`, after the taskqueue and mutex are torn down (the `sx` is ordered below the mutex in the lock graph; destroy it after the mutex for symmetry with init):

```
sx_destroy(&sc->stats_cache_sx);
```

No waiters should be present at destroy time. Readers may still be in progress if detach races with a `sysctl`, but the detach path does not access the cache `sx` so the two do not directly conflict. If a `sysctl` is executing when detach proceeds, the `sysctl` framework holds its own reference and the context will tear down in order.

15.4.7 Observing the Effect

Read the cached stat a thousand times quickly:

```
# for i in $(jot 1000 1); do
    sysctl -n dev.myfirst.0.stats.bytes_written_10s >/dev/null
done
```

Most reads hit the cache without promoting. Only the first read after a cache expiry refreshes. The result: near-zero contention on the stats cache `sx` under read-mostly load.

Observe refresh rate via `DTrace`:

```
# dtrace -n '
    fbt::myfirst_stats_cache_refresh:entry {
        @[execname] = count();
    }
' -c 'sleep 10'
```

Should show roughly ten refreshes per second (one per cache expiry), regardless of how many read requests arrived.

15.4.8 The `sx` Macro Vocabulary

A few macros and helpers the chapter has not used yet that are worth knowing.

`sx_xlocked(&sx)` returns non-zero if the current thread holds the `sx` exclusively. Useful inside assertions. Does not tell you whether a different thread holds it; there is no equivalent query for that.

`sx_xholder(&sx)` returns the thread pointer of the exclusive holder, or `NULL` if no one holds it exclusively. Useful in debugging output.

`sx_assert(&sx, what)` asserts a property of the lock state. `SX_LOCKED`, `SX_SLOCKED`, `SX_XLOCKED`, `SX_UNLOCKED`, `SX_XLOCKED | SX_NOTRECURSED`, and others are valid. Panics on mismatch when `INVARIANTS` is enabled.

For the Chapter 15 refactor we use `sx_xlocked` in the cache refresh `KASSERT`. The other macros are available when you need them.

15.4.9 Trade-offs and Cautions

Some trade-offs worth naming.

Shared locks have overhead. An `sx` in shared mode still takes a spin on the internal spin lock plus a couple of atomic operations. For extremely hot paths (tens of millions of operations per second), this can be measurable. `atomic(9)` with a seq-cst fence is sometimes cheaper. For the driver's workloads, `sx` is fine.

Upgrade failures are a real possibility. A workload with many concurrent readers will see `sx_try_upgrade` fail often. The fallback path (drop shared, acquire exclusive, re-check) does the right thing but has slightly higher latency. For true read-mostly workloads where upgrades are rare, the success path dominates.

Sx locks can sleep. Unlike a mutex, `sx`'s slow path blocks. Do not call `sx_slock`, `sx_xlock`, `sx_try_upgrade`, or `sx_downgrade` from a context that cannot sleep (callouts initialised without a sleepable lock, interrupt filters, etc.). Chapter 13 explains that the older `CALLOUT_MPSAFE` flag is deprecated; the modern test is whether the callout was set up through `callout_init(, 0)` or `callout_init_mtx(, &mtx, 0)`.

Lock order still matters. Adding an `sx` to the driver means adding a new node to the lock graph. Every code path that holds multiple locks must respect a consistent order. The Chapter 15 driver's final lock order is `sc->mtx -> sc->cfg_sx -> sc->stats_cache_sx`; `WITNESS` enforces it.

15.4.10 Wrapping Up Section 3

An `sx` lock covers many-readers-or-one-writer naturally. `sx_try_upgrade` and `sx_downgrade` extend that to read-mostly-with-promotion. The pattern with a happy-path upgrade and a fallback re-check is the canonical way to express "a reader noticed a need to write, briefly". Stage 2 of the driver added a small statistics cache with this pattern; Stage 3 will refine signal-interruptible waits.

15.5 Section 4: Condition Variables with Timeout and Interruption

The `cv_wait_sig` and `cv_timedwait_sig` primitives are already in the driver. Chapter 12 introduced them; Chapter 13 refined them for the tick-source driver. This section takes the next step: it distinguishes the return values these primitives produce, shows how to handle `EINTR` and `ERESTART` correctly, and refactors the driver's read path to preserve partial progress across signal interruption. This is Stage 3 of the Chapter 15 driver.

Unlike the previous sections, this one does not introduce a new primitive. It introduces a discipline for using a primitive you already know.

15.5.1 What the Return Values Mean

`cv_wait_sig`, `cv_timedwait_sig`, `mtx_sleep` with the `PCATCH` flag, and similar signal-aware waits can return several values:

- **0**: normal wakeup. The caller was woken by a matching `cv_signal` or `cv_broadcast`. Re-check the predicate; if true, proceed; if false, wait again.
- **EINTR**: interrupted by a signal that has a handler installed. The caller should abandon the wait, do any appropriate cleanup, and return `EINTR` to its own caller.
- **ERESTART**: interrupted by a signal whose handler specifies automatic restart. The kernel will re-invoke the syscall. The driver should return `ERESTART` to the syscall layer, which arranges for the restart.
- **EWOULDBLOCK**: only from timed waits. The timeout fired before any wakeup or signal arrived.

The distinction between `EINTR` and `ERESTART` matters because the driver returns these values back through the syscall path and userland handles them differently:

- If the syscall returns `EINTR`, userland's `read(2)` or `write(2)` returns -1 with `errno` set to `EINTR`. User code that did not install a `SA_RESTART` signal handler sees this explicitly.
- If the syscall returns `ERESTART`, the syscall machinery restarts the syscall transparently. Userland never sees the signal delivery at this level; the signal handler ran, but the read call continues.

The practical consequence: if your `cv_wait_sig` returns `EINTR`, the user will see an `EINTR` from their `read(2)` and any partial progress they might have expected must be explicit (the read returns the bytes copied before the signal, not an error, by convention). If it returns `ERESTART`, the restart happens and the read continues where the kernel saw fit.

15.5.2 The Partial-Progress Convention

UNIX convention for `read(2)` and `write(2)`: if a signal arrives after some data has been transferred, the syscall returns the number of bytes transferred, not an error. If no data has been transferred, the syscall returns `EINTR` (or restarts, depending on signal disposition).

Translating to the driver: at the entry of the read path, record the initial `uio_resid`. When the blocking wait returns a signal error, compare the current `uio_resid` with the recorded one. If progress was made, return 0 (which the syscall layer translates to “return the number of bytes copied”). If no progress was made, return the signal error.

The Chapter 12 driver already implements this convention for `myfirst_read` via the `nbefore` local and the “return -1 to caller to indicate partial progress” trick. Chapter 15 refines the handling, makes it explicit, and extends it to the write path.

15.5.3 The Refactored Read Path

The Chapter 14 Stage 4 read path has this shape:

```
while (uio->uio_resid > 0) {  
    MYFIRST_LOCK(sc);
```

```

        error = myfirst_wait_data(sc, ioflag, nbefore, uio);
        if (error != 0) {
            MYFIRST_UNLOCK(sc);
            return (error == -1 ? 0 : error);
        }
        ...
    }

```

And `myfirst_wait_data` returns -1 to signal “partial progress; return 0 to the user”. That convention is correct but cryptic. The Stage 3 refactor replaces the -1 magic value with a named sentinel and documents the convention in a comment:

```

#define MYFIRST_WAIT_PARTIAL    (-1)    /* partial progress already made */

static int
myfirst_wait_data(struct myfirst_softc *sc, int ioflag, ssize_t nbefore,
    struct uio *uio)
{
    int error, timo;

    MYFIRST_ASSERT(sc);
    while (cbuf_used(&sc->cb) == 0) {
        if (uio->uio_resid != nbefore) {
            /*
             * Some bytes already delivered on earlier loop
             * iterations. Do not block further; return
             * "partial progress" so the caller returns 0
             * to the syscall layer, which surfaces the
             * partial byte count.
             */
            return (MYFIRST_WAIT_PARTIAL);
        }
        if (ioflag & IO_NDELAY)
            return (EAGAIN);

        timo = sc->read_timeout_ms;
        if (timo > 0) {
            int ticks_total = (timo * hz + 999) / 1000;
            error = cv_timedwait_sig(&sc->data_cv, &sc->mtx,
                ticks_total);
        } else {
            error = cv_wait_sig(&sc->data_cv, &sc->mtx);
        }
        switch (error) {

```

```

        case 0:
            break;
        case EWOULDBLOCK:
            return (EAGAIN);
        case EINTR:
        case ERESTART:
            if (uio->uio_resid != nbefore)
                return (MYFIRST_WAIT_PARTIAL);
            return (error);
        default:
            return (error);
    }
    if (!sc->is_attached)
        return (ENXIO);
}
return (0);
}

```

Several changes from the Chapter 14 version.

The magic -1 is now MYFIRST_WAIT_PARTIAL, with a comment explaining what it means.

The error handling after the cv wait is explicit about what each return value means. EWOULDBLOCK becomes EAGAIN (which is the conventional user-facing error for “try again later”). EINTR and ERESTART are checked for partial progress: if any bytes were delivered, we return the partial sentinel; if not, we propagate the signal error.

The default case handles any other error the cv wait might return. Currently the kernel’s cv_timedwait_sig returns only the values listed above, but explicit handling of the unexpected case is a habit worth keeping.

15.5.4 Handling at the Caller

In myfirst_read the handling of the sentinel becomes slightly clearer:

```

while (uio->uio_resid > 0) {
    MYFIRST_LOCK(sc);
    error = myfirst_wait_data(sc, ioflag, nbefore, uio);
    if (error != 0) {
        MYFIRST_UNLOCK(sc);
        if (error == MYFIRST_WAIT_PARTIAL)
            return (0);
        return (error);
    }
    ...
}

```

The reader can see at a glance what “partial progress” means. A maintainer adding a new early-exit reason later knows to check whether it should propagate to the user or be suppressed as partial.

15.5.5 The Write Path Gets the Same Treatment

The Chapter 14 write path already implements partial-progress handling in `myfirst_wait_room`. Stage 3 applies the same refactor there: replace `-1` with `MYFIRST_WAIT_PARTIAL`, make the error-handling switch explicit, and document the convention.

One small additional change for the write path. The write path’s `sema_wait` from Section 2 is not signal-interruptible. Before the semaphore change, a blocked write would be interruptible via `cv_wait_sig` inside `myfirst_wait_room`. After adding the semaphore, a write that blocks on `sema_wait` (waiting for a writer slot) is not interruptible.

Is that acceptable? For most workloads yes, because the writer cap is typically not contended. For a workload where the cap is 1 and writers genuinely queue for long periods, users would expect `SIGINT` to work. The trade-off is an explicit trade-off; Section 5 will show how to make the wait interruptible by layering a signal-aware wait around `sema_trywait`.

For Stage 3, we accept the non-interruptible `sema_wait` for the default case and note the trade-off in a comment:

```
/*
 * The writer-cap semaphore wait is not signal-interruptible. For a
 * workload where the cap is rarely contended this is acceptable. If
 * you set writers_limit=1 and create a real queue of writers, consider
 * the interruptible alternative in Section 5.
 */
sema_wait(&sc->writers_sema);
```

15.5.6 The Interruptible Wait Pattern

For readers who want the fully interruptible version now: combine `sema_trywait` with a retry loop that uses a `cv` for interruptible sleep. The code is moderately verbose, which is why Chapter 15 defers it to an optional subsection.

```
static int
myfirst_writer_enter_interruptible(struct myfirst_softc *sc)
{
    int error;

    MYFIRST_LOCK(sc);
    while (!sema_trywait(&sc->writers_sema)) {
        if (!sc->is_attached) {
            MYFIRST_UNLOCK(sc);
```

```

        return (ENXIO);
    }
    error = cv_wait_sig(&sc->writers_wakeup_cv, &sc->mtx);
    if (error != 0) {
        MYFIRST_UNLOCK(sc);
        return (error);
    }
}
MYFIRST_UNLOCK(sc);
return (0);
}

```

This requires a second cv (`writers_wakeup_cv`) that the exit path signals after every `sema_post`:

```

sema_post(&sc->writers_sema);
/* Wake one interruptible waiter so they can retry sema_trywait. */
cv_signal(&sc->writers_wakeup_cv);

```

The interruptible version preserves `EINTR/ERESTART` handling correctly. It is longer than the plain `sema_wait` version, and for most drivers the trade-off is not worth the extra code. But the pattern exists when it is needed.

15.5.7 Common Mistakes

Treating `EWOULDBLOCK` as a normal wakeup. The timed wait returns `EWOULDBLOCK` when the timer fires. Treating this as 0 and re-testing the predicate is wrong: the predicate is probably still false and the loop spins indefinitely.

Treating `EINTR` as a recoverable wakeup. `EINTR` means the caller should abandon the wait. A loop that does `while (... != 0) cv_wait_sig(...)` with no `EINTR` handling never propagates signals back to user space.

Forgetting the partial-progress check. A read that copied half its bytes and gets interrupted should return the half; a naive implementation returns `EINTR` with zero bytes copied, losing the partial data.

Mixing `cv_wait` with signal-interruptible callers. `cv_wait` (without `_sig`) blocks even during signal delivery. A syscall that uses `cv_wait` cannot be interrupted; users' `SIGINT` does nothing until the predicate is satisfied. Always use `cv_wait_sig` in syscall contexts.

Forgetting to re-check the predicate after wakeup. Both signals and `cv_signal` wake the waiter. The predicate may not be true on wakeup (spurious wakeups are allowed by the API). Always check the predicate in a loop.

15.5.8 Wrapping Up Section 4

Signal-interruptible waits have four distinct return values: 0 (normal), `EINTR` (signal without restart), `ERESTART` (signal with restart), `EWOULDBLOCK` (timeout). Each has a specific meaning and the driver must

handle each explicitly. The partial-progress convention (return the bytes copied so far, not an error) is the UNIX standard for reads and writes. Stage 3 of the driver applied this discipline and made the partial-progress sentinel explicit. Section 5 takes the coordination story further.

15.6 Section 5: Synchronization Between Modules or Subsystems

Up to now every primitive in the driver has been local to a single function or file section. A mutex protects a buffer; a cv signals readers; a sema limits writers; an sx caches statistics. Each primitive solves one problem in one place.

Real drivers have coordination that spans across subsystems. A callout fires, needs a task to finish its work, needs a user thread to see the resulting state, and needs another subsystem to notice that shutdown is in progress. The primitives you already know are sufficient; the difficulty is in composing them so the cross-component handshake is explicit and maintainable.

This section teaches the composition. It introduces a small atomic-flag discipline for cross-context shutdown visibility, a state-flag handshake between the callout and the task, and the beginnings of a wrapper layer that Section 6 will formalise. Stage 4 of the Chapter 15 driver begins here.

15.6.1 The Shutdown-Flag Problem

A recurring problem in driver detach: several contexts need to know that shutdown is in progress. The Chapter 14 driver uses `sc->is_attached` as this flag, read under the mutex in most places and occasionally read unprotected (with the comment “read at handler entry may be unprotected”). This works, but it has two subtle issues.

First, the unprotected read is technically undefined behaviour in pure C. A concurrent writer and an unsynchronised reader is a data race; the compiler is free to transform the code in ways that assume no concurrent access. Current kernel compilers rarely do, but the code is not strictly portable and a future compiler could break it.

Second, the mutex-protected reads serialise across a lock even when the only thing you want is a quick “is it shutdown yet” peek. In a hot path this cost is measurable.

The modern discipline: use `atomic_load_int` for reads and `atomic_store_int` (or `atomic_store_rel_int`) for writes. These operations are defined by the C memory model to be well-ordered and race-free. They are also very cheap: on x86 a plain load or store with the right barriers; on other architectures a single atomic instruction.

15.6.2 The Atomic API in One Page

`/usr/src/sys/sys/atomic_common.h` and architecture-specific headers define the atomic operations. The ones you will use most:

- `atomic_load_int(p)`: reads `*p` atomically. No memory barrier.
- `atomic_load_acq_int(p)`: reads `*p` atomically with acquire semantics. Subsequent memory accesses cannot be reordered before the load.
- `atomic_store_int(p, v)`: writes `v` to `*p` atomically. No memory barrier.

- `atomic_store_rel_int(p, v)`: writes `v` to `*p` atomically with release semantics. Preceding memory accesses cannot be reordered after the store.
- `atomic_fetchadd_int(p, v)`: returns old `*p` and sets `*p = *p + v` atomically.
- `atomic_cmpset_int(p, old, new)`: if `*p == old`, sets `*p = new` and returns 1; otherwise returns 0.

For the shutdown flag the pattern is:

- Writer (detach): `atomic_store_rel_int(&sc->is_attached, 0)`. The release ensures any prior state changes (draining, cv broadcasts) are visible before the flag becomes 0.
- Readers (any context): `if (atomic_load_acq_int(&sc->is_attached) == 0) { ... }`. The acquire ensures any subsequent checks see the state the writer intended.

The chapter uses `atomic_load_acq_int` in read-side shutdown checks and `atomic_store_rel_int` in the detach path. This makes the shutdown visibility correct across every context without introducing a mutex cost in the hot path.

15.6.3 Why Not Just a Mutex-Protected Flag?

A fair question. The answer is “because the atomic pattern is cheaper and equally correct for this specific invariant”. The flag has exactly two states (1 and 0), the transition is one-way (from 1 to 0, then never back to 1 in this lifetime), and no reader needs atomicity-with-other-state-changes; each reader only wants “is it still attached?”.

For an invariant with multiple fields or bidirectional transitions a mutex is the right tool. For a monotonic one-bit flag, atomics win.

15.6.4 Applying the Atomic Flag

The Stage 4 refactor converts `sc->is_attached` reads to atomic loads where they currently happen outside the mutex. The places to change are:

- `myfirst_open`: the entry check `if (sc == NULL || !sc->is_attached)`.
- `myfirst_read`: the entry check after `devfs_get_cdevpriv`.
- `myfirst_write`: the entry check after `devfs_get_cdevpriv`.
- `myfirst_poll`: the entry check.
- Every callout callback: `if (!sc->is_attached) return;`
- Every task callback’s equivalent check (if any).
- `myfirst_tick_source` after acquiring the mutex (this one is under the mutex; it could be an atomic load but does not have to be).

The mutex-held checks inside `myfirst_wait_data`, `myfirst_wait_room`, and the blocking re-checks after cv wakeup stay as-is: they are already serialised by the mutex.

The detach write becomes:

```
MYFIRST_LOCK(sc);
if (sc->active_fhs > 0) {
    MYFIRST_UNLOCK(sc);
```

```

        return (EBUSY);
    }
    atomic_store_rel_int(&sc->is_attached, 0);
    cv_broadcast(&sc->data_cv);
    cv_broadcast(&sc->room_cv);
    MYFIRST_UNLOCK(sc);

```

The store-release pairs with the atomic-load-acquire reads in the other contexts. Any state change that happened before the store (for example, any prior shutdown preparation) is visible to any thread that later does an acquire-read.

The handler entry checks become:

```

if (sc == NULL || atomic_load_acq_int(&sc->is_attached) == 0)
    return (ENXIO);

```

For the callout callbacks the check was under the mutex; we leave it under the mutex for consistency with the rest of the callback's serialisation. Some drivers convert even the callout check to an atomic read for performance; the Chapter 15 driver does not, because the mutex cost is negligible at the callout firing rate.

15.6.5 The Callout-to-Task Handshake

A different cross-component coordination problem. Suppose the watchdog callout detects a stall and wants to trigger a recovery action in a task. The callout cannot do the recovery itself (it might sleep, call user-space, etc.). The current driver solves this by enqueueing a task from the callout. What it does not solve is “do not enqueue the task if the previous recovery is still in progress”.

A small state flag solves it. Add to the softc:

```

int recovery_in_progress;    /* 0 or 1; protected by sc->mtx */

```

The callout:

```

static void
myfirst_watchdog(void *arg)
{
    struct myfirst_softc *sc = arg;
    /* ... existing watchdog logic ... */

    if (stall_detected && !sc->recovery_in_progress) {
        sc->recovery_in_progress = 1;
        taskqueue_enqueue(sc->tq, &sc->recovery_task);
    }
}

```

```

        /* ... re-arm as before ... */
    }

```

The task:

```

static void
myfirst_recovery_task(void *arg, int pending)
{
    struct myfirst_softc *sc = arg;

    /* ... recovery work ... */

    MYFIRST_LOCK(sc);
    sc->recovery_in_progress = 0;
    MYFIRST_UNLOCK(sc);
}

```

The flag is protected by the mutex (both writes happen under the mutex; the read in the callout happens under the mutex because callouts hold the mutex via `callout_init_mtx`). The invariant “at most one recovery task at a time” is preserved. A watchdog firing during recovery sees the flag set and does not enqueue.

This is a minimal example, but the pattern generalises. Any time the driver needs to coordinate “do X only if Y is not already happening”, a state flag protected by an appropriate lock is the right tool.

15.6.6 The Stage 4 Softc

Pulling it together. Stage 4 adds these fields:

```

/* Semaphore and its diagnostic fields (from Stage 1). */
struct sema    writers_sema;
int            writers_limit;
int            writers_trywait_failures;

/* Stats cache (from Stage 2). */
struct sx      stats_cache_sx;
uint64_t       stats_cache_bytes_10s;
uint64_t       stats_cache_last_refresh_ticks;

/* Recovery coordination (new in Stage 4). */
int            recovery_in_progress;
struct task    recovery_task;
int            recovery_task_runs;

```

All three fields form a coherent subsystem-coordination substrate. Section 6 encapsulates the vocabulary. Section 8 ships the final version.

15.6.7 Memory Ordering in One Subsection

Memory ordering can feel abstract; a concrete summary helps.

On strongly-ordered architectures (x86, amd64), plain loads and stores of aligned int-sized values are atomic with respect to other aligned int-sized values. A plain `int flag = 0` write is visible to all other CPUs promptly. You rarely need barriers.

On weakly-ordered architectures (arm64, riscv, powerpc), the compiler and CPU are free to reorder loads and stores as long as the sequence would appear correct to a single thread. A plain write by one CPU may be delayed from being visible to another CPU, and reads on the other CPU may be reordered relative to each other.

The `atomic(9)` API papers over the difference. `atomic_store_rel_int` and `atomic_load_acq_int` produce the correct barriers on every architecture. You do not need to know which architecture is weak or strong; you use the API and the right thing happens.

For the Chapter 15 driver, using `atomic_store_rel_int` on the detach write and `atomic_load_acq_int` on the entry checks gives you a driver that works correctly on both x86 and arm64. If the driver ever ships on arm64 systems (and FreeBSD 14.3 supports arm64 well), the discipline pays off.

15.6.8 Wrapping Up Section 5

Cross-component coordination in a driver uses the same primitives as local synchronisation, composed. The atomic API covers cheap shutdown flags with correct memory ordering. State flags protected by the appropriate lock coordinate “at most one” invariants across callouts, tasks, and user threads. Stage 4 of the Chapter 15 driver added both patterns. Section 6 takes the next step and encapsulates the synchronisation vocabulary in a dedicated header.

15.7 Section 6: Synchronization and Modular Design

The driver now uses five kinds of synchronisation primitives: a mutex, two condition variables, two sx locks, a counting semaphore, and atomic operations. Each one appears in several places across the source. A maintainer reading the file for the first time must reconstruct the synchronisation strategy from the scattered call sites.

This section encapsulates the synchronisation vocabulary in a small header, `myfirst_sync.h`, that names every operation the driver performs. The header does not add new primitives; it gives the existing primitives readable names and documents their contracts in one place. Stage 4 of the Chapter 15 driver introduces the header and updates the main source to use it.

A note on status before we go further. The `myfirst_sync.h` wrapper is **a recommendation, not a FreeBSD convention**. Most drivers under `/usr/src/sys/dev` call `mtx_lock`, `sx_xlock`, `cv_wait`, and friends directly; they do not ship a private synchronisation header. If you skim the tree, you will not find a community expectation that every driver provides such a layer. What the FreeBSD community *does* expect is a clear, documented lock order and a `LOCKING.md`-style comment block that a reviewer can follow, and that expectation we satisfy in every chapter of Part 3. The wrapper header is a stylistic extension that has worked well for several medium-sized drivers inside and outside the tree; it is valuable for this book because it turns the synchronisation vocabulary into something you can name, audit, and change in one place. If your future driver does not need the extra readability, skipping the header and keeping the primitive calls in the source is a perfectly normal choice. The

underlying discipline, lock order, drain on detach, explicit contracts, is what matters; the wrapper is one way to keep that discipline visible, not the only way.

15.7.1 Why Encapsulate

Three concrete benefits.

Readability. A code path that reads `myfirst_sync_writer_enter(sc)` tells the reader exactly what the call does. The same code path written as `if (ioflag & IO_NDELAY) { if (!sema_trywait(&sc->writers_sema)) ...` is correct but tells the reader less.

Changeability. If the synchronisation strategy changes (say, the writer-cap semaphore is replaced by an interruptible cv-based wait from Section 4), the change happens in one place in the header. The call sites in `myfirst_write` do not change.

Verifiability. The header is the single place where the synchronisation contracts are documented. A code review can verify “does every enter have a matching leave?” by grepping the header. Without the header the review must walk every call site.

The cost of encapsulation is minimal. A header of 100 to 200 lines. A half-hour of refactoring. A slight layer of indirection that a modern compiler inlines away.

15.7.2 The Shape of `myfirst_sync.h`

The header names every synchronisation operation. It does not define new structures; the structures stay in the softc. It provides inline functions or macros that wrap the primitives.

A sketch:

```
#ifndef MYFIRST_SYNC_H
#define MYFIRST_SYNC_H

#include <sys/lock.h>
#include <sys/mutex.h>
#include <sys/sx.h>
#include <sys/sema.h>
#include <sys/condvar.h>

struct myfirst_softc;      /* Forward declaration. */

/* Data-path mutex operations. */
static __inline void      myfirst_sync_lock(struct myfirst_softc *sc);
static __inline void      myfirst_sync_unlock(struct myfirst_softc *sc);
static __inline void      myfirst_sync_assert_locked(struct myfirst_softc *sc);

/* Configuration sx operations. */
static __inline void      myfirst_sync_cfg_read_begin(struct myfirst_softc *sc);
```

```

static __inline void    myfirst_sync_cfg_read_end(struct myfirst_softc *sc);
static __inline void    myfirst_sync_cfg_write_begin(struct myfirst_softc *sc);
static __inline void    myfirst_sync_cfg_write_end(struct myfirst_softc *sc);

/* Writer-cap semaphore operations. */
static __inline int     myfirst_sync_writer_enter(struct myfirst_softc *sc,
                                                int ioflag);
static __inline void    myfirst_sync_writer_leave(struct myfirst_softc *sc);

/* Stats cache sx operations. */
static __inline void    myfirst_sync_stats_cache_read_begin(
                        struct myfirst_softc *sc);
static __inline void    myfirst_sync_stats_cache_read_end(
                        struct myfirst_softc *sc);
static __inline int     myfirst_sync_stats_cache_try_promote(
                        struct myfirst_softc *sc);
static __inline void    myfirst_sync_stats_cache_downgrade(
                        struct myfirst_softc *sc);
static __inline void    myfirst_sync_stats_cache_write_begin(
                        struct myfirst_softc *sc);
static __inline void    myfirst_sync_stats_cache_write_end(
                        struct myfirst_softc *sc);

/* Attach-flag atomic operations. */
static __inline int     myfirst_sync_is_attached(struct myfirst_softc *sc);
static __inline void    myfirst_sync_mark_detaching(struct myfirst_softc *sc);

#endif /* MYFIRST_SYNC_H */

```

Each function wraps exactly one primitive call plus any convention the call site needs. For example, `myfirst_sync_writer_enter` takes the `ioflag` parameter and picks between `sema_trywait` (for `IO_NDELAY`) and `sema_wait`. The caller does not have to know the trywait-vs-wait logic; the header does.

15.7.3 The Implementation

Each function is a simple inline wrapper. Example implementations (for the most interesting ones):

```

static __inline void
myfirst_sync_lock(struct myfirst_softc *sc)
{
    mtx_lock(&sc->mtx);
}

static __inline void

```

```
myfirst_sync_unlock(struct myfirst_softc *sc)
{
    mtx_unlock(&sc->mtx);
}

static __inline void
myfirst_sync_assert_locked(struct myfirst_softc *sc)
{
    mtx_assert(&sc->mtx, MA_OWNED);
}

static __inline int
myfirst_sync_writer_enter(struct myfirst_softc *sc, int ioflag)
{
    if (ioflag & IO_NDELAY) {
        if (!sema_trywait(&sc->writers_sema)) {
            mtx_lock(&sc->mtx);
            sc->writers_trywait_failures++;
            mtx_unlock(&sc->mtx);
            return (EAGAIN);
        }
    } else {
        sema_wait(&sc->writers_sema);
    }
    if (!myfirst_sync_is_attached(sc)) {
        sema_post(&sc->writers_sema);
        return (ENXIO);
    }
    return (0);
}

static __inline void
myfirst_sync_writer_leave(struct myfirst_softc *sc)
{
    sema_post(&sc->writers_sema);
}

static __inline int
myfirst_sync_is_attached(struct myfirst_softc *sc)
{
    return (atomic_load_acq_int(&sc->is_attached));
}

static __inline void
```

```
myfirst_sync_mark_detaching(struct myfirst_softc *sc)
{
    atomic_store_rel_int(&sc->is_attached, 0);
}
```

The `writer_enter` wrapper is the most complex; everything else is a one-liner. A header of this shape produces zero runtime overhead (the compiler inlines every call) and adds substantial readability.

15.7.4 How the Source Changes

Every `mtx_lock(&sc->mtx)` in the main source becomes `myfirst_sync_lock(sc)`. Every `sema_wait(&sc->writers_sema)` becomes `myfirst_sync_writer_enter(sc, ioflag)` or a variant. Every `atomic_load_acq_int(&sc->is_attached)` becomes `myfirst_sync_is_attached(sc)`.

The main source reads more clearly:

```
/* Before: */
if (ioflag & IO_NDELAY) {
    if (!sema_trywait(&sc->writers_sema)) {
        MYFIRST_LOCK(sc);
        sc->writers_trywait_failures++;
        MYFIRST_UNLOCK(sc);
        return (EAGAIN);
    }
} else {
    sema_wait(&sc->writers_sema);
}
if (!sc->is_attached) {
    sema_post(&sc->writers_sema);
    return (ENXIO);
}

/* After: */
error = myfirst_sync_writer_enter(sc, ioflag);
if (error != 0)
    return (error);
```

Five lines of intent become one. A reader who wants to know what `myfirst_sync_writer_enter` does opens the header and reads the implementation. A reader who accepts the interface reads on.

15.7.5 Naming Conventions

A short discipline for picking names in a synchronisation wrapper layer.

Name operations, not primitives. `myfirst_sync_writer_enter` describes what the caller is doing (entering the writer section). `myfirst_sync_sema_wait` would describe the primitive (calling `sema_wait`), which is less useful.

Use enter/leave pairs for scoped acquisition. Every `enter` has a matching `leave`. This makes it visually obvious whether the driver always releases what it acquires.

Use read/write pairs for shared/exclusive access. `cfg_read_begin/cfg_read_end` for shared; `cfg_write_begin/cfg_write_end` for exclusive. The `begin/end` suffix mirrors the call-site structure.

Use `is_` for predicates that return bool-like values. `myfirst_sync_is_attached` reads like English.

Use `mark_` for atomic state transitions. `myfirst_sync_mark_detaching` describes the transition.

15.7.6 What Not to Put in the Header

The header should wrap synchronisation primitives, not business logic. A function that acquires a lock and also does “interesting” work should stay in the main source; only the pure lock manipulation belongs in the header.

The header also should not hide important details. For example, `myfirst_sync_writer_enter` returns `EAGAIN` or `ENXIO` or `0`; the caller must check. A header that silently “returned” on `ENXIO` would hide an important error path. The wrapper’s contract must be explicit.

15.7.7 A Related Discipline: Assertions

The header is a good place to put the assertions that document invariants. A function that must be called under the mutex can call `myfirst_sync_assert_locked(sc)` at entry:

```
static void
myfirst_some_helper(struct myfirst_softc *sc)
{
    myfirst_sync_assert_locked(sc);
    /* ... */
}
```

On a debug kernel (with `INVARIANTS`) the assertion fires if the helper is ever called without the mutex. On a production kernel the assertion is elided.

The Chapter 14 code uses `MYFIRST_ASSERT`; the Chapter 15 refactor keeps this as `myfirst_sync_assert_locked` with the same behaviour.

15.7.8 A Short WITNESS Walkthrough: Sleeping Under a Non-Sleepable Lock

Chapter 34 walks through a lock-order reversal between two mutexes. A separate class of `WITNESS` warning, equally common and just as cheap to prevent, deserves a short mention here because it lands squarely in the middle of Chapter 15’s territory: the interaction between mutexes and `sx` locks.

Imagine a first-attempt refactor of the configuration read path. The author has just added a new `sx_slock` over the config blob for read-mostly access, and, without thinking, calls it from inside a code path that still holds the data-path mutex:

```
static int
myfirst_read(struct cdev *dev, struct uio *uio, int ioflag)
{
    struct myfirst_softc *sc = dev->si_drv1;
    int error;

    MYFIRST_LOCK(sc);           /* mtx_lock: non-sleepable */
    sx_slock(&sc->cfg_sx);      /* sx_slock: sleepable */
    error = myfirst_copy_out_locked(sc, uio);
    sx_sunlock(&sc->cfg_sx);
    MYFIRST_UNLOCK(sc);
    return (error);
}
```

The code compiles and, in light testing on a non-debug kernel, appears to run correctly. Load it on a kernel built with options `WITNESS` and run the same lab, and the console reports something close to this:

```
lock order reversal: (sleepable after non-sleepable)
 1st 0xfffff800... myfirst_sc_mtx (mutex) @ /usr/src/sys/modules/myfirst/myfirst.c:...
 2nd 0xfffff800... myfirst_cfg_sx (sx) @ /usr/src/sys/modules/myfirst/myfirst.c:...
stack backtrace:
 #0 witness_checkorder+0x...
 #1 _sx_slock+0x...
 #2 myfirst_read+0x...
```

Two things are worth reading carefully in this report. The parenthetical “(sleepable after non-sleepable)” tells you exactly what the reversal is: the thread took a non-sleepable lock first (the mutex) and then asked for a sleepable one (the `sx` lock). `WITNESS` rejects this because `sx_slock` can sleep, and sleeping while a non-sleepable lock is held is a defined kernel bug class: the scheduler cannot take the thread off-CPU without also migrating the mutex’s waiters, and the invariants that make `MTX_DEF` cheap stop holding. The second thing is that `WITNESS` reports it the very first time the path runs, long before any real contention. You do not have to reproduce a race; the warning fires on the ordering itself.

The fix is ordering discipline, not a different primitive. Take the `sx` lock first, then the mutex:

```
sx_slock(&sc->cfg_sx);
MYFIRST_LOCK(sc);
error = myfirst_copy_out_locked(sc, uio);
MYFIRST_UNLOCK(sc);
sx_sunlock(&sc->cfg_sx);
```

Or, better for most drivers, read the config under the sx lock into a local snapshot and release the sx lock before touching the data-path mutex at all. The encapsulation in `myfirst_sync.h` helps here because the lock-order contract is named and documented in one place; a review that sees `myfirst_sync_cfg_slock` followed by `myfirst_sync_lock` can confirm the ordering at a glance.

This walkthrough deliberately stays shorter than Chapter 34's. The category of bug is different, and the lesson is specific to the sleepable/non-sleepable distinction Chapter 15 is built around. The broader lock-order reversal walkthrough belongs to the debugging chapter; this one belongs where the reader first composes sx locks and mutexes in the same code path.

15.7.9 Wrapping Up Section 6

A small synchronisation header names every operation the driver performs and centralises the contracts. The main source reads more clearly; the header is the one place a maintainer looks to understand or change the strategy. Stage 4's `myfirst_sync.h` adds no new primitives; it encapsulates the ones from Sections 2 through 5. Section 7 writes the tests that validate the whole composition.

15.8 Section 7: Testing Advanced Synchronization

Every primitive this chapter introduced has a failure mode. A semaphore with a missing `sema_post` leaks slots. An sx upgrade that does not re-check the predicate refreshes redundantly. A signal-interruptible wait that ignores EINTR deadlocks the caller. A state flag read without the right lock or atomic discipline silently reads stale values.

This section is about writing tests that surface those failure modes before users find them. The tests are not unit tests in the pure sense; they are stress harnesses that exercise the driver under concurrent load and check invariants. The Chapter 15 companion source includes three test programs; this section walks through each.

15.8.1 Why Stress Tests Matter

Synchronisation bugs rarely show up in single-threaded testing. A forgotten `sema_post` is invisible until enough writers have passed through that the semaphore runs out. A misplaced atomic read is invisible until a specific interleaving occurs. A detach race is invisible until detach and unload happen with real concurrency.

Stress tests find these bugs by running the driver in configurations that expose the interleavings. Many concurrent readers and writers. Fast tick source. Frequent detach/reload cycles. Simultaneous `sysctl` writes. The harder the driver works, the more likely a latent bug is to surface.

The tests do not replace `WITNESS` or `INVARIANTS`. `WITNESS` catches lock-order violations at any load. `INVARIANTS` catches structural violations. The stress tests catch logic errors that neither static nor lightweight dynamic checks can detect.

15.8.2 Test 1: Writer-Cap Correctness

The writer-cap semaphore's invariant is "at most `writers_limit` writers in `myfirst_write` at once". A test program starts many concurrent writers, each of which writes a few bytes, records its process ID in a tiny marker

at the start of its writes, and proceeds. A monitor process reads the cbuf in the background and counts concurrent markers.

The test is in `examples/part-03/ch15-more-synchronization/tests/writer_cap_test.c`:

```
/*
 * writer_cap_test: start N writers and verify no more than
 * writers_limit are simultaneously inside the write path.
 */
#include <sys/param.h>
#include <sys/time.h>
#include <err.h>
#include <errno.h>
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/sysctl.h>
#include <unistd.h>

#define N_WRITERS 16

int
main(int argc, char **argv)
{
    int fd, i;
    char buf[64];
    int writers = (argc > 1) ? atoi(argv[1]) : N_WRITERS;

    for (i = 0; i < writers; i++) {
        if (fork() == 0) {
            fd = open("/dev/myfirst", O_WRONLY);
            if (fd < 0)
                err(1, "open");
            snprintf(buf, sizeof(buf), "w%d\n", i);
            for (int j = 0; j < 100; j++) {
                write(fd, buf, strlen(buf));
                usleep(1000);
            }
            close(fd);
            _exit(0);
        }
    }
    while (wait(NULL) > 0)
        ;
}
```

```
    return (0);  
}
```

The test fires `N_WRITERS` processes, each of which writes 100 short messages with a 1 ms delay. A reader process reads `/dev/myfirst` and observes interleaving.

A simple invariant check: the reader reads 100 bytes at a time and records how many distinct writer prefixes appear in that window. If `writers_limit` is 4, the reader should see at most 4 prefixes in any 100-byte window (plus or minus). More than 4 indicates the cap is not being enforced.

A more rigorous check uses `sysctl dev.myfirst.0.stats.writers_trywait_failures` to observe the failure rate in the `O_NONBLOCK` mode. If you set `writers_limit=2` and run 16 non-blocking writers, most of them should see `EAGAIN`; the failure count should grow rapidly.

15.8.3 Test 2: Stats Cache Concurrency

The stats cache invariant is “many readers concurrently, refreshed at most once per second”. A test:

- Start 32 concurrent reader processes, each reading `dev.myfirst.0.stats.bytes_written_10s` in a tight loop.
- Start 1 writer that keeps writing to the device.
- Watch the cache refresh rate via `DTrace`:

```
# dtrace -n '  
fbt::myfirst_stats_cache_refresh:entry {  
    @["refreshes"] = count();  
}  
tick-10s { printa(@); exit(0); }  
,
```

Expected: approximately 10 refreshes per 10 seconds (one per stale expiry). Not 32 per 10 seconds; the cache eliminates the per-reader recomputation.

If the refresh rate spikes under contention, the `sx_try_upgrade` fast path is failing too often and the fallback (drop-and-reacquire) is introducing races. The driver code should handle this correctly; if it does not, the test exposes the bug.

15.8.4 Test 3: Detach Under Load

The detach invariant is “detach completes cleanly even when every Chapter 14 and 15 primitive is under load”. A detach test:

```
# ./stress_all.sh &  
# STRESS_PID=$!  
# sleep 5
```

```
# kldunload myfirst
# kill -TERM $STRESS_PID
```

Where `stress_all.sh` runs:

- Several concurrent writers.
- Several concurrent readers.
- The tick source enabled at 1 ms.
- The heartbeat enabled at 100 ms.
- The watchdog enabled at 1 s.
- Occasional `bulk_writer_flood` sysctl writes.
- Occasional `writers_limit` sysctl adjustments.
- Occasional stats-cache reads.

The detach should complete. If it hangs or panics, the ordering discipline has a bug. With the Chapter 14 and 15 code correctly ordered, the test should pass reliably.

15.8.5 Observing With DTrace

DTrace is the scalpel for synchronisation debugging. A few useful one-liners:

Count cv wakeups per cv name.

```
# dtrace -n 'fbt::cv_signal:entry { @[stringof(arg0)] = count(); }'
```

Interpreting the output requires knowing your cv names; the driver's are "myfirst_data" and "myfirst_room".

Count semaphore operations.

```
# dtrace -n '
  fbt::_sema_wait:entry { @[probecount] = count(); }
  fbt::_sema_post:entry { @[probecount] = count(); }
'
```

In a balanced driver the post count equals the wait count over a long run (plus the initial value from `sema_init`).

Observe task firings.

```
# dtrace -n 'fbt::taskqueue_run_locked:entry { @[execname] = count(); }'
```

Shows which taskqueue threads are running, which is useful for confirming the private taskqueue is getting work.

Observe callout firings.

```
# dtrace -n 'fbt::callout_reset:entry { @[probefunc] = count(); }'
```

Shows how often callouts are being re-armed, which should match the configured interval rate.

Run each one-liner under your stress workload. The counts should match your expectations. Unexpected imbalance is a debugging starting point.

15.8.6 WITNESS, INVARIANTS, and the Debug Kernel

The first line of defence remains the debug kernel. If WITNESS is unhappy about a lock order, fix the order before shipping. If INVARIANTS asserts in `cbuf_*` or `sema_*`, fix the caller before shipping. These checks are cheap; running without them in development is a false economy.

A few WITNESS outputs to expect or avoid:

- **“acquiring duplicate lock of same type”**: you acquired a lock you already hold, probably by accident. Review the call path.
- **“lock order reversal”**: two locks were acquired in different orders on different paths. Pick one order, enforce it, update `LOCKING.md`.
- **“blockable sleep from an invalid context”**: you called something that can sleep from a context where sleeping is not allowed. Check whether the context is a callout or interrupt.

Every WITNESS warning in `dmesg` from your driver is a bug. Treat them as panic-equivalent; fix each one.

15.8.7 Regression Discipline

After every Chapter 15 stage, run:

1. The Chapter 11 IO smoke tests (basic read, write, open, close).
2. The Chapter 12 synchronisation tests (bounded reads, sx-protected config).
3. The Chapter 13 timer tests (heartbeat, watchdog, tick source at various rates).
4. The Chapter 14 taskqueue tests (poll waiter, bulk writer flood, delayed reset).
5. The Chapter 15 tests (writer-cap, stats cache, detach under load).

The whole suite should pass on a debug kernel. If any test fails, the regression is recent; roll back to the previous stage, find the delta, and debug.

15.8.8 Wrapping Up Section 7

Advanced synchronisation needs advanced testing. Stress tests that exercise concurrent writers, readers, and sysctls surface bugs that single-threaded testing misses. DTrace makes the internals of the synchronisation primitives observable. WITNESS and INVARIANTS catch what remains. Running the whole stack under a debug kernel is the closest thing to “good enough” testing that a driver can get. Section 8 closes Part 3.

15.9 Section 8: Refactoring and Versioning Your Coordinated Driver

Stage 4 is the consolidation stage for Chapter 15. It does not add new functionality; it reorganises and documents the Chapter 15 additions, updates `LOCKING.md`, bumps the version to 0.9-coordination, and runs the full regression suite across Chapters 11 through 15.

This section walks through the consolidation, extends `LOCKING.md` with the Chapter 15 sections, and closes Part 3.

15.9.1 File Organisation

The Chapter 15 refactor introduces `myfirst_sync.h`. The file list becomes:

- `myfirst.c`: the main driver source.
- `cbuf.c`, `cbuf.h`: unchanged from Chapter 13.
- `myfirst_sync.h`: new header with synchronisation wrappers.
- `Makefile`: unchanged except for the addition of `myfirst_sync.h` to the headers the source depends on (for make dependency tracking if needed).

Inside `myfirst.c`, the Chapter 15 organisation follows the same pattern as Chapter 14 with a few additions:

1. Includes (now includes `myfirst_sync.h`).
2. `Softc` structure (extended with Chapter 15 fields).
3. File-handle structure (unchanged).
4. `cdevsw` declaration (unchanged).
5. Buffer helpers (unchanged).
6. Cache helpers (new; `myfirst_stats_cache_refresh`).
7. Condition-variable wait helpers (revised with explicit `EINTR/ERESTART` handling).
8. `Sysctl` handlers (extended with `writers_limit`, `stats_cache`, `recovery`).
9. Callout callbacks (revised to use `atomic_load_acq_int` for `is_attached` where appropriate).
10. Task callbacks (extended with `recovery_task`).
11. `Cdev` handlers (revised to use `myfirst_sync_*` wrappers).
12. Device methods (`attach/detach` extended with `sema`, `sx`, and atomic-flag discipline).
13. Module glue (version bump).

The key change across every section is the use of `myfirst_sync.h` wrappers where the Chapter 14 code used direct primitive calls. This is visible in `attach`, `detach`, and every handler.

15.9.2 The `LOCKING.md` Update

The Chapter 14 `LOCKING.md` had sections for the mutex, cvs, sx, callouts, and tasks. Chapter 15 adds Semaphores, Coordination, and an updated Lock Order section.

Semaphores

The driver owns one counting semaphore:

- `writers_sema`: caps concurrent writers at `sc->writers_limit`.
Default limit: 4. Range: 1-64. Configurable via the
`dev.myfirst.N.writers_limit` sysctl.

Semaphore operations happen outside `sc->mtx`. The internal `sema_mtx` is not in the documented lock order because it does not conflict with `sc->mtx`; the driver never holds `sc->mtx` across a `sema_wait` or `sema_post`.

Lowering `writers_limit` below the current semaphore value is best-effort: the handler lowers the target and lets new entries observe the lower cap as the value drains. Raising posts additional slots immediately.

Sema Drain Discipline

The driver tracks `writers_inflight` as an atomic int. It is incremented before any `sema_*` call (specifically at the top of `myfirst_sync_writer_enter`) and decremented after the matching `sema_post` (in `myfirst_sync_writer_leave` or on every error return).

Detach waits for `writers_inflight` to reach zero before calling `sema_destroy`. This closes the use-after-free race where a woken waiter is between `cv_wait` return and its final `mtx_unlock(&sema->sema_mtx)` when `sema_destroy` tears down the internal mutex.

`sema_destroy` itself is called only after:

1. `is_attached` has been cleared atomically.
2. `writers_limit` wake-up slots have been posted to the sema.
3. `writers_inflight` has been observed to reach zero.
4. Every callout, task, and selinfo has been drained.

Coordination

The driver uses three cross-component coordination mechanisms:

1. **Atomic is_attached flag.** Read via `atomic_load_acq_int`, written via `atomic_store_rel_int` in detach. Allows every context (callout, task, user thread) to check shutdown state without acquiring `sc->mtx`.

2. ****recovery_in_progress state flag.**** Protected by ``sc->mtx``. Set by the watchdog callout, cleared by the recovery task. Ensures at most one recovery task is pending or running at a time.
3. ****Stats cache sx.**** Shared reads, occasional upgrade-promote-downgrade for refresh. See the Stats Cache section.

Stats Cache

The ``stats_cache_sx`` protects a small cached statistic. The refresh pattern is:

```

```c
sx_slock(&sc->stats_cache_sx);
if (stale) {
 if (sx_try_upgrade(&sc->stats_cache_sx)) {
 refresh();
 sx_downgrade(&sc->stats_cache_sx);
 } else {
 sx_sunlock(&sc->stats_cache_sx);
 sx_xlock(&sc->stats_cache_sx);
 if (still_stale)
 refresh();
 sx_downgrade(&sc->stats_cache_sx);
 }
}
value = sc->stats_cache_bytes_10s;
sx_sunlock(&sc->stats_cache_sx);
```text

```

Lock Order

The complete driver lock order is:

```

```text
sc->mtx -> sc->cfg_sx -> sc->stats_cache_sx
```text

```

``WITNESS`` enforces this order. The writer-cap semaphore's **internal** mutex is not in the graph because the driver never holds ``sc->mtx`` (or any other driver lock) across a ``sema_wait``/``sema_post`` call.

Detach Ordering (updated)

1. Refuse detach **if** ``sc->active_fhs > 0``.

```

2. Clear `sc->is_attached` under `sc->mtx` via
   `atomic_store_rel_int`.
3. `cv_broadcast(&sc->data_cv)`; `cv_broadcast(&sc->room_cv)`.
4. Release `sc->mtx`.
5. Post `writers_limit` wake-up slots to `writers_sema`.
6. Wait for `writers_inflight == 0` (sema drain).
7. Drain the three callouts.
8. Drain every task including recovery_task.
9. `seldrain(&sc->rsl)`; `seldrain(&sc->wsl)`.
10. `taskqueue_free(sc->tq)`; `sc->tq = NULL`.
11. `sema_destroy(&sc->writers_sema)` (safe: drain completed).
12. `sx_destroy(&sc->stats_cache_sx)`.
13. Destroy cdev, free sysctl context, destroy cbuf, counters,
    cvs, cfg_sx, mtx.

```

15.9.3 The Version Bump

The version string advances from 0.8-taskqueues to 0.9-coordination:

```
#define MYFIRST_VERSION "0.9-coordination"
```

And the driver's probe string:

```
device_set_desc(dev, "My First FreeBSD Driver (Chapter 15 Stage 4)");
```

15.9.4 The Final Regression Pass

The Chapter 15 regression suite adds its own tests but also re-runs every earlier chapter's tests. A compact ordering:

1. **Build cleanly** on a debug kernel with all the usual options enabled.
2. **Load** the driver.
3. **Chapter 11 tests**: basic read, write, open, close, reset.
4. **Chapter 12 tests**: bounded reads, timed reads, cv broadcasts, sx config.
5. **Chapter 13 tests**: callouts at various rates, watchdog detection, tick source.
6. **Chapter 14 tests**: poll waiter, coalescing flood, delayed reset, detach under load.
7. **Chapter 15 tests**: writer-cap correctness, stats cache concurrency, signal interruption with partial progress, detach under full load.
8. **WITNESS pass**: every test, zero warnings in dmesg.
9. **DTrace verification**: wakeup counts and task firings match expectations.
10. **Long-duration stress**: hours of load with periodic detach-reload cycles.

Every test passes. Every WITNESS warning is resolved. The driver is at 0.9-coordination and Part 3 is done.

15.9.5 Documentation Audit

A final documentation pass.

- `myfirst.c` top-of-file comment is updated with the Chapter 15 vocabulary.
- `myfirst_sync.h` has a top-of-file comment summarising the design.
- `LOCKING.md` has the Semaphores, Coordination, and Stats Cache sections.
- The chapter's `README.md` under `examples/part-03/ch15-more-synchronization/` describes each stage.
- Every `sysctl` has a description string.

Updating documentation feels like overhead. It is the difference between a driver the next maintainer can change and a driver they have to rewrite.

15.9.6 A Final Audit Checklist

- ☐ Does every `sema_wait` have a matching `sema_post`?
- ☐ Does every `sx_slock` have a matching `sx_sunlock`?
- ☐ Does every `sx_xlock` have a matching `sx_xunlock`?
- ☐ Does every atomic read use `atomic_load_acq_int` and every atomic write use `atomic_store_rel_int` where ordering matters?
- ☐ Does every `cv_*_sig` call handle `EINTR`, `ERESTART`, and `EWOULDBLOCK` explicitly?
- ☐ Does every blocking-wait caller record and check partial progress?
- ☐ Is every synchronisation primitive wrapped in `myfirst_sync.h`?
- ☐ Does every primitive appear in `LOCKING.md`?
- ☐ Is the detach ordering in `LOCKING.md` accurate?
- ☐ Does the driver pass the full regression suite?

A driver that answers every item cleanly is a driver you can hand to another engineer with confidence.

15.9.7 Wrapping Up Section 8

Stage 4 consolidates. The header is in place, `LOCKING.md` is current, the version reflects the new capability, the regression suite passes, the audit is clean. The driver is `0.9-coordination` and the synchronisation story is complete.

Part 3 is complete as well. Five chapters, five primitives added one at a time, each composed with what came before. The Wrapping Up section after the labs and challenges frames what Part 3 accomplished and how Part 4 will use it.

15.10 Additional Topics: Atomic Operations, epoch(9) Revisited, and Memory Ordering

The main body of Chapter 15 taught the essentials. Three adjacent topics deserve a somewhat deeper mention because they recur in real driver code and because the underlying ideas round out the synchronisation story.

15.10.1 Atomic Operations in More Depth

The Chapter 15 driver used three atomic primitives: `atomic_load_acq_int`, `atomic_store_rel_int`, and implicitly `atomic_fetchadd_int` via `counter(9)`. The `atomic(9)` family is larger and more structured than these three operations suggest.

Read-modify-write primitives.

- `atomic_fetchadd_int(p, v)`: returns the old value of `*p`, sets `*p += v`. Useful for free-running counters.
- `atomic_cmpset_int(p, old, new)`: if `*p == old`, sets `*p = new` and returns 1; otherwise returns 0 and does not modify. The classic compare-and-swap. Useful for implementing lock-free state machines.
- `atomic_cmpset_acq_int`, `atomic_cmpset_rel_int`: variants with acquire or release semantics.
- `atomic_readandclear_int(p)`: returns the old value and sets `*p = 0`. Useful for “take the current value, reset”.
- `atomic_set_int(p, v)`: sets bits `*p |= v`. Useful for flag-set coordination.
- `atomic_clear_int(p)`: clears bits `*p &= ~v`. Useful for flag-clear coordination.
- `atomic_swap_int(p, v)`: returns old `*p`, sets `*p = v`. Useful for taking ownership of a pointer.

Width variants. `atomic_load_int`, `atomic_load_long`, `atomic_load_32`, `atomic_load_64`, `atomic_load_ptr`. The integer size in the name matches the C type. Use the one that matches your variable’s type.

Barrier variants. `atomic_thread_fence_acq`, `atomic_thread_fence_rel`, `atomic_thread_fence_acq_rel`, `atomic_thread_fence_seq_cst`. Pure barriers that order preceding and following memory accesses without atomically modifying a specific location. Occasionally useful.

Picking the right variant is a small discipline. For a flag that readers poll, use `atomic_load_acq`. For a writer that commits a flag after preceding setup, use `atomic_store_rel`. For a counter that is free-running and readers never synchronise on exactly, use `atomic_fetchadd` (no barriers). For a CAS-based state machine, use `atomic_cmpset`.

15.10.2 epoch(9) In One Page

Chapter 14 introduced `epoch(9)` briefly; here is a slightly deeper sketch, within the boundary of what a driver writer usefully knows.

An epoch is a short-lived synchronisation barrier that protects read-mostly data structures without locks. Code that reads shared data enters the epoch with `epoch_enter(epoch)` and leaves with `epoch_exit(epoch)`. The epoch guarantees that any object freed via `epoch_call(epoch, cb, ctx)` is not actually reclaimed until every reader that was inside the epoch when the free was requested has exited.

This is similar in spirit to Linux’s RCU (read-copy-update) but with different ergonomics. The FreeBSD epoch is a coarser tool; it protects large, rarely-changing structures like the `ifnet` list.

A driver that wants to use epoch typically does not create its own. It uses one of the kernel-provided epochs, most commonly `net_epoch_preempt` for network state. Driver writers outside of network code rarely reach for epoch directly.

What a driver writer should know is how to recognise the pattern in other code, and when a taskqueue’s `NET_TASK_INIT` is creating a task that runs inside an epoch. Section 14 covered this.

15.10.3 Memory Ordering, A Little Deeper

The atomic API hides the architecture-specific details of memory ordering. When you use `atomic_store_rel_int` and `atomic_load_acq_int` in matching pairs, the right barrier is inserted on each architecture. You do not need to know the details.

But a one-page intuition helps.

On x86, every load is an acquire-load and every store is a release-store, at the hardware level. The CPU's memory model is "total store order". So `atomic_load_acq_int` on x86 is just a plain `MOV` with no extra instructions. `atomic_store_rel_int` is a plain `MOV` too.

On arm64, loads and stores have weaker default ordering. The compiler inserts `LDAR` (load-acquire) for `atomic_load_acq_int` and `STLR` (store-release) for `atomic_store_rel_int`. These are cheap (a few cycles) but not free.

The implication: correctness-wise, you write the same code on both architectures. Performance-wise, x86 "pays" nothing for the barriers while arm64 pays a small cost. For a rare operation like a shutdown flag, the cost is negligible on both.

The further implication: testing on x86 alone is insufficient for validating memory ordering. Code that works on x86 with plain loads might deadlock or misbehave on arm64 if the atomic barriers were omitted. FreeBSD 14.3 supports arm64 well; drivers shipped to users who run on arm64 hardware need to be correct on the weaker memory model. Using the `atomic(9)` API consistently is how you guarantee this without thinking about architecture per-call.

15.10.4 When to Reach for Each Tool

A small decision tree to close the section.

- **Protect a small invariant read by many, written rarely?** `atomic_load_acq_int/atomic_store_rel_int`.
- **Protect a small invariant with an intricate relation to other state?** `Mutex`.
- **Wait for a predicate?** `Mutex` plus condition variable.
- **Wait for a predicate with signal handling?** `Mutex` plus `cv_wait_sig` or `cv_timedwait_sig`.
- **Admit at most N participants?** `sema(9)`.
- **Many readers or one writer with occasional promotion?** `sx(9)` with `sx_try_upgrade`.
- **Run code later in thread context?** `taskqueue(9)`.
- **Run code at a deadline?** `callout(9)`.
- **Coordinate shutdown across contexts?** Atomic flag + `cv` broadcast (for blocked waiters).
- **Protect a read-mostly structure in network code?** `epoch(9)`.

That decision tree is the mental map Part 3 has been building. Chapter 15 added the last few branches. Chapter 16 will apply the map to hardware.

15.10.5 Wrapping Up Additional Topics

Atomic operations, `epoch(9)`, and memory ordering round out the synchronisation toolkit. For most drivers the common case is a `mutex` plus a `cv` plus occasional atomics; the other primitives are there for specific shapes. Knowing the whole set lets you pick the right tool without the guesswork.

15.11 Hands-On Labs

Four labs apply the Chapter 15 material to concrete tasks. Allocate one session per lab. Labs 1 and 2 are the most important; Labs 3 and 4 stretch the reader.

15.11.1 Lab 1: Observe Writer-Cap Enforcement

Objective. Confirm that the writer-cap semaphore limits concurrent writers and that the limit is configurable at runtime.

Setup. Build and load the Stage 4 driver. Compile the `writer_cap_test` helper from the companion source.

Steps.

1. Verify the default limit: `sysctl dev.myfirst.0.writers_limit`. Should be 4.
2. Check the semaphore value: `sysctl dev.myfirst.0.stats.writers_sema_value`. Should also be 4 (no writers active).
3. Start sixteen blocking writers in the background:

```
# for i in $(jot 16 1); do
    (cat /dev/urandom | head -c 10000 > /dev/myfirst) &
done
```

4. Observe the semaphore value while they run. Should be near zero most of the time (all slots in use).
5. Lower the limit to 2:

```
# sysctl dev.myfirst.0.writers_limit=2
```

6. Observe that the semaphore value eventually drops to 0 and stays there (writers drain faster than they re-enter).
7. Raise the limit to 8:

```
# sysctl dev.myfirst.0.writers_limit=8
```

8. The driver posts four additional slots immediately; writers that were blocked in `sema_wait` wake up and enter.
9. Wait for all writers to finish; verify the final semaphore value equals the current limit.

Expected outcome. The semaphore acts as the admission controller; reconfiguring it at runtime reconfigures the limit. Under heavy load the sema drains to zero; when load eases, it refills to the configured limit.

Variation. Try with non-blocking writers using a helper that opens with `O_NONBLOCK`. Watch `sysctl dev.myfirst.0.stats.writers_trywait_failures` grow when the sema is exhausted.

15.11.2 Lab 2: Stats Cache Contention

Objective. Observe that the stats cache serves many reads with few refreshes under a read-mostly workload.

Setup. Stage 4 driver loaded. DTrace available.

Steps.

1. Start 32 concurrent reader processes, each reading the cached stat in a tight loop:

```
# for i in $(jot 32 1); do
    (while ;; do
        sysctl -n dev.myfirst.0.stats.bytes_written_10s >/dev/null
    done) &
done
```

2. In a separate terminal, observe the cache refresh rate via DTrace:

```
# dtrace -n 'fbt::myfirst_stats_cache_refresh:entry { @ = count(); }'
```

3. Let the workload run for 30 seconds, then Ctrl-C DTrace. Record the count.

Expected outcome. Approximately 30 refreshes over 30 seconds: one per second, regardless of how many readers are reading. If you see substantially more refreshes, the cache is being invalidated too aggressively; if substantially fewer, the readers are not actually triggering the stale path.

Variation. Run the test with a write workload in parallel (also using `/dev/myfirst`). The refresh rate should not change: the refresh is triggered by cache staleness, not by writes.

15.11.3 Lab 3: Signal Handling and Partial Progress

Objective. Confirm that a `read(2)` interrupted by a signal returns the bytes copied so far, not `EINTR`.

Setup. Stage 4 driver loaded. Stopped tick source, empty buffer.

Steps.

1. Start a reader that asks for 4096 bytes with no timeout:

```
# dd if=/dev/myfirst bs=4096 count=1 > /tmp/out 2>&1 &
# READER=$!
```

2. Enable the tick source at a slow rate:

```
# sysctl dev.myfirst.0.tick_source_interval_ms=500
```

The reader slowly accumulates bytes, one every 500 ms.

3. After about 2 seconds, send `SIGINT` to the reader:

```
# kill -INT $READER
```

4. `dd` reports the number of bytes copied before the signal.

Expected outcome. `dd` reports a partial result (say, 4 bytes copied out of 4096 requested) and exits 0 (partial success), not an error. The driver returned the partial byte count to the syscall layer; the syscall layer surfaced it as a normal short read.

Variation. Set `read_timeout_ms` to 1000 and repeat. The driver should return either a partial result (if any bytes arrived) or `EAGAIN` (if the timeout fired first with zero bytes). Signal handling should still preserve partial bytes.

15.11.4 Lab 4: Detach Under Maximum Load

Objective. Confirm that the detach ordering is correct under full concurrent load.

Setup. Stage 4 driver loaded. All the Chapter 14 and 15 stress tools compiled.

Steps.

1. Start the full stress kit:
 - 8 concurrent writers.
 - 4 concurrent readers.
 - Tick source at 1 ms.
 - Heartbeat at 100 ms.
 - Watchdog at 1 s.
 - Sysctl flood every 100 ms: `bulk_writer_flood=1000`.
 - Sysctl flood every 500 ms: adjust `writers_limit` between 1 and 8.
 - Concurrent sysctl reads of `stats.bytes_written_10s`.
2. Let the stress run for 30 seconds to ensure maximum load.
3. Unload the driver:

```
# kldunload myfirst
```

4. Kill the stress processes. Observe that the unload completed cleanly.

Expected outcome. The unload succeeds (not `EBUSY`, not a panic, no hang). All stress processes fail gracefully (open returning `ENXIO`, outstanding reads/writes returning `ENXIO` or short results). `dmesg` has no `WITNESS` warnings.

Variation. Repeat the cycle 20 times (load, stress, unload). Every cycle should behave identically. If one cycle panics or hangs, there is a race; investigate.

15.12 Challenge Exercises

The challenges go beyond the chapter's body. They are optional; each consolidates a specific Chapter 15 idea.

15.12.1 Challenge 1: Replace sema with Interruptible Wait

The writer-cap uses `sema_wait`, which is not signal-interruptible. Rewrite the write path's admission control to use `sema_trywait` plus an interruptible `cv_wait_sig` loop. Preserve the partial-progress convention.

Expected outcome: a writer blocked waiting for a slot can be `SIGINT`'d cleanly. Bonus: use the encapsulation in `myfirst_sync.h` so `myfirst_sync_writer_enter` has the same signature but different internals.

15.12.2 Challenge 2: Read-Mostly with a Background Refresher

The stats cache refreshes on-demand when a reader notices staleness. Change the design so the cache is refreshed by a periodic callout instead, and readers never trigger a refresh. Compare the resulting code to the upgrade-promote-downgrade pattern.

Expected outcome: understand when on-demand caching is better than background caching. Answer: on-demand is simpler (no callout lifetime to manage) but wastes a refresh on a cache that nobody reads. Background is more predictable but requires the extra primitive. Most drivers pick on-demand for small caches and background for large ones.

15.12.3 Challenge 3: Multiple Writer-Cap Semaphores

Imagine the driver is layered over a storage backend that has separate pools for different classes of IO: “small writes” and “large writes”. Add a second semaphore that caps large writes separately, with its own limit. Writers entering the write path choose which semaphore to acquire based on their `uio_resid`.

Expected outcome: practical experience with multiple semaphores. Think through: if a writer acquires the “large” sema, then the `uio` turns out to be small, does the write path want to release and re-acquire? Or keep the acquired slot? Document your choice.

15.12.4 Challenge 4: Atomic-Based Recovery Flag Elimination

Replace the `recovery_in_progress` state flag with an atomic compare-and-swap. The watchdog does `atomic_cmpset_int(&sc->recovery_in_progress, 0, 1)`; on success it enqueues the task. The task clears the flag with `atomic_store_rel_int`.

Expected outcome: the recovery mechanism no longer requires the mutex. Compare the two implementations in terms of correctness, complexity, and observability.

15.12.5 Challenge 5: Epoch for a Hypothetical Read Path

Study `/usr/src/sys/sys/epoch.h` and `/usr/src/sys/kern/subr_epoch.c`. Sketch (in comments, not in code) how you would convert the read path to use a private epoch that protects a “current configuration” pointer that writers occasionally update.

Expected outcome: a written proposal with the trade-offs. Since the driver’s current config is small and `sx` already handles it well, this is a thought exercise rather than a practical refactor. The point is to understand when epoch would be a win.

15.12.6 Challenge 6: Stress Test a Specific Race

Pick one race condition from Section 7. Write a script that triggers it reliably. Verify that the Stage 4 driver does not exhibit the bug. Verify that a deliberately broken version (revert the fix) does exhibit the bug.

Expected outcome: the satisfaction of seeing a race condition produced on demand, and the reassurance that the production code handles it.

15.12.7 Challenge 7: Read a Real Driver's Synchronization Vocabulary

Open `/usr/src/sys/dev/bge/if_bge.c` (or a similar mid-size driver with many primitives). Walk through its attach and detach paths. Count:

- Mutexes.
- Condition variables.
- Sx locks.
- Semaphores (if any; many drivers have none).
- Callouts.
- Tasks.
- Atomic operations.

Write a one-page summary of the driver's synchronisation strategy. Compare to `myfirst`. What does the real driver do differently, and why?

Expected outcome: reading a real driver's synchronisation strategy is the fastest way to make your own feel familiar. After one such read, opening any other driver in `/usr/src/sys/dev/` becomes easier.

15.13 Troubleshooting Reference

A flat reference list for common Chapter 15 problems.

15.13.1 Semaphore Deadlock or Leak

- **Writers pile up and never proceed.** The semaphore's counter is zero and no one posts. Check: is every `sema_wait` matched by a `sema_post`? Is there an early-return path that forgets the post?
- **`sema_destroy` panics with "waiters" assertion.** The destroy happened while a thread was still inside `sema_wait`. Fix: ensure the detach path quiesces all potential waiters before destroying. Usually this means clearing `is_attached` and doing a cv broadcast first.
- **`sema_trywait` returns unexpected values.** Remember: 1 on success, 0 on failure. Inverse of most FreeBSD APIs. Recheck the call-site logic.

15.13.2 Sx Lock Issues

- **`sx_try_upgrade` fails always.** The calling thread probably shares the sx with another reader. Check: is there a path that holds `sx_slock` persistently in a different thread?
- **Deadlock between sx and another lock.** Lock order violation. Run under `WITNESS`; the kernel will name the violation.
- **`sx_downgrade` with no `sx_try_upgrade` pair.** Make sure the sx is actually held exclusively before downgrading. `sx_xlocked(&sx)` asserts this.

15.13.3 Signal-Handling Issues

- **`read(2)` does not respond to SIGINT.** The blocking wait is `cv_wait` (not `cv_wait_sig`), or `sema_wait`. Convert to the signal-interruptible variant.

- **read(2) returns EINTR with partial bytes lost.** The partial-progress check is missing. Add the `uio_resid != nbefore` check on the signal-error path.
- **read(2) loops after EINTR.** The loop continues on signal-error instead of returning. Add the EINTR/ERESTART handling.

15.13.4 Atomic and Memory Ordering

- **Shutdown flag check misses.** A context reads `sc->is_attached` with a plain load and sees a stale value. Convert to `atomic_load_acq_int`.
- **Write order not observed on arm64.** Writes were reordered across architectures. Use `atomic_store_rel_int` for the last write in the pre-detach sequence.

15.13.5 Coordination Bugs

- **Recovery task runs multiple times.** The state flag is not protected or the atomic CAS is misused. Either use the mutex-protected flag pattern or audit the CAS logic.
- **Recovery task never runs.** The flag is never cleared, or the watchdog is not enqueueing. Check which side has the bug with a `device_printf` on each path.

15.13.6 Testing Issues

- **Stress test passes sometimes and fails others.** A race with low probability. Run many more iterations, increase concurrency, or add timing noise (`usleep` at random points) to expose it.
- **DTrace probes do not fire.** The kernel was built without FBT probes, or the function was inlined away. Check `dtrace -l | grep myfirst`.
- **WITNESS warnings flood the logs.** Do not ignore them. Every warning is a real bug. Fix one at a time and iterate.

15.13.7 Detach Issues

- **kldunload returns EBUSY.** Open file descriptors still exist. Close them and retry.
- **kldunload hangs.** A drain is waiting for a primitive that cannot complete. Usually a task or callout. Use `procstat -kk` on the `kldunload` thread to find where it is stuck.
- **Kernel panic during unload.** Use-after-free in a task or callout callback; the ordering is wrong. Review the detach sequence in `LOCKING.md` against the actual code.

15.14 Wrapping Up Part 3

Chapter 15 is the last chapter of Part 3. Part 3 had a specific mission: give the `myfirst` driver a full synchronisation story, from the first mutex in Chapter 11 to the last atomic flag in Chapter 15. The mission is complete.

A short inventory of what Part 3 delivered.

15.14.1 The Mutex (Chapter 11)

The first primitive. A sleep mutex protects the driver's shared data from concurrent access. Every path that touches the cbuf, the open count, the active-fh count, or the other mutex-protected fields acquires `sc->mtx` first. `WITNESS` enforces the rule.

15.14.2 The Condition Variable (Chapter 12)

The waiting primitive. Two cvs (`data_cv`, `room_cv`) let readers and writers sleep until the buffer state is acceptable. `cv_wait_sig` and `cv_timedwait_sig` make the waits signal-interruptible and time-bounded.

15.14.3 The Shared/Exclusive Lock (Chapter 12)

The read-mostly primitive. `sc->cfg_sx` protects the configuration structure. Shared acquisition for reads, exclusive for writes. Chapter 15 added `sc->stats_cache_sx` with the upgrade-promote-downgrade pattern.

15.14.4 The Callout (Chapter 13)

The time primitive. Three callouts (heartbeat, watchdog, tick source) give the driver internal time without requiring a dedicated thread. `callout_init_mtx` makes them lock-aware; `callout_drain` makes them tear down safely.

15.14.5 The Taskqueue (Chapter 14)

The deferred-work primitive. A private taskqueue with three tasks (selwake, bulk writer, recovery) moves work from constrained contexts to thread context. The detach sequence drains every task before freeing the queue.

15.14.6 The Semaphore (Chapter 15)

The bounded-admission primitive. `writers_sema` caps concurrent writers. The API is small and ownership-free; the driver uses `sema_trywait` for non-blocking entries and `sema_wait` for blocking.

15.14.7 Atomic Operations (Chapter 15)

The cross-context flag. `atomic_load_acq_int` and `atomic_store_rel_int` on `is_attached` make the shut-down flag visible to every context with correct memory ordering.

15.14.8 Encapsulation (Chapter 15)

The maintenance primitive. `myfirst_sync.h` wraps every synchronisation operation in a named function. A future reader understands the driver's synchronisation strategy by reading one header.

15.14.9 What the Driver Can Now Do

A short inventory of the driver's capabilities at the end of Part 3:

- Serve concurrent readers and writers on a bounded ring buffer.
- Block readers until data arrives, with optional timeout.
- Block writers until room is available, with optional timeout.
- Cap concurrent writers via a configurable semaphore.
- Expose configuration (debug level, nickname, soft byte limit) protected by an sx lock.
- Emit a periodic heartbeat log line.
- Detect stalled buffer drainage via a watchdog.
- Inject synthetic data via a tick source callout.
- Defer `se_lwakeup` out of the callout callback via a task.
- Demonstrate task coalescing via a configurable bulk writer.
- Schedule a delayed reset via a timeout task.
- Expose a cached statistic via an upgrade-aware sx pattern.
- Coordinate detach across every primitive without races.
- Answer signals correctly during blocking operations.
- Respect partial-progress semantics on read and write.

That is a substantial driver. The `myfirst` module at `0.9-coordination` is a compact but complete example of the synchronisation patterns that every real FreeBSD driver uses. The patterns transfer.

15.14.10 What Part 3 Did Not Cover

A short list of topics Part 3 deliberately left for later parts:

- Hardware interrupts (Part 4).
- Memory-mapped register access (Part 4).
- DMA and bus space operations (Part 4).
- PCI device matching (Part 4).
- USB and network-specific subsystems (Part 6).
- Advanced performance tuning (specialised chapters later).

Part 3 focused on the internal synchronisation story. Part 4 will add the hardware-facing story. The synchronisation story does not go away; it becomes the foundation on which the hardware story rests.

15.14.11 A Reflection

You started Chapter 11 with a driver that supported one user at a time. You end Chapter 15 with a driver that supports many users, coordinates several kinds of work, and tears down cleanly under load. Along the way you learned the kernel's main synchronisation primitives, each introduced with a specific invariant in mind, each composed with what came before.

The learning pattern was deliberate. Each chapter introduced one new concept, applied it to the driver in a small refactor, documented it in `LOCKING.md`, and added regression tests. The result is a driver whose synchronisation

is not an accident. Every primitive is there for a reason; every primitive is documented; every primitive is tested.

That discipline is the most durable thing Part 3 teaches. The specific primitives (mutex, cv, sx, callout, taskqueue, sema, atomic) are the currency, but the discipline of “pick the right primitive, document it, test it” is the investment. Drivers built with that discipline survive growth, maintenance handoffs, and surprising load patterns. Drivers built without it accumulate subtle bugs and hard-to-explain crashes.

Part 4 opens the door to hardware. The primitives you now know stay with you. The discipline you have practised is what will let you add the hardware-facing story without getting lost.

Take a moment. This is a real accomplishment. Then move to Chapter 16.

15.15 Part 3 Checkpoint

Five chapters of synchronization is a lot of material. Before Part 4 opens the door to hardware, it is worth confirming that the primitives and the discipline have settled.

By the end of Part 3 you should be able to do each of the following confidently:

- Choose among `mutex(9)`, `sx(9)`, `rw(9)`, `cv(9)`, `callout(9)`, `taskqueue(9)`, `sema(9)`, and the `atomic(9)` family with a clear sense of which invariant each one is appropriate for, rather than by habit or guesswork.
- Document a driver’s locking in a `LOCKING.md` that names every primitive, the invariant it enforces, the data it protects, and the rules callers must follow.
- Implement a sleep-and-wake handshake using either `mtx_sleep/wakeup` or `cv_wait/cv_signal`, and explain why you chose one over the other.
- Schedule timed work with `callout(9)`, including cancellation under detach, without leaving dangling timers behind.
- Defer heavy or ordered work through `taskqueue(9)`, including the detach-time drain that prevents tasks from running against freed state.
- Keep a `myfirst` running cleanly under `INVARIANTS` and `WITNESS` kernels while multi-threaded stress tests hammer every entry point.

If any of those are still vague, revisit the labs that introduced them:

- Locking discipline and regression: Lab 11.2 (Verify the Locking Discipline with `INVARIANTS`), Lab 11.4 (Build a Multi-threaded Tester), and Lab 11.7 (Long-Running Stress).
- Condition variables and `sx`: Lab 12.2 (Add Bounded Reads), Lab 12.5 (Detect a Deliberate Lock Order Reversal), and Lab 12.7 (Verify the Snapshot-and-Apply Pattern Holds Under Contention).
- Callouts and timed work: Lab 13.1 (Add a Heartbeat Callout) and Lab 13.4 (Verify Detach With Active Callouts).
- Taskqueues and deferred work: Lab 2 (Measuring Coalescing Under Load) and Lab 3 (Verify the Detach Ordering) in Chapter 14.
- Semaphores: Lab 1 (Observe Writer-Cap Enforcement) and Lab 4 (Detach Under Maximum Load) in Chapter 15.

Part 4 will layer hardware onto everything Part 3 just built. Specifically, the chapters that follow will expect:

- The synchronization model internalized rather than memorized, so that an interrupt context can be added as one more kind of caller rather than as a new universe of rules.
- Detach ordering treated as a single, shared discipline across primitives, since Part 4 will add interrupt teardown and bus-resource release into the same chain.
- Continued comfort with INVARIANTS and WITNESS as the default development kernel, since Part 4's harder bugs will usually trip one of the two long before they surface as a visible panic.

If those hold, Part 4 is within reach. If one still feels shaky, the fix is a lap through the relevant lab rather than a push forward.

15.16 Bridge to Chapter 16

Chapter 16 opens Part 4 of the book. Part 4 is titled *Hardware and Platform-Level Integration*, and Chapter 16 is *Hardware Basics and Newbus*. Part 4's mission is to give the driver a hardware story: how a driver announces itself to the kernel's bus layer, how it is matched against hardware the kernel has discovered, how it receives interrupts, how it accesses memory-mapped registers, and how it manages DMA.

The synchronisation story from Part 3 does not go away. It becomes the foundation on which Part 4 builds. A hardware interrupt handler runs in a context you now know how to reason about (no sleeping, no sleepable locks, no uimove). It communicates with the rest of the driver through primitives you now know how to use (taskqueues for deferred work, mutexes for serialisation, atomic flags for shutdown). The difference is that the driver now also has to talk to the hardware directly, and the hardware has its own rules.

Chapter 16 prepares the hardware ground in three specific ways.

First, **you already know about context boundaries**. Part 3 taught you that callouts, tasks, and user threads each have their own rules. Interrupts add one more context with stricter rules. The mental model ("which context am I in; what can I safely do here") transfers directly.

Second, **you already know about detach ordering**. Part 3 built up a detach discipline across five primitives. Part 4 adds two more (interrupt teardown, resource release) that slot into the same discipline. The ordering rules grow; the shape does not.

Third, **you already know about LOCKING.md as a living document**. Chapter 16 adds a Hardware Resources section. The discipline is the same; the vocabulary extends.

Specific topics Chapter 16 will cover:

- The newbus(9) framework: how drivers are identified, probed, and attached.
- `device_t`, `devclass`, `driver_t`, and `device_method_t`.
- `bus_alloc_resource` and `bus_release_resource` for memory-mapped regions, IRQ lines, and other resources.
- `bus_setup_intr` and `bus_teardown_intr` for interrupt registration.
- Filter handlers versus interrupt threads.
- The relationship between newbus and the PCI subsystem (preparing for Chapter 17).

You do not need to read ahead. Chapter 15 is sufficient preparation. Bring your `myfirst` driver at 0.9-coordination, your `LOCKING.md`, your WITNESS-enabled kernel, and your test kit. Chapter 16 starts where Chapter 15 ended.

A small closing reflection. The driver you started Part 3 with knew how to serve one syscall. The driver you have now has a full internal synchronisation story, with six kinds of primitives, each selected for a specific shape of invariant, each encapsulated in a readable wrapper layer, each documented, each tested. It is ready to face the hardware.

The hardware is the next chapter. Then the one after that. Then every chapter of Part 4. The foundation is built. The tools are on the bench. The blueprint is ready.

Turn the page.

15.17 Reference: Pre-Production Synchronisation Audit

Before shipping a synchronisation-heavy driver, run through this audit. Each item is a question; each should be answerable with confidence.

15.17.1 Mutex Audit

- ☐ Does every `sc->mtx` hold region end in an `mtx_unlock` on every path?
- ☐ Is the mutex always released before calling `uiomove`, `copyin`, `copyout`, `selwakeup`, or any other sleepable operation?
- ☐ Are there any places the mutex is held across a `cv wait`? If so, is the wait the intended primitive?
- ☐ Is the lock order `sc->mtx -> sc->cfg_sx -> sc->stats_cache_sx` respected everywhere?

15.17.2 Condition Variable Audit

- ☐ Does every `cv wait` call `cv_wait_sig` or `cv_timedwait_sig` in a syscall context?
- ☐ Is `EINTR` handled with partial-progress preservation where appropriate?
- ☐ Is `ERESTART` propagated correctly?
- ☐ Does every `cv` have a matching broadcast on detach?
- ☐ Are wakeups done with the mutex held for correctness (or the mutex released for throughput, with the trade-off documented)?

15.17.3 Sx Audit

- ☐ Does every `sx_slock` have a matching `sx_sunlock`?
- ☐ Does every `sx_xlock` have a matching `sx_xunlock`?
- ☐ Does every `sx_try_upgrade` failure path correctly handle the re-check after dropping and re-acquiring?
- ☐ Does every `sx_downgrade` happen on a lock that is actually held exclusively?

15.17.4 Semaphore Audit

- ☐ Does every `sema_wait` have a matching `sema_post` on every path?
- ☐ Is the semaphore destroyed only after all waiters have been quiesced?
- ☐ Is `sema_trywait`'s return value (1 on success, 0 on failure) read correctly?

- ☐ If the semaphore is used with interruptible syscalls, is the non-interruptibility of `sema_wait` documented?
- ☐ Is there an in-flight counter (e.g., `writers_inflight`) that detach drains before calling `sema_destroy`?
- ☐ Does every path between counter increment and counter decrement actually use the sema (no early returns that bypass the increment)?

15.17.5 Callout Audit

- ☐ Does every callout use `callout_init_mtx` with the appropriate lock?
- ☐ Does every callout callback check `is_attached` and exit early if false?
- ☐ Is every callout drained at detach before the state it touches is freed?

15.17.6 Task Audit

- ☐ Does every task callback hold the appropriate locks when touching shared state?
- ☐ Does every task callback call `se_lwakeup` only with no driver lock held?
- ☐ Is every task drained at detach after the callouts that enqueue it have been drained?
- ☐ Is the private taskqueue freed after every task is drained?

15.17.7 Atomic Audit

- ☐ Does every shutdown flag read use `atomic_load_acq_int`?
- ☐ Does every shutdown flag write use `atomic_store_rel_int`?
- ☐ Are any other atomic operations justified by a specific memory-ordering requirement?

15.17.8 Cross-Component Audit

- ☐ Does every cross-component state flag have a clear ownership (which path sets, which path clears)?
- ☐ Are the flags protected by the appropriate lock or atomic discipline?
- ☐ Is the handshake documented in `LOCKING.md`?

15.17.9 Documentation Audit

- ☐ Does `LOCKING.md` list every primitive?
- ☐ Does `LOCKING.md` document the detach ordering?
- ☐ Does `LOCKING.md` document the lock order?
- ☐ Are any subtle cross-component handshakes explained?

15.17.10 Testing Audit

- ☐ Has the driver been run under `WITNESS` for an extended stress test with no warnings?
- ☐ Have detach cycles been tested under full load?
- ☐ Have signal-interrupt tests confirmed partial-progress preservation?
- ☐ Have configuration changes at runtime (`sysctl` tuning) been tested?

A driver that passes this audit is a driver you can ship.

15.18 Reference: Synchronisation Primitive Cheat Sheet

15.18.1 When to Use Which

Primitive	Best for	Not good for
<code>struct mtx (MTX_DEF)</code>	Short critical sections; mutual exclusion.	Waiting for a condition.
<code>struct cv + mtx</code>	Waiting for a predicate; signalled wakeups.	Bounded admission.
<code>struct sx</code>	Read-mostly state; shared reads with occasional writes.	Hot contention.
<code>struct sema</code>	Bounded admission; producer-consumer completion.	Interruptible waits.
<code>callout</code>	Time-based work.	Work that must sleep.
<code>taskqueue</code>	Deferred thread-context work.	Sub-microsecond latency.
<code>atomic_*</code>	Small cross-context flags; lock-free coordination.	Complex invariants.
<code>epoch</code>	Read-mostly shared structures in network code.	Drivers without shared structures.

15.18.2 API Quick Reference

Mutex. - `mtx_init(&mtx, name, type, MTX_DEF)` - `mtx_lock(&mtx)`, `mtx_unlock(&mtx)` - `mtx_assert(&mtx, MA_OWNED)` - `mtx_destroy(&mtx)`

Condition variable. - `cv_init(&cv, name)` - `cv_wait(&cv, &mtx)`, `cv_wait_sig` - `cv_timedwait(&cv, &mtx, timo)`, `cv_timedwait_sig` - `cv_signal(&cv)`, `cv_broadcast(&cv)` - `cv_destroy(&cv)`

Sx. - `sx_init(&sx, name)` - `sx_slock(&sx)`, `sx_sunlock(&sx)` - `sx_xlock(&sx)`, `sx_xunlock(&sx)` - `sx_try_upgrade(&sx)`, `sx_downgrade(&sx)` - `sx_xlocked(&sx)`, `sx_xholder(&sx)` - `sx_destroy(&sx)`

Semaphore. - `sema_init(&s, value, name)` - `sema_wait(&s)`, `sema_timedwait(&s, timo)`, `sema_trywait(&s)` - `sema_post(&s)` - `sema_value(&s)` - `sema_destroy(&s)`

Callout. - `callout_init_mtx(&co, &mtx, 0)` - `callout_reset(&co, ticks, fn, arg)` - `callout_stop(&co)`, `callout_drain(&co)`

Taskqueue. - `TASK_INIT(&t, 0, fn, ctx)`, `TIMEOUT_TASK_INIT(...)` - `taskqueue_create(name, flags, enqueue, ctx)` - `taskqueue_start_threads(&tq, count, pri, name, ...)` - `taskqueue_enqueue(tq, &t)`, `taskqueue_enqueue_timeout(...)` - `taskqueue_cancel(tq, &t, &pend)`, `taskqueue_drain(tq, &t)` - `taskqueue_free(tq)`

Atomic. - `atomic_load_acq_int(p)`, `atomic_store_rel_int(p, v)` - `atomic_fetchadd_int(p, v)`, `atomic_cmpset_int(p, old, new)` - `atomic_set_int(p, v)`, `atomic_clear_int(p, v)` - `atomic_thread_fence_seq_cst()`

15.18.3 Context Rules

Context	Can sleep?	Sleepable locks?	Notes
Syscall	Yes	Yes	Full thread context.
Callout callback (lock-aware)	No	No	Registered mutex held.
Task callback (thread-backed)	Yes	Yes	No driver lock held.
Task callback (fast/swi)	No	No	SWI context.
Interrupt filter	No	No	Very limited.
Interrupt thread	No	No	Slightly more than filter.
Epoch section	No	No	Very limited.

15.18.4 Partial Progress Convention

A `read(2)` or `write(2)` that copies `N` bytes before being interrupted should return `N` (as a successful partial short read/write), not `EINTR`. The driver's wait helper returns a sentinel (`MYFIRST_WAIT_PARTIAL`) on the partial path; the caller converts it to 0 so the syscall layer returns the byte count.

15.18.5 Detach Ordering

The canonical order for Chapter 15 detach:

1. Refuse if `active_fhs > 0`.
2. Clear `is_attached` atomically.
3. Broadcast all cvs; release mutex.
4. Drain all callouts.
5. Drain all tasks (including timeout tasks and recovery).
6. `seldrain` for `rsl`, `wsl`.
7. Free taskqueue.
8. Destroy semaphore.
9. Destroy stats-cache `sx`.
10. Destroy `cdev`, `sysctls`, `cbuf`, counters.
11. Destroy `cvs`, `cfg sx`, mutex.

Memorise the shape. Adapt the order when you add new primitives.

15.19 Reference: Further Reading

15.19.1 Manual Pages

- `sema(9)`: kernel semaphores.
- `sx(9)`: shared/exclusive locks.

- `mutex(9)`: mutex primitives.
- `condvar(9)`: condition variables.
- `atomic(9)`: atomic operations.
- `epoch(9)`: epoch-based synchronisation.
- `locking(9)`: overview of kernel locking primitives.

15.19.2 Source Files

- `/usr/src/sys/kern/kern_sema.c`: semaphore implementation.
- `/usr/src/sys/sys/sema.h`: semaphore API.
- `/usr/src/sys/kern/kern_sx.c`: sx implementation.
- `/usr/src/sys/sys/sx.h`: sx API.
- `/usr/src/sys/kern/kern_mutex.c`: mutex implementation.
- `/usr/src/sys/kern/kern_condvar.c`: cv implementation.
- `/usr/src/sys/kern/subr_epoch.c`: epoch implementation.
- `/usr/src/sys/sys/epoch.h`: epoch API.
- `/usr/src/sys/dev/hyperv/storvsc/hv_storvsc_drv_freebsd.c`: real-world sema usage.
- `/usr/src/sys/dev/bge/if_bge.c`: rich synchronisation example.

15.19.3 Books and External Material

- *The Design and Implementation of the FreeBSD Operating System* (McKusick et al.): has detailed chapters on the kernel synchronisation subsystems.
- *FreeBSD Handbook*, developer section: sections on kernel locking.
- FreeBSD mailing list archives: searches for primitive names (`taskqueue`, `sema`, `sx`) reveal historical design discussions.

15.19.4 Suggested Reading Order

For a reader new to advanced synchronisation:

1. `mutex(9)`, `condvar(9)`: the basic primitives.
2. `sx(9)`: the read-mostly primitive.
3. `sema(9)`: the bounded-admission primitive.
4. `atomic(9)`: the cross-context tool.
5. `epoch(9)`: the network-drivers' read-lock-free tool.
6. A real driver source: `/usr/src/sys/dev/bge/if_bge.c` or similar.

Reading in order takes a full afternoon and gives you a solid mental map.

15.20 Reference: A Glossary of Chapter 15 Terms

Counting semaphore. A primitive that holds a non-negative integer and supports wait (decrement, blocking if zero) and post (increment, waking one waiter).

Binary semaphore. A counting semaphore that only holds 0 or 1. Behaviourally similar to a mutex but without ownership.

Priority inheritance. A scheduler technique where a high-priority thread waiting on a lock temporarily raises the priority of the current holder. FreeBSD mutexes support it; semaphores do not.

Signal-interruptible wait. A blocking primitive (e.g. `cv_wait_sig`) that returns with `EINTR` or `ERESTART` when a signal arrives. The caller can then abandon the wait and surface the signal.

Partial progress convention. UNIX-standard behaviour: a `read(2)` or `write(2)` that transferred some bytes and was then interrupted returns the byte count as success, not an error.

EINTR vs ERESTART. Two signal return codes. `EINTR` surfaces to user space as `errno EINTR`. `ERESTART` causes the syscall layer to restart the syscall transparently, based on signal disposition.

Acquire barrier. A memory barrier on a load that prevents subsequent memory accesses from being reordered before the load.

Release barrier. A memory barrier on a store that prevents preceding memory accesses from being reordered after the store.

Compare-and-swap (CAS). An atomic operation that writes a new value only if the current value matches an expected one. Basis for lock-free state machines.

Upgrade-promote-downgrade. An sx pattern: acquire shared, detect need to write, try to upgrade to exclusive, write, downgrade back to shared.

Coalescing. Taskqueue property: redundant enqueues of the same task fold into a single pending state with an incremented counter, rather than being linked separately.

Encapsulation layer. A header (`myfirst_sync.h`) that names every synchronisation operation the driver performs, so the strategy can be changed in one place and understood at a glance.

State flag. A small integer in the `softc` that records whether a specific condition is in progress. Protected by the appropriate lock or atomic discipline.

Cross-component handshake. A coordination between multiple execution contexts (callout, task, user thread) using a state flag, `cv`, or atomic.

Chapter 15 ends here. Part 4 begins next.

15.21 Reference: Reading `kern_sema.c` Line by Line

The implementation of `sema(9)` is short enough to read end-to-end. Doing so once cements the mental model of what the primitive actually does. The file is `/usr/src/sys/kern/kern_sema.c`, under two hundred lines. A narrated pass follows.

15.21.1 `sema_init`

```
void
sema_init(struct sema *sema, int value, const char *description)
{
    KASSERT((value >= 0), ("%s(): negative value\n", __func__));

    bzero(sema, sizeof(*sema));
    mtx_init(&sema->sema_mtx, description, "sema backing lock",
        MTX_DEF | MTX_NOWITNESS | MTX_QUIET);
    cv_init(&sema->sema_cv, description);
    sema->sema_value = value;

    CTR4(KTR_LOCK, "%s(%p, %d, \"%s\")", __func__, sema, value, description);
}
```

Six lines of logic. Assert the initial value is non-negative. Zero the structure. Initialise the internal mutex; note the flags `MTX_NOWITNESS | MTX_QUIET`, which tell `WITNESS` not to track the internal mutex (because the semaphore itself is what the user cares about, not its backing mutex). Initialise the internal cv. Set the counter.

The implication: a semaphore is literally a mutex plus a cv plus a counter, assembled into a small package. Understanding this assembly is understanding the primitive.

15.21.2 sema_destroy

```
void
sema_destroy(struct sema *sema)
{
    CTR3(KTR_LOCK, "%s(%p) \"%s\"", __func__, sema,
        cv_wmesg(&sema->sema_cv));

    KASSERT((sema->sema_waiters == 0), ("%s(): waiters\n", __func__));

    mtx_destroy(&sema->sema_mtx);
    cv_destroy(&sema->sema_cv);
}
```

Two lines of logic after the tracing. Assert no waiters exist. Destroy the internal mutex and cv. The assertion is what forces you to quiesce waiters before destroying; violating it panics a debug kernel.

15.21.3 _sema_post

```
void
_sema_post(struct sema *sema, const char *file, int line)
{

    mtx_lock(&sema->sema_mtx);
    sema->sema_value++;
    if (sema->sema_waiters && sema->sema_value > 0)
        cv_signal(&sema->sema_cv);

    CTR6(KTR_LOCK, "%s(%p) \"%s\" v = %d at %s:%d", __func__, sema,
        cv_wmesg(&sema->sema_cv), sema->sema_value, file, line);

    mtx_unlock(&sema->sema_mtx);
}
```

Three lines of logic. Lock, increment, signal one waiter if any. The signal is conditional on two things: the waiters count is non-zero (no need to signal if nobody is waiting), and the value is positive (signals with a zero value would wake a waiter who would immediately sleep again). The second condition is subtle; it protects against a situation where `sema_value` went positive and then became zero again between a post and the current post. In practice on simple usage the conditions are both true.

15.21.4 `_sema_wait`

```
void
_sema_wait(struct sema *sema, const char *file, int line)
{

    mtx_lock(&sema->sema_mtx);
    while (sema->sema_value == 0) {
        sema->sema_waiters++;
        cv_wait(&sema->sema_cv, &sema->sema_mtx);
        sema->sema_waiters--;
    }
    sema->sema_value--;

    CTR6(KTR_LOCK, "%s(%p) \"%s\" v = %d at %s:%d", __func__, sema,
        cv_wmesg(&sema->sema_cv), sema->sema_value, file, line);

    mtx_unlock(&sema->sema_mtx);
}
```

Four lines of logic. Lock. Loop while the value is zero: increment waiters, wait on the cv, decrement waiters. Once value is positive, decrement it and unlock.

Two observations.

The loop is what makes the primitive safe against spurious wakeups. `cv_wait` can return without `cv_signal` having been called. The loop re-checks the value every time, so a spurious wakeup just re-sleeps.

The wait uses `cv_wait`, not `cv_wait_sig`. This is what makes `sema_wait` non-interruptible. A signal to the caller does nothing. The loop continues until a real `sema_post` arrives.

15.21.5 `_sema_timedwait`

```
int
_sema_timedwait(struct sema *sema, int timo, const char *file, int line)
{
    int error;

    mtx_lock(&sema->sema_mtx);

    for (error = 0; sema->sema_value == 0 && error == 0;) {
        sema->sema_waiters++;
        error = cv_timedwait(&sema->sema_cv, &sema->sema_mtx, timo);
        sema->sema_waiters--;
    }
    if (sema->sema_value > 0) {
        sema->sema_value--;
        error = 0;
        /* ... tracing ... */
    } else {
        /* ... tracing ... */
    }

    mtx_unlock(&sema->sema_mtx);
    return (error);
}
```

Slightly more complex. The loop uses `cv_timedwait`, again not `cv_timedwait_sig`, so the timed wait is also not interruptible. The loop exits when the value is positive or when the error becomes non-zero (usually `EWOLDBLOCK`).

After the loop: if the value is positive, we claim it and return 0 (success). Otherwise, we return the error (`EWOLDBLOCK`). Note the `cv` error is preserved from the last loop iteration in the error case.

A subtlety the comment in the source calls out: a spurious wakeup resets the effective timeout interval because each iteration uses a fresh `timo`. This means the actual wait may be slightly longer than the caller requested, but never shorter. The `EWOLDBLOCK` return eventually fires.

15.21.6 _sema_trywait

```
int
_sema_trywait(struct sema *sema, const char *file, int line)
{
    int ret;

    mtx_lock(&sema->sema_mtx);

    if (sema->sema_value > 0) {
        sema->sema_value--;
        ret = 1;
    } else {
        ret = 0;
    }

    mtx_unlock(&sema->sema_mtx);
    return (ret);
}
```

Two lines of logic. Lock. If value is positive, decrement and return 1. Otherwise return 0. No blocking, no cv, no waiter accounting.

15.21.7 sema_value

```
int
sema_value(struct sema *sema)
{
    int ret;

    mtx_lock(&sema->sema_mtx);
    ret = sema->sema_value;
    mtx_unlock(&sema->sema_mtx);
    return (ret);
}
```

One line of logic. Returns the current value. The value can change immediately after the mutex is released, so the result is a snapshot, not a guarantee. Useful for diagnostics.

15.21.8 Observations

Reading the whole file takes ten minutes. At the end you understand:

- Semaphores are built from a mutex and a cv.
- `sema_wait` is not signal-interruptible because it uses `cv_wait`.
- `sema_destroy` asserts no waiters, which is why you must quiesce before destroying.
- Coalescing does not exist (every post decrements the counter by one, no “pending” accounting).
- The primitive is simple; its contracts are precise.

This kind of reading is the shortest path to mastery of any kernel primitive. The `sema(9)` file is a particularly good starter because it is so short.

15.22 Reference: Standardising Synchronization Primitives Across a Driver

As the driver accumulates more primitives, consistency matters more than cleverness.

15.22.1 One Naming Convention

The Chapter 15 convention, which the reader can adopt or modify:

- **Mutex:** `sc->mtx`. Only one per driver. If the driver needs more than one, each has a purpose suffix: `sc->tx_mtx`, `sc->rx_mtx`.
- **Condition variable:** `sc-><purpose>_cv`. E.g., `data_cv`, `room_cv`.
- **Sx lock:** `sc-><purpose>_sx`. E.g., `cfg_sx`, `stats_cache_sx`.
- **Semaphore:** `sc-><purpose>_sema`. E.g., `writers_sema`.
- **Callout:** `sc-><purpose>_co`. E.g., `heartbeat_co`.
- **Task:** `sc-><purpose>_task`. E.g., `selwake_task`.
- **Timeout task:** `sc-><purpose>_delayed_task`. E.g., `reset_delayed_task`.
- **Atomic flag:** `sc-><purpose>` as an int. No suffix; the type tells the story. E.g., `is_attached`, `recovery_in_progress`.
- **State flag under mutex:** same as atomic; the comment in the softc names the lock.

15.22.2 One Init/Destroy Pattern

Each primitive has a canonical init and destroy. The order in attach mirrors the reverse in detach.

Attach order: 1. Mutex. 2. Cvs. 3. Sx locks. 4. Semaphores. 5. Taskqueue. 6. Callouts. 7. Tasks. 8. Atomic flags (no init required; initialised by softc zeroing).

Detach order (roughly reverse): 1. Clear atomic flag. 2. Broadcast cvs. 3. Release mutex. 4. Drain callouts. 5. Drain tasks. 6. Free taskqueue. 7. Destroy semaphores. 8. Destroy sxs. 9. Destroy cvs. 10. Destroy mutex.

The rule of thumb: destroy in the opposite order to init, and drain anything that can still fire before destroying what it touches.

15.22.3 One Encapsulation Pattern

The `myfirst_sync.h` pattern from Section 6 scales. Every primitive has a wrapper. Every wrapper is named for what it does, not for the primitive it wraps.

15.22.4 One LOCKING.md Template

A LOCKING.md section per primitive. Each section names:

- The primitive.
- Its purpose.
- Its lifetime.
- Its contract with other primitives (lock order, ownership, interaction with the atomic flag).

A new primitive added to the driver adds a new section. A modified primitive changes its existing section. The document is always current.

15.22.5 Why Standardise

The benefits are the same as in Chapter 14. Reduced cognitive load. Fewer mistakes. Easier review. Easier handoff. The costs are small and one-time.

15.23 Reference: When Each Primitive Is Wrong

Synchronisation primitives are tools. Every tool has misuses. A short list of anti-patterns to recognise.

15.23.1 Mutex Misuses

- **Holding a mutex across a sleep.** Prevents other threads from making progress; may cause deadlock if the sleep depends on state another thread needs the mutex for.
- **Nesting mutexes in inconsistent order.** Creates a lock-order cycle; WITNESS catches it.
- **Using a mutex where an atomic would do.** For a single-bit flag checked often, a mutex is heavier than needed.
- **Missing `mtx_assert` in helpers that require the mutex.** Without the assertion, the helper can be called in a context where the mutex is not held; the bug may be silent.

15.23.2 Cv Misuses

- **Using `cv_wait` in a syscall context.** Cannot be interrupted by signals; makes the syscall unresponsive.
- **Not re-checking the predicate after wake-up.** Spurious wakeups are allowed; code that assumes a wakeup means the predicate is true is buggy.
- **Signalling without holding the mutex.** Usually allowed by the API but typically unwise; the waiter may miss the signal if the timing is unlucky.
- **Using `cv_signal` where `cv_broadcast` is needed.** A detach path that wakes only one waiter leaves others blocked.

15.23.3 Sx Misuses

- **Using `sx` where a mutex would do.** Sx has higher overhead than a mutex in the uncontended case; if there is no shared-access benefit, mutex is simpler.

- **Forgetting that `sx` can sleep.** `Sx` cannot be acquired from a non-sleeping context. Callouts initialised with `callout_init_mtx(, &mtx, 0)` are fine; filter interrupts are not. (Historical note: the older `CALLOUT_MPSAFE` flag named the same distinction. Chapter 13 walks through its deprecation.)
- **Using `sx_try_upgrade` without the fallback.** A naive upgrade that does not handle failure races against another upgrader.

15.23.4 Sema Misuses

- **Expecting signal interruption.** `sema_wait` does not interrupt.
- **Expecting priority inheritance.** `sema` does not raise the poster's priority.
- **Destroying with waiters.** Panics a debug kernel, silently corrupts a production kernel.
- **Forgetting a post on an error path.** Leaks a slot; eventually the semaphore drains to zero and all waiters block.

15.23.5 Atomic Misuses

- **Using plain atomics where acquire/release is needed.** Correct on x86, broken on arm64. Always think about memory ordering.
- **Protecting a complex invariant with a single atomic.** If the invariant involves multiple fields, atomics alone are insufficient; a lock is needed.
- **Using CAS where a simple load-store would do.** Wastes an atomic instruction.

15.23.6 Pattern Misuses

- **Rolling your own semaphore from mutex-plus-counter-plus-cv.** The kernel's `sema(9)` already does this; reinventing it creates maintenance debt.
- **Rolling your own read-write lock from mutex-plus-counter.** `sx(9)` does this; reinventing it creates maintenance debt.
- **Rolling your own encapsulation in the driver source.** Put it in a header (`myfirst_sync.h`); do not duplicate it inline.

Recognising anti-patterns is half of good synchronisation. The other half is choosing the right primitive in the first place, which the main body of the chapter has covered.

15.24 Reference: Observability Cheat Sheet

15.24.1 Sysctl Knobs Your Driver Should Expose

For Chapter 15, add these to the driver's sysctl tree (at `dev.myfirst.N.stats.*` or `dev.myfirst.N.*` as appropriate):

- `writers_limit`: current writer cap.
- `stats.writers_sema_value`: snapshot of the semaphore value.
- `stats.writers_trywait_failures`: count of non-blocking writers refused.

- stats.stats_cache_refreshes: count of cache refreshes.
- stats.recovery_task_runs: count of recovery invocations.
- stats.is_attached: current atomic flag value.

These read-only counters give an operator a window into the driver's synchronisation behaviour without a debugger.

15.24.2 DTrace Probes

Count cv signals per cv:

```
dtrace -n 'fbt::cv_signal:entry { @[stringof(args[0]->cv_description)] = count(); }'
```

Count sema waits and posts:

```
dtrace -n '
  fbt::_sema_wait:entry { @["wait"] = count(); }
  fbt::_sema_post:entry { @["post"] = count(); }
'
```

Measure sema wait latency:

```
dtrace -n '
  fbt::_sema_wait:entry { self->t = timestamp; }
  fbt::_sema_wait:return /self->t/ {
    @ = quantize(timestamp - self->t);
    self->t = 0;
  }
'
```

Useful for understanding how long writers block on the writer-cap in practice.

Measure sx contention:

```
dtrace -n '
  lockstat:::sx-block-enter /arg0 == (uintptr_t)&sc_addr/ {
    @ = count();
  }
'
```

Replace sc_addr with the actual address of your sx. Shows how often the sx blocked.

Observe taskqueue_run_locked for recovery:

```
dtrace -n 'fbt::myfirst_recovery_task:entry { printf("recovery at %Y", walltimestamp);  
↵ }'
```

Prints a timestamp every time the recovery task fires.

15.24.3 procstat

`procstat -t | grep myfirst`: shows taskqueue worker threads and their state.

`procstat -kk <pid>`: kernel stack of a specific thread. Useful when something is stuck.

15.24.4 ps

`ps ax | grep taskq`: list every taskqueue worker by name.

15.24.5 ddb

`db> show witness`: dump the WITNESS lock graph.

`db> show locks`: list currently held locks.

`db> show sleepchain <tid>`: walk a sleep chain to find deadlocks.

15.25 Reference: A Worked Stage-by-Stage Diff Summary

A compact summary of the driver diff from Chapter 14 Stage 4 to Chapter 15 Stage 4, for readers who want to see the whole change at a glance.

15.25.1 Stage 1 Diff (v0.8 -> v0.8+writers_sema)

Softc additions:

```
struct sema    writers_sema;  
int            writers_limit;  
int            writers_trywait_failures;  
int            writers_inflight;  /* atomic int; drain counter */
```

Attach additions:

```
sema_init(&sc->writers_sema, 4, "myfirst writers");  
sc->writers_limit = 4;  
sc->writers_trywait_failures = 0;  
sc->writers_inflight = 0;
```

Detach additions (after is_attached=0 and all cv broadcasts):

```
sema_destroy(&sc->writers_sema);
```

New sysctl handler: myfirst_sysctl_writers_limit.

Write-path changes: sema acquisition at entry, release at exit, O_NONBLOCK via sema_trywait.

15.25.2 Stage 2 Diff (+stats_cache_sx)

Softc additions:

```
struct sx      stats_cache_sx;
uint64_t      stats_cache_bytes_10s;
uint64_t      stats_cache_last_refresh_ticks;
```

Attach additions:

```
sx_init(&sc->stats_cache_sx, "myfirst stats cache");
sc->stats_cache_bytes_10s = 0;
sc->stats_cache_last_refresh_ticks = 0;
```

Detach additions (after mutex destroy):

```
sx_destroy(&sc->stats_cache_sx);
```

New helper: myfirst_stats_cache_refresh.

New sysctl handler: myfirst_sysctl_stats_cached.

15.25.3 Stage 3 Diff (EINTR/ERESTART + partial-progress)

No softc changes.

Wait-helper refactor: MYFIRST_WAIT_PARTIAL sentinel; explicit switch on error codes from cv waits.

Caller changes: explicit checks for the sentinel.

15.25.4 Stage 4 Diff (coordination + encapsulation)

Softc additions:

```
int      recovery_in_progress;
struct task recovery_task;
int      recovery_task_runs;
```

Attach additions:

```
TASK_INIT(&sc->recovery_task, 0, myfirst_recovery_task, sc);
sc->recovery_in_progress = 0;
sc->recovery_task_runs = 0;
```

Detach additions:

```
taskqueue_drain(sc->tq, &sc->recovery_task);
```

Atomic flag conversions: `is_attached` reads in handlers and callbacks become `atomic_load_acq_int`; the detach write becomes `atomic_store_rel_int`.

New header: `myfirst_sync.h` with inline wrappers.

Source edits: every primitive-specific call in the main source becomes a wrapper call.

Watchdog refactor: enqueue recovery task on stall, guarded by the `recovery_in_progress` flag.

Version bump: `MYFIRST_VERSION "0.9-coordination"`.

15.25.5 Total Lines Added

Rough count across the four stages:

- Softc: ~10 fields.
- Attach: ~15 lines.
- Detach: ~10 lines.
- New functions: ~80 lines (sysctl handlers, `recovery_task`, helpers).
- Modified functions: ~20 line edits.
- Header file: ~150 lines.

Net addition to the driver: approximately 300 lines. Compare to the approximately 100 lines Chapter 14 added and the 400 lines Chapter 13 added. The Chapter 15 additions are modest in volume; large in what they enable.

15.26 Reference: The Chapter 15 Driver Lifecycle

A summary of the lifecycle with the Chapter 15 additions explicit.

15.26.1 Attach Sequence

1. `mtx_init(&sc->mtx, ...)`.
2. `cv_init(&sc->data_cv, ...)`, `cv_init(&sc->room_cv, ...)`.
3. `sx_init(&sc->cfg_sx, ...)`.
4. `sx_init(&sc->stats_cache_sx, ...)`.
5. `sema_init(&sc->writers_sema, 4, ...)`.

6. `sc->tq = taskqueue_create(...); taskqueue_start_threads(...)`.
7. `callout_init_mtx(&sc->heartbeat_co, ...)`, two more.
8. `TASK_INIT(&sc->selwake_task, ...)`, three more (including `recovery_task`).
9. `TIMEOUT_TASK_INIT(sc->tq, &sc->reset_delayed_task, ...)`.
10. Softc fields initialised.
11. `sc->bytes_read = counter_u64_alloc(M_WAITOK)`; same for `bytes_written`.
12. `cbuf_init(&sc->cb, ...)`.
13. `make_dev_s(...)` for the `cdev`.
14. Sysctl tree set up.
15. `sc->is_attached = 1` (initial store is not strictly atomic-ordered because no reader can see the softc until it is attached).

15.26.2 Runtime

- User threads enter/leave via `open/close/read/write`.
- Callouts fire periodically.
- Tasks fire on enqueue.
- Watchdog detects stalls, enqueues recovery task.
- Atomic flag read via `myfirst_sync_is_attached` in entry checks.

15.26.3 Detach Sequence

1. `myfirst_detach` is called.
2. Check `active_fhs > 0`; return `EBUSY` if so.
3. `atomic_store_rel_int(&sc->is_attached, 0)`.
4. `cv_broadcast(&sc->data_cv, cv_broadcast(&sc->room_cv))`.
5. Release `sc->mtx`.
6. `callout_drain` three times.
7. `taskqueue_drain` three times (`selwake`, `bulk_writer`, `recovery`).
8. `taskqueue_drain_timeout` once (`reset_delayed`).
9. `seldrain` twice.
10. `taskqueue_free(sc->tq)`.
11. `sema_destroy(&sc->writers_sema)`.
12. `destroy_dev` twice.
13. `sysctl_ctx_free`.
14. `cbuf_destroy`, `counter_u64_free` twice.
15. `sx_destroy(&sc->stats_cache_sx)`.
16. `cv_destroy` twice.
17. `sx_destroy(&sc->cfg_sx)`.
18. `mtx_destroy(&sc->mtx)`.

15.26.4 Notes on the Sequence

- Every primitive init in `attach` has a matching `destroy` in `detach`, in reverse order.

- Every drain happens before the thing drained is freed.
- The atomic flag is the very first step after the `active_fhs` check, so every subsequent observer sees the shutdown.
- The taskqueue is freed before the semaphore is destroyed because a task might (in some extended design) wait on the semaphore.

Memorising this lifecycle is the single most useful thing a reader can do with Part 3.

15.27 Reference: Costs and Comparisons

A concise table of the synchronisation primitives' costs.

Primitive	Uncontended cost	Contended cost	Sleep?
<code>atomic_load_acq_int</code>	~1 ns on amd64	~1 ns (same)	No
<code>atomic_fetchadd_int</code>	~10 ns	~100 ns	No
<code>mtx_lock</code> (uncontended)	~20 ns	microseconds	Slow path sleeps
<code>cv_wait_sig</code>	n/a	full scheduler wakeup	Yes
<code>sx_slock</code>	~30 ns	microseconds	Slow path sleeps
<code>sx_xlock</code>	~30 ns	microseconds	Slow path sleeps
<code>sx_try_upgrade</code>	~30 ns	n/a (fails fast)	No
<code>sema_wait</code>	~40 ns	wakeup latency	Yes
<code>sema_post</code>	~30 ns	~100 ns	No
<code>callout_reset</code>	~100 ns	n/a	No
<code>taskqueue_enqueue</code>	~50 ns	wakeup latency	No

The figures above are order-of-magnitude estimates on typical FreeBSD 14.3 amd64 hardware, and the microsecond entries in the contended column correspond to low-microsecond wakeup latencies on that same class of machine. Actual numbers depend on cache state, contention, and system load, and can move by a factor of two or more across CPU generations. Use this table to decide where to optimise; a call taking hundreds of nanoseconds is not a bottleneck on a path that runs once per syscall. See Appendix F for a reproducible benchmark of these figures on your own hardware.

15.28 Reference: A Worked Synchronization Walk

For a fully concrete example, here is the complete control-flow of a blocking `read(2)` in the Chapter 15 Stage 4 driver, from syscall entry to data delivery.

1. User calls `read(fd, buf, 4096)`.
2. Kernel's VFS layer routes to `myfirst_read`.
3. `myfirst_read` calls `devfs_get_cdevpriv` to get the fh.

4. `myfirst_read` calls `myfirst_sync_is_attached(sc)`:
 - Expands to `atomic_load_acq_int(&sc->is_attached)`.
 - Returns 1 (attached).
5. Loop enters: `while (uio->uio_resid > 0)`.
6. `myfirst_sync_lock(sc)`:
 - Expands to `mtx_lock(&sc->mtx)`.
 - Acquires the mutex.
7. `myfirst_wait_data(sc, ioflag, nbefore, uio)`:
 - `while (cbuf_used == 0)`: buffer is empty.
 - Not partial (`nbefore == uio_resid`).
 - Not `IO_NDELAY`.
 - `read_timeout_ms` is 0, so uses `cv_wait_sig`.
 - `cv_wait_sig(&sc->data_cv, &sc->mtx)`:
 - Releases the mutex.
 - Thread sleeps on the cv.
 - Time passes. A writer (or the `tick_source`) calls `cv_signal(&sc->data_cv)`.
 - Thread wakes, `cv_wait_sig` re-acquires the mutex, returns 0.
 - `!sc->is_attached`: false.
 - Loop re-iterates: `cbuf_used` is now `> 0`.
 - Exits the loop; returns 0.
8. `myfirst_buf_read(sc, bounce, take)`:
 - Calls `cbuf_read(&sc->cb, bounce, take)`.
 - Copies data into the bounce buffer.
 - Increments `bytes_read` counter.
9. `myfirst_sync_unlock(sc)`.
10. `cv_signal(&sc->room_cv)`: wake a blocked writer if any.
11. `selwakeup(&sc->wsel)`: wake any poller waiting for write.
12. `uiomove(bounce, got, uio)`: copy from kernel to user space.
13. Loop continues: check `uio->uio_resid > 0`; eventually falls out.
14. Returns 0 to the syscall layer.
15. Syscall layer returns the number of bytes copied to user.

Every primitive in Chapter 15 is visible in the walk:

- The atomic flag (step 4).
- The mutex (step 6, 7, 9).
- The cv wait with signal handling (step 7's `cv_wait_sig`).
- The counter (step 8's `counter_u64_add`).
- The cv signal (step 10).
- The `selwakeup` (step 11, done outside the mutex per discipline).

A walk like this is a useful cross-check. Every primitive in the driver's vocabulary is exercised on the read path. If you can narrate the walk from memory, the synchronisation is internalised.

15.29 Reference: A Minimal Working Template

For copy-and-adapt convenience, a template that compiles and demonstrates Chapter 15's core additions in the smallest possible form. Every element has been introduced in the chapter; the template assembles them.

```
#include <sys/param.h>
#include <sys/kernel.h>
#include <sys/module.h>
#include <sys/systm.h>
#include <sys/bus.h>
#include <sys/mutex.h>
#include <sys/lock.h>
#include <sys/sx.h>
#include <sys/sem.h>
#include <sys/taskqueue.h>
#include <sys/priority.h>

struct template_softc {
    device_t      dev;
    struct mtx     mtx;
    struct sx      stats_sx;
    struct sema    admission_sema;
    struct taskqueue *tq;
    struct task     work_task;
    int            is_attached;
    int            work_in_progress;
};

static void
template_work_task(void *arg, int pending)
{
    struct template_softc *sc = arg;
    mtx_lock(&sc->mtx);
    /* Work under mutex if needed. */
    sc->work_in_progress = 0;
    mtx_unlock(&sc->mtx);
    /* Unlocked work here. */
}

static int
template_attach(device_t dev)
{
    struct template_softc *sc = device_get_softc(dev);
    int error;
```

```

    sc->dev = dev;
    mtx_init(&sc->mtx, device_get_nameunit(dev), "template", MTX_DEF);
    sx_init(&sc->stats_sx, "template stats");
    sema_init(&sc->admission_sema, 4, "template admission");

    sc->tq = taskqueue_create("template taskq", M_WAITOK,
        taskqueue_thread_enqueue, &sc->tq);
    if (sc->tq == NULL) { error = ENOMEM; goto fail_sema; }
    error = taskqueue_start_threads(&sc->tq, 1, PWAIT,
        "%s taskq", device_get_nameunit(dev));
    if (error != 0) goto fail_tq;

    TASK_INIT(&sc->work_task, 0, template_work_task, sc);

    atomic_store_rel_int(&sc->is_attached, 1);
    return (0);

fail_tq:
    taskqueue_free(sc->tq);
fail_sema:
    sema_destroy(&sc->admission_sema);
    sx_destroy(&sc->stats_sx);
    mtx_destroy(&sc->mtx);
    return (error);
}

static int
template_detach(device_t dev)
{
    struct template_softc *sc = device_get_softc(dev);

    atomic_store_rel_int(&sc->is_attached, 0);

    taskqueue_drain(sc->tq, &sc->work_task);
    taskqueue_free(sc->tq);
    sema_destroy(&sc->admission_sema);
    sx_destroy(&sc->stats_sx);
    mtx_destroy(&sc->mtx);
    return (0);
}

/* Entry on the hot path: */
static int
template_hotpath_enter(struct template_softc *sc)

```

```

{
    sema_wait(&sc->admission_sema);
    if (!atomic_load_acq_int(&sc->is_attached)) {
        sema_post(&sc->admission_sema);
        return (ENXIO);
    }
    return (0);
}

static void
template_hotpath_leave(struct template_softc *sc)
{
    sema_post(&sc->admission_sema);
}

```

The template is not a complete driver. It shows the shape of the primitives the chapter introduced. A real driver with this template plus the rest of the Chapter 14 and earlier patterns would be a fully functional synchronised device driver.

15.30 Reference: Comparison With POSIX User-Space Synchronization

Many readers come to FreeBSD kernel driver work from user-space systems programming. A short comparison clarifies the mapping.

Concept	POSIX user-space	FreeBSD kernel
Mutex	pthread_mutex_t	struct mtx
Condition variable	pthread_cond_t	struct cv
Read-write lock	pthread_rwlock_t	struct sx
Semaphore	sem_t (or sem_open)	struct sema
Thread creation	pthread_create	kproc_create, kthread_add
Deferred work	No direct analogue; common to roll your own	struct task + struct taskqueue
Periodic execution	timer_create + signal	struct callout
Atomic operations	<stdatomic.h> or __atomic_*	atomic(9)

The primitives are similar in shape but different in detail. Key differences:

- Kernel mutexes have priority inheritance; POSIX mutexes do only with the `PRIO_INHERIT` attribute.
- Kernel cvs have no name; POSIX cvs are anonymous too, so parity here.
- Kernel sx locks are more flexible than pthread_rwlock (try_upgrade, downgrade).

- Kernel semaphores are not signal-interruptible; POSIX semaphores (some variants) are.
- Kernel taskqueues have no direct POSIX analogue; POSIX thread pools are roll-your-own.
- Kernel atomics are more comprehensive (more operations, better barrier control) than older C11 atomics.

A reader comfortable with POSIX synchronisation will find the kernel primitives intuitive with minor adjustments. The main adjustment is the context awareness: kernel code cannot assume the ability to block.

15.31 Reference: A Worked Pattern Catalog

Ten synchronisation patterns that recur in real drivers. Each is a variation on the primitives Chapter 15 introduced.

15.31.1 Pattern 1: Producer/Consumer With Bounded Queue

Chapter 14's `cbuf` plus Chapter 12's `cvs` already implement this. The producer writes, the consumer reads, the mutex protects the queue, the `cvs` signal empty-to-nonempty and full-to-nonfull transitions.

15.31.2 Pattern 2: Completion Semaphore

A submitter initialises a semaphore to 0 and waits. A completion handler posts. The submitter unblocks. Used for request-reply patterns. See `/usr/src/sys/dev/hyperv/storvsc/hv_storvsc_drv_freebsd.c`.

15.31.3 Pattern 3: Admission Control

A semaphore initialised to N. Each participant `sema_waits` on entry and `sema_posts` on exit. Chapter 15 Stage 1 uses this pattern.

15.31.4 Pattern 4: Upgrade-Promote-Downgrade Read Cache

An `sx` lock with a staleness-based refresh. Readers take shared; on stale they `try_upgrade`, `refresh`, `downgrade`. Chapter 15 Stage 2 uses this pattern.

15.31.5 Pattern 5: Atomic Flag Coordination

An atomic flag read by many contexts, written by one. Use `atomic_load_acq` for reads, `atomic_store_rel` for writes. Chapter 15 Stage 4 uses this for `is_attached`.

15.31.6 Pattern 6: At-Most-One State Flag

A state flag protected by a lock or CAS. The “start of operation” path sets the flag; the “end of operation” path clears it. Chapter 15 Stage 4 uses this for `recovery_in_progress`.

15.31.7 Pattern 7: Signal-Interruptible Bounded Wait

`cv_timedwait_sig` with explicit `EINTR/ERESTART/EWOULDBLOCK` handling. Chapter 15 Stage 3 refines this pattern.

15.31.8 Pattern 8: Periodic Refresh via Callout

A callout periodically invokes a refresh function. The refresh holds a lock briefly. Simpler than Pattern 4 when the refresh interval is fixed.

15.31.9 Pattern 9: Deferred Teardown via Reference Count

Object has a reference count. “Free” decrements; actual free happens when the count reaches zero. Atomic decrement ensures correctness.

15.31.10 Pattern 10: Cross-Subsystem Handshake

Two subsystems coordinate via a shared state flag plus a `cv` or `sema`. One signals “my part is done”; the other waits. Useful for staged shutdown.

Knowing these patterns makes reading real driver source faster. Every Chapter 15 primitive is a building block for one or more of these patterns, and every real driver picks the patterns its workload needs.

15.32 Reference: A Glossary of Part 3 Terms

For final reference, a consolidated glossary spanning Chapters 11 through 15.

Atomic operation. A read, write, or read-modify-write primitive that executes without possibility of concurrent interference at the hardware level.

Barrier. A directive that prevents the compiler or CPU from reordering memory operations past a specific point.

Blocking wait. A synchronisation operation that puts the caller to sleep until a condition is met or a timeout fires.

Broadcast. Wake every thread blocked on a `cv` or `sema`.

Callout. A deferred function scheduled to run at a specific tick count in the future.

Coalescing. Folding multiple requests into a single operation (e.g., task enqueues into `ta_pending`).

Condition variable. A primitive that allows a thread to sleep until another thread signals a state change.

Context. The execution environment of a code path (syscall, callout, task, interrupt, etc.) with its own rules about what operations are safe.

Counter. A per-CPU accumulator primitive (`counter(9)`) used for lock-free statistics.

Drain. Wait until a pending operation is no longer pending and not currently executing.

Enqueue. Add a work item to a queue. Typically triggers a wakeup of the consumer.

Epoch. A synchronisation mechanism that allows lock-free reads of shared structures; writers defer reclamation via `epoch_call`.

Exclusive lock. A lock held by at most one thread; writers use exclusive mode.

Filter interrupt. An interrupt handler that runs in hardware context with severe restrictions on what it can do.

Grouptaskqueue. A scalable taskqueue variant with per-CPU worker queues; used by high-rate network drivers.

Interruptible wait. A blocking wait that can be woken by a signal, returning `EINTR` or `ERESTART`.

Memory ordering. Rules about the visibility and order of memory accesses across CPUs.

Mutex. A primitive ensuring mutual exclusion; at most one thread inside the lock at a time.

Partial progress. Bytes already copied on a read or write when an interrupt or timeout fires; conventionally returned as success with a short count.

Priority inheritance. A scheduler mechanism where a high-priority waiter temporarily raises the priority of the current holder.

Release barrier. A barrier on a store that ensures preceding accesses cannot be reordered after the store.

Semaphore. A primitive with a non-negative counter; `post` increments, `wait` decrements (blocking if zero).

Shared lock. A lock held by many threads at once; readers use shared mode.

Spinlock. A lock whose slow path busy-waits rather than sleeping. `MTX_SPIN` mutex.

Sx lock. A shared/exclusive lock; FreeBSD's read-write lock primitive.

Task. A deferred-work item with a callback and context, submitted to a taskqueue.

Taskqueue. A queue of pending tasks serviced by one or more worker threads.

Timeout. A duration beyond which a wait should abandon and return `EWOULDBLOCK`.

Timeout task. A task scheduled for a specific future moment via `taskqueue_enqueue_timeout`.

Upgrade. Promoting a shared `sx` lock to exclusive without releasing it (`sx_try_upgrade`).

Wakeup. Waking a thread blocked on a `cv`, a `sema`, or a sleep queue.

Part 3 ends here. Part 4 begins with Chapter 16, *Hardware Basics and Newbus*.

15.33 Reference: A Worked Debugging Scenario

A narrative walkthrough of a realistic synchronisation bug. Imagine you inherit a driver written by a colleague. The colleague is on holiday. Users report “under heavy load, the driver panics on detach with a stack trace ending in `selwakeup`”.

This section walks through how you would diagnose and fix the problem using the Chapter 15 toolkit.

15.33.1 Step 1: Reproduce

First priority: get a reliable reproduction. Without one, fixes are guesses.

Start by reading the bug report for specifics. “Heavy load” plus “panics on detach” is a strong hint that the race is between a running worker and the detach path. A stack trace ending in `selwakeup` suggests the panic is inside the `selinfo` code.

Write a minimal stress script that reproduces the scenario:

```
#!/bin/sh
kldload ./myfirst.ko
sysctl dev.myfirst.0.tick_source_interval_ms=1
(while ;; do dd if=/dev/myfirst of=/dev/null bs=1 count=100 2>/dev/null; done) &
READER=$!
sleep 5
kldunload myfirst
kill -TERM $READER
```

Run the script in a loop until the panic fires. On a debug kernel, this is the kind of bug that panics within seconds. On a production kernel, it may take longer.

15.33.2 Step 2: Capture the Stack

A debug kernel has KDB enabled. After the panic, you land in the in-kernel debugger. Commands:

- `bt`: stack trace of the panicking thread.
- `show locks`: locks held at the moment of the panic.
- `show witness`: the WITNESS state.

Record everything. On a production crash, a kernel dump is collected; retrieve it with `crashinfo` and analyse offline with `kgdb`.

A typical stack for this bug:

```
panic: selwakeup: freed selinfo
kdb_enter
vpanic
panic
selwakeup
myfirst_selwake_task
taskqueue_run_locked
taskqueue_thread_loop
fork_exit
```

The panic is in `selwakeup`, called from `myfirst_selwake_task`, called from the taskqueue worker. The `selwakeup`’s assertion says the `selinfo` it was given is freed.

15.33.3 Step 3: Identify the Race

The bug is visible in the stack. The task callback called `selwakeup(&sc->rsel)`, but `sc->rsel` had been drained or freed. Two possible causes:

A. The detach path `seldrain`'d the `selinfo` before draining the task. Then the task fired after `seldrain`, against the freed state. B. The detach path freed the `softc` (containing `rsel`) before draining the task. Then the task fired against freed memory.

Both are ordering violations. Look at the actual detach code in the driver:

```
/* Current order in the buggy driver: */
seldrain(&sc->rsel);
seldrain(&sc->wsel);
taskqueue_drain(sc->tq, &sc->selwake_task);
```

The `seldrain` is before the `taskqueue_drain`. That is exactly cause A. The fix is to swap the order.

15.33.4 Step 4: Apply the Fix

Change the detach to:

```
taskqueue_drain(sc->tq, &sc->selwake_task);
seldrain(&sc->rsel);
seldrain(&sc->wsel);
```

The task drain now guarantees the task is not running. Only then does `seldrain` proceed.

But wait. The task could still be enqueued from a running callout. Check: is the callout drained before the task drain? Read the code again:

```
/* Full order after fix: */
MYFIRST_CO_DRAIN(&sc->heartbeat_co);
MYFIRST_CO_DRAIN(&sc->watchdog_co);
MYFIRST_CO_DRAIN(&sc->tick_source_co);
taskqueue_drain(sc->tq, &sc->selwake_task);
seldrain(&sc->rsel);
seldrain(&sc->wsel);
```

Callouts drained, then task drained, then `sel` drained. This is the correct order.

15.33.5 Step 5: Verify

Run the reproduction script again with the fix. The panic should no longer fire. Run it 100 times to gain confidence. On a debug kernel the race surfaces quickly; 100 clean runs is strong evidence the fix is correct.

Add a regression test that exercises this specific scenario. The test should be part of the driver's test kit so the bug does not return.

15.33.6 Step 6: Document

Update `LOCKING.md` with a comment explaining why the order is what it is. A future maintainer who considers reordering the drains for some reason will see the comment and reconsider.

15.33.7 Takeaways

- The bug was visible in the stack trace; the skill was recognising what the trace meant.
- The fix was one line (reorder two calls); the diagnosis was the work.
- The debug kernel made the bug reproducible; without it, the bug would be intermittent and mysterious.
- The test kit prevents regression; without it, a future refactor could reintroduce the bug silently.

Chapter 14 already taught this specific ordering rule. A production driver written by a colleague who had not internalised Chapter 14 could easily have this bug. The chapter's discipline and the Chapter 15 testing chapter together are what keep this bug out of your own code.

This is a short, contrived scenario. Real bugs are subtler. The same methodology applies: reproduce, capture, identify, fix, verify, document. The primitives and the discipline from Part 3 are the toolbox for the “identify” step, which is usually the hardest.

15.34 Reference: Reading a Real Driver's Synchronization

For a concrete, exam-style exercise: pick one Ethernet driver in `/usr/src/sys/dev/` and walk through its synchronisation vocabulary. This section walks through `/usr/src/sys/dev/ale/if_ale.c` briefly as a template for the exercise.

The `ale(4)` driver is a 10/100/1000 Ethernet driver for the Atheros AR8121/AR8113/AR8114. It is not large (a few thousand lines) and has a clean structure.

15.34.1 Primitives It Uses

Open the file and search for the primitives.

```
$ grep -c 'mtx_init\|mtx_lock\|mtx_unlock' /usr/src/sys/dev/ale/if_ale.c
```

The driver uses one mutex (`sc->ale_mtx`). Uniform acquisition via `ALE_LOCK(sc)` and `ALE_UNLOCK(sc)` macros.

It uses callouts: `sc->ale_tick_ch` for periodic link-state polling.

It uses a taskqueue: `sc->ale_tq`, created with `taskqueue_create_fast`, started with `taskqueue_start_threads(..., 1, PI_NET, ...)`. The fast variant (spin-mutex-backed) is used because the interrupt filter enqueues onto it.

It uses a task on the queue: `sc->ale_int_task` for interrupt post-processing.

It does not use sema or sx. The driver's invariants fit a single mutex.

It uses atomics: several `atomic_set_32` and `atomic_clear_32` calls on hardware registers (via `CSR_WRITE_4` and similar). These are for hardware register manipulation, not driver-level coordination.

15.34.2 Patterns It Demonstrates

Filter-plus-task interrupt split. `ale_intr` is the filter, which masks the IRQ at the hardware and enqueues the task. `ale_int_task` is the task, which processes the interrupt work in thread context.

Callout for link polling. `ale_tick` is a periodic callout that re-arms itself, used for link-state polling.

Standard detach ordering. `ale_detach` drains callouts, drains tasks, frees the taskqueue, destroys the mutex. Same pattern as `myfirst`.

15.34.3 What It Does Not Demonstrate

- No `sx` lock. Configuration is protected by the single mutex.
- No semaphore. No bounded admission.
- No epoch. The driver does not touch network state directly from unusual contexts.
- No `sx_try_upgrade`. No read-mostly cache.

15.34.4 Takeaways

The `ale(4)` driver uses the subset of Part 3 primitives that its workload needs. A driver that needed an `sx` lock or a sema would add it; `ale(4)` does not, so it does not.

Reading one real driver like this is worth more than reading the chapter twice. Pick a driver, read it for 30 minutes, write down what primitives it uses and why.

Do the same exercise with a larger driver (`bge(4)`, `iwm(4)`, `mfx5(4)` are good candidates). Notice how the vocabulary scales. A driver with more state needs more primitives; a driver with simpler state uses fewer.

The `myfirst` driver at the end of Chapter 15 uses every primitive Part 3 introduced. Most real drivers use a subset. Both are valid; the choice depends on the workload.

15.35 Reference: The Full `myfirst_sync.h` Design

The companion source under `examples/part-03/ch15-more-synchronization/stage4-final/` includes the complete `myfirst_sync.h`. For reference, here is a full version that can be used as a template.

```
/*-
 * SPDX-License-Identifier: BSD-2-Clause
 *
 * Copyright (c) 2026 Edson Brandi
 *
 * myfirst_sync.h: the named synchronisation vocabulary of the
 * myfirst driver.
 *
 * Every primitive the driver uses has a wrapper here. The main
 * source calls these wrappers; the wrappers are inlined away, so
```

```
* the runtime cost is zero. The benefit is a readable,
* centralised, and easily-changeable synchronisation strategy.
*
* This file depends on the definition of `struct myfirst_softc`
* in myfirst.c, which must be included before this header.
*/

#ifndef MYFIRST_SYNC_H

{
    sx_downgrade(&sc->stats_cache_sx);
}

static __inline void
myfirst_sync_stats_cache_write_begin(struct myfirst_softc *sc)
{
    sx_xlock(&sc->stats_cache_sx);
}
```

```
static __inline void
myfirst_sync_stats_cache_write_end(struct myfirst_softc *sc)
{
    sx_xunlock(&sc->stats_cache_sx);
}

/*
 * Attach-flag atomic operations. Every context that needs to
 * check "are we still attached?" uses these.
 */
static __inline int
myfirst_sync_is_attached(struct myfirst_softc *sc)
{
    return (atomic_load_acq_int(&sc->is_attached));
}

static __inline void
myfirst_sync_mark_detaching(struct myfirst_softc *sc)
{
    atomic_store_rel_int(&sc->is_attached, 0);
}

static __inline void
myfirst_sync_mark_attached(struct myfirst_softc *sc)
{
    atomic_store_rel_int(&sc->is_attached, 1);
}

#endif /* MYFIRST_SYNC_H */
```

The file is under 200 lines including comments. It names every primitive operation. It adds zero runtime overhead. It is the single place a future maintainer looks to understand or change the synchronisation strategy.

15.36 Reference: Extended Lab: The “Break a Primitive” Exercise

An optional lab that stretches Chapter 15’s material. For each of the primitives Chapter 15 introduced, deliberately break it and observe the failure.

This is pedagogically valuable because seeing the failure mode makes the correct usage concrete.

15.36.1 Break the Writer-Cap

In Stage 1, remove one `sema_post` in the write path (say, on the error-return path). Rebuild. Run the writer-cap test. The `writers_sema_value` sysctl should drift downward over time and never recover. Eventually all writers block. This demonstrates why the post must be on every path.

Restore the post. Verify the drift stops and the sema stays balanced under load.

15.36.2 Break the Sx Upgrade

In Stage 2, remove the re-check after the upgrade fallback:

```
sx_sunlock(&sc->stats_cache_sx);
sx_xlock(&sc->stats_cache_sx);
/* re-check removed */
myfirst_stats_cache_refresh(sc);
sx_downgrade(&sc->stats_cache_sx);
```

Rebuild. Under heavy reader load, the refresh happens multiple times in quick succession because multiple readers race into the fallback path. The refresh counter grows much faster than one per second.

Restore the re-check. Verify the counter settles back to one refresh per second.

15.36.3 Break the Partial-Progress Handling

In Stage 3, remove the partial-progress check on the `EINTR` path:

```
case EINTR:
case ERESTART:
    return (error); /* Partial check removed. */
```

Rebuild. Run the signal-handling lab. A `SIGINT` during a partially-completed read now returns `EINTR` instead of the partial byte count. User-space code expecting the UNIX convention is surprised.

Restore the check. Verify partial-progress works again.

15.36.4 Break the Atomic Read

In Stage 4, replace `atomic_load_acq_int(&sc->is_attached)` with a plain read `sc->is_attached` in the read path's entry check. On x86 this still works (strong memory model). On arm64 it may occasionally miss a detach, producing an `ENXIO`-or-not-`ENXIO` race.

If you do not have arm64 hardware, this one is hard to demonstrate experimentally. Understand it intellectually and move on.

Restore the atomic. The discipline is the same regardless of test outcome.

15.36.5 Break the Detach Ordering

Swap the order of `sel drain` and `taskqueue_drain` in Stage 4's detach (as in the earlier debugging scenario). Run the stress test with detach cycles. Observe the eventual panic.

Restore the correct order. Verify stability.

15.36.6 Break the Sema Destroy Lifetime

Call `sema_destroy(&sc->writers_sema)` early, before the taskqueue is fully drained. On a debug kernel this panics with "sema: waiters" the moment a thread is still inside `sema_wait`. The KASSERT fires.

Restore the correct order. The destroy happens after all waiters have drained.

15.36.7 Why This Matters

Deliberately breaking code is uncomfortable. It is also the fastest way to internalise why the correct code is written the way it is. Each Chapter 15 primitive has failure modes; seeing them live makes the correct usage unforgettable.

After running the break-and-observe exercise for each primitive, the chapter's material will feel solid. You will know not just what to do, but why, and what happens if you skip a step.

15.37 Reference: When To Split A Driver

A meta-observation that belongs here rather than in a specific section.

Part 3 has developed the `myfirst` driver to a moderate size: about 1200 lines in the main source, plus the `myfirst_sync.h` header, plus the `cbuf`. That is small for a real driver. Real drivers range from 2000 lines (simple device support) to 30000 or more (network drivers with offload support).

At what size does a driver warrant being split into multiple source files?

A few heuristics.

- **Under 1000 lines:** one file. The overhead of multiple files exceeds the readability benefit.
- **1000 to 5000 lines:** one file is still fine. Use clear section markers in the file.
- **5000 to 15000 lines:** two or three files. Typical split: main attach/detach logic in `foo.c`, dedicated subsystem logic (e.g., a ring buffer manager) in `foo_ring.c`, hardware register definitions in `foo_reg.h`.
- **Over 15000 lines:** modular design is required. A header for shared structures; several implementation files for subsystems; a top-level `foo.c` that ties them together.

The `myfirst` driver at Chapter 15 Stage 4 is comfortable as a single file plus a sync header. As later chapters add hardware-specific logic, a natural split will emerge: `myfirst_reg.h` for register definitions, `myfirst_intr.c` for interrupt-related code, `myfirst_io.c` for the data path. Those splits will happen in Part 4 when the hardware story justifies them.

The rule of thumb: split when a file exceeds what you can mentally hold at once. For most readers that is around 2000 to 5000 lines. Split earlier if the subsystem boundary is natural; split later if the code is so interleaved that a split would feel forced.

15.38 Reference: A Final Summary of Part 3

Part 3 was a walkthrough of five primitives and their composition. A final summary frames what has been accomplished.

Chapter 11 introduced concurrency into the driver. One user became many users. The mutex made that safe.

Chapter 12 introduced blocking. Readers and writers could wait for state changes. Condition variables made the wait efficient; sx locks made configuration access scalable.

Chapter 13 introduced time. Callouts let the driver act on its own at chosen moments. Lock-aware callouts and drain-at-detach made the timers safe.

Chapter 14 introduced deferred work. Tasks let callouts and other edge contexts hand work off to threads that could actually do the work. Private taskqueues and coalescing made the primitive efficient.

Chapter 15 introduced the remaining coordination primitives. Semaphores capped concurrency. Refined sx patterns enabled read-mostly caches. Signal-interruptible waits with partial-progress preserved the UNIX conventions. Atomic operations made cross-context flags cheap. Encapsulation made the whole vocabulary readable.

Together, the five chapters built a driver with a complete internal synchronisation story. The driver at 0.9-coordination has no synchronisation feature missing; every invariant it cares about has a named primitive, a named operation in the wrapper header, a named section in `LOCKING.md`, and a test in the stress kit.

Part 4 adds the hardware story. The synchronisation story stays.

15.39 Reference: Chapter 15 Deliverables Checklist

Before closing Chapter 15, confirm all deliverables are in place.

15.39.1 Chapter Content

- ☐ `content/chapters/part3/chapter-15.md` exists.
- ☐ Section 1 through Section 8 are written.
- ☐ Additional Topics section is written.
- ☐ Hands-On Labs are written.
- ☐ Challenge Exercises are written.
- ☐ Troubleshooting Reference is written.
- ☐ Wrapping Up Part 3 is written.
- ☐ Bridge to Chapter 16 is written.

15.39.2 Examples

- ☐ `examples/part-03/ch15-more-synchronization/` directory exists.
- ☐ `stage1-writers-sema/` has a working driver.
- ☐ `stage2-stats-cache/` has a working driver.
- ☐ `stage3-interruptible/` has a working driver.

- ☐ `stage4-final/` has the consolidated driver.
- ☐ Each stage has a `Makefile`.
- ☐ `stage4-final/` has `myfirst_sync.h`.
- ☐ `labs/` has test programs and scripts.
- ☐ `README.md` describes each stage.
- ☐ `LOCKING.md` has the updated synchronisation map.

15.39.3 Documentation

- ☐ The main source has a top-of-file comment summarising the Chapter 15 additions.
- ☐ Every new `sysctl` has a description string.
- ☐ Every new structure field has a comment.
- ☐ `LOCKING.md` sections match the driver.

15.39.4 Testing

- ☐ The stage 4 driver builds cleanly.
- ☐ The stage 4 driver passes WITNESS.
- ☐ The Chapter 11-14 regression tests still pass.
- ☐ The Chapter 15 specific tests pass.
- ☐ Detach under load is clean.

A driver and chapter that pass this checklist are done.

15.40 Reference: An Invitation to Experiment

Before closing, a final invitation.

The Chapter 15 driver is a vehicle for learning, not a shipping product. Every primitive it uses is real; every technique it demonstrates is used in real drivers. But the driver itself is deliberately contrived to exercise the full range of primitives in one place. A real driver typically uses a subset.

As you close Part 3, consider experimenting beyond the chapter's worked examples.

- Add a second type of admission control: a semaphore that caps concurrent readers as well as writers. Does it improve or hurt the system? Why?
- Add a watchdog that times out a single write operation (not the whole driver). Implement it with a timeout task. What edge cases do you encounter?
- Convert the configuration `sx` to a set of atomic fields. Measure the performance difference with DTrace. Which design would you ship? Why?
- Write a userland test harness in C that exercises the driver in ways the shell can't. What primitives do you reach for?
- Read a real driver in `/usr/src/sys/dev/` and identify a single synchronisation decision it made. Do you agree with the decision? What would you have chosen instead, and why?

Each experiment is a day or two of work. Each teaches more than a chapter of text. The myfirst driver is a lab; the FreeBSD source is a library; your own curiosity is the syllabus.

Part 3 has taught you the primitives. The rest is practice. Good luck with Part 4.

15.41 Reference: `cv_signal` vs `cv_broadcast`, Precisely

One recurring question when reading or writing driver code: should a signal wake one waiter (`cv_signal`) or all of them (`cv_broadcast`)? The answer is not always obvious; this reference digs in.

15.41.1 The Semantic Difference

`cv_signal(&cv)` wakes at most one thread currently blocked on the `cv`. If multiple threads are waiting, exactly one of them wakes; the kernel chooses which (usually FIFO, but this is not guaranteed by the API).

`cv_broadcast(&cv)` wakes all threads currently blocked on the `cv`. Every blocked thread wakes and re-contentends for the mutex.

15.41.2 When `cv_signal` Is Correct

Two conditions must both hold for `cv_signal` to be safe.

Any one waiter can satisfy the state change. If you signal because a slot became available in a bounded buffer, and any waiter can take that slot, signal is appropriate. The single wakeup is enough.

All waiters are equivalent. If every waiter is running the same predicate and would respond the same way to the wakeup, signal is appropriate. Waking just one avoids the thundering-herd effect of waking all and having all but one immediately re-sleep.

Classic example: a producer/consumer with one item freshly produced. Waking one consumer is sufficient; waking all would wake many consumers who would then see an empty queue and re-sleep.

15.41.3 When `cv_broadcast` Is Correct

A few specific cases make broadcast the right choice.

Multiple waiters may succeed. If a state change unblocks more than one waiter (for example, “the bounded buffer went from full to 10 slots free”), broadcast wakes them all and each one can try. Signaling only one would leave the others blocked even though progress is possible.

Different waiters have different predicates. If some waiters are waiting for “bytes > 0” and others for “bytes > 100”, signal of one might wake a waiter whose predicate is not satisfied, while another waiter whose predicate is satisfied stays asleep. Broadcast ensures every waiter re-evaluates its own predicate.

Shutdown or state invalidation. When the driver detaches, every waiter must see the change and exit. `cv_broadcast` is required because every waiter must return, not just one.

The Chapter 12-15 driver uses `cv_broadcast` on detach (`cv_broadcast(&sc->data_cv)`, `cv_broadcast(&sc->room_cv)`) for exactly this reason. It uses `cv_signal` on normal buffer-state transitions because each transition unblocks at most one waiter productively.

15.41.4 A Subtle Case: The Reset Sysctl

Chapter 12 added a reset sysctl that clears the cbuf. After reset, the buffer is empty and has full room. Which wakeup is correct?

```
cv_broadcast(&sc->room_cv);  /* Room is now fully available. */
```

The driver uses cv_broadcast. Why not signal? Because the reset unblocked potentially many writers who were all waiting for room. Waking them all lets all of them re-check. A signal would wake only one; the others would stay blocked until a write path signalled on a per-byte basis later.

This is the “multiple waiters may succeed” case. Broadcast is correct.

15.41.5 Cost Consideration

cv_broadcast is more expensive than cv_signal. Every woken thread makes the scheduler do work, and every thread that wakes and immediately re-sleeps pays context-switch overhead. For a cv with many waiters, broadcast can be expensive.

For a cv with one or two typical waiters, the cost difference is negligible. Use whichever is semantically correct.

15.41.6 Rules of Thumb

- **Blocking read wakeup after a byte arrives:** cv_signal. One byte can unblock at most one reader.
- **Blocking write wakeup after bytes drain:** depends on how many bytes drained. If one byte drained, signal is fine. If the buffer was emptied by a reset, broadcast.
- **Detach:** always cv_broadcast. Every waiter must exit.
- **Reset or state invalidation that could unblock many:** cv_broadcast.
- **Normal incremental state change:** cv_signal.

When in doubt, cv_broadcast is correct (just more expensive). Prefer signal when you can prove it suffices.

15.42 Reference: The Rare Case Where You Write Your Own Semaphore

A thought experiment. If sema(9) did not exist, how would you implement a counting semaphore with only a mutex and a cv?

```
struct my_sema {
    struct mtx    mtx;
    struct cv     cv;
    int          value;
};

static void
```

```
my_sema_init(struct my_sema *s, int value, const char *name)
{
    mtx_init(&s->mtx, name, NULL, MTX_DEF);
    cv_init(&s->cv, name);
    s->value = value;
}

static void
my_sema_destroy(struct my_sema *s)
{
    mtx_destroy(&s->mtx);
    cv_destroy(&s->cv);
}

static void
my_sema_wait(struct my_sema *s)
{
    mtx_lock(&s->mtx);
    while (s->value == 0)
        cv_wait(&s->cv, &s->mtx);
    s->value--;
    mtx_unlock(&s->mtx);
}

static void
my_sema_post(struct my_sema *s)
{
    mtx_lock(&s->mtx);
    s->value++;
    cv_signal(&s->cv);
    mtx_unlock(&s->mtx);
}
```

Compact, correct, and functionally identical to `sema(9)` for the simple cases. Reading this makes clear what `sema(9)` is doing internally: exactly this, wrapped in an API.

Why does `sema(9)` exist if it is so simple to write? A few reasons:

- It factors the code out of every driver that would otherwise reinvent it.
- It provides a documented, tested primitive with tracing support.
- It optimises the post to avoid `cv_signal` when no waiters are present.
- It provides a consistent vocabulary for code review.

The same argument applies to every kernel primitive. You could roll your own mutex, cv, sx, taskqueue, callout. You do not because the kernel's primitives are better-tested, better-documented, and better-understood by the community. Use them.

The exception is a primitive that is not in the kernel. If your driver needs a specific synchronisation idiom that no kernel primitive provides, implementing it is justified. Document it carefully.

15.43 Reference: A Parting Observation on Kernel Synchronization

An observation that spans Part 3.

Every kernel synchronisation primitive is built from simpler primitives. At the bottom is a spinlock (technically, a compare-and-swap on a memory location, plus barriers). Above spinlocks are mutexes (spinlocks plus priority inheritance plus sleeping). Above mutexes are condition variables (sleep queues plus mutex handoff). Above cvs are sx locks (cv plus a reader counter). Above sxs are semaphores (cv plus a counter). Above semaphores are higher-level primitives (taskqueues, gtaskqueues, epochs).

Each layer adds a specific capability and hides the complexity below. When you call `sema_wait`, you do not think about the cv inside it, the mutex inside the cv, the spinlock inside the mutex, the CAS inside the spinlock. The abstraction works.

The payoff of this layering is that you can reason about one layer at a time. The payoff of knowing the layering is that when a layer fails, you can descend to the one below and debug.

Part 3 introduced the primitives at each layer in order. Part 4 uses them. If a Part 4 bug baffles you, the diagnosis might require descending: from “taskqueue is stuck” to “the task callback is blocked on a mutex” to “the mutex is held by a thread waiting on a cv” to “the cv is waiting for a state change that will never happen because of a different bug”. The tools for this descent are the primitives you now know.

That is the real payoff of Part 3. Not a specific driver pattern, though that is valuable. Not a specific set of API calls, though those are necessary. The real payoff is a mental model of synchronisation that scales with the complexity of the problem. That model is what will carry you through Part 4 and the rest of the book.

Chapter 15 is complete. Part 3 is complete.

Continue to Chapter 16.

15.44 Reference: A Final Note on Testing Discipline

Every chapter of Part 3 ended with tests. The discipline was consistent: add a primitive, refactor the driver, write a test that exercises it, run the whole regression suite, update `LOCKING.md`.

That discipline is what turns a sequence of chapters into a maintainable body of code. Without it, the driver would be a patchwork of features that work individually and break in combination. With it, every chapter’s additions compose with what came before.

Keep the discipline in Part 4. Hardware introduces new primitives (interrupt handlers, resource allocations, DMA tags) and new failure modes (hardware-level races, DMA corruption, register-ordering surprises). Each addition deserves its own test, its own documentation entry, its own integration into the existing regression suite.

The cost of the discipline is a small amount of extra work per chapter. The benefit is that the driver, at whatever stage of development, is always shippable. You can hand it to a colleague, and it will work. You can put it aside

for six months, come back, and still understand what it does. You can add one more feature without fearing that something unrelated will break.

That is the ultimate payoff of Part 3. Not just primitives; not just patterns; a working discipline.

16 Accessing Hardware

16.1 Reader Guidance & Outcomes

Part 3 ended with a driver that knew how to coordinate itself. The `myfirst` module at version 0.9-coordination has a mutex protecting its data path, a pair of condition variables that let readers and writers wait patiently for the buffer state they need, a shared and exclusive lock protecting its configuration, three callouts that give it internal time, a private taskqueue with three tasks that defer work out of constrained contexts, a counting semaphore that caps concurrent writers, an atomic flag that carries the shutdown story across every context, and a small header that names every synchronisation primitive the driver uses. The chapters that built it introduced seven primitives, tied them together with one detach ordering, and documented the whole story in a living `LOCKING.md`.

What the driver does not yet have is a hardware story. Every invariant it coordinates is internal. Every byte that flows through it originates in user space through `write(2)` or is produced by a callout from its own imagination. Nothing in the driver reaches outside the kernel's own memory. A real FreeBSD driver usually exists because there is a device to talk to: a network card, a storage controller, a serial port, a sensor, a custom FPGA, a GPU. That conversation is what Part 4 is about, and Chapter 16 is where it begins.

Chapter 16's scope is deliberately narrow. It teaches the mental model of hardware I/O and the vocabulary of `bus_space(9)`, the FreeBSD abstraction that lets a single driver talk to a device the same way on every supported architecture. It walks through a simulated register block so the reader can practise register-style access without owning real hardware, and it integrates that simulation into the `myfirst` driver in a way that evolves naturally from Chapter 15 rather than throwing the driver away. It covers the safety rules that MMIO demands (memory barriers, access ordering, locking around shared registers) and shows how to debug and trace register-level access. It ends with a small refactor that separates hardware-access code from the driver's business logic, preparing the file layout every later Part 4 chapter will rely on.

Several questions are deliberately postponed so that Chapter 16 can dwell on the vocabulary itself. Dynamic register behaviour, callout-driven status changes, and fault injection belong to Chapter 17. Real PCI devices, BAR mapping, vendor and device ID matching, `pciconf` and `pci(4)`, and the `newbus` glue that ties PCI drivers to the bus subsystem belong to Chapter 18. Interrupts and their split between filter handlers and interrupt threads are Chapter 19. DMA and bus master programming are Chapter 20 and Chapter 21. Chapter 16 stays inside the ground it can cover well, and it hands off explicitly when a topic deserves its own chapter.

Part 4 opens here, and an opening deserves a small pause. Part 3 taught you how to behave inside the driver when many actors touch shared state. Part 4 teaches how the driver reaches outside itself. An interrupt handler runs in a context Part 3 taught you how to reason about and accesses memory Part 4 will teach you how to map. A register write in Part 4 must respect a lock Part 3 taught you how to manage. The disciplines stack. Chapter 16 is your first practice with `bus_space(9)`; Part 3's discipline is what keeps the practice honest.

16.1.1 Why `bus_space(9)` Earns a Chapter of Its Own

You may already be wondering whether MMIO really needs a whole chapter. Why not jump into Chapter 17's simulation or Chapter 18's real PCI work and pick up the accessor vocabulary in passing? If you have used `bus_space(9)` before, the primitive calls in this chapter will not be new to you.

What Chapter 16 adds is the mental model. Hardware I/O is a topic where a small set of ideas done well pays off across every subsequent chapter, and a small set of ideas done sloppily produces quiet, persistent bugs that are hard to find later. The distinction between memory-mapped I/O and port-mapped I/O is simple once you have it and confusing until you do. The meaning of a `bus_space_tag_t` and a `bus_space_handle_t` is simple once you see what they stand for and opaque until then. The reason memory barriers matter around register access is obvious once you have thought about cache coherence and compiler reordering and irrelevant until the day a driver misbehaves for reasons you cannot explain.

The chapter also earns its place by being the chapter where the `myfirst` driver gains its first hardware-facing layer. Until now, the `softc` held only internal state: a circular buffer, some locks, some counters, some flags. After Chapter 16, the `softc` will hold a simulated register block and the accessors that read and write it. That change in the driver's shape is small but formative. It sets up the file organisation and the locking discipline that every later Part 4 chapter will extend. Skipping Chapter 16 would leave the reader trying to learn register-access idioms in the middle of learning PCI, interrupts, or DMA. Doing them one at a time is kinder.

16.1.2 Where Chapter 15 Left the Driver

A short checkpoint before we go further. Chapter 16 extends the driver produced at the end of Chapter 15 Stage 4, tagged as version `0.9-coordination`. If any of the items below feels uncertain, return to Chapter 15 before starting this chapter.

- Your `myfirst` driver compiles cleanly and identifies itself as version `0.9-coordination`.
- The `softc` holds a data-path mutex (`sc->mtx`), a configuration `sx` (`sc->cfg_sx`), a stats-cache `sx` (`sc->stats_cache_sx`), two condition variables (`sc->data_cv`, `sc->room_cv`), three callouts (`heartbeat_co`, `watchdog_co`, `tick_source_co`), a private taskqueue (`sc->tq`) with four tasks (`selwake_task`, `bulk_writer_task`, `reset_delayed_task`, `recovery_task`), and a counting semaphore (`writers_sema`) that caps concurrent writers.
- A header `myfirst_sync.h` encapsulates every synchronisation operation under named inline functions.
- The lock order `sc->mtx -> sc->cfg_sx -> sc->stats_cache_sx` is documented in `LOCKING.md` and enforced by `WITNESS`.
- `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` are enabled in your test kernel, and you have built and booted it.
- The Chapter 15 stress kit runs cleanly under the debug kernel.

That driver is what Chapter 16 extends. The additions are again modest in volume: one new header (`myfirst_hw.h`), one new structure inside the `softc` (a simulated register block), a handful of accessor helpers, a small hardware-driven task, and a set of barriers and locks around register access. The mental model change is larger than the line count suggests.

16.1.3 What You Will Learn

Walking away from this chapter, you should be able to:

- Describe what hardware I/O means in a driver context and why a driver cannot usually touch device memory by simply dereferencing a pointer.
- Distinguish memory-mapped I/O (MMIO) from port-mapped I/O (PIO), and explain why MMIO dominates modern FreeBSD drivers on modern platforms.
- Explain what a register is, what an offset is, and what a control or status field means, using the vocabulary real device datasheets use.
- Read a simple register map table and translate it into a C header of offsets and bitmasks.
- Describe the roles of `bus_space_tag_t` and `bus_space_handle_t` and why they are an abstraction rather than just a pointer.
- Recognise the shape of `bus_space_read_*`, `bus_space_write_*`, `bus_space_barrier`, `bus_space_read_multi`, `bus_space_read_region_*`, and their `bus_*` shorthand counterparts defined over a `struct resource`.
- Simulate a register block in kernel memory, wrap access to it behind accessor helpers, and use those helpers to build a small driver-visible device that behaves like a real MMIO device without touching real hardware.
- Integrate simulated register access into the evolving `myfirst` driver, with the data path reading and writing through register accessors instead of touching a raw buffer.
- Identify when a register read has side effects and when a register write does, and why that matters for caching, compiler reordering, and debugging.
- Use `bus_space_barrier` correctly to enforce access ordering where it is needed, and recognise when it is not needed.
- Protect shared register state with the right kind of lock, and avoid busy-wait loops that starve other threads.
- Log register access in a way that helps you debug a driver without drowning the reader in noise.
- Refactor a driver so that its hardware-access layer is a named, documented, testable unit of code.
- Tag the driver as version `0.9-mmio`, update `LOCKING.md` and `HARDWARE.md`, and run the full regression suite with hardware-access enabled.

The list is long; each item is narrow. The point of the chapter is the composition.

16.1.4 What This Chapter Does Not Cover

Several adjacent topics are explicitly deferred so Chapter 16 stays focused.

- **Full hardware simulation with dynamic behaviour.** The simulation in this chapter is static enough to teach the register-access vocabulary. Chapter 17 makes the simulation dynamic, with timers that change status registers, events that flip ready bits, and fault injection paths.
- **The PCI subsystem.** `pci(4)`, vendor and device ID matching, `pciconf`, `pci_enable_busmaster`, BAR mapping, MSI and MSI-X, and power management quirks belong to Chapter 18. Chapter 16 mentions PCI only when it is useful to say “this is where your BAR would come from if this were real”.
- **Interrupt handlers.** `bus_setup_intr(9)`, filter handlers, interrupt threads, `INTR_MPSAFE`, and the filter-plus-task split are Chapter 19. Chapter 16 hints at them only to explain why a read with side effects matters.

- **DMA.** `bus_dma(9)`, `bus_dma_tag_create`, `bus_dmamap_load`, bounce buffers, cache flushing around DMA, and scatter-gather lists are Chapter 20 and Chapter 21.
- **Architecture-specific register access oddities.** Weakly-ordered memory models, arm64 device memory attributes, big-endian byte swapping on MIPS and PowerPC, and non-coherent caches on some embedded platforms are mentioned in passing; a deep treatment belongs to the portability chapters.
- **Real-world driver case studies.** Chapter 16 points at `if_ale.c`, `if_em.c`, and `uart_bus_pci.c` as examples of the patterns taught here, but it does not dissect them at length. Later chapters do that work where it fits their own themes.

Staying inside those lines keeps Chapter 16 a chapter about the vocabulary of hardware access. The vocabulary is what transfers; the specific subsystems are what Chapters 17 through 22 apply the vocabulary to.

16.1.5 Estimated Time Investment

- **Reading only:** three to four hours. The vocabulary is small but it requires thinking carefully about each term.
- **Reading plus typing the worked examples:** seven to nine hours over two sessions. The driver evolves in four stages and each stage is a small but real refactor.
- **Reading plus all labs and challenges:** twelve to fifteen hours over three or four sessions, including stress testing and reading some real FreeBSD drivers.

Section 2 and Section 3 are the densest. If the abstraction of a tag and a handle feels opaque on first pass, that is normal. Stop, re-read the worked mapping in Section 3, and continue when the shape has settled.

16.1.6 Prerequisites

Before starting this chapter, confirm:

- Your driver source matches Chapter 15 Stage 4 (`stage4-final`). The starting point assumes every Chapter 15 primitive, every Chapter 14 taskqueue, every Chapter 13 callout, every Chapter 12 cv and sx, and the Chapter 11 concurrent IO model.
- Your lab machine runs FreeBSD 14.3 with `/usr/src` on disk and matching the running kernel.
- A debug kernel with `INVARIANTS`, `WITNESS`, `WITNESS_SKIPSPIN`, `DDB`, `KDB`, and `KDB_UNATTENDED` is built, installed, and booting cleanly.
- You understand the Chapter 15 detach ordering well enough to extend it without getting lost.
- You are comfortable reading hexadecimal offsets and bitmasks.

If any item above is shaky, fix it now rather than pushing through Chapter 16 and trying to reason from a moving foundation. Hardware-access code is sensitive to small mistakes, and a debug kernel catches most of them on first contact.

16.1.7 How to Get the Most Out of This Chapter

Three habits will pay off quickly.

First, keep `/usr/src/sys/sys/bus.h` and `/usr/src/sys/x86/include/bus.h` bookmarked. The `bus.h` file in `/usr/src/sys/sys/` defines the shorthand `bus_read_*` and `bus_write_*` macros over a `struct resource *`. The per-architecture `bus.h` in `/usr/src/sys/x86/include/` (or its equivalent for your platform) defines the lower-level `bus_space_read_*` and `bus_space_write_*` functions and shows you exactly what they compile to. Reading those two files once takes about thirty minutes and removes almost all the mystery from the chapter.

Second, compare every new accessor to what you would have written with plain C. The exercise “if I did not have `bus_space_read_4`, how would I express this register read?” is instructive. The answer on x86 is usually “a volatile pointer dereference plus a compiler barrier”. Seeing the contrast is how the value of the abstraction becomes concrete: the abstraction is the same code, wrapped in a name that carries portability, tracing, and documentation.

Third, type the changes by hand and run each stage. Hardware-access code is code where muscle memory matters. Typing `sc->regs[MYFIRST_REG_CONTROL]` and `bus_write_4(sc->res, MYFIRST_REG_CONTROL, value)` a dozen times is how the difference between raw access and abstracted access becomes visible at a glance. The companion source under `examples/part-04/ch16-accessing-hardware/` is the reference version, but the muscle memory comes from typing.

16.1.8 Roadmap Through the Chapter

The sections in order are:

1. **What Is Hardware I/O?** The mental model of register access, how the driver talks to the device without touching its internals, and what kinds of resources drivers care about.
2. **Understanding Memory-Mapped I/O (MMIO).** How devices appear as memory regions, why a raw pointer cast is not how a driver reaches them, and what alignment and endianness mean here.
3. **Introduction to `bus_space(9)`.** The tag and handle abstraction, the shape of the read and write functions, and the difference between the `bus_space_*` family and the `bus_*` shorthand over a `struct resource *`.
4. **Simulating Hardware for Testing.** A register block allocated with `malloc(9)`, shaped to resemble a real device, with accessors that mirror `bus_space` semantics. Stage 1 of the Chapter 16 driver.
5. **Using `bus_space` in a Real Driver Context.** Integrating the simulated block into `myfirst`, exposing a tiny read-write register interface through the driver, and demonstrating how a task can change register state over time. Stage 2 begins here.
6. **Safety and Synchronisation with MMIO.** Memory barriers, access ordering, locking around registers, and why busy-wait loops are a mistake. Stage 3 of the driver adds the safety discipline.
7. **Debugging and Tracing Hardware Access.** Logging, DTrace, `sysctl` probes, and the small observability layer that makes register access visible without cluttering the driver.
8. **Refactoring and Versioning Your MMIO-Ready Driver.** The final split into `myfirst_hw.h` and `myfirst.c`, the documentation update, and the version bump to `0.9-mmio`. Stage 4 of the driver.

After the eight sections come hands-on labs, challenge exercises, a troubleshooting reference, a Wrapping Up that closes Part 3’s habits and opens Part 4’s, and a bridge to Chapter 17. The reference-and-cheat-sheet material at the end of the chapter is meant to be re-read as you work through later Part 4 chapters; the vocabulary of Chapter 16 is reused in every one of them.

If this is your first pass, read linearly and do the labs in order. If you are revisiting, Sections 3 and 6 stand alone and make good single-sitting reads.

16.2 Section 1: What Is Hardware I/O?

The Chapter 15 driver's world is small. Everything it cares about, it allocates for itself. The circular buffer is a `cbuf_t` inside the `softc`. The heartbeat is a `struct callout` inside the `softc`. The writers semaphore is a `struct sema` inside the `softc`. Every piece of state the driver touches is memory the kernel allocator has given it. Reading from or writing to that state is a plain C memory access: a field assignment, a pointer dereference, or a call to a helper that does one of those things under a lock.

Hardware changes that world. A hardware device is not kernel memory. It is a separate piece of silicon, usually on a different chip from the CPU, with its own registers, its own buffers, its own internal state, and its own rules for how the CPU may communicate with it. A driver's job is to translate the kernel's view of the world, which is software, into the device's view of the world, which is hardware. The first step in that translation is learning how the CPU and the device talk to each other at all.

This section introduces the mental model. Later sections build on it. The goal of Section 1 is not to make you write any code yet. The goal is to establish the vocabulary and the model clearly enough that everything that follows lands softly.

16.2.1 The Device as a Cooperating Partner

A useful first picture is to think of a hardware device not as an object the driver controls, but as a cooperating partner the driver talks to. The device does some fixed amount of work autonomously. A disk rotates whether the driver is attentive or not. A network card receives packets off the wire without asking permission. A temperature sensor measures temperature continuously. A keyboard controller scans the keyboard matrix on a timer of its own. In every case, the device has internal behaviour the driver cannot directly influence.

What the driver can do is send the device commands and receive the device's status and data. The device exposes a small interface: a set of registers, each with a specific meaning, each with a specific protocol for how the driver may read or write it. The driver writes a value to a control register to tell the device what to do. The driver reads a value from a status register to find out what the device is doing. The driver reads a value from a data register to get data the device has received. The driver writes a value to a data register to send data the device should transmit.

Registers, in this picture, are the conversation. The driver does not call a method on the device and does not pass arguments in the C sense. The driver writes a specific value at a specific offset, and the device reads that write and responds. The device writes a specific value at a specific offset, and the driver reads that write to see what the device is telling it. The protocol is entirely defined by the device's documentation, which is usually a datasheet. The driver's job is to follow the protocol.

That word "partner" is doing a lot of work. Hardware is famously unforgiving. A device does not document every wrong thing the driver could do; it simply does something wrong, or undefined, if the driver breaks the protocol. A driver that writes the wrong value to a control register may brick a device until the next power cycle. A driver that reads a status register before the device has finished a previous command may see stale data and make a bad decision. A driver that does not clear an interrupt flag before returning from an interrupt handler

may leave the device thinking the interrupt is still pending. The partner metaphor is cooperative in intent; the actual relationship is one where the driver must be very polite and very attentive, because the device has no way to object except by misbehaving.

16.2.2 What “Accessing Hardware” Really Means

The phrase “accessing hardware” shows up in every kernel programming text, and it rewards a closer look. What does the CPU actually do when a driver reads a register from a device?

On modern platforms the most common answer is: the CPU issues a memory access to a specific physical address, and the memory controller routes that access to the device rather than to RAM. From the CPU’s point of view, it looks like an ordinary load or store. From the device’s point of view, it is a message from the CPU addressed to a specific internal register. The wiring in between, the memory controller and the bus fabric, is what makes the routing work.

That is memory-mapped I/O. The CPU uses normal load and store instructions. The address happens to be routed to a device instead of to RAM. The device exposes its registers as a range of physical addresses, and the driver reads and writes within that range the way it would read and write any other memory.

An older, less common answer on x86 CPUs is: the CPU issues a special I/O instruction (`in` or `out`) to a specific I/O port number, and the chipset routes that instruction to the device. The CPU is not using a load or store; it is using a dedicated instruction that operates on a separate address space, called I/O port space or port-mapped I/O. This was the original mechanism on x86 and is still in use for some legacy devices, but modern drivers rarely see it except in compatibility paths.

FreeBSD abstracts both mechanisms behind a single API. The driver does not care, most of the time, whether a register is reached through a memory access or through an I/O instruction. The abstraction is `bus_space(9)`, which Section 3 introduces. For now, notice that “accessing hardware” is a physical operation on the CPU that the OS hides behind a software interface. The driver writes `bus_space_write_4(tag, handle, offset, value)`, and the kernel does the right thing depending on the platform and the resource type.

16.2.3 Why a Raw Pointer Cast Is Not How Drivers Reach Hardware

A new reader might reasonably ask: if a device appears as a range of physical addresses, why not just take the address of the device’s registers, cast it to a `volatile uint32_t *`, and dereference it? Technically, on some platforms, that works. Practically, no FreeBSD driver does this, and several real reasons make the raw cast a poor choice.

First, the driver does not know the physical address of the device at compile time. The address is assigned by the bus enumeration code at boot or hotplug, based on the Base Address Registers (BARs) that the device advertises. The driver’s attach routine asks the bus subsystem for the resource; the bus subsystem returns a handle that carries the mapping. The driver then uses the handle through the `bus_space` API. There is no place in the driver’s source where the physical address is a constant.

Second, physical addresses are not virtual addresses. The CPU runs in virtual address mode; dereferencing a pointer reads from virtual memory, not physical memory. The kernel’s `pmap(9)` layer maintains the translation. A driver that wants to dereference a device’s registers needs a virtual mapping into the device’s physical range, with the right cache and access attributes. `bus_space_map` does this. A raw pointer cast does not.

Third, different architectures require different access attributes for device memory than for RAM. Device memory must usually be marked uncached, or weakly-cached, or marked as “device memory” in the MMU’s page tables, so that the CPU does not reorder or cache the accesses in ways that confuse the device. On arm64, device memory pages use the nGnRnE or nGnRE attributes that disable speculative prefetching. On x86, the PAT and MTRR mechanisms mark device regions as uncached or write-combining. A raw pointer cast uses whatever attributes the surrounding virtual mapping happens to have, which is usually cached, which is usually wrong for device registers.

Fourth, `bus_space` carries extra information beyond just where to read and write. The tag encodes which address space (memory or I/O port) is in use. On architectures where the two are different, the tag chooses the correct CPU instruction. On architectures where a driver might map a region with byte-swapping for endianness, the tag encodes that too. The tag-plus-handle interface is a portable way to express “access this device with the right semantics”, where a raw pointer is just “poke this virtual address and hope”.

Fifth, `bus_space` supports tracing, hardware access auditing, and optional sanity checks through the `bus_san(9)` layer when the kernel is built with sanitisers enabled. A raw pointer cast is invisible to those tools. If you ever want to know when your driver read a particular register, `bus_space` can tell you; a raw dereference cannot.

The short version is: FreeBSD drivers use `bus_space` because it abstracts a real problem the driver needs to solve, and the raw pointer cast works on some platforms by accident rather than by design. Accepting the abstraction is inexpensive; refusing it creates bugs that surface weeks after deployment.

16.2.4 Categories of Resources a Driver Cares About

Most drivers deal with a small handful of resource categories. Each has a different access pattern. Chapter 16 focuses on one of them (memory-mapped registers), and the others are covered in later chapters. Knowing the whole catalogue helps you place the current topic.

Memory-mapped I/O (MMIO) registers. A range of device physical addresses, mapped into the kernel’s virtual address space, used to send commands and receive status. Every modern device has at least one MMIO region; most have several. Chapter 16’s focus.

Port-mapped I/O (PIO) registers. A range of I/O port numbers on x86, accessed through the `in` and `out` CPU instructions. Older devices used this as their primary mechanism. Newer devices sometimes expose a small compatibility window through ports (a legacy serial controller, for example) while putting the main interface in MMIO. The `bus_space` API abstracts both behind the same read and write calls, which is why this chapter treats them together.

Interrupts. A signal from the device to the CPU that something has happened. The driver registers an interrupt handler through `bus_setup_intr(9)`, and the kernel arranges for the handler to run when the interrupt line asserts. Chapter 19 covers interrupts.

DMA channels. The device reads or writes directly into system RAM, bypassing the CPU. The driver prepares a DMA descriptor that tells the device which RAM addresses it may use. FreeBSD’s `bus_dma(9)` API manages the mappings, the cache coherence, and the synchronisation. Chapters 20 and 21 cover DMA.

Configuration space. On PCI, a separate address space per device, used to describe the device to the OS. BARs live here, the vendor and device IDs live here, power management state lives here. Most drivers read

configuration space only once, during attach, to discover the device's capabilities. Chapter 18 covers PCI configuration space.

Bus-specific capabilities. MSI, MSI-X, PCIe extended capabilities, hot-plug events, errata workarounds. Bus-specific chapters cover these.

This chapter lives in the MMIO box. The `bus_space` abstraction also covers PIO, so we will see port-mapped paths in passing, but the working example is MMIO throughout.

16.2.5 The Register, Closer Up

A register, in the device's language, is a unit of communication. It has a name, an offset, a width, a set of fields, and a protocol.

The **name** is how the datasheet refers to it. `CONTROL`, `STATUS`, `DATA_IN`, `DATA_OUT`, `INTR_MASK`. Names are for humans; the device does not know them.

The **offset** is the distance from the start of the device's register block to the start of this specific register. Offsets are usually given in hexadecimal. `CONTROL` at `0x00`. `STATUS` at `0x04`. `DATA_IN` at `0x08`. `DATA_OUT` at `0x0c`. `INTR_MASK` at `0x10`. The driver uses offsets in every read and write.

The **width** is how many bits the register carries. Common widths are 8, 16, 32, and 64 bits. A 32-bit register is accessed with `bus_space_read_4` and `bus_space_write_4`, where the 4 is the width in bytes. Mismatching the width is a surprisingly common bug; reading a 32-bit register with an 8-bit access reads only one byte, and on some platforms with byte-lane restrictions it may return the wrong byte or no byte at all.

The **fields** inside a register are sub-bit-ranges that each mean something specific. A 32-bit `CONTROL` register might have an `ENABLE` bit at bit 0, a `RESET` bit at bit 1, a 4-bit `MODE` field at bits 4 through 7, and a 16-bit `THRESHOLD` field at bits 16 through 31, with the remaining bits reserved. The driver uses bit masks and shifts to extract or set specific fields, and the datasheet defines every mask and shift.

The **protocol** is the rules the driver must follow when reading or writing the register. Some protocols are trivial ("write this register with the value you want"). Some are subtle ("set the `ENABLE` bit, then poll the `READY` bit in `STATUS` for up to 100 microseconds, then write the `DATA_IN` register"). Some have side effects that the driver must know about ("reading `STATUS` clears the error bits"). Getting the protocol right is the bulk of driver development time in many hardware projects.

For Chapter 16 the registers are simple, because the device is simulated. But the vocabulary is the vocabulary of real datasheets, and every term introduced here transfers directly to any real device you will meet later.

16.2.6 A First Mental Model: The Control Panel

A useful analogy, only if you keep it disciplined, is that of a control panel on an industrial machine. The machine does its work on its own schedule. The panel exposes knobs the operator can turn to tell the machine what to do, gauges the operator can read to see what the machine is doing, and a few lights that go on and off to signal events. The operator does not reach inside the machine; the operator reaches the machine through the panel.

The driver is the operator. The register block is the control panel. A knob on the panel is a control field in a register. A gauge is a status field. A light is a status bit. The wiring behind the panel is the device's internal logic, which the driver does not see and cannot directly influence. The cable between the operator and the panel

is `bus_space`: it carries the operator's turns of the knob and the gauge's readings back and forth, in a language the operator and the panel both understand.

The analogy breaks down quickly if pushed. Real hardware has timing constraints the panel does not. Real hardware has side effects that the panel does not. Real hardware speaks a protocol that changes when the machine's internal state changes. But for the first pass, the panel is good enough: the driver writes to a control field, the device reacts, the driver reads a status field, the device tells it what happened.

Later sections replace the analogy with more precise mental models: the register block as a window into device state, the MMIO region as a memory range with side-effects, the `bus_space` interface as a platform-aware messenger. For now, the panel is the on-ramp.

16.2.7 Why Simulating Hardware Is a Good First Practice

Chapter 16's teaching strategy is to simulate a device rather than require the reader to have a specific piece of real hardware. The reasons are practical and deliberate.

A reader who is practising register-style access for the first time benefits enormously from an environment where they can see the register values directly. A real PCI device's registers are hidden behind a BAR; the reader can read them with `pciconf -r`, but only for specific known offsets, and the values change based on device state in ways a datasheet may not fully document. A simulated device, by contrast, is a struct in kernel memory. The reader can print its contents with a `sysctl`. The reader can modify it from user space through an `ioctl`. The reader can inspect it in `ddb`. The simulation closes the loop between action and observation, which is what makes the practice effective.

A simulated device is also safe. A real device that receives a wrong register value may lock up, corrupt data, or require a physical power cycle. A simulated device that receives a wrong register value does nothing worse than set a wrong bit in kernel memory; if the driver leaks that, `INVARIANTS` will complain. Beginners benefit from the safety net.

A simulated device is reproducible. Every reader running the Chapter 16 code sees the same register values in the same order. A real device's behaviour depends on firmware version, hardware revision, and environmental conditions. Teaching over a reproducible target is much easier than teaching over the union of every possible target.

Chapter 17 expands the simulation with timers, events, and fault injection. Chapter 18 introduces a real PCI device (typically a `virtio` device in a VM) so the reader can practise the real-hardware path. Chapter 16 lays the ground by teaching the vocabulary against a static simulation, which is the gentlest version of the material.

16.2.8 A Glance at Real Drivers That Use Hardware I/O

Before moving on, a short tour of real FreeBSD drivers that exercise the patterns Chapter 16 teaches. You do not need to read these files yet; they are waypoints you can return to as the chapter unfolds.

`/usr/src/sys/dev/uart/uart_bus_pci.c` is a PCI glue layer for UART (serial) controllers. It shows how a driver finds its PCI device, claims an MMIO resource, and hands the resource to a lower layer that actually drives the hardware. It is small and readable, and it uses `bus_space` only indirectly.

`/usr/src/sys/dev/uart/uart_dev_ns8250.c` is the real UART driver for the classic 8250-family serial controller. It is the file where register reads and writes happen. The register layout is defined in `uart_bus.h` and `uart_dev_ns8250.h`. The reads use the abstraction the chapter teaches.

`/usr/src/sys/dev/ale/if_ale.c` is an Ethernet driver for the Attansic L1E chipset. Its `if_alevar.h` defines `CSR_READ_4` and `CSR_WRITE_4` macros over `bus_read_4` and `bus_write_4`, which is a pattern you will adopt in your own driver by Stage 4 of this chapter.

`/usr/src/sys/dev/e1000/if_em.c` is the driver for Intel's gigabit Ethernet controllers (e1000 family). It is larger and more complex than `if_ale.c`, but it uses the same `bus_space` vocabulary. Its attach path is a good reference for how a non-trivial driver allocates MMIO resources.

`/usr/src/sys/dev/led/led.c` is the LED driver. It is a pseudo-device driver that does not talk to real hardware at all; it exposes a small interface through `/dev/led.NAME` and delegates the actual LED control to whichever driver registered it. Chapter 16's simulated device borrows the shape of this driver: a small, self-contained module with a clear interface and no dependency on external hardware.

These files will reappear throughout Part 4. Chapter 16 uses them as tour points; later chapters dissect them where their patterns are the chapter's focus.

16.2.9 What Comes Next in This Chapter

Section 2 moves from the abstract picture to the specific mechanism of memory-mapped I/O. It explains what a mapping is, why device memory is accessed with different rules than ordinary memory, and how the driver can think about alignment, endianness, and caching. Section 3 introduces `bus_space(9)` itself. Section 4 builds the simulated device. Section 5 integrates it into `myfirst`. Section 6 adds the safety discipline. Sections 7 and 8 finish the chapter with debugging, refactoring, and versioning.

The pace from here is slower than Section 1. Section 1 was meant to be read linearly and absorbed as a whole; the later sections are meant to be read section by section, with breaks to type the code and run it.

16.2.10 Wrapping Up Section 1

Hardware I/O is the activity through which a driver talks to a device. The driver cannot reach inside the device; it can only send commands and read status through a defined register interface. On modern platforms the interface is usually memory-mapped; on x86 there is a legacy port-mapped path as well. The FreeBSD abstraction `bus_space(9)` hides the difference from the driver most of the time. A register is a named, offset-located, width-specific unit of communication, with fields and a protocol that the device's datasheet defines.

Chapter 16's simulation lets you practise the vocabulary without real hardware. Later Part 4 chapters apply the vocabulary to real subsystems. The vocabulary is what transfers, and the rest of this chapter exists to give you that vocabulary with enough depth to use it comfortably.

Section 2 begins by looking closely at memory-mapped I/O.

16.3 Section 2: Understanding Memory-Mapped I/O (MMIO)

Section 1 introduced the idea that a device's registers can be reached through ordinary-looking memory accesses. That idea is worth slowing down for. Memory-mapped I/O is the dominant mechanism on modern

FreeBSD platforms, and understanding it well is what makes every later chapter in Part 4 feel tractable rather than mysterious.

This section answers three closely related questions. How does a device appear in memory? Why must the CPU access that memory with different rules than ordinary memory? What does a driver need to think about when reading and writing a register?

The section works from the ground up: physical addresses, virtual mappings, cache attributes, alignment, and endianness. Each piece is small. The composition is where the subtlety lives.

16.3.1 Physical Addresses and Device Memory

The CPU executes instructions. Each load and store instruction names a virtual address, which the memory management unit (MMU) translates into a physical address. Physical addresses are what the memory controller sees. The memory controller's job is to route the access to the right destination.

For most physical addresses, the destination is DRAM. The controller reads or writes a location in system RAM and returns the result to the CPU. This is the common case. Every `malloc(9)` allocation the driver makes returns kernel memory whose physical address is backed by DRAM.

Some physical address ranges, however, are routed to devices instead. The memory controller is configured at boot (by firmware, usually by the BIOS or UEFI on x86, or by the device tree on arm and the `acpi` tables on everything) to send accesses in certain ranges to specific devices. A PCI device might live at physical address `0xfebf0000` through `0xfebfffff`, a 64 KiB region. An embedded UART might live at `0x10000000` through `0x10000fff`, a 4 KiB region. Whatever the range, an access inside it routes to the device rather than to RAM.

From the CPU's point of view, the access looks identical to an access to RAM. The instruction is the same; the address happens to be elsewhere. From the device's point of view, the access looks like an incoming message: a read at offset *X* of the device's internal register file, or a write of some value at offset *Y*.

The key property is that the same CPU instruction (a load or a store) is being reused for a different purpose. That is where "memory-mapped" in MMIO comes from: the device's interface is mapped into the CPU's memory address space, so memory-access instructions reach it.

Port-mapped I/O, the x86 alternative, uses separate instructions (`in`, `out`, and their wider variants) that target a different address space. The port space has its own 16-bit address range on x86. Modern FreeBSD drivers rarely reach port space directly, because modern devices prefer MMIO, but the abstraction is the same: the driver writes a value at an address, and the address happens to route to a device.

16.3.2 The Virtual Mapping

The CPU does not access physical memory directly. Every memory access goes through the MMU, which translates a virtual address into a physical address using page tables. The kernel maintains those page tables in its `pmap(9)` layer. For a driver to read device registers, it needs a virtual mapping into the device's physical range.

When the kernel's bus subsystem discovers a device and the driver's attach routine requests an MMIO resource, the bus layer does two things. First, it finds the physical address range the device occupies, which the device's Base Address Register (BAR) or the platform's device tree describes. Second, it establishes a virtual mapping

from a fresh kernel virtual address range to that physical range, with appropriate cache and access attributes. The result is a virtual address that, when dereferenced, produces an access at the corresponding physical address, which the memory controller then routes to the device.

The handle that `bus_alloc_resource` returns is (on most platforms) a wrapper around that kernel virtual address. The driver does not typically see the address; it passes the resource handle to `bus_space_read_*` and `bus_space_write_*`, which extract the virtual address internally. But the underlying mechanism is a plain virtual-to-physical mapping, set up once at attach and torn down at detach.

This matters for two reasons. First, it explains why `bus_alloc_resource` is not something a driver can skip. Without the resource allocation, there is no virtual mapping; without a virtual mapping, any attempt to access the device will fault or access random memory. Second, it explains why the virtual address is not a constant: the kernel picks it at attach time, and two boots of the same system may produce different addresses.

16.3.3 Cache Attributes Matter

Memory pages have cache attributes. Ordinary RAM uses “write-back” caching: the CPU caches reads and writes in its L1, L2, and L3 caches, writing back to RAM only when the cache line is evicted or explicitly flushed. Write-back caching is great for performance on RAM, where the memory controller’s job is to preserve whatever value the CPU most recently wrote.

Device memory is different. A device’s registers usually have side effects on read and on write. Reading a STATUS register may consume an event the device has signalled. Writing a DATA_IN register may queue data for transmission. Caching a read of a status register means the CPU returns a stale value on the second read; caching a write of a data register means the write goes to the cache and never reaches the device until the cache happens to evict the line.

For these reasons, device memory pages are marked with different cache attributes than ordinary memory. On x86, the attributes are controlled through the PAT (Page Attribute Table) and MTRR (Memory Type Range Registers). Device memory is typically marked UC (uncached) or WC (write-combining). On arm64, device memory pages use the Device-nGnRnE or Device-nGnRE attributes, which disable caching and speculation. The specific names are architecture-dependent; the principle is the same: the CPU must treat device memory differently from RAM.

`bus_space_map` (or the equivalent path inside `bus_alloc_resource`) knows to request the right cache attributes when it establishes the virtual mapping. A driver that dereferences a raw pointer into a device region without going through `bus_space` skips this step and gets whatever attributes the surrounding mapping happens to have, which is usually wrong.

This is one of the most concrete reasons to use the FreeBSD abstraction: the abstraction encodes a correctness requirement (uncached access to devices) that a raw pointer cast cannot.

16.3.4 Alignment

Hardware registers have alignment requirements. A 32-bit register must be accessed with a 32-bit load or store at an offset that is a multiple of 4. A 64-bit register must be accessed with a 64-bit load or store at an offset that is a multiple of 8. On most architectures, an unaligned access to device memory is either slower (decomposed into multiple smaller accesses by the hardware) or outright illegal (trapping with an alignment fault).

The rule for drivers is simple: when reading or writing a register, use the function whose width matches the register's width, and use the correct offset. If the register is 32 bits wide at offset 0x10, the access is `bus_space_read_4(tag, handle, 0x10)` or `bus_space_write_4(tag, handle, 0x10, value)`. If the register is 16 bits wide at offset 0x08, it is `bus_space_read_2(tag, handle, 0x08)` or `bus_space_write_2(tag, handle, 0x08, value)`. The byte-wide variants `bus_space_read_1` and `bus_space_write_1` exist for 8-bit registers.

Mismatching the width is a common early-stage bug and often silent on x86, which has very permissive alignment rules. On arm64 the same code may fault on first contact. Drivers that are developed on x86 and then ported to arm64 often trip on exactly this issue, which is why the FreeBSD style guidance favours matching widths strictly from the beginning.

There is also an offset alignment rule. The offset must be a multiple of the access width. A 32-bit read at offset 0x10 is fine (0x10 is a multiple of 4). A 32-bit read at offset 0x11 is wrong, even if the device nominally has a register starting there; the hardware will usually refuse or return garbage. This rule is easy to follow when the offsets come from a well-named header; it becomes a trap when offsets are computed arithmetically and the arithmetic is wrong.

16.3.5 Endianness
